Title: RNA export through nuclear envelope budding in premature aging disorders

Authors: *Y. LI, L. HASSINGER, J. ASHLEY, J. NUNNARI, M. MOORE, V. BUDNIK; UMMS, Worcester, MA

Abstract: We have recently uncovered a novel, nuclear pore complex-independent mechanism by which large ribonucleoprotein (megaRNP) granules exit the nucleus (Speese et al., (2012) Cell 149:832) This process, called nuclear envelope budding, is similar to the means by which Herpes-type viral nucleocapsids escape the host cell nucleus and is essential for postsynaptic development. An important process during nuclear envelope budding is the local reorganization of the nuclear lamina, a protein network localized beneath the inner nuclear membrane, and formed by the intermediate filament proteins, the lamins. Mutations in the *Drosophila* A-type lamin gene, *lamC*, prevent nuclear envelope budding, and result in abnormal synaptic development. In humans, mutations in the A-type lamin gene, *LMNA*, result in severe hereditary conditions, the laminopathies, affecting a number of tissues and leading to various dystrophies and premature aging disorders. In particular, specific mutations in *LMNA* cause dominant progeroid syndromes, including Hutchinson-Gilford progeria (HGPS) and Werner syndrome. To determine if progeroid phenotypes were related to abnormalities in nuclear envelope budding, we examined the nucleus of fibroblasts from HGPS patients, and generated the corresponding progeria mutations in fly *lamC.* Our preliminary ultrastructural studies reveal similar nuclear abnormalities both in HGPS fibroblasts and *Drosophila* cells expressing progeria-causing *lamC* mutant transgenes. In particular, the nuclear lamina is grossly abnormal, likely leading to abnormal nuclear envelope budding. We are currently using approaches to test the impact of these mutations in synaptic development and aging. These studies may shed new light on our current understanding of premature aging disorders, as well as their relationship to mRNA export through nuclear envelope budding and synaptic development.

Title: Presynaptic α2δ subunits are essential for synapse formation and calcium channel trafficking

Authors: *C. L. SCHÖPF[1], M. CAMPIGLIO[1], S. GEISLER[1], R. STANIKA[1], A. LIEB[2], B. E. FLUCHER[1], B. NIMMERVOLL[1], G. J. OBERMAIR[1];
[1]Div. of Physiol., Med. Univ. Innsbruck, Innsbruck, Austria; [2]Dept. of Pharmacol. and Toxicology LFU Innsbruck, Innsbruck, Austria

Abstract: Auxiliary $\alpha_2\delta$ subunits modulate membrane trafficking and current properties of voltage-gated Ca^{2+} channels and have recently been implicated in neuronal functions like synaptic transmission and synapse formation. The CNS stably expresses $\alpha_2\delta$-1, -2, and -3 however, whether and how the individual isoforms contribute to specific functions in neurons simultaneously expressing all isoforms is elusive. In order to elucidate $\alpha_2\delta$ subunit-specific neuronal functions we studied the subcellular distribution of all three epitope-tagged $\alpha_2\delta$ isoforms in hippocampal neurons, and we established double knockout mice by crossbreeding single knockout ($\alpha_2\delta$-1 and -3) or mutant (*du*, $\alpha_2\delta$-2) mice. Moreover we established a cellular $\alpha_2\delta$ triple knock-out model by employing $\alpha_2\delta$-1 shRNA knock-down in cultured hippocampal neurons derived from *du*/$\alpha_2\delta$-3 double-knockout mice. Live-cell staining of cultured wildtype neurons expressing HA-tagged $\alpha_2\delta$-1, -2, and -3 revealed somato-dendritic, axonal, and presynaptic surface expression of all isoforms. Nevertheless expression levels of presynaptic $Ca_V2.1$ Ca^{2+} channels were mainly increased by $\alpha_2\delta$-2 and -3. This isoform specificity correlated with their propensity to increase $Ca_V2.1$ current density upon heterologous coexpression in tsA201cells (ΔI_{Ca}: $\alpha_2\delta$-3>$\alpha_2\delta$-2>>$\alpha_2\delta$-1). All double knockout mouse models showed strongly

reduced life spans, although to different degrees. This indicates that $\alpha_2\delta$ subunit functions are partly redundant, but essential for survival. Ca^{2+} current densities in double (*du*/$\alpha_2\delta$-3) and triple knockout neurons were significantly reduced to 65% and 50%, respectively, when compared to single $\alpha_2\delta$-3 knockout ($p<0.05$) or wildtype neurons ($p<0.01$). Axons from triple knockout neurons displayed axonal varicosities resembling presynaptic boutons, however, strongly reduced presynaptic synapsin and $Ca_V2.1$ content suggested a failure in synapse formation. Concomitant reduction in postsynaptic PSD-95 labeling indicated a role of $\alpha_2\delta$ subunits in the transsynaptic organization. In contrast, postsynaptic triple-knockout neurons still developed dendritic spines containing PSD-95 clusters opposite functional presynaptic boutons, which were formed by axons from $\alpha_2\delta$-1 containing neurons. Thus we conclude that the defect in proper induction and differentiation of synapses is caused by a presynaptic mechanism. Taken together our data demonstrate that $\alpha_2\delta$ isoforms partly differ with respect to trafficking and regulation of presynaptic Ca^{2+} channels. However, the essential role of $\alpha_2\delta$ subunits in presynaptic synaptogenesis is highly redundant.

Title: Impaired synaptogenesis and learning in MARK2/Par1b knockout mice

Authors: *Q. WU[1], X. WANG[2], Z. PANG[2], G. WAGNER[3], H. ZHANG[1];
[1]Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; [2]Child Hlth. Inst. of New Jersey, New Brunswick, NJ; [3]Dept. of Psychology, Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: Partitioning defective1 (Par1), also called Microtubule-affinity regulating kinase (MARK), plays an essential role in many cellular contexts including embryogenesis, asymmetric cell division, directional migration, and epithelial morphogenesis. Previously, we found Par1 is required for normal spine morphogenesis in cultured hippocampal neurons. In addition, we found that Par-1 functions through phosphorylating the synaptic scaffolding protein PSD-95 at Ser561 in this process. However, it remains unclear what role Par1 plays during neuronal development

in vivo. Here we show that MARK2/Par1b knockout mice showed impaired dendritic spine moprhogensis, similar to what was observed in cultured hippocampal neurons expressing a Par1b shRNA. Additionally, Par1b knockout mice showed a decrease in mEPSC frequency but not mEPSC amplitude. Finally, we show that Par1b knockout mice exhibit poor performance in the Morris Water Maze as compared with wild type or heterozygotic controls. Together, our findings showed an important role of Par1 in learning and memory processes by regulating dendritic spine morphogenesis and synaptic transmission.

Abstract: The proper wiring of neuronal networks required for normal brain development is crucially dependent upon regulated synapse formation. Synaptic organizing proteins mediate synapse formation by orchestrating pre- and postsynaptic differentiation. The leucine-rich repeat transmembrane proteins (LRRTMs) are synaptic organizing proteins that regulate synapse development and function in a cell type and brain region specific manner. LRRTMs have been linked to both schizophrenia (LRRTM1) and bipolar disorder (LRRTM2) suggestive of a critical role in neuropsychiatric disorders. Additionally, LRRTM1 and LRRTM2 are highly expressed in

the hippocampus, a brain structure essential for memory formation. To elucidate the function of LRRTMs in synapse regulation, we generated LRRTM1-/- LRRTM2-/- double knockout mice (LRRTM1/2 DKO). In LRRTM1/2 DKOs we observed a reduction in excitatory synapse number as indicated by a reduction in punctate immunofluorescence for VGlut1by confocal imaging, reduced dendritic spine density by Golgi staining, and decreased asymmetric synapse density by electron microscopy. mEPSC frequency was similarly decreased consistent with reduced excitatory synapse numbers. To determine if LRRTMs mediate synaptic plasticity, long-term potentiation was induced in CA1 of WT and DKO hippocampal slices. The duration of LTP was significantly reduced in DKO mice relative to wild-type (WT) littermate controls. To determine if reductions in LTP were recapitulated at a behavioral level, DKO and WT mice were trained in a contextual fear conditioning task which assays CA1-dependent memory performance. DKO mice exhibited impaired memory function at a long but not short time after training. Taken together, these data implicate LRRTMs as mediators of synapse formation, synaptic plasticity and memory and suggest mechanisms by which mutations in LRRTMs may contribute to neuropsychiatric disorders.

Title: Localization of kirrel3 in the synapses during postnatal and adult stages in the mouse cerebellum

Authors: ***T. HISAOKA**[1], T. KITAMURA[2], Y. MORIKAWA[1];
[1]Dept. of Anat. & Neurobiology, Wakayama Med. Univ., Wakayama, Japan; [2]Div. of Cell. Therapy, Advanced Clin. Res. Center, The Inst. of Med. Science, The Univ. of Tokyo, Tokyo, Japan

Abstract: In the previous study, we have demonstrated that a member of the immunoglobulin superfamily, kirrel3, is expressed in the brain, including the cerebellum using *in situ* hybridization histochemistry. Recently, Kong *et al*. (Neurosci Lett 543: 22-26, 2013) have reported that a rat homolog of *kirrel3* is expressed in the granule cell layer (GCL) and Purkinje cell layer (PCL) during postnatal development. However, the detailed expression pattern and the function of kirrel3 in the mouse cerebellum remain unknown. In order to gain insights into the role of kirrel3 in the cerebellum, we characterized kirrel3-expressing cells in the postnatal and adult cerebellum using *kirrel3-lacZ* knockin mice, in which kirrel3 expression is detected as β-galactosidase (β-gal) activity. From postnatal day (P) 0 to P70 (adult mice), β-gal$^+$ cells were observed in both deep cerebellar nuclei and cerebellar cortex. In the cerebellar cortex, the expression of β-gal was found in the internal GCL and PCL from P0 to P70. On the other hand, β-gal$^+$ cells were observed in the external GCL at P0 and in the molecular layer (ML) from P7 to P70. The expression levels of β-gal reached a peak at P0 in the PCL, at P14 in the GCL, and at P21 in the ML, which are peak periods of the synaptogenesis in each region. In the PCL, small clusters of β-gal$^+$ cells were arranged as parasagittal bands in the posterior and nodular zones of the vermis. In the PCL of the nodular zone (vestibulo-cerebellum), Hsp25, a marker for a specific stripe of Purkinje cells (PCs) in the central and nodular zones, was expressed in β-gal$^+$ cells, suggesting that β-gal$^+$ cells may form a specific vestibulo-cerebellar circuit. Thus, kirrel3 is highly expressed in the projection neurons and interneurons of specific circuits in the cerebellum during the development of synapse. We further investigated the localization of kirrel3 protein in the cerebellum using immunohistochemistry. At P14, intense expression of kirrel3 protein was observed in the GCL and gradually decreased as development proceeded. Double-immunofluorescence staining for kirrel3 with PSD-95 revealed that kirrel3 was colocalized with PSD-95 in synapses and attachment plaques of the glomeruli of GCL at P14. Between P14 and P70, the expression of kirrel3 protein was also observed in the HCN1$^+$ basket cell terminals, which form pinceau around the axon initial segment of PCs. These findings suggest that kirrel3 may be involved in the synaptic formation/plasticity in granule cells and interneurons of the cerebellum during postnatal and adult stages.

Title: Circuit integration of VIP+ interneurons during development

Authors: *D. VAN VERSENDAAL, S. LEE, S. N. TUNCDEMIR, X. JAGLIN, B. WAMSLEY, G. MIYOSHI, G. FISHELL;

Abstract: The diversity of interneurons is most readily evident in their unique gene expression and physiological properties. Nonetheless, it is their precise connectivity that allows them to achieve specialized functional roles in cortical processing, such as balancing network activity, gain control and gating of signal propagation. As such unraveling the mechanisms that drive cell-type specific connectivity are paramount to understanding how brain assembly is achieved. Interneurons that express vasointestinal peptide (VIP+) are positioned in the superficial layers of the cortex, predominantly receive long-range input from other brain areas and primarily act to mediate disinhibition. How they achieve their connectivity and function is unknown. Circuit assembly is tightly temporally and spatially coordinated and dependent on both genetic programs as well as neural activity. This study aims to resolve how these competing processes are coordinated to integrate VIP+ interneurons into a well-described circuit. We have begun by examining the events associated with the establishment of VIP+ connectivity. To this end, we used rabies tracing to identify the the sources of their afferent inputs and their developmental profile. Furthermore, we have utilized fluorescently-tagged synaptic proteins to study the structural dynamics of the afferent and efferent connections of VIP+ interneurons and explored how transcriptional regulation and activity contribute to their establishment during development.

Title: Foxp2 is required for morphological development of medium-sized spiny neurons in the mouse striatum

Authors: Y.-C. CHEN, *F.-C. LIU;
Inst. Neurosci, Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: A severe speech and language disorder was found in the KE family. The genetic linkage study shows that the affected family members carry a missense R553H mutation of FOXP2 which causes the spoken language disorder. FOXP2 is therefore the first gene identified to be involved in speech and language. Clinical neuroimaging studies indicate that the caudate nucleus of striatum and the inferior frontal gyrus are structurally and functionally abnormal in the KE patient's brain. FOXP2R553H allele may function as a null allele which causes haploinsufficiency of FOXP2. In the present study, we studied the neurobiological function of the mouse homologue Foxp2 which differs three amino acids from human FOXP2. We focused on the morphological changes of striatal neurons by studying Foxp2 knockout (KO) mice. The Golgi's stain showed that the neurite lengths were dramatically decreased in the medium-spiny striatal neurons (MSN) of postnatal day (P12) Foxp2 KO brains. Moreover, the dendritic spine density in MSN was also significantly reduced in Foxp2 KO striatum. In parallel to the decreased dendritic spine density, the expression of PSD95, a post-synaptic marker, was also reduced in Foxp2 KO striatum. Taken together, our study suggests that Foxp2 is essential for morphological and dendritic spines/synapse development of MSN in the mouse striatum.

Title: Leptin controls synaptogenesis by regulating the expression of Kruppel-like factor 4 (KLF4) and STAT3 signaling

Authors: *G. A. WAYMAN, M. DHAR, H. SHIINA, K. TYSON, M. ZHU, S. M. APPLEYARD;
Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Kruppel-like factor 4 (KLF4) is a transcription factor first identified in the gut and skin epithelium. It has been studied mostly in pre-mitotic cells, where it can act as either a transcription repressor or a transcription activator depending on the gene and the context. In the CNS, KLF4 levels rise significantly in the hippocampus of post-natal rats during a time of rapid synapse formation as well as in response to neuronal activity, which is required for synaptogenesis. Using high-throughput genome-wide screens we have identified KLF4 as an important target of neurotrophic factors such as leptin and BDNF, both of which stimulate synaptogenesis. Previously, KLF4 has been shown to inhibit axonal regeneration in nerve-injury models. Developing neurons polarize an axonal projection before they develop a dendritic arbor and form of synapses. We hypothesize that KLF4 acts a developmental switch from a period of axonal growth to a period of increased dendritic arborization and synapse formation in response to neurotrophic factors in hippocampal neurons. To study this we measured synaptogenesis in neonatal rat hippocampal cultures. We found that over-expressing KLF4 in dissociated hippocampal cultures increased spinogenesis. Whole-cell voltage-clamp experiments showed KLF4 over-expression also increased the frequency of miniature excitatory post-synaptic currents (mEPSCs), consistent with the formation of functional excitatory synapses. Over expression of KLF4 also increased spinogenesis in organotypic slice cultures. The hormone leptin, which increases synaptogenesis in hippocampal neurons, transiently increased KLF4 mRNA expression 1-2 hour post-treatment and KLF4 mRNA levels returned to baseline levels 4 hour post-leptin treatment. This increase in KLF4 transcription is required for leptin-induced synapse formation since reducing KLF4 expression using a targeted shRNA inhibits leptin-stimulated spine formation. KLF4 induces synaptogenesis in part by suppressing STAT3 dependent transcription. Transfection of KLF4 decreased pSTAT3 and nuclear localized STAT3, as well as STAT3 dependent transcription. Furthermore, expression of a constitutively active STAT3 attenuates leptin stimulated spinogenesis. In conclusion, we have identified KLF4 as a factor whose overexpression stimulates synaptogenesis and that is required for leptin-induced synapse formation, in part through suppression of STAT3.

Title: Neuron specific gene 2 (Nsg2): a novel AMPA receptor interacting protein involved in secretory vesicle transport

Authors: P. CHANDER, *J. P. WEICK;
Neurosci., Univ. of New Mexico, Albuquerque, NM

Abstract: AMPA receptor (AMPAR) trafficking is a well-established mechanism underlying transient and enduring changes in synaptic efficacy during learning and memory. Altered glutamatergic neurotransmission has been implicated in a variety of neurological disorders such as Autism, Down syndrome, and Schizophrenia among others. Surprisingly, little is known about how newly-synthesized AMPARs are trafficked through the secretory pathway and delivered to nascent synaptic sites during development. We discovered that NSG2, along with the GluA2 AMPAR subunit, are two of the most highly-upregulated transcripts during functional maturation of human pluripotent stem cell-derived neurons (hPSNs). Based on sequence homology, NSG2 (also known as HMP19) has been classified as a member of a family of three, single transmembrane domain-containing proteins including Calcyon and NEEP21 (NSG1). Both Calcyon and NEEP21 are endosomal proteins shown to regulate AMPA receptor (AMPAR) trafficking during synaptic plasticity. Thus, we hypothesized that NSG2 was involved in trafficking newly-synthesized AMPARs to sites along neuronal arbors that are destined to form synaptic junctions during functional development. In addition to previously demonstrated golgi localization, overexpression of NSG2-mCherry resulted in small fluorescent punctae located throughout developing neuronal arbors. Time-lapse imaging revealed dynamic antero- and retrograde transport (~1μm/sec), consistent with active transport along microtubules. Endogenous and overexpressed NSG2 was found co-localized with intracellular compartments including endosomes and golgi apparatus. Co-immunoprecipitation experiments showed that NSG2 bound to both overexpressed and endogenous forms of the GluA2 subunit of AMPARs *in vitro* and from whole brain lysates from neonatal mouse pups. Lastly, modulation of NSG2 protein levels revealed predicted alterations in AMPAR-mediated glutamatergic neurotransmission. Together, these data support the notion that NSG2 is a critical mediator of AMPAR trafficking in developing neurons. In addition, these data support the use of hPSNs for the discovery of relatively late neurodevelopmental processes that occur *in vivo*.

Title: Neuromuscular NMDA receptors modulate developmental synapse elimination

Authors: ***S. B. UDIN**[1], B. SLUSHER[3], C. GARCIA[2], M. BANCONE[2], M. MORALES[1], K. PERSONIUS[2];
[1]Physiol. and Biophysics, [2]Rehabil. Sci., SUNY, BUFFALO, NY; [3]Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Motor neurons form excess synaptic connections with muscle fibers during normal development. After birth, the extraneous connections are lost, leading to mono-innervation. This synapse elimination is controlled by differential activity: the more active motor inputs gain synaptic territory, while the less active are deleted. The field has focused on acetylcholine as the mediator of activity, but our data indicate that NMDA receptors are the pivotal system activated by differential activity. NMDA and AMPA receptors have previously been described at the adult neuromuscular junction (NMJ) by Berger et al. (1995) and Mays et al. (2009). Using immunohistochemical methods in postnatal day 4 (P4) and P18 CD-1 mice, we find post-synaptic expression of GluA1, GluN1 and GluN2A at the NMJ. To test the role of ionotropic glutamate receptors in synapse elimination, we inhibited those receptors by implanting slices of the slow-release polymer Elvax infused with CNQX and AP-5 between the anterior and posterior compartments of the leg at P4. Contralateral muscles were implanted with saline-infused Elvax. At P11, immunostaining to reveal the extent of polyneuronal innervation demonstrated a highly significant slowing of synapse elimination in the CNQX-AP5 treated muscles. Another test of the hypothesis that NMDA receptors promote synapse elimination of weak inputs, and/or stabilization of the strongest input, utilized a morpholino to knock down expression of the NMDA receptor GluN1 subunit. Anti-GluN1 or scrambled control morpholinos were injected at the endplate region at P4. At P11, there again was highly significant slowing of synapse elimination in the experimental muscles vs control. The glutamate at the NMJ is likely to originate from N-acetyl-aspartylglutamate (NAAG) released from the motor neuron. NAAG can

be enzymatically cleaved by glutamate carboxypeptidase II (GCPII) to yield glutamate. We thus hypothesized that blocking GCPII would have an effect comparable to blocking glutamate receptors. We infused the GCPII inhibitor 2-(Phosphonomethyl)pentane-1,5-dioic acid via Elvax from P4-P11 and again obtained highly significant slowing of synapse elimination. To assess the response of the EDL muscle to glutamate from P3-adult, we have begun to use calcium imaging. Our results to date indicate much more vigorous response in muscles up to P14 than at older ages. Our data support the hypothesis that glutamate, produced from enzymatic breakdown of NAAG, activates NMDA receptors and thus contributes to reduction of polyneuronal innervation at the developing NMJ. This work was supported by University at Buffalo Rehabilitation Science Collaborative Grants to KEP.

Title: Afadin plays a role in formation of puncta adherentia junction and differentiation of presynapses in hippocampal neurons

Authors: *D. TOYOSHIMA[1,2,3], K. MANDAI[2,3], T. MARUO[2,3], I. SUPRIYANTO[4,3], M. MORI[4,3], Y. TAKAI[2,3];

Sch. of Med., Kobe, Japan; [3]CREST, Japan Sci. and Technol. Agency, Kobe, Japan; [4]Fac. of Hlth. Sciences, Kobe Univ. Grad. Sch. of Hlth. Sci., Kobe, Japan

Abstract: A synapse, a specialized form of a cell-cell adhesion site in neurons, consists of synaptic junctions and puncta adherentia junctions (PAJs). PAJs are highly developed in mossy fiber-CA3 pyramidal cell synapses in the hippocampus. The formation and remodeling of the mossy fiber-CA3 pyramidal cell synapses are implicated in the cellular basis of learning and memory. Although afadin and its binding cell adhesion molecules such as nectin-1, nectin-3, and N-cadherin, are concentrated at PAJs in these synapses, the function of these molecules has remained elusive. Here, we investigated the roles of afadin in PAJ formation and presynaptic differentiation in the mossy fiber-CA3 pyramidal cell synapses. In the mice of which afadin gene was conditionally inactivated before synaptogenesis, the immunofluorescence signals for the PAJ components such as nectin-1, nectin-3 and N-cadherin, disappeared almost completely, while those for the presynaptic components such as VGLUT1 and bassoon, were markedly decreased. In addition, these signals were significantly decreased in cultured afadin-deficient hippocampal neurons. Furthermore, the interevent interval of miniature excitatory postsynaptic currents (mEPSCs) was prolonged in the cultured afadin-deficient hippocampal neurons compared with control neurons, indicating that presynaptic release functions were suppressed or the number of synapses was reduced in the afadin-deficient neurons. Analyses of presynaptic vesicle recycling and paired recordings revealed that the cultured afadin-deficient neurons showed impaired presynaptic functions. These results indicate that presynaptic functions were suppressed or the number of synapses was reduced in the afadin-deficient neurons. Taken together, afadin regulates both PAJ formation and presynaptic differentiation in most mossy fiber-CA3 pyramidal cell synapses, while in a considerable population of the neurons, afadin regulates only PAJ formation but not presynaptic differentiation.

Title: Maintenance of the large-scale depolarization wave in the embryonic chick brain against deprivation of the rhythm generator

Authors: *Y. MOMOSE-SATO[1], K. SATO[2];

[2]Dept Hlth. & Nutr. Sci., Komazawa Women's Univ., Tokyo, Japan

Abstract: Widely correlated spontaneous activity in the developing nervous system is transiently expressed and is considered to play a fundamental role in neural circuit formation. The depolarization wave, which spreads over a long distance along the neuraxis, maximally extending to the lumbosacral cord and forebrain, is an example of this spontaneous activity. Although the depolarization wave is typically initiated in the spinal cord in intact preparations, spontaneous discharges have also been detected in the isolated brainstem. Although this suggests that the brainstem has the ability to generate spontaneous activity, but is paced by a caudal rhythm generator of higher excitability, a number of questions remains. Does brainstem activity simply appear as a passive consequence, or does any active change occur in the brainstem network to compensate for this activity? If the latter is the case, does this compensation occur equally at different developmental stages? Where is the new rhythm generator in the isolated brainstem? To answer these questions, we optically analyzed spatio-temporal patterns of activity detected from the chick brainstem before and after transection at the obex. The results revealed that the depolarization wave was homeostatically maintained, which was characterized by an increase in excitability and/or the number of neurons recruited to the wave. The wave was more easily maintained in younger embryos. Furthermore, we demonstrated that the ability of brainstem neurons to perform such an active compensation was not lost even at the stage when the depolarization wave was no longer observed in the intact brainstem.

Title: Optical survey of initial expression of synaptic function in the embryonic chick trigeminal sensory nucleus

Authors: *K. SATO[1], Y. MOMOSE-SATO[2];
[1]Dept. Hlth. & Nutr. Sci., Komazawa Women's Univ., Tokyo, Japan; [2]Dept. Hlth. & Nutr., Kanto-Gakuin Univ. Coll. Human & Environ. Studies, Yokohama, Japan

Abstract: We examined the initial expression of synaptic function in the embryonic chick trigeminal nucleus using voltage-sensitive dye recording. Brainstem preparations with three trigeminal nerve afferents, the ophthalmic nerve (N. V1), maxillary nerve (N. V2) and mandibular nerve (N. V3), were dissected from 5.5- to 6.5-day-old chick embryos. In our previous study [Sato et al., 1999], we detected slow signals corresponding to glutamatergic excitatory postsynaptic potentials and identified the principal sensory nucleus of the trigeminal nerve (Pr5), spinal sensory nucleus of the trigeminal nerve (Sp5) and trigeminal motor nucleus. In this study, we examined the effects of removing Mg2+ from the physiological solution, which enhanced N-methyl-D-aspartate receptor function in the sensory nuclei. In 6.5-day-old (St 29) embryos, the slow signal was observed in Pr5 and Sp5 only when N. V1 was stimulated, whereas it appeared in Mg2+-free solution with every nerve stimulation. In 6-day-old (St 28) embryos, the slow signal was observed in Sp5 with N. V1 stimulation, and the appearance of synaptic function in Mg2+-free solution varied, depending on the nerves and preparations used. In 5.5-day-old (St 27) embryos, synaptic function was not detected even when external Mg2+ was removed. These results indicate that the initial expression of synaptic function in the trigeminal system occurs earlier than previously considered, and that the developmental organization of synaptic function differs among the three trigeminal nerves and between the two sensory nuclei.

Title: Matricryptins derived from collagen XIX induce inhibitory synapse formation

Authors: *J. SU, M. FOX;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Although inhibitory synapses comprise only ~20% of the total synapses in the mammalian cerebrum, they play essential roles in controlling neural activity. In fact, perturbing inhibitory synapse assembly or function has been associated with autism, epilepsy and schizophrenia. Although many types of inhibitory synapses exist, these developmental disorders have been strongly linked to defects in inhibitory synapses formed by parvalbumin (PV)-expressing interneurons. Despite their importance we lack a complete understanding of the mechanisms that underlie the formation of these inhibitory synapses. With that in mind our attention has been drawn to collagen XIX, an unconventional collagen expressed by interneurons during synaptogenesis. Mice lacking collagen XIX exhibit spontaneous generalized motor and absence seizures and are more susceptible to drug-induced seizure induction, both phenotypes associated with defects in inhibitory signaling. Here we show that these collagen XIX-deficient mice exhibit defects in PV+ synapse formation in subiculum, visual cortex and prefrontal cortex. Like other unconventional collagens, the C-terminal domain of collagen XIX is proteolytically shed and functions as a matricryptin (i.e. a fragment of an ECM molecule that exhibits a unique function from the full length molecule from which it was released from). Since other matricryptins have been shown to be synaptogenic, we speculated that collagen XIX-derived matricryptins (termed NC1[XIX]) are synaptogenic. Here, *in vitro* assays show that NC1[XIX] induces the formation of functionally active inhibitory nerve terminals and is sufficient to rescue synaptic defects in the absence of full-length collagen XIX. Moreover, the synaptogenic activity of NC1[XIX] can be blocked with RGD-containing peptides, indicating that integrins are required for NC1[XIX] function. Taken together, these results reveal a novel set of mechanisms governing the formation of inhibitory synapses in the mammalian cerebrum.

Title: Loss of synaptogenic collagen XIX results in spontaneous seizures, increased seizure susceptibility, and schizophrenia-related behaviors

Authors: *K. M. LIPPOLD, J. SU, J. CHEN, M. FOX;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Inhibitory synapses comprise only a small fraction of the total synapses in the mammalian cerebrum, but play essential roles in controlling neural activity. Perturbing inhibitory synapse assembly or function has been associated with autism, epilepsy and schizophrenia. We recently identified collagen XIX as a trans-synaptic synaptic organizing cue that is expressed by cerebral interneurons and is necessary for the proper assembly of inhibitory nerve terminals in hippocampus and cortex. In humans, deletion of the genomic region encoding this unconventional collagen has been linked to familial schizophrenia. Here, we discovered that genetically modified mice lacking collagen XIX exhibit spontaneous generalized motor and absent seizures. Video EEG/EMG recordings were employed to document rapid spiking waves and spike-wave complexes during seizures in collagen XIX-deficient mutants. In addition to spontaneous seizures, deletion of collagen XIX increased susceptibility to PTZ-induced and significantly impaired the ability to terminate drug-induced seizures. This result is particularly interesting to us since we hypothesize that collagen XIX is essential for the formation of inhibitory PV+ synapses and these synapses regulate seizure termination. Finally, based on these phenotypes and the mapping of familial schizophrenia to the genomic region encoding collagen XIX, we asked whether mice lacking collagen XIX exhibit schizophrenia-related behaviors. Data presented here demonstrate that mice lacking this synaptogenic collagen display impaired responses to pre-pulse inhibition assays and a striking lack of nest-building activity. Taken together with data showing a role of collagen XIX in being critical for inhibitory synapse formation, these data reveal that collagen XIX-deficient mutants exhibit anatomical, physiological and behavioral defects consistent with defects associated with schizophrenia. Moreover, these studies are beginning to provide cellular and molecular data that increase our understanding of why mutations of collagens lead to complex brain disorders.

Title: Astrocyte transforming growth factor beta 1 promotes inhibitory synapse formation via CAM kinase II signaling

Authors: L. P. DINIZ[1], V. TORTELLI[1], M. N. GARCIA[1], A. BÉRGAMO[1], H. M. MELO[2], G. S. S. DA SILVA[2], F. G. DE FELICE[2], S. V. ALVES-LEON[3], J. M. DE SOUZA[3], L. F. ROMÃO[4], *F. C. GOMES[1];
[1]Inst. of Biomed. Sci., [2]Inst. of Med. Biochem., [3]Universitary Hosp., [4]Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Introduction: Astrocytes play an important role in the development and function of neuronal circuitry. Recent studies have indicated that, in addition to regulating excitatory synaptogenesis, astrocytes also regulate inhibitory synapse formation. However, the molecule(s) and the molecular mechanisms that control this event remain unknown. One putative candidate belongs to the Transforming Growth Factor Beta (TGF-β) superfamily, which multifunctional polypeptide members are critical for the modulation of GABAA synaptic transmission and dendritic homeostasis. Recently, we demonstrated that TGF-β1 induces formation of excitatory synapses between cortical neurons (Diniz et al., J. Biol. Chem. 2012). However, its effect on inhibitory synapses is unknown. Objective: To verify if TGF-β derived from murine and human astrocytes regulates the formation of inhibitory synapses between cortical neurons. Methods and Results: Conditioned media derived from human and murine astrocytes induced formation of inhibitory synapses between cerebral cortex neurons *in vitro*, an event inhibited by both pharmacologic and genetic manipulation of the TGF-β pathway. TGF-β1 induction of inhibitory synapses was dependent on glutamatergic activity and activation of CaM kinase II, which thus increased the levels of the synaptic adhesion protein, Neuroligin 2, and induced its localization to the inhibitory postsynaptic terminals. Additionally, intraventricular injection of TGF-β1 enhanced inhibitory synapse number in the cerebral cortex. Our results identify TGF-β1/CaMKII pathway as a novel molecular mechanism underlying astrocyte control of inhibitory synapse formation. We propose here that the balance between excitatory and inhibitory inputs might be provided by astrocytes signals, at least partly achieved via TGF-β1 downstream pathways. Our work contributes to the understanding of the GABAergic synapse formation and may be of relevance to further the current knowledge on the mechanisms underlying the development of various neurological disorders, which commonly involve impairment of inhibitory synapse transmission.

Title: FGF22 and FGFBP1 regulate presynaptic differentiation

Authors: ***M. J. TENGA**[1], H. UMEMORI[2], G. VALDEZ[1,3];
[1]Virginia Tech. Carilion Res. Inst., Roanoke, VA; [2]Boston Children's Hospital, Harvard Univ., Boston, MA; [3]Dept. of Biol. Sci., Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: Synaptic development is a multistep process that includes the selective aggregation of molecular machineries during the transformation of nerve terminals to mature presynaptic sites. Previous findings have shown that signaling mediated by the FGF receptor 2b (FGFR2b) is required for the proper maturation of presynaptic terminals in the central and peripheral nervous systems. In this study, we assessed the roles of FGF22, a ligand for FGFR2b, and the FGF binding protein 1 (FGFBP1), a molecule that enhances the activity of FGF22, in promoting presynaptic differentiation. Using animals that lack FGF22, FGFBP1 or both (dKO), we examined presynaptic differentiation at early postnatal stages at the neuromuscular junction and at parvalbumin-positive brain synapses. Compared to control animals, presynaptic differentiation was delayed at neuromuscular junctions in single and double knockout animals. These defects were characterized by delayed apposition of presynaptic vesicles to the postsynapse, with synaptic vesicles found aggregated along the axon and outside of the nerve terminal. Although these developmental defects are short lived in FGF22 knockout animals, they persist in FGFBP1 knockout and dKO mice. In addition to presynaptic defects, neuromuscular junctions in FGFBP1 and dKO mice exhibit additional structural alterations, including fragmentation. These findings suggest important roles for FGF22 and FGFBP1 during presynaptic differentiation. In addition, the long-lasting synaptic defects seen in FGFBP1 and dKO mice indicate that other FGFs, regulated by FGFBP1, are involved in synaptic maturation.

Abstract: Evolution of network behavior is determined both by excitatory and inhibitory synaptogenesis. Attempts have been made to count synapses at different developmental stages in cell cultures, however, little is known about the individual densities of excitatory and inhibitory synapses. To quantify synaptogenesis, we counted the number of excitatory and inhibitory synapses at four critical stages during development: 5, 8, 14 and 20 days *in vitro* (DIV). We used immunofluorescence to label: 1) dendrites (MAP-2), 2) pre- and 3) postsynaptic puncta of excitatory synapses (vGlut/PSD-95) and inhibitory synapses (VGAT/gephyrin), 4) nuclei in cell bodies (DAPI). High resolution (50nm x 50nm pixel) images were acquired on Leica confocal microscope and deconvolved using Huygens software to remove distortions arising from a microscope's point spread function. Subsequently, ImageJ software was employed to obtain the synaptic counts from colocalization of dendrites, pre- and postsynaptic puncta. We developed a novel method to detect these colocalizations and to obtain a noise estimate associated with the detections. First, we created binary masks of the a) dendrites by tracing the outline structure, b) pre- and c) postsynaptic puncta, by extracting single pixel local-maxima of fluorescence intensity and expanding them by two pixels in all directions. Overlap detected from binary AND of the three masks was counted as a colocalized synapse on dendrites. Next, to estimate colocalizations that occur by chance, we repeated the detection procedure after destroying the spatial correlation between pre- and postsynaptic puncta by a) randomizing images of local-maxima, b) shifting the original pre- and postsynaptic masks relative to each other (cross-correlation). Both these

methods produced similar results for colocalizations by chance, which was used as detector baseline noise. We thus estimated excitatory and inhibitory synaptic density as number of synaptic counts per unit dendritic area, normalized by total cell count. Our preliminary results show that the density of excitatory synapses increases rapidly from 5 DIV to 14 DIV and decreases during the last developmental stage, 20 DIV. In contrast, the density of inhibitory synapses grows steadily with age and approaches the density of excitatory synapses at the last stage. Given that the typical ratio of excitatory to inhibitory populations is 80:20 in hippocampal networks, these data suggest that excitatory synaptogenesis naturally predominates during the first three weeks *in vitro*, while inhibitory synaptogenesis increases steadily to eventually balance the excitation towards the fourth week of maturation.

Title: Development of asymmetric inhibition required for direction selectivity in the retina

Authors: *R. D. MORRIE, M. B. FELLER;
Dept. of Mol. and Cell Biol., Univ. of California, Berkeley, Berkeley, CA

Abstract: In the murine retina, direction selective ganglion cells (DSGCs) fire action potentials maximally to objects in the visual scene moving in their preferred direction, but minimally to objects moving in the opposite, or null, direction. These directional responses are produced by an asymmetry in overall inhibitory conductance onto DSGCs, such that object motion in the null direction elicits a greater amount of GABAergic inhibition from starburst amacrine cells (SACs.). Though it has been established that this asymmetry in inhibition emerges during the second postnatal week, the synaptic basis of the asymmetry remains to be determined. Here we assess the quantal properties of inhibitory transmission between SACs and DSGCs during

development. First, we performed paired voltage-clamp recordings between genetically labeled SACs and DSGCs in the mouse and measured the amplitude and time course of paired pulse depression to compare the probability of release. We found no significant differences between null and preferred side synapses at P7 or P14. In addition, we found no significant difference in the kinetics of the GABA-A receptor mediated responses, indicating there were not differences in quantal content. Last, we have conducted analysis on spontaneous events, which we previously determined increase in frequency but not amplitude between these two ages. Preliminary data indicates that across development there is a significant change in frequency of events. Together, these findings suggest that the over the course of development there is an asymmetric increase in the number, but not the strength, of SAC to DSGC synapses. This implicates synaptogenesis from null side SACs as the driving force for the development of the direction selective circuit.

Abstract: Precise coordination of extracellular and intrinsic factors is critical for various developmental processes during the formation of the mammalian cerebral cortex. Among the scaffold proteins which serve as platforms for the formation of multi-signaling components to

transduce extracellular signals to intracellular targets, Axin (axis inhibitor) is one that is expressed at high levels in mouse brain at embryonic and postnatal stages. Our laboratory recently reported that Axin and its phosphorylation at Thr485 by cyclin-dependent kinase 5 (Cdk5) is crucial for the cerebral cortex development, particularly in the regulation of embryonic neurogenesis and axon outgrowth. However, the roles of Axin in other neurodevelopmental processes remain unclear. Interestingly, we found that Axin and its Thr485 phosphorylated form were enriched in the post-synaptic compartments in mouse brain, and well co-localized with post-synaptic marker PSD-95. Whereas knockdown of Axin by targeted shRNA impaired dendritic growth and reduced the density of dendritic spines in cultured hippocampal neurons, these developmental defects could be rescued by re-expression of the RNAi-resistant Axin construct. In addition, stabilization of Axin increased the phosphorylation of GluA receptors at Ser831. Taken together, our study suggests that Axin plays a critical role in dendrite and spine development in the hippocampus.

Title: Exploring cell-type specific alternative splicing activity in neurons using bichromatic reporters

Authors: *T.-M. NGUYEN, D. SCHREINER, P. SCHEIFFELE;
Biozentrum, Univ. of Basel, Basel, Switzerland

Abstract: Neurexins represent a highly polymorphic family of receptors that contributes to the differentiation and function of neuronal synapses. The large molecular diversity results from combinatorial usage of alternative exons at six alternative spliced segments. The respective alternative splicing modulates protein structures and regulates the interaction with different synaptic ligands. The polymorphic nature and selective biochemical interactions of Neurexins raise the question whether specific isoforms are linked to the genetic identity of neurons.

Furthermore it remains unknown if neurons of same population display similar preference of the exon usage at an alternatively spliced segment or if cell-to-cell heterogeneity exists in the alternative splicing activity. Due to the cellular complexity of the brain as well as the molecular diversity of Neurexins the analysis of isoform expression with the single-cell resolution level using mRNA methods or histological tools has been challenging. To address these questions we have developed a bichromatic reporter system to monitor and quantify alternative splicing of individual cells *in situ*. Through introduction of a single nucleotide insertion in the alternatively spliced exon, two different translational reading frames are generated. Therefore changes in the alternative splicing choice are converted into changes in the reading-frame that can be detected at the protein level. We will present our results of validating and applying these reporters in cell cultures and in mouse brain *in vivo*.

Title: Spikar, a novel transcriptional coactivator, regulates the formation and stabilization of dendritic spines dependent on drebrin

Authors: *H. YAMAZAKI, T. SHIRAO;
Gunma Univ., Maebashi, Japan

Abstract: Dendritic spines are small, actin-rich protrusions on dendrites whose development is fundamental for the formation of neural circuits. The actin cytoskeleton is a central player in dendritic spine morphogenesis. Drebrin is an actin-binding protein, which is thought to initiate the spine formation through forming unique drebrin-actin complex at postsynaptic sites. In this study, we have isolated a novel drebrin-binding protein, spikar. Spikar has bromo domain, two zinc-finger domains, and LXXLL nuclear-receptor box. A reporter gene assay demonstrated that spikar acts as a transcriptional coactivator for thyroid hormone receptor and estrogen receptor. In cultured neurons, spikar was localized mainly in nuclei and dendritic spines. Using RNA interference (RNAi) approaches, we found that spikar knockdown in cultured neurons resulted in

decrease of dendritic spines and filopodia. In addition, electrophysiological study demonstrated that Spikar knockdown resulted in a decrease of mEPSC frequency. These data suggested that spikar is involved in the spine formation. Rescue and overexpression experiment using mutated-NLS spikar (mNLS-spikar) showed that spikar is involved in spine formation in cytoplasm by modulating de novo spine formation and retraction of existing spines. We then examined whether the spine-formation activity of mNLS-spikar would require the presence of drebrin. We cotransfected mNLS-spikar and drebrin-shRNA into cultured neurons and measured the numbers of spines and filopodia. The drebrin knockdown abolished the mNLS-spikar-induced increase in spine and filopodium density. The inhibition of mNLS-spikar function by drebrin knockdown was rescued by the co-expression of an RNAi-resistant drebrin mutant. We further employed fluorescent recovery after photobleaching (FRAP) to evaluate the stability of spikar in dendritic spines. In drebrin-knockdown neurons, the stable fraction of mNLS-spikar was smaller than that of control neurons. These data indicate that extranuclear spikar facilitates spine and filopodium formation depending on drebrin.

Univ., Seoul, Korea, Republic of; [4]Sch. of Mechanical and Aerospace Engineering, Seoul Natl. Univ., Seoul, Korea, Republic of; [5]Weill Med. Col. of Cornell Univ., New York, NY

Abstract: The mechanism of local protein synthesis in dendrites and axons is currently under intense investigation. Recent studies identified a large number of mRNAs localized at distal axons and growth cones, suggesting that local axonal translation may play an important role in different steps of neuronal development. In line with these evidences, early studies in axons demonstrated the requirement of local translation during axon chemotrophic responses to guidance cues. Moreover, it was demonstrated that local axonal translation is required for other neurodevelopmental mechanisms, such as axonal outgrowth, neuronal survival and axon regeneration. Interestingly, recent studies in *Aplysia*, suggest that local translation might be important for synapse formation. However, the role of local protein synthesis in presynaptic differentiation is largely unknown. Using a novel platform, a microfluidic chamber system which allows the physical separation of axons from cell bodies and dendrites, we were able to specifically manipulate axons without the cell body contribution. Our results demonstrate that FGF22 induced the clustering of synaptic vesicles, a hallmark of presynaptic assembly, when added specifically to axons. Additionally, when protein synthesis is inhibited specifically in axons, SV2 clustering is reduced to basal levels. FGF22 leads to the phosphorylation of 4E-BP1, a translational repressor, in an asymmetric pattern and induces intra-axonal translation of a beta-actin reporter, a destabilized form of EGFP fused to the 3'UTR of beta-actin. Taken together our results show that FGF22 activates cap-dependent translation and that this intra-axonal mRNA translation is required for presynaptic differentiation.

Title: Thyroid hormones induce neural differentiation and synapse formation in the cerebral cortex

Authors: *R. S. DEZONNE, SR, J. STIPURSKY, F. GOMES;
Inst. de Ciências Biomédicas-ICB, Bloco B, Sala F-15, Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Thyroid hormones (TH) are crucial for brain morphogenesis, acting in several steps like proliferation of progenitor cells, neuronal differentiation, maturation and migration, and synapse formation. We have previously shown that TH effects in neonatal cerebral cortex are mediated by astrocytes, although the mechanisms underlying these events during early phases of neural development are still unknown.In this study, we investigated the role of TH in neural cells (neuronal and glial progenitors) differentiation and maturation. By using cultures of neurons and radial glia cells (RG) derived from the cerebral and *in vivo* model of hypothyroidism, we analyzed neuronal and RG differentiation, neurite outgrowth and synaptogenesis.We observed that T4 significant reduced neuronal death and increased neuronal progenitors' proliferation and terminal differentiation. This was followed by neuronal morphological maturation, revealed by increased number and size of neurites in response to hormone treatment. Further, T4 induced excitatory and inhibitory synaptogenesis *in vitro*. These *in vitro* data was corroborated by the observation that hypothyroidism reduced the number of excitatory synapses in the cerebral cortex. In addition,THs induce astrocyte differentiation form RG. RG treated cells switch their neurogenic state to a gliogenic one, and change their radial morphology to resembles mature astrocytes.Together, our data suggest an important role for TH during neuronal maturation, and contribute to the understanding of the cellular and molecular mechanisms associated with cognitive deficits that accompany neuroendocrine disorders.

Abstract: Proper brain function requires balanced inhibitory and excitatory microcircuitry within the neocortex. To establish this balance, precise connections matching cell identity and spatial distribution are required. Previous work has shown that loss of the transcription factor, Fezf2, converts the fate of corticofugal projection neurons (CFuPN) to callosal projection neurons (CPN) in the deep layers, which in turn leads to abnormal lamination of inhibitory neurons and altered GABAergic inhibition (Lodato et al, 2011). It remains unclear whether the identity of individual pyramidal neuron targets or extracellular signals contained within different cortical layers instruct the local connectivity of inhibition. Here, we took the approach of direct lineage programming of CPN to CFuPN by *in utero* expression of Fezf2 in post-mitotic layer 2/3 neurons to dissect these possibilities. Reprogramming of CPNs to CFuPNs did not disturb gross lamination of cortical structure. Using single-cell real-time PCR, we first confirmed that reprogrammed CPNs acquired molecular signatures of deep layer CFuPNs. By whole-cell electrophysiology in brain slices, Fezf2-expressing layer 2/3 neurons were classified into two groups by supervised learning using a generalized linear model. The intrinsic membrane properties of reprogrammed CPNs were found to be distinct from neighboring CPNs, but similar to CFuPNs. Further, Fezf2-expressing layer 2/3 neurons showed higher frequency of miniature inhibitory post-synaptic events, indicating that changing the identity of individual pyramidal neurons from CPN to CFuPN recruited more inhibitory synapses. In particular, the functional inputs from Parvalbumin expressing interneurons onto Fezf2-expressing neurons were increased, in agreement with increased number of PV puncta on reprogrammed CPNs. Taken together, the identity of cortical pyramidal neurons is critical in establishing local circuit inhibition.

Title: Interleukin-1β alters cortical connectivity in development and disease through regulating synaptic localization of IL-1β receptors

Authors: *M. ESTES[1], A. MCALLISTER[2];
[1]UC Davis, Davis, CA; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: M.L. ESTES, A. K. MCALLISTER; Univ. of California Davis, Davis, CA Abstract: Autism spectrum disorder (ASD) and schizophrenia (SZ) appear to be caused by both genetic mutations and environmental factors, many of which alter synaptic function and/or the immune response. The pro-inflammatory cytokine IL-1β, in particular, has been implicated in both disorders. IL-1 is elevated in the plasma and cerebrospinal fluid in ASD and polymorphisms in the IL-1 gene cluster, as well as mutations in components of the IL-1β receptor complex, including IL1RAPL1, are linked to ASD and SZ. During brain development, IL1RAPL1 and another IL-1β receptor, IL-1RAcP, function as central synaptic organizers through trans-synaptic interactions with PTPδ. Recently, our lab discovered that IL-1 levels are altered in the postnatal brain of offspring following maternal immune activation (MIA), which is the most compelling environmental risk factor for both ASD and SZ. These data suggest that IL-1 signaling might mediate the effects of a maternal peripheral immune response in altering connectivity and leading to ASD- and SZ-like behaviors in offspring. We have started to test this hypothesis by assessing the effects of MIA and exogenous IL-1 on IL-1 receptor composition and synapse density in dissociated cortical cultures. IL-1β and its receptors are present in the healthy, developing brain where it bi-directionally regulates cortical connectivity in a dose-dependent manner. At elevated concentrations, as seen in the brains of MIA offspring, IL-1β decreases synapse density through altering the synaptic localization of immune receptors that double as trans-synaptic adhesion molecules. In contrast, physiological concentrations of IL-1β promote synapse formation through an alternative mechanism. Similar to the effects of MIA, elevated concentrations of IL-1β that decrease glutamatergic synapse density also increase MHCI

expression on neurons, which itself causes synapse elimination. We are currently determining the relative roles for, and potential interactions between, IL-1β and MHCI in mediating the effects of MIA on cortical development. Together, these results suggest that environmental factors that alter IL-1 levels, and genetic mutations in IL-1 receptors themselves, converge on the synaptic localization of IL-1 receptors as a central mechanism of altering cortical connectivity in ASD and SZ.

Title: Dissecting the structural role of GABA(A) receptors in synapse formation

Authors: L. E. BROWN, J. E. BENILLOUCHE-ARAMA, M. W. NICHOLSON, F. A. STEPHENSON, A. M. THOMSON, *J. N. JOVANOVIC;

Abstract: The formation of inhibitory synapses is a precisely controlled process that is initiated by the establishment of specific cell-cell contacts between the presynaptic GABAergic neurons and their postsynaptic targets. Although the interactions between cell surface molecules are known to be the key regulators of this process, the molecular and functional characterization of these interactions remains sparse. Our recent experiments have indicated that GABA(A) receptors, themselves the main postsynaptic functional components of these synapses, play an important regulatory role (*Fuchs C, et al. (2013) Eur J Neurosci **38**, 3146*). Our aim is to characterize further the structural role of GABA(A) receptors in synapse formation. We have developed a heterologous co-culture model system, which incorporates the embryonic medium spiny neurons (MSNs) and HEK293 cells expressing various combinations of GABA(A) receptor subunits: α1/β2, α1/β2/γ2, α1/β2/δ, α1/β3 or α1/β3/γ2. After 24 h in co-culture, synapse formation was analyzed by immunolabelling with antibodies specific for the vesicular gamma-

aminobutyric acid transporter, as a presynaptic marker, and GABA(A) receptor subunits as postsynaptic markers. The activity of synapses was assessed using FM4-64 uptake. Synapse formation was quantified using Image J software. Our results indicate that the γ2 subunit promotes synapse formation. However, the magnitude of the effect of the γ2 subunit is influenced by the type of the β subunit, with the α1/β2/γ2 combination being significantly more effective than the α1/β3/γ2 combination. In comparison, minimal, if any contacts, formed between the MSNs and control HEK293 cells or those expressing the α1/β2/δ combination. The synaptogenic effects of GABA(A) receptors may be mediated by interactions between their large N-terminal extracellular domains (ECDs) and the proteins residing in the synaptic cleft. To investigate this, we have cloned, expressed and purified the N-terminal ECDs of α1, α2, β2 and γ2 subunits using a baculovirus/Sf9 cell system. The controls were prepared using the extracts of untransfected Sf9 cells which were taken through the same purification protocol. Synapse formation was reduced in the presence of the exogenous ECDs, probably due to competition in binding with the endogenous ECDs of GABA(A) receptors. These findings further support the structural role of GABA(A) receptors in synapse formation.

Title: Receptors and signaling that distinctly mediate excitatory and inhibitory presynaptic differentiation induced by the presynaptic organizers FGF22 and FGF7

Authors: *A. K. DABROWSKI[1,3], A. TERAUCHI[3,2], C. STRONG[1], H. UMEMORI[3,2]; [1]MBNI, [2]Mbni, Univ. of Michigan, Ann Arbor, MI; [3]F.M. Kirby Neurobio. Ctr., Boston Children's Hosp., Boston, MA

Abstract: Formation of synaptic connections between appropriate partner neurons is crucial to proper brain development. During early stages of synapse development, molecules exchanged between complementary neurons facilitate differentiation of nascent synapses. We have shown that two target-derived fibroblast growth factors (FGFs), FGF22 and FGF7, are secreted from dendrites of CA3 pyramidal neuron and differentially promote excitatory and inhibitory presynaptic development in the CA3 of the hippocampus (Terauchi et al. 2010). Here we ask the signaling mechanisms through which FGF22 and FGF7 promote specific differentiation of excitatory and inhibitory presynaptic terminals, respectively. For this, we performed a series of *in vivo* and *in vitro* experiments in mice constitutively or conditionally lacking putative FGF receptors (FGFRs). We found that mice lacking FGFR2b or FGFR1b have excitatory presynaptic deficits phenocopying loss of FGF22, and mice lacking FGFR2b have inhibitory presynaptic deficits phenocopying loss of FGF7 in hippocampal CA3 *in vivo*. We then used an *in vitro* responsiveness assay and found that neurons lacking FGFR2b or FGFR1b do not respond to FGF22, and neurons lacking FGFR2b do not respond to FGF7. Since FGF22 requires both FGFR2b and FGFR1b, while FGF7 only requires FGFR2b, we propose that FGFR2b is a general signal to promote presynaptic differentiation, while FGFR1b provides specificity to the FGF22 response. We further asked whether FGFRs are functioning presynaptically in response to FGF22, and which signaling pathways are required downstream of FGFRs. To do this, we selectively knocked out FGFR2 and FGFR1 from the presynaptic cells, the dentate granule cells (DGCs), *in vitro*, and assayed their responsiveness to FGF22. We found that both FGFR2 and FGFR1 are required for DGCs to respond to FGF22. Furthermore, we created FGFR2b constructs that are kinase dead, FRS2 binding deficient, PI3K binding deficient, and PLCg binding deficient, which we selectively overexpressed in DGCs. We found that loss of kinase activity, or FRS2 or PI3K binding blocked response to FGF22, suggesting that the FRS2/AKT pathways are required for FGF22 responsiveness in the presynaptic cell. Together, our results suggest a model in which FGFR2b and FGFR1b function in the presynaptic cell to respond to target-derived FGF22, activating signaling pathways downstream of FRS2 and AKT to organize excitatory presynaptic terminals, while FGFR2b alone responds to FGF7 to promote inhibitory presynaptic differentiation. Our results provide insight into signaling mechanisms of how FGF22 and FGF7 selectively promote excitatory and inhibitory synapse differentiation.

Title: Ephrin-B3 regulates excitatory synapse density through cell-cell competition

Authors: N. T. HENDERSON, S. LEMARCHAND, *M. HRUSKA, M. DALVA;
Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Synaptic communication is fundamental to the function of the nervous system, providing a means for rapid signaling and computation within neural networks. The number of synaptic inputs received by individual neurons varies across different brain regions and cell types from thousands to hundreds of thousands, yet the mechanisms by which this heterogeneity in synapse density is determined remain largely unknown. Eph receptors and their ligands, the ephrins, function as trans-synaptic cell adhesion molecules that play important roles in synapse development and function. Previous work has shown that ephrin-B3 functions postsynaptically to regulate excitatory synapse density in cortical pyramidal neurons through direct binding to Erk1/2, inhibiting MAPK signaling. Synapse density in neurons from ephrin-B3 knockout (KO) mice remains unchanged with respect to wild-type controls both *in vitro* and *in vivo*, indicating that ephrin-B3 is not required for synapse formation. However, in mixed cultures of wild-type and ephrin-B3 KO neurons, synapse density is reduced in ephrin-B3 KO neurons and increased in wild-type neurons, suggesting that relative levels of ephrin-B3 determine synapse density by a mechanism involving cell-cell competition. To directly test this hypothesis, we studied isolated neurons or pairs of neurons cultured on microislands and asked whether ephrin-B3 regulates synapse density through direct competition between individual neurons. In single-neuron microislands, knockdown of ephrin-B3 did not affect synapse density when compared to control-transfected neurons. In two neuron microislands, knockdown of ephrin-B3 in one neuron resulted in a decrease in synapse density compared to the untransfected neuron, while synapse density was increased in the untransfected neuron. Interestingly, the overall number of synapses in these microislands remained the same. Taken together, these data provide strong evidence for a model in which ephrin-B3-mediated cell-cell competition regulates the density of excitatory synaptic inputs received by individual neurons.

Title: EphB tyrosine kinase signaling in living dendritic filopodia

Authors: Y. MAO, J. ZHU, K. HANAMURA, *M. B. DALVA;
Dept Neurosci, Thomas Jefferson Univ., PHILADELPHIA, PA

Abstract: The formation of synapses is induced at sites of contact between axons and dendrites of neurons by specific protein-protein interactions. Contact between axons and dendrites are driven by motile axonal and dendritic filopodia while a number of proteins including EphBs and ephrin-Bs can induce synapse development. EphB kinases are required for the movement of dendritic filopodia and excitatory synapse formation. However, whether EphB localize in filopodia and what the local signaling by EphBs is to mediate filopodia motility and synaptogenesis are not well understood. Here we demonstrate that EphB2 proteins are localized to the tips of certain types of dendritic filopodia that are thought to be important for synapse formation. In order to study the activity of Eph tyrosine kinases at cellular level in living cells, we have developed a set of dual color genetically-encoded Eph indicators. These tools enable the visualization of the local signaling by specific Eph receptors (both EphA4 and EphB2) in HEK cells and neurons. In cells, we find that EphA4 and EphB2 kinases have different rates of deactivation consistent with differences in signaling by these receptors. In cultured cortical neurons, EphB signaling is higher within stable dendritic filopodia that contact axons than in moving filopodia. These findings suggest that EphB signaling is tightly linked the generation of stable contacts and consistent with previous work indicating the role of EphBs in the induction of synapse formation. Our indicator tools demonstrate that tyrosine kinase signaling by EphBs within living cells can be restricted to small sub-cellular domains. The design of these tools should enable visualization of tyrosine kinase activity at high resolution and should allow us to determine the relationship between kinase activity and cell behavior.

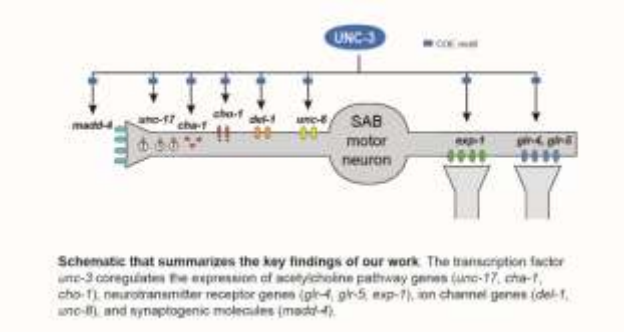
Title: Transcriptional coordination of synaptogenesis and neurotransmitter signaling in *C. elegans* motor neurons

Authors: *P. KRATSIOS[1], B. PINAN-LUCARRÉ[2], S. KERK[1], J.-L. BESSEREAU[2], O. HOBERT[1];
[1]Columbia Univ., New York, NY; [2]Univ. Claude Bernard Lyon1, Villeurbanne, France

Abstract: How the process of synaptogenesis is coordinated with the adoption of other neuron type-specific identity features during neuronal differentiation is a largely unexplored question in developmental neuroscience. Synaptogenic events could be controlled in a manner that is independent of the adoption of, for example, neuronal signaling features of a specific neuron type, such as the choice which neurotransmitter system to use to communicate with postsynaptic partners (“neurotransmitter identity”), or they could be tightly coupled. We describe here two distinct mutant *C.elegans* strains, retrieved from a genetic screen for mutants in which the SAB head motor neurons (MNs), a previously little studied class of MNs in the *C. elegans* nervous system, fail to form synapses with their muscle targets. One mutant strain harbors a loss of function allele of the Collier/Olf/Ebf (COE)-type transcription factor UNC-3, the other carries a mutation in the ADAMTS-like extracellular matrix protein MADD-4/Ce-punctin, a presynaptically secreted synapse organizing molecule that clusters postsynaptic receptors. We demonstrate that *madd-4* expression is controlled by UNC-3 via an UNC-3-binding site in the *madd-4* locus. In addition to postsynaptic receptor clustering defects, *unc-3* mutants also fail to assemble presynaptic specializations. Apart from being required to assemble synaptic specialization, UNC-3 directly controls, via UNC-3 binding sites, the coordinated expression of enzymes and transporters that define the cholinergic neurotransmitter phenotype of the SAB neurons. The coupling of neurotransmitter choice and synaptogenesis appears to be a common theme in MN differentiation, as we find that *unc-3* coregulates cholinergic neurotransmitter pathway genes and *madd-4* in other, distinct types of cholinergic MNs in *C. elegans*. These findings show how neuron type-specific signaling features of a neuron are hardwired together

through coordinated transcriptional control, and provide a simple and robust mechanism for the development and maintenance of a functional motor circuit.



Schematic that summarizes the key findings of our work. The transcription factor unc-3 coregulates the expression of acetylcholine pathway genes (unc-17, cha-1, cho-1), neurotransmitter receptor genes (glr-4, glr-5, exp-1), ion channel genes (del-1, unc-8), and synaptogenic molecules (madd-4).

Title: The gamma-protocadherins interact physically and functionally with the neurexin-neuroligin adhesion complex

Authors: M. J. MOLUMBY[1], D. J. NEWBOLD[2], D. SCHREINER[4], N. K. KOBLESKY[2], A. M. GARRETT[5], J. J. RADLEY[3], *J. A. WEINER[2];
[1]Biol., The Univ. of Iowa, Iowa City, IA; [2]Dept. of Biol., The Univ. of Iowa, IOWA CITY, IA; [3]Psychology, The Univ. of Iowa, Iowa City, IA; [4]Biozentrum, Univ. of Basel, Basel, Switzerland; [5]The Jackson Lab., Bar Harbor, ME

Abstract: The γ-Protocadherins (γ-Pcdhs) are cadherin superfamily adhesion molecules encoded by the Pcdhg gene cluster. The cluster consists of 22 “variable” exons--each encoding most of a single isoform--and three small “constant” exons encoding a shared C-terminal domain. The γ-Pcdhs are combinatorially expressed, with each neuron estimated to express ~5-7. We showed that the γ-Pcdhs promiscuously form cis-tetramers that interact homophilically in

trans, which indicates that this family could generate over 10,000 distinct adhesive interfaces. Depending on the neuronal cell type, the γ-Pcdhs play critical roles in synaptogenesis, dendrite arborization, and developmental apoptosis. Their far-from-exclusively synaptic localization suggests that they may regulate synapse number indirectly, through modifying the function of other synaptogenic molecules. Here we report a physical and functional interaction between the γ-Pcdhs and the neurexin-neuroligin synapse adhesion complex. Multiple tagged γ-Pcdh isoforms (including members of the γA, γB, and γC subfamilies) co-immunoprecipitate with neuroligin-1, -2, and -3 in transfected cells. This physical interaction occurs via the extracellular domains, as it persists when constructs lack cytoplasmic domains. To identify a function for this interaction, we used an assay measuring binding of a soluble neurexin-Fc protein to HEK cells transfected with neuroligin. Co-expression of a γ-Pcdh in the HEK cells disrupts neurexin-Fc binding, suggesting that the γ-Pcdhs somehow block the interaction between neurexin and neuroligins. Using the "artificial synapse" assay in which neurons are co-cultured with COS cells, we show that the presence of γ-Pcdhs along with neuroligins reduces the clustering of synaptic vesicle proteins at sites of COS cell contact, compared to that on cells expressing neuroligins alone. Together, these data suggest that the γ-Pcdhs bind postsynaptic neuroligins in cis and prevent them from promoting the formation or stabilization of synapses through binding their presynaptic ligands, the neurexins. One possibility is that homophilic trans-interactions between matched γ-Pcdh tetramers free neuroligins to bind to neurexins and promote synapse development. To test this hypothesis, we are performing artificial synapse assays in which neuronal γ-Pcdh complements are manipulated to match, or not match, that of the neuroligin-expressing COS cells. Consistent with these *in vitro* results, loss of the γ-Pcdhs in the cortex *in vivo* results in dendritic spine alterations; further analysis of mice overexpressing individual γ-Pcdhs, and thus increasing homophilic matching, are in progress.

Title: Stepping out of the neurogenic shadow: Role of basic helix loop helix protein, daughterless, in post-mitotic neurons in *Drosophila* melanogaster

Authors: *M. D'ROZARIO[1], F. LIEBL[2], D. MARENDA[1];
[1]Drexel Univ., Philadelphia, PA; [2]Southern Illinois Univ. - Edwardsville, Edwardsville, IL

Abstract: Neurogenesis, the production of neuronal and glial lineages from undifferentiated precursor cells, is a critical step for embryonic neurodevelopment. Proneural proteins of class I/II Basic helix-loop-helix (bHLH) proteins are a large family of evolutionarily conserved transcription factors that have well-established roles in neurogenesis and neural differentiation across multiple species. However, their role in post-mitotic neurons remains less clear. Here, we report that the bHLH transcription factor Daughterless (Da, Tcf4 in mammals) is expressed in post-mitotic, differentiated motor neurons where it is required to restrict synaptic growth and axonal arborization at the *Drosophila* Neuromuscular Junction (NMJ). We have used bioinformatic tools to identify candidate genes whose transcription is regulated by Da and have identified and validated a small number of specific target genes required for Da-mediated restriction of of synaptic growth.

Title: Decreased number of muscle synergy during gait is associated with neural dysfunction and motor function in cerebral palsy

Authors: *Y. HASHIGUCHI[1], K. OHATA[2], R. KITATANI[2], N. YAMAKAMI[3], S. OSAKO[2], Y. AGA[2], S. YAMADA[2];
[1]Shogoin, Kyoto Univ. Human Hlth. Sci., Kyoto, Japan; [2]Kyoto Univ., Kyoto, Japan; [3]Fujita Hlth. Univ. Hosp., Aichi, Japan

Abstract: INTRODUCTION Synergy is defined as the grouping of a neural output to simplify motor control. Non-negative matrix factorization (NNMF) was recently used to assess the

characteristics of synergy during a reaching task and during gait. Clark et al. showed that synergies during gait are altered after stroke. And the number of synergies is associated with severity and gait speed. It is reported that children with cerebral palsy (CP) exhibit a lowered number of synergies during gait compared with healthy adults. However, the relationship between the number of synergies and neural dysfunction or motor function in children with CP has not been reported. The objective of this study is to clarify the relationship between the number of synergies and clinical or gait parameters. METHODS Sixteen children with CP were enrolled. Electromyography (EMG) data were recorded from eight muscles on an impaired lower limb during gait. The EMG data were decomposed using NNMF into an activation pattern of each synergy and a weight ratio of muscles for each synergy. Variability accounted for was used to determine the number of synergies in each child. Further, children were classified into two groups. The “patterned group” comprised children who had two or fewer synergy patterns, whereas the “isolated group” comprised children who had three or more synergy patterns. The modified Ashworth scale (MAS) and the modified Trost selective motor scale (mTSMC) were used to assess the spasticity and selective motor control. We measured gait speed and foot pressure using an FDM system (Zebris Inc.) during gait. The foot pressure data were used to calculate the average displacement of the center of pressure (dCOP) during stance phase. We used the Mann-Whitney U test and Student’s t test to assess significance of differences between the two groups. RESULTS Six children had two synergy patterns, eight children had three synergy patterns, and two children had four synergy patterns. Significant differences were found in mTSMC ($p = 0.036$) and dCOP ($p < 0.001$). DISCUSSION mTSMC can detect the neural disorder and a decrease in the number of synergy patterns. dCOP is a biomechanical factor and influences the number of synergies. In a previous study, a smaller number of synergies during gait was demonstrated in children with CP than in a typical toddler, which showed that healthy toddlers have four synergy patterns. Similarly, Neptune et al. showed that the number of synergies corresponds to the biomechanical function during gait in healthy adults. Therefore, results of the present study show that the number of synergies determined using NNMF reflects the neural and biomechanical function in children with CP.

Title: The role of GAD67 and VGAT in the functional and morphological development of motor neurons

Authors: *M. J. FOGARTY, R. KANJHAN, M. C. BELLINGHAM, P. G. NOAKES;
Sch. of Biomed. Sci., Univ. of Queensland, Brisbane, Australia

Abstract: We have investigated developmental roles of glycinergic and GABAergic neurotransmitter deficiency on motor neuron (MN) spontaneous synaptic activity and dendritic morphology at embryonic day 18/birth. To achieve this, we have used mice lacking GABAergic (67 kDa isoform of glutamate decarboxylase, GAD67 knockout) and mice lacking both glycinergic and GABAergic transmission (vesicular inhibitory amino acid transporter, VGAT knockout) to study the development of hypoglossal (XII) MNs. Brainstem slices (300μm) from wild type (n=18) and mutant mice (GAD67: n=17; VGAT: n=22) at E18.5 were used to record spontaneous synaptic currents from XII MNs that were filled with Neurobiotin post recording. These slices were then immuno-stained for the distribution of excitatory glutamatergic and inhibitory GABAergic neurochemical synapses on the dye-filled cell within confocal z-stacks. Data was analyzed by one-way ANOVA, with all reported increases compared to wild type controls having $P<0.05$. In mice lacking GABA or GABA and glycine neurotransmission, XII MNs responded by increasing the length (GAD67: +50%; VGAT: +104%) and complexity of their dendritic branches (GAD67: +35%; VGAT: +45%), and the number of somatic (GAD67: +95%; VGAT: +210%) and dendritic spine density (GAD67: +195%; VGAT: +290%). We also observed that excitatory glutamatergic neurochemical synapses were increased (GAD67: +55%; VGAT: +90%), but inhibitory neurochemical synapses were unaltered. Spontaneous synaptic current analyses showed increased frequency of excitatory post-synaptic currents (GAD67: +35%; VGAT: +65%). However, we observed no compensatory increases in inhibitory spontaneous synaptic transmission in either mutant. We speculate that before switching to their mature inhibitory activity, deficiency in GABAergic and/or glycinergic synaptic activity during embryogenesis may be compensated for by increases in glutamatergic neurotransmission. Our results suggest that glycinergic and GABAergic synaptic activity play vital roles in regulating XII MN morphology and network properties during late embryonic development.

Title: The differential effects of prenatal LPS challenge on neurobehavioral outcomes in affected offspring depend on gestational age

Authors: *M. STRALEY[1,2,3], S. J. CRAMPTON[1,2,3], J. F. CRYAN[1,3], S. O'MANONY[1,3], G. W. O'KEEFFE[1,2,3];

Abstract: During development the nervous system is assembled and sculpted by an orchestrated series of neurodevelopmental events that ultimately generate and refine the neural circuitry that governs all facets of human behavior. Many clinical and epidemiological studies have now shown that perturbations in this developmental program, such as those caused by prenatal maternal infection, can increase the risk in affected offspring for a number of neurodevelopmental and neuropsychiatric disorders, including autism, ADHD and schizophrenia. However, the cellular and molecular basis of this increased risk remains to be fully elucidated, in particular the effects of gestational age on neurobehavioral outcome. In this study we aimed to assess the impact of maternal inflammation at different stages of pregnancy on offspring neurobehavioral outcome, especially those related to the dopaminergic system, using the well-established lipopolysaccharide (LPS) rat model of maternal infection. Pregnant rats were administered a 50μg/kg dose of LPS or saline via i.p. injection on E12, E14, E16 or E18 and fetal brain samples were microdissected 48h post. RT-PCR showed an increase in mRNA abundance for IL-1β and TNF at each age, indicating a fetal inflammatory response in the developing brain. To determine if the timing of maternal infection altered neurobehavioral outcome, depending on gestational age, we performed an array of behavioral tests including righting reflex, geotaxis test, ultrasonic vocalization, and open field on P9 rat offspring, following similar maternal immune activation. Preliminary ultrasonic vocalization analysis revealed that animals whose mothers received LPS on E12, E14, E16 and E18 resulted in offspring who made more calls for longer duration when separated from the mother compared to controls. These data suggest an anxiety-like phenotype associated with *in utero* LPS exposure. Currently, we have expanded the study and are analyzing behaviors in adolescent as well as adult offspring following *in utero* LPS exposure. Using the validated LPS rat model of maternal infection, this study describes the differential effects of maternal inflammation at different gestational ages and shows that the timing of exposure can have profound consequences for fetal

neurobehavioral outcome and normal cognitive development. These data suggest that understanding how and why the developing brain is more susceptible to the effects of maternal infection at different gestational ages will be important for developing effective strategies for neuroprotection to prevent against the adverse consequences of maternal infection-induced fetal programming.

Title: Experience-dependent regulation of singing-driven gene expression in the song system during the critical period for vocal learning

Authors: ***S. HAYASE**, E. OHGUSHI, M. KOBAYASHI, K. WADA;
Hokkaido Univ., Sapporo/Hokkaido, Japan

Abstract: Vocal learning in human and other species requires coordination of sensory and motor experiences in order to mimic a set of previously perceived models. Vocal learning has the critical period as a time when performances improve efficiently. However, the neural mechanisms underlying the critical period for vocal learning are not well understood. For vocal learning and production, songbirds possess specific neural circuits consisting of several brain nuclei, so called the song system, where many genes are regulated during singing. A male zebra finch develops its syllable acoustic features dramatically in the critical period; especially in morning time during juvenile stage. The singing-driven immediate early genes (IEGs) are strongly induced during juvenile stage, suggesting that the singing-driven IEGs may be regulated in a daily basis and contribute to modification of syllable acoustic features. Thus, we examined expression of the neuroplasticity-related IEGs (Arc; activity-regulated cytoskeleton associated gene, Egr1; Early growth response 1 and c-fos; FBJ murine osteosarcoma viral oncogene homolog) in juvenile and adult birds, which sang at different time points during the day. We found that glutamatergic projection neurons in the pallial nuclei RA and NIf were selectively regulated with their induction of IEGs matching syllable acoustic changes. These data suggest a potential relationship between changes of syllable acoustic features and strong induction of IEGs

in RA and NIf during song learning. In addition, the resulting IEG induction rates in RA and NIf were dependent on singing experience both in a short term daily way and a long term mechanism during the critical period. These results indicate a singing amount-dependent mechanism for regulation of IEG expressionn in a brain region- and critical period- specific manners.

Title: Optimizing inhibitory effect in primary motor cortex by low-frequency repetitive transcranial magnetic stimulation

Authors: ***M. CHEN**, H. DENG, R. SCHMIDT, T. KIMBERLEY;
Physical Med. and Rehabil., Univ. of Minnesota, Minneapolis, MN

Abstract: Introduction Low-frequency repetitive transcranial magnetic stimulation (rTMS) generally inhibits cortical excitability. The primary motor cortex (M1) can be inhibited by low-frequency rTMS applied to: 1) M1 directly or 2) premotor cortex (PMC). The comparison between these two methods has been reported by previous studies with inconsistent results. This work compared inhibition to M1, PMC and a PMC-blocked method which first inhibits PMC then M1 (PMC-M1). The purpose of this work was to determine the most effective method of inhibition. We hypothesized that PMC-M1 method will demonstrate greater inhibitory increase than equal dose of PMC method or M1 method. Method 10 young healthy subjects (3 males; mean age: 25.2 ± 5.4y) were recruited for a randomized cross-over design with a wash-out (1 week) between visits. Each visit consisted of a pre-test, an rTMS intervention and a post-test. Measures included short interval intracortical inhibition (SICI), intracortical facilitation (ICF) and cortical silent period (CSP). Subjects received one of the three interventions at each visit including: M1, PMC and PMC-M1. Change scores of all of the measures were calculated and tested by t-test for pre-post change effect. For the intervention effect, one-way ANOVA was

used with post-hoc testing as appropriate (Bonferroni adjusted pairwise comparisons). Results All excitability measures showed different levels of inhibition after each intervention. For SICI, there was no significant difference between the 3 interventions although there was a trend that M1 decreased inhibition more than the other two (P=0.0581); for ICF and CSP, the PMC-M1 method showed significantly greater inhibition than the other two (ICF: P=0.0006 and CSP: P<0.0001). Discussion PMC-M1 method may have demonstrated greater inhibitory effect because the excitatory projection from PMC to M1 was "blocked" first. Thus, M1 may have been inhibited indirectly without the influence from PMC. Conclusion The PMC-M1 stimulation pattern could be used to probe the relationship between PMC to M1 in individuals with neurological disorders to help elucidate the pathophysiology or may be a more effective inhibitory protocol.

Title: Emergence of motor cortex activity as infants develop functional motor skills

Authors: *R. NISHIYORI[1,2], S. BISCONTI[2], B. ULRICH[1,2];
[1]Kinesiology, [2]Ctr. for Human Growth and Develop., Univ. of Michigan, Ann Arbor, MI

Abstract: The neural changes underlying the emergence of reaching and stepping, two important milestones during infancy have yet to be determined. Functional near-infrared spectroscopy (fNIRS) has the potential to address some limitations presented by using fMRI and EEG and offer a unique insight into the neural changes associated with the emergence of these motor skills early in life. The purpose of this study was to use fNIRS to determine the changes in motor cortical activity during reaching and stepping in infants. We employed a cross-sectional design to compare motor cortical activity of typically developing infants at 6 months and 12 months during reaching and stepping. We chose these ages as reaching emerges around 4 to 5

months, while walking emerges around 11 months of age. All infants performed reaching and stepping tasks while recording fNIRS. For the reaching task, infants were secured into a customized infant seat. We presented a toy within reach at mid-chest level for the infants. We only included successful reaches and grasp of the toy. For the stepping task, an experimenter held the infant under the arms over a pediatric treadmill. Infants were only positioned over the belt once the belt started to move. We only included steps with the moving belt. Four emitters and 8 detectors (for a total of 12 recording channels) were centered over Cz and extended bilaterally to the C3 and C4 electrode locations (International 10-20 system) to cover the primary motor cortex. We used Homer2, a pre-processing software (Huppert et al., 2009) to apply a wavelet motion correction algorithm (Brigadoi et al., 2013), band-pass filters, and averaging trials. All successful trials were grouped to obtain an average response per channel. We compared rest with task to detect any significant changes in hemodynamic activity during task performance. Preliminary results (6 younger and 6 older infants) show that when compared to rest, younger infants while reaching showed activation in 7 channels distributed bilaterally out of 12 channels, whereas the older infants showed 4 channels unilaterally. During stepping, younger infants showed activation in 8 channels distributed bilaterally out of 12 channels, whereas the older infants showed 6 channels bilaterally out of the 12 channels. These results show that younger infants demonstrate a dispersed area of activation within the motor cortex during both reaching and stepping when compared to older infants. The results support the idea that infants explore options achieving their motor goal and learn, with self-initiated goal-directed movements to refine the neural activity as well as the behavioral outcomes.

Title: Postnatal development of the corticospinal system examined in awake animals using indwelling stimulation and recording techniques

Authors: E. SINOPOULOU[1], P. T. WILLIAMS[1], *J. H. MARTIN[2];
[1]Physiol, Pharmacol & Neurosci, The City Col. of the City Univ. of NY, New York, NY;
[2]Physiol, Pharmacol & Neurosci, The City Col. of the City Univ. of NY, NEW YORK, NY

Abstract: Development of the corticospinal (CS) system in animals has been investigated by taking single snapshots of its anatomical and physiological organization at different postnatal time points. Using this approach, studies in the cat support a sequence of early exuberant CS tract (CST) spinal projections and refinement to achieve the mature projection pattern, followed by development of the motor cortex (M1) motor map and further strengthening of stable projections. Two critical unanswered questions for understanding the functional development of the CS system are: 1) when does the corticospinal system begin to participate in the control of skilled movements, and 2) when does the system become mature? The single snapshot approach of acute investigation is limited in answering these questions because of the affects of anesthesia and that different animals mature at somewhat different rates. Rather, it is essential to study motor development in awake animals and follow individual animals during development. In this study we used chronic stimulation and recording techniques to monitor changes in the strength of M1 to muscle connectivity in awake kittens from postnatal week (PW) 4-15 and in adult cats. Animals were instrumented with epidural stimulating electrodes over the forelimb area of M1, bilateral forelimb EMG electrodes (biceps, ECR), and free-floating microwire recording electrodes within M1. Individual animals were followed for several weeks to months, depending on implantation age (n=3, PW 4-8; n=2, PW 9-15; n=2 Adult). Here, we focus on M1 stimulation in awake animals at rest. We compared EMG responses at different ages and computed EMG recruitment curves (response to M1 stimulation at multiples of threshold; tested mostly in older kittens and adults) across sessions. Between PW 4-5, M1 stimulation evoked contralateral forelimb movements and EMG responses (biceps or ECR), but became less effective by the end of this period. Beginning at about PWs 5-6 stimulation became progressively more effective and consistent in evoking responses. Responses evoked by PW 10-15 were similar to adults, suggesting maturation of the CS projection. Our studies are the first to use chronic stimulation/recording approaches to monitor changes in M1-to-muscle connection strength. Our findings suggest multiple developmental phases. The phase beginning at PW 5-6, which is before the onset of M1 map development, may mark the start of a period of continuous and rapid ramping of connection strength that gives M1 access to spinal motor circuits for movement control.

Abstract: The corticospinal (CS) tract is essential for voluntary movement, but what we know about the organization and development of the CS tract remains limited. To determine the total cortical area innervating the 7th cervical (C7) and 4th lumbar (L4) spinal cord segments, we injected retrograde tracers (fluorescent microspheres) into C7 and/or L4 such that it would spread widely within the unilateral gray matter (to > 80%), but not to the ventralmost dorsal column (CS tract). Subsequent detection of the tracer showed that, in both infant and adult mice, neurons distributed over an unexpectedly broad area of the rostral two-thirds of the cerebral cortex converge to C7. This included cortical areas controlling the hindlimb. With aging from the infant to the adult, the cell densities greatly declined, mainly due to axon branch elimination. Labeling of axons and presynaptic structures through cotransfection of DsRed and synaptophysin-EGFP expression plasmids using exo utero electroporation suggest that at least more than 80% of CS axons present in the gray matter at this period make synaptic connections with spinal neurons. Whole cell recordings from spinal cord neurons evoked by selective optogenetic stimulation of CS axons also revealed that the neurons received CS inputs widely distributed in the gray matter. These implicate C7 neuronal circuits incorporated the CS innervation are largely reorganized during development. By contrast, the cortical areas innervating L4 are limited to the conventional hindlimb area, and the cell distribution and density showed little or no change during development. To investigate the developmental changes of axonal distribution of CS neurons located in M1/S1, M2 and S2, we injected replication-incompetent adeno-associated virus serotype 1 vectors expressing fluorescent proteins (XFPs) of different colors fused with channelrhodopsin-2 (ChR2) into the cortical areas separately at P0. ChR2-XFPs labeled axons clearly without gaps down to their terminals because ChR2 is the transmembrane protein, and the tagged XFPs are located just beneath the plasma membranes of axons. In addition, these neurons can be activated by photostimulation. The mice underwent the viral injection were fixed at P7, P14 and P21. We analyzed the axonal distribution in the C7 and found that the axon terminals derived from M1/S1 and S2 in the spinal cord were differentially distributed. CS axons from S2 were predominantly distributed at the dorsal part of spinal cord, and those from M1/S1 were observed at both dorsal and ventral parts.

Title: Differential expression of nachrs at zebrafish red and white fiber nmjs during development

Authors: *K. T. AHMED, D. W. ALI;
Dept. of Biol. Sci., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Nicotinic acetylcholine receptors (nAChRs) are ligand gated ion channels that are highly expressed at the vertebrate neuromuscular junction (NMJ), where they are required for muscle fiber activation. Developmental regulation of the NMJ ensures proper muscle development and fine control of muscular movement, whereas improper development can lead to poor fiber recruitment and weak muscle contraction. Therefore, understanding the factors that underlie NMJ development is critical for a complete understanding of muscle function. Embryonic and larval zebrafish express two morphologically and functionally distinct muscle fibers: white twitch fibers and red tonic fibers. As functionally different muscle fibers require different mechanisms to control muscle activation, we examined the properties of nAChRs that are expressed by red and white muscle fibers during development, from 30 hours post fertilization (hpf) to 5 days post fertilization (dpf). Miniature endplate currents (mEPCs) recorded by whole cell patch clamp electrophysiology exhibited significant differences between the red and white muscle fibers in embryonic and larval fish. Most mEPCs from 36 hpf white fibers decayed relatively slowly, with a single exponential component. By 2 and 3 days post fertilization the mEPC kinetics sped up, and decayed with a double exponential component. By 5 dpf the exponential decay was further sped up and consisted of a single component. However, mEPCs from red fibers exhibited a different developmental profile with respect to their decay kinetics. In 36 hpf embryos, most mEPCs decayed with a single, slow exponential time course, which sped up and switched to a double exponential time course by 2 dpf. By 5 dpf mEPC kinetics were slightly faster but remained as a double exponential component in contrast to white fibers. We recorded single channel activity of nAChRs via the outside-out patch clamp configuration and identified three major conductance levels (39-46 pS, 59-62 pS, and 72-81 pS)

and two open time constants (0.38-0.52 ms, 2.14-4.75 ms), expressed in both red and white fibers at 36 hpf, 2 dpf and 5 dpf. Channels with long open time constants constituted 30% of single channel activity analyzed from red fibers, whereas they were less than 1% of the channel activity obtained from white. Single channel mean open times were significantly smaller from white fibers compared to red fibers at all ages. Finally, there was a trend towards smaller mean open times of nAChRs obtained from red and white fibers of older animals. Our findings reveal previously unknown differences between the nAChRs expressed at NMJs of red and white fibers in embryonic and larval zebrafish.

Title: Timing is everything: hormonal control of the developing SNB in mice

Authors: *A. M. WELSCH, C. L. JORDAN, S. M. BREEDLOVE;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: In rats there is a critical period for the organizational masculinization of soma size in motoneurons of the spinal nucleus of the bulbocavernosus (SNB) that extends beyond the critical period for masculinization of SNB cell number. This finding demonstrates that critical periods of hormone-dependent development do not all occur within the same window. The current study aimed to assess similar critical periods in the mouse. Female mice were exposed to testosterone propionate (TP) or vehicle during one of three potential critical periods (embryonic days 16-18), early postnatal (PN 1, 3, 5), or late postnatal (PN 7, 9, 11)). Testosterone (T) was then given in adulthood via Silastic capsules to half of the animals in each group to serve as “activational” background from which organizational effects of the perinatal hormones could be detected. Early postnatal TP treatment significantly increased the number of SNB motoneurons in female mice by doubling their number (control females, mean = 21.6 ± 4.63 (SEM) motoneurons compared to

early postnatal TP-treated females, 53.3 ± 4.26; $p < 0.01$). Early postnatal TP treatment also increased the size of SNB somas (481.1 ± 17.12 μm^2) compared to control females (395.2 ± 18.61 μm^2; $p = 0.001$). This perinatal effect was also observed in the size of SNB nuclei (control females: 125.3 ± 6.68 vs. early postnatal TP mice, 147.4 ± 6.15; $p = 0.001$). Further, adult T treatment significantly increased SNB soma size (blank capsules: 395.7 ± 13.04 μm^2 compared to 491.6 ± 13.33μm^2 in T-treated; $p < 0.001$) and the size of nuclei in SNB motoneurons (control females w/ blank: 124.5 ± 4.69 μm^2. T treated: 151.9 ± 4.79μm^2; $p < 0.01$). There was no significant interaction of perinatal and adult hormone treatment on cell number, soma size, or nuclear size. These results begin to define the critical periods in which androgens masculinize the SNB system in mice where genetic tools are available to perturb, and thus understand, mechanisms of androgen action on SNB development.

Title: Spontaneous network activity in the embryonic spinal cord is regulated by presynaptic nicotinic modulation of GABAergic transmission

Authors: *C. E. GONZALEZ-ISLAS[1], M. GARCIA-BEREGUIAIN[2], P. WENNER[2]; [2]Physiol., [1]Emory Univ. Sch. Med., Atlanta, GA

Abstract: Developing neural circuits display episodic patterned spontaneous activity due to a recurrently connected network in which both GABA- and glutamate-mediated neurotransmission are excitatory. In the embryonic spinal cord, a form of this activity known as spontaneous network activity (SNA) is involved in multiple aspects of motor maturation, such as muscle and joint development, axonal pathfinding and regulation of the strength of synaptic inputs to motoneurons. SNA is a network-driven phenomenon that depends on the chemical nature of the synapses between spinal neurons. Nevertheless, the neurotransmitter receptors that support SNA change during development. In early stages (embryonic day 4 to 6, E4-6) nicotinic cholinergic receptors appear to be most important, but excitatory GABAA receptors also contribute. Later in

development (E8-12), glutamatergic receptors become increasingly important, and nicotinic receptor influence decreases, however, nicotinic modulators still influence the frequency of SNA. We hypothesized that nicotinic transmission influences SNA frequency through postsynaptic phasic activation of nicotinic receptors. However, we found little evidence supporting the activation of postsynaptic nicotinic currents. Rather, it became clear that nicotinic modulators influenced presynaptic release of GABAergic vesicles. We found that nicotinic antagonists decreased GABAergic mPSC frequency and evoked GABAergic responses, while nicotine increased GABAergic mPSC frequency and evoked GABAergic responses. Furthermore, we demonstrate that this response is mediated through the activation of presynaptic non-α7 nACh-Rs. We propose that the nicotinic modulation of SNA frequency occurs through a presynaptic control of GABA release.

Title: Differential gene expression in purified populations of mouse sympathetic neurons that express neuropeptide Y

Authors: *J. P. HORN, K. M. SIKORA, P. H. M. KULLMANN;
Dept of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Neuropeptide Y (NPY) is selectively expressed by 50-70% of paravertebral sympathetic neurons, most of which are involved in modulation of cardiovascular function. Using NPY as a marker, the goal of this study was to discover new genes that are differentially expressed in NPY-positive and NPY-negative neurons. We used a transgenic reporter mouse in which humanized Renilla green fluorescent protein expression is driven by a bacterial artificial chromosome that contains large upstream and downstream sequences surrounding the NPY peptide coding sequence (Jackson Laboratory [strain B6.FVB-Tg(Npy-hrGFP)1Lowl/J]; J Neurosci 29:462239 (2009)). Antibody staining of the superior cervical ganglion (SCG) confirmed that all neurons with bright GFP fluorescence were immunoreactive for NPY, but

revealed some cells with weak GFP expression were ambiguous in their NPY immunoreactivity. For gene screening, SCGs were removed from 15 - 28 week old male mice, enzymatically dissociated and plated on glass coverslips. Within 2.5 hours of harvesting the ganglia, groups of 10 single cells were manually sorted using coarse glass micropipettes on the basis being fluorescent or non-fluorescent. Cells were deposited into an oligonucleotide extraction buffer and then processed to amplify mRNA and convert it to cDNA (Nugen Ovation One-Direct System). cDNA samples were then tested for the presence of mRNA for NPY using qPCR. Taking this approach enabled us to focus on paired samples in which the differential expression of NPY was very high. Samples meeting this criterion were then run on Illumina mouse WG-6 BeadChip microarrays, which contain 45,200 target sequences. Paired cell samples from 5 mice were then compared using NIH BRB Array tools software (R Simon & BRB-ArrayTools Development Team). The microarray data indicated a 17-fold higher expression of NPY mRNA in samples that had been selected using GFP fluorescence and qPCR validation. Statistical analysis of the microarray data identified 244 genes that fall into many functional categories. These include G-protein coupled receptors, kinases, axon guidance molecules, cytoskeletal proteins, transcription factors and ion channels. We are now studying these genes to identify potential new molecular tools for targeting the specialized sympathetic neurons that control cardiovascular and non-cardiovascular functions.

Title: Expression of membrane-targeted Arch in the spinal cord, dorsal root ganglia and peripheral nerves of embryonic chick

Authors: *A. A. SHARP[1], H. L. DEAL[2], S. FROMHERZ[1];
[1]Dept Anat, SIU Sch. Med., CARBONDALE, IL; [2]Benedictine Univ., Springfield, IL

Abstract: The ability to control the membrane potential of neurons during development would allow for a better understanding of how excitability contributes to the process of proper

development. Polarity and excitability are known to contribute to cell migration, neuronal pathfinding, neuronal survival and the generation of patterned embryonic behaviors. However, traditional electrophysiological and pharmacological method for manipulating membrane potential are particularly challenging in the embryonic environment. Given the relative transparency of thin embryonic tissues to light, optogenetic manipulation of membrane potential is a feasible approach to this problem. We have been utilizing an electroporation-based transposon system to introduce genes encoding light-activated ion channels into the neurons of the spinal cord and dorsal root ganglia (DRGs) of embryonic chick. This system allows for stable transformation of precursor cells such that our genes of interest can be expressed throughout the lifetime of all subsequently derived cells. In prior work, we have demonstrated the ability to establish persistent expression of channelrhodopsin, halorhodopsin and archaerhodopsin in neurons of the spinal cord and DRGs. Both channelrhodopsin and halorhodopsin are primarily expressed in the membranes of neuronal somata as well as axonal and dendritic processes. Peripheral expression of channelrhodopsin is sufficient that illumination of peripheral nerves with a blue LED is sufficient to both evoke leg movement and modulate spontaneous motility. Halorhodopsin activation in transformed embryos produces subtle modulation of motility that varies significantly between embryos. Many investigators have reported difficulties in getting robust inhibition of neuronal activity with halorhodopsin, and archaerhodopsin often proves a better choice. Unfortunately, our original archaerhodopsin protein product was found primarily in the cytoplasm and did not allow for behavioral manipulation of embryos. Therefore, we have now inserted the coding sequence for a modified archaerhodopsin, eArch3.0, that contains membrane-targeting sequences (Mattis et al., Nature Methods, 2012). This form of archaerhodopsin is expressed largely in the membranes of neurons both centrally and peripherally. Experiments are currently in progress to determine if peripheral activation of this archaerhodopsin can be used to regulate embryonic behaviors.

Title: A role for gap junction coupling in segregating axial and appendicular spinal locomotor networks in metamorphosing Xenopus laevis tadpoles

Authors: M. WAGNER, *K. T. SILLAR;
Sch. of Psychology and Neurosci., Univ. St Andrews, St Andrews, United Kingdom

Abstract: The spinal locomotor networks in Xenopus laevis frog tadpoles undergo a remarkable transformation during metamorphosis to accommodate a switch from axial-based swimming to a limb-based locomotor strategy. For a brief period during ontogeny, both the axial- and limb-based systems are present and functional, but reliant on different central pattern generators (CPGs) that are simultaneously active (Combes et al., (2004) J. Physiol. 559, 17-24). However, the mechanisms controlling the functional coupling both within and between these locomotor networks is unknown. At metamorphosing larval stages (53-58), retrograde motoneuron (MN) backfilling from both axial (13th-14th post-otic segments) and hindlimb muscles with fluorescent rhodamine- and fluorescein-conjugated dextran dyes revealed two discrete MN populations (axial and appendicular) within the spinal cord. We found evidence that the two MN pools in the lumbar enlargement may be coupled by gap junctions (GJs), since backfills revealed a number of MNs which were clearly co-labelled (n=6; 13.67±6.83 co-labelled cells). This co-labelling between axial and appendicular MN pools was absent when the GJ blocker carbenoxolone (CBNX) was applied (200μM; n=8; 0±0 co-labelled cells). Preliminary functional electrophysiological data from animals at the same larval stages suggest that axial CPG activity is modified and its output desynchronised by GJ blockers (CBNX 200-400μM, n=9; 18-β-glycyrrhetinic acid 100μM, n=8). For spontaneous fictive locomotor bouts, the number of episodes initially increased, but then sharply decreased from control levels ~15-20 minutes after drug application. The number of swim cycles in spontaneous and electrically evoked episodes increased and remained elevated. Additionally, burst durations increased and became less synchronised, again for both spontaneous and evoked swimming, effects that usually reversed in the wash. These data suggest that axial CPG output partly regulated by GJs. Our anatomical data also suggest that GJs exist between the axial and limb MN pools and may be involved in the initial cycle-by-cycle coupling of the two CPG outputs. Thus the rhythm of the appendicular CPG is initially highly dependent on that of the axial CPG, which in turn is dependent on its own GJ connections within the spinal circuit. It appears that the immature limb MN pools in the lumbar spinal cord possess functional connections via electrical synapses to the axial locomotor system, which are presumably “pruned” as metamorphosis proceeds, and eventually lost completely by the adult stages when the limb network has become completely independent.

Title: Gene expression programs for retinal ganglion cell type development

Authors: *T. C. BADEA, S. SAJGO, M. G. GHINIA, M. BROOKS;
Retinal Circuits Develop. and Genetics/N-NRL/DIR/NEI/NIH, Natl. Eye Inst., Bethesda, MD

Abstract: The mammalian retina consists of about 50 distinct neuronal cell types, which participate in a variety of circuits, resulting in about 20 channels, conveyed by specific Retinal Ganglion Cell (RGCs) types to the brain. Whereas we have some understanding of the development and functions of RGCs as a class, the morphology, physiology, circuit function, and development of distinct RGC types are active areas of investigation. At the molecular level, it is believed that individual cell types may be defined by the unique expression pattern of sets of molecular markers, which convey specific developmental and functional properties. We have been focusing on the transcriptional code that defines the generation of RGC types. Previously we had we uncovered combinatorial expression and distinct functions of the three Brn3 transcription factors in the definition of RGC types. Using conditional reporter knock-in alleles we had generated for Brn3a, Brn3b and Brn3c. We now report immuno-magnetic affinity purification of Brn3aAP/WT, Brn3aAP/KO, Brn3bAP/WT and Brn3bAP/KO RGCs, coupled with deep sequencing of RNA and whole genome expression profiling of these subpopulations of RGCs at specific times during development. We report combinatorial expression of multiple gene families of transcription factors, adhesion molecules and cytoskeletal adaptors which have the potential to participate in a complex combinatorial code of neuronal cell type specification.

Title: Darkness does not restore visual or neural plasticity in the central visual pathways of adult cats

Authors: K. HOLMAN, K. R. DUFFY, *D. E. MITCHELL;
Dept of Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: In a recent study (Duffy & Mitchell, Curr. Biol. 23: 383-386, 2013) it was shown that a 10 day period of total darkness could rejuvenate plasticity in the visual cortex and promote fast and complete recovery of vision in kittens with experimentally induced amblyopia. These kittens were about 3 months of age when placed in darkness and so were still within the critical period of ocular dominance plasticity in the visual cortex that extends to between 6 and 8 months age. In order to establish whether the beneficial effects of darkness were confined to an early period of plasticity, we conducted four studies to examine the ability of the same10 day period of darkness to restore either visual or anatomical plasticity in adult cats that were about 1 year of age. The ability of darkness to restore plasticity was examined in terms of its ability to either promote recovery from the effects of an early period of monocular deprivation (MD) or to re-establish susceptibility to MD in adults. The behavioural studies of the extent of visual recovery were conducted on 3 cats that had received a period of MD from postnatal day (PD) 30 to either PD37 or PD43 after which longitudinal measurements of the grating acuity of each eye were made by use of a jumping stand. Animals were placed in darkness for 10 days at PD383 to PD412. An additional 2 animals were reared normally until PD482 at which time they both received a 14 day period of MD. For one animal the period of MD was immediately preceded (at PD472) by 10 days of darkness. Longitudinal measurements of visual acuity revealed no evidence of a reduction in the vision of the deprived eye in either cat, suggestive that darkness did not restore susceptibility to the effects of MD. Two anatomical studies of the potential benefits of darkness imposed in adulthood were conducted in parallel to the behavioural studies. In the first we studied the ability of darkness imposed in adulthood to promote recovery of soma size and immunolabeling for neurofilament in the dorsal lateral geniculate nucleus (dLGN) of 7 cats that had received a period of MD from PD30 - PD365. The second anatomical study imposed a 7 day period of MD on 5 cats at PD375 that followed 10 days of darkness and examined the effects on the soma size and neurofilament immunolablling in the dLGN. Neither anatomical study revealed any evidence of a change in the dLGN that could be attributed to the period of darkness. On the basis of the behavioural and anatomical studies we conclude that the dramatic and beneficial effects of a 10 day period of darkness observed in kittens are not observed in adulthood suggesting that the former effects are limited to an as yet undetermined critical period.

Title: Eye-specific organization of retinal ganglion cell axons between intermediate and thalamic targets of the mouse retinogeniculate pathway

Authors: *A. A. SITKO[1], T. KUWAJIMA[2], C. A. MASON[3];
[1]Dept. Neurosci., [2]Dept. Pathology & Cell Biol., [3]Neuroscience, Pathology & Cell Biology, Ophthalmology, Columbia Univ., New York, NY

Abstract: Growing axons must navigate a complex series of guidance cues to reach and innervate their appropriate targets in the brain. The molecular and spatiotemporal specificity of such cues that establishes accurate neural circuitry in the growing brain have been studied at intermediate targets and locally in final targets in various systems. However, axon organization and its molecular mechanisms in tracts between intermediate and final targets remain less well studied, and may be a crucial step in the neural circuit formation. We are investigating how cohorts of axons are organized in the developing axon tract of the mouse binocular visual system. Retinal ganglion cells (RGCs) extend axons either ipsi- or contralaterally at the optic chiasm (OC), the intermediate target of the retinogeniculate system. RGC axons then travel in the optic tract (OT) to their thalamic target, the dorsal lateral geniculate nucleus (dLGN), where they terminate in eye-specific zones (i.e., ipsi- or contralateral). We aim to characterize the eye-specific RGC axon organization in the developing OT and distinguish various axon-intrinsic and extrinsic factors mediating that organization. We show that ipsi- and contralateral RGC axons are segregated in the developing mouse OT, where ipsilateral axons are situated in the lateral OT surrounded by contralateral axons. This order is evident early in development starting around E16, when it appears as though early-growing contralateral axons avoid the lateral OT, where ipsilateral axons later grow. Previous studies indicate that axon position within the OT reflects retinal topography and age of outgrowth. Here we examine other possible mechanisms, previously unexplored, for the eye-specific axon organization we observe in the OT: axon cohort position at the OC exit; position in the OT of ipsi- and contralateral axons originating from the

same topographic retinal region; the relationship between eye-specific RGC axons and glia in the OT; and selective fasciculation of each cohort of axons. We explore these factors *in vivo* from E15 to early postnatal ages and we use an *in vitro* retinal explant co-culture system to further investigate the suggestion that ipsilateral RGC axons have a greater tendency to fasciculate than do their contralateral counterparts. Understanding these aspects of eye-specific organization in the OT will set the stage for probing the role axon organization in the tract plays in establishing the appropriate synaptic connections in the target.

Abstract: Can individuals who have been blind for the first several years of life acquire the ability to visually distinguish faces from non-faces after sight restoring surgery? What kinds of neural changes underlie the very initial stages of such development? Can localized functional specialization develop late in life, and if so, how rapidly does it emerge? Is it spatially and topographically similar in organization to that found in the normally developed brain? We report here results from an unusual opportunity to address these questions by studying congenitally blind individuals whose sight we were able to restore post-adolescence. Our behavioral tests reveal the development of face/non-face discrimination skills over the span of a few months after sight onset. We complemented these assessments with fMRI studies. In order to examine the

development of category-specific response regions in the ventral stream, images of several distinct categories - faces, objects, places, and scrambled patterns - were shown to three subjects in a block paradigm. The experiment was conducted as close to the surgery date as possible and repeated several times in the subsequent months, depending on each subject's availability. We find strong evidence of brain plasticity in these subjects. There is a rapid emergence of spatially localized, functionally specific responses in higher visual cortical areas after surgery. Taken together, these findings have important implications for our understanding of brain plasticity as well as the development of object representations in the brain.

Title: A novel class of fast spiking neurons identified in the Xenopus tadpole optic tectum

Authors: A. S. HAMODI[1], C. M. CIARLEGLIO[2], C. D. AIZENMAN[3], *K. G. PRATT[1]; [1]Zoology and Physiol., Univ. of Wyoming, Laramie, WY; [2]Dept. of Neurosci., [3]Brown Univ., Providence, RI

Abstract: The Xenopus laevis tadpole optic tectum is the primary visual structure in the tadpole brain. It receives direct input from the contralateral retina. The immature tectum has only two principal layers: The innermost layer is adjacent to the middle ventricle and contains the majority of tectal cell somata, while the outermost layer encompasses the neuropil. Electrophysiological characterization of neurons in the developing tectum remains incomplete, since most studies have focused on whole cell electrophysiological recordings from principal neurons closest to the ventricular surface in the innermost layer, as these are the most accessible. As a result nothing is known about the physiology of neurons situated within or close to the neuropil. To remedy this, we developed a preparation that allows for the visualization and recording of neurons from across all layers of the tectum. This preparation involves making a horizontal cut through the

most dorsal third of the tectum, then orienting the brain so that the horizontal sliced side is facing up in the recording chamber. Using this preparation, we have identified a novel population of neurons in the outer layer that exhibit distinct physiology compared to neurons of the innermost layer, including faster excitatory synaptic currents and larger voltage-gated sodium and potassium currents. These cells are also able to fire more action potentials in response to current injection and, unlike typical neurons in the innermost layer, display less spike accommodation. They also display a distinct spike form that features a fast and robust repolarization, similar to action potentials of mammalian GABAergic neurons. To further characterize these neurons, we are constructing a profile linking information regarding the physiology, morphology, and neurotransmitter phenotype of these cells.

Title: Local repulsive interactions in retinal mosaic generate long-range order and consistent periodicity

Authors: ***J. JANG**, P. SAILAMUL, S.-B. PAIK;
Bio and Brain Eng, KAIST, Daejeon, Korea, Republic of

Abstract: Orientation map is of great interest among functional maps in visual cortex, but its developmental mechanism has been controversial. Recently, a theoretical model suggested that a moiré interference pattern between ON and OFF Retinal Ganglion Cell (RGC) mosaics can develop a quasi-periodic orientation map (Paik and Ringach, 2011), but it remained a question how this interference pattern can generate consistent spatial periodicity. Here we suggest a developmental model that a homotypic local interaction in ON/OFF RGCs can develop a long-

range ordered hexagonal lattice mosaics and a heterotypic local interaction can control the alignment between ON/OFF mosaics, which provides an answer to above question about the development of a consistent periodicity in orientation maps. First, we examined how a local repulsive interaction can generate a long-range ordered structure in RGC mosaics. Previously, it was reported that the pairwise interaction point process (PIPP) model, where cell positions are determined by a birth-and-death procedure that only considers a local interaction (Eglen et al., 2005), could not develop a long-range ordered structure in the mosaic (Hore et al., 2012). We modified this model, assuming that cell positions can be gradually shifted by a local repulsive interaction between the nearby cells, and performed computer simulations on the development of model RGC mosaics. We confirmed that this local interaction model in monotypic layer can develop a long-range order, well fitted to a hexagonal lattice pattern. Next, we assumed that there also exists a heterotypic repulsive interaction between ON/OFF mosaics, and examined how this can affect the alignment between two mosaics. By simultaneously simulating the development of both mosaics, we found the heterotypic interaction significantly alters the alignment between two layers. In addition, when the distance between two layers varied, we observed that the alignment angle between two layers was restricted, at a certain range of inter-layer distance, which is required by the moiré interference model of orientation map development. Our result suggests that a simple local interaction between RGCs can develop a long-ranged structure in the mosaic, and that when ON and OFF mosaics are developed with heterotypic repulsive interaction with certain range of distance between the layers, the alignment angle between ON and OFF mosaics can be restricted and this leads to a consistent spatial periodicity of orientation map. Therefore, our model provides a complementary explanation of how the cortical orientation maps can be developed from the moiré interference in the retinal mosaics structure.

Title: The role of the minor spliceosome in acute and chronic stress response in the mouse retina

Authors: *M. BAUMGARTNER;
Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: Splicing, the removal of non-coding introns from pre-mRNA transcripts, is essential for proper eukaryotic gene expression. Splicing begins with the recognition of conserved exon-intron boundary sequences, which occurs through the base-pairing of the small nuclear RNAs (snRNAs) U1 and U2; the following steps require the snRNAs U4, U5, and U6 to excise the intron and fuse its flanking exons. Together, these five snRNAs and other associated proteins comprise the spliceosome. While most exon/intron boundaries have the consensus sequence AG/GT, a minority of eukaryotic introns (<1%) contain the divergent boundary sequence AT/AC, to which U1 and U2 cannot bind to initiate splicing. This necessitates the existence of distinct snRNAs that can base-pair with this unique boundary sequence. These snRNAs include U11, U12, U4atac, and U6atac, which, together with U5, constitute the minor spliceosome, named due to its processing of a minority of introns. Minor introns are present and conserved in many eukaryotes, including plants, insects, and mammals. In humans, dysfunction of minor splicing causes microcephalic osteodysplastic primordial dwarfism type I (MOPD1), a severe autosomal recessive developmental disorder that normally results in death within 1 year. This indicates that minor intron splicing is crucial for normal development. However, the specific role that minor intron-containing genes (MIGs) play during development has not been investigated. Our goal was to understand the evolutionary pressures that drove these specific genes to maintain minor introns and how they are expressed during development. To do this, we mined deep sequencing data generated from two time points in mouse retinal development: embryonic day (E) 16 and postnatal day (P) 0. The data were then analyzed using a novel pipeline to extract biological functions associated with the MIGs expressed in the retina. This analysis revealed that MIGs expressed in the developing retina were linked to cellular stress response. To study the role of minor splicing in the retinal stress response, we examined the expression kinetics of the minor snRNAs during both acute stress, caused by UV radiation, and chronic stress, using the FVB/NJ retinal degeneration model. qRT-PCR analysis revealed that U12, a key snRNA component of the minor spliceosome, was upregulated in both acute and chronic stress.

Title: Postnatal changes of expression patterns of VGLUT1, VGLUT2 and VGAT1 in mouse visual cortex and thalamus

Authors: *T. TAKAHATA[1], T. A. HACKETT[1,2];
[1]Dept Psychology, Vanderbilt Univ., NASHVILLE, TN; [2]Dept. of Hearing and Speech, Vanderbilt Univ., Nashville, TN

Abstract: Mammalian brains experience dynamic changes in gene expression and neurochemical components during neonatal development. Glutamate transport to presynaptic axon terminals is mediated by vesicular glutamate transporters (VGLUTs). Three subtypes of VGLUTs, VGLUT1, VGLUT2 and VGLUT3 are known, and the first two forms are strongly expressed in the mouse brain. Interestingly, their mRNA expression patterns are mostly complimentary with each other in adult mice: VGLUT1 is abundant in the cortex and scarce in the thalamus, while it is converse for VGLUT2. It has also been reported that their physiological functions are different from each other. Considered with importance of glutamate transmission in the normal brain development and behavior, their expression patterns may be distinct during postnatal development. We studied here the mRNA and protein expression of VGLUT1 and VGLUT2 in postnatal day (P) 7, P11, P14 and P21, as well as adult, in mouse visual cortex and dorsal lateral geniculate nucleus (dLGN). We also examined the expression of vesicular GABA transporter 1 (VGAT1), which is expressed in most of the GABAergic neurons, for comparison. Overall expression pattern of VGLUT1 mRNA was constant throughout the developmental period, but it was transiently more robust at P11 and P14 compared to other ages. In contrast, the immunohistochemistry showed a relatively steady increase in staining intensity from P7 to adult. While the expression of VGLUT2 mRNA was almost exclusively confined to subcortical regions in adult, it was abundant in layers 2-4 of the visual cortex in postnatal animals. There were no noticeable changes in VGAT1 mRNA expression. These results indicate that VGLUT1 and VGLUT2 continue to mature during the first 3 postnatal weeks, while the transporter of GABAergic system is relatively constant.

Title: Measuring order in retinotopic projections: Assessing technical and biological sources of variability

Authors: *J. HJORTH[1], E. SAVIER[2], D. C. STERRATT[3], M. REBER[2], S. J. EGLEN[1];
[1]Dept. of Applied Mathematics and Theoretical Physics, Cambridge Computat. Biol. Inst., Cambridge, United Kingdom; [2]Inst. of Cell. and Integrative Neurosciences, Univ. of Strasbourg, Strasbourg, France; [3]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The mouse retinotopic map is a model system for studying self-organisation during neurodevelopment. Gradients of Eph receptors and ephrin ligands in the retina and the superior colliculus, together with waves of retinal activity, specify retinal ganglion cell axons organise into a topographic projection on the superior colliculus. These maps can be quantified by focal tracer injections, labelling small numbers of axons in the retina and visualising their termination zones in the superior colliculus. Prior to dissection, a nasal cut is made in the eye at the level of the nictitans membrane, indicating the nasal pole of the retina the labeled retina is then dissected and flattened by 4 orthogonal cuts (nasal, ventral, temporal and dorsal).To define the nasotemporal axis of the retina, two opposite lines are drawn, connecting the corners of the nasal-ventral/nasal-dorsal (line A) and temporal-ventral/temporal-dorsal (line B) leaflets, A third line connecting the center of line A to line B via the optic disk defines the nasal-temporal axis of the retina. This transformation from a curved axis in a 3D structure to a line in a 2D plane introduces errors. A recently developed software package "Retistruct" allows the image of a flattened retina to be folded back onto a sphere, enabling us to work in the native 3D coordinates of the retina. The uncertainty in our assessment comes from two sources, technical variability and biological variability. By using two different methods to analyse the data we can get an estimate of the technical variability. To address the biological variability we use one method, but either repeat our experiments or resample the experimental data. The new analysis methods enables us to better assess phenomena such as the collapse point in the heterozygous Isl2-EphA3 mutant. Title: A study of the daphnia magna hedgehog gene and its role in eye development

Authors: M. GRAFELMAN, *M. L. BECKMAN;
Biol., Augsburg Col., MINNEAPOLIS, MN

Abstract: Early in the development of a *Daphnia magna* embryo two distinct eye spots are observed within the eye field. As the embryo continues to develop the two eye spots grow larger and fuse, resulting in a central cyclopean eye. No details regarding the developmental genetic basis of this eye fusion event are yet known. The present study focused on cloning a candidate gene, *Hedgehog*, and characterizing the developmental time-course of its expression using RT-PCR and *in situ* hybridization. The homologous human gene, *Sonic hedgehog*, when mutated, is associated with holoprosencephaly (HPE), a disorder that can be manifested in a variety of midline defects, including cyclopia. This study sought to determine if similarities exist between *D. magna hedgehog* and the mutated *H. sapiens Sonic hedgehog*, which may explain the comparable phenotypes. We compared the known human Sonic hedgehog amino acid sequence alterations associated with HPE to the wild-type *D. magna* Hedghog protein sequence and found no obvious amino acid changes that might be associated with cyclopia in this protein. Amino acid sequence analysis revealed high identities between the *D. magna* Hedgehog protein and human Sonic hedgehog sequences in the N-terminal domain (79.6%), but only 35.1% identity in the C-terminal domain. A similar pattern of sequence identity was observed between the *D. magna* Hedgehog and the *M. musculus* Sonic hedgehog (80.3% in the N-term and 35.3% in the C-term), while a moderate sequence identity was found between the *D. magna* Hedgehog and the

D. melanogaster Hedgehog in both regions (68.8% in the N-term and 46.9% in the C-term). Preliminary expression studies in *D. magna* reveal *hedgehog* mRNA transcripts are present throughout early embryogenesis (RT-PCR) and in the anterior midline of the developing animal (*in situ* hybridization). Preliminary studies of the Hedgehog signaling pathway using pharmacological methods show that when cholesterol synthesis is inhibited with U18666a, *Daphnia* eye development is altered. Further studies will focus on establishing a high-resolution time-course and spatial map of *hedgehog* gene expression using *in situ* hybridization and RT-PCR. In addition, we will pursue the study of additional cholesterol synthesis inhibitors to further determine what role Hedgehog plays in *Daphnia magna* cyclopean eye development.

Abstract: Although the development of the retina proceeds along a central-to-peripheral gradient a possible cortical counterpart has not yet been identified. The timing and duration of the maturation of the central and peripheral visual field representations in cat primary visual areas 17 and 18 remains unknown. In cats binocular deprived from birth from pattern vision (BD), a model for congenital cataract, motion perception impairments co-occur with anatomical modifications in the temporal Y-type alpha retinal ganglion cells (Burnat et al. 2012). BD might

thus disrupt the normal development of the motion-sensitive cortex driven by Y-type input including area 18 and peripheral area 17. The impact of early BD from eye opening for 2, 4 or 6 months, and late onset BD upon 2 months of normal vision, on cortex maturation was measured using the expression pattern of the visually-driven activity reporter gene zif268 as readout. Decreasing zif268 mRNA levels between month 2 and 4 characterized the normal maturation of the (supra)granular layers of the central and peripheral visual field representations in area 17 and 18. In general, all BD animals had higher than normal zif268 levels. In area 17, early BD showed a central-to-peripheral developmental gradient based on a delayed decrease in zif268 signal. In contrast in area 18, the decrease occurred between month 2 and 4 in both central and peripheral visual field representations. A parallel functional proteomics investigation for central and peripheral area 17 further revealed age- and region specific protein expression changes for normal and BD kittens. Lack of pattern vision stimulation during the first 4 months of life therefore has a different impact on the development of central and peripheral regions of area 17.

Title: The normal development of resting state functional connectivity in infant macaque monkeys

Authors: *J. L. VINCENT, K. SRIHASAM, M. S. LIVINGSTONE;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Spontaneous Blood Oxygenation Level-Dependent (BOLD) fluctuations are correlated within distributed functional brain networks in the adult brain. These so-called "resting-state" networks correspond to anatomical networks identified using anatomical tracers, as well as to functional networks identified using task paradigms. To explore in the normal development of these networks, we collected 30-45 minutes of fMRI data in two newborn monkeys while they rested quietly with their eyes closed. To enhance signal-to-noise, the monkeys were injected with 12 mg/kg of a Monocrystalline Iron Oxide Nanoparticle contrast agent before each scanning session. In these two infant monkeys (B5: 10-days-old and B4: 18-days-old), we observed interhemispheric functional correlations using seed regions placed in primary motor cortex, primary visual cortex, and several other regions in the frontal, parietal, and temporal lobes. In the 10-day-old infant, seeds in the oculomotor network (FEF or LIP) showed robust interhemispheric correlations, and weak frontal-parietal correlations. However, in the 18-day-old infant, there were robust frontal-parietal correlations within the oculomotor network. In the default network, correlations were observed between posterior cingulate and medial prefrontal cortex in both the 10- and 18-day-old infants. These results suggest that coherent resting state networks are present early in development, which is consistent with resting-state functional connectivity studies of human infants.

Title: Loss of Hgs in developing retinas causes defective photoreceptor outer segment development

Authors: *T. THEIN, L. JIANG, S. BLACKSHAW;
Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Hepatocyte Growth Factor-Regulated Tyrosine Kinase Substrate (Hgs/Hrs) is an evolutionarily conserved component of the endosomal sorting complex required for transport (ESCRT) machinery that regulate protein trafficking from endosomes to lysosomes. Recent

studies suggest that some ESCRT components play an important role in eye development and diseases. However, the role of Hgs, an ECCRT-0, during eye development is not well-characterized. Hgs is strongly and selectively expressed in developing photoreceptors of early postnatal mice. In order to determine whether Hgs plays a role in photoreceptor development, we used *in vivo* electroporation to deliver shRNA targeting Hgs to retinal progenitor cells of newborn mice. We have found that shRNA electroporated photoreceptors failed to develop proper outer segments. This defect is rescued by co-electroporation of shRNA-resistant Hgs constructs. Thus, our findings suggest that Hgs is important for proper development of photoreceptor outer segments.

Title: Synaptotagmin I in RGCs regulates the patterned spontaneous activity in the developing rat retina

Authors: *C.-C. YANG, C.-T. WANG;
Inst. of Mol. and Cell. Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: During a critical period of the developing vertebrate visual system, the patterned spontaneous activity is required for visual circuit refinement, termed retinal waves. Retinal waves in mammals can be classified into three stages that are mediated by various mechanisms. The stage II waves, appearing from postnatal day P0 to P9 in rats, are initiated by starburst amacrine cells (SACs) undergoing Ca2+-regulated exocytosis, thus releasing neurotransmitters onto other SACs and retinal ganglion cells (RGCs). Our previous study showed that in the developing SACs, a Ca2+ sensor protein, Synaptotagmin I (Syt I), can regulate the patterns of retinal waves via Ca2+ binding to its Ca2+-binding domains, C2A and C2B. Although Syt I is also expressed in the developing RGCs, it remains unclear whether Syt I in RGCs may involve in regulating the properties of retinal waves. To address this question, we expressed Syt I or its C2A mutant (D230S, designated Syt I-C2A*) in RGCs by utilizing a RGC-specific promoter

(pBrn3b). Live Ca2+ imaging was subsequently performed to monitor the wave-associated Ca2+ transients after pBrn3b-driven expression. We found that Syt I significantly increased the frequency of Ca2+ transients compared to control, but Syt I-C2A* significantly decreased the Ca2+ transient frequency compared to control and Syt I. Moreover, Syt I reduced the amplitude of Ca2+ transients compared to control, whereas Syt I-C2A* increased the amplitude and duration of Ca2+ transients compared to control and Syt I. Therefore, our results suggest that Syt I in RGCs may regulate the properties of retinal waves via Ca2+ binding to its C2A domain.

Title: Functions of the GFL/Ret signaling pathway in the development of the peripheral taste system

Authors: *C. R. DONNELLY, B. A. PIERCHALA;
Biologic and Materials Sci., Univ. of Michigan - Sch. of Dent., Ann Arbor, MI

Abstract: During the development of the peripheral nervous system, target-derived neurotrophic factors aid in the establishment of synaptic connections and govern neuronal survival and differentiation. In the peripheral taste system, neurotrophin-4 (NT-4) and brain-derived neurotrophic factor (BDNF), signaling through the TrkB receptor, are important mediators of axon guidance and survival of chemosensory geniculate neurons projecting to the anterior tongue. While the functions of the neurotrophins in the development of the peripheral taste system have been extensively explored, it is unknown whether additional families of neurotrophic factors are involved in this process. Furthermore, it is unknown whether distinct subpopulations of geniculate neurons exist that can be delineated based on their dependence on different neurotrophic factors, as in other sensory populations. In this study, we provide evidence that the glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs), signaling through the receptor tyrosine kinase, Ret, have an important role in the development of the peripheral taste system. Utilizing a recently developed Ret reporter line, we observed that Ret is

expressed in a subset of taste receptor cells in the circumvallate and fungiform papillae, a subset of chemosensory axons innervating fungiform taste buds, and a subset of somatosensory axons innervating fungiform and filiform papillae. Additionally, we observed distinct subgroups of Ret+/TrkB-, Ret+/TrkB+, and Ret-/TrkB+ geniculate ganglion neurons. Analysis of both Ret germline knockout mice and neuron-specific Ret conditional knockout mice (using the Synapsin-Cre driver), we observed a loss of fungiform taste buds, but not a loss of fungiform papillae. Furthermore, genetic deletion of Ret resulted in innervation defects by E18.5. Collectively, these data indicate that Ret is required for the development of a subset of geniculate ganglion neurons, and may represent a novel subpopulation with unique functional properties. Ongoing experiments are analyzing the expression of Ret at additional developmental time points, identifying the spatiotemporal expression of the GFLs, and examining whether geniculate and/or trigeminal ganglion neurons are lost in Ret knockout mice.

Title: Postnatal reorganization of primary gustatory afferent terminal fields in the mouse brainstem is altered by prenatal dietary sodium history

Authors: *S. ZHENG, C. SUN, D. L. HILL;
Univ. Virginia, CHARLOTTESVLE, VA

Abstract: Age-related decreases in terminal field sizes occur in a variety of sensory systems at various neural levels. In rat, we have shown that the terminal fields of the greater superficial petrosal (GSP), chorda tympani (CT), and glossopharyngeal (IX) nerves decrease in the amount of spread in the nucleus of the solitary tract (NTS). Moreover, offspring of pregnant rats fed a sodium-restricted diet when they were embryonic day 3 (E3) to E12 results in a lack of postnatal pruning. In fact, the amount of terminal spread for all three nerves in the NTS increases dramatically after postnatal 35. Thus, a very early period of dietary sodium restriction leads to a late-onset expansion of terminal fields in the rat NTS. We also demonstrated earlier that terminal

field size in E3-E12 sodium restricted mice, as measured by amount of terminal field label, is at least doubled at adulthood compared to mice fed normal lab chow throughout development. Here, we examined the normal postnatal development of the three terminal fields and their overlapping fields in the NTS and compared this development to that of E3–E12 sodium restricted mice. Our preliminary findings show that the terminal field volume of each of the three nerves decreases from postnatal day 15 (P15) to P60 in control mice, albeit at different rates. In contrast, the terminal fields of the three nerves in E3-E12 sodium restricted mice are similar to that in controls at young ages; however instead of pruning, the terminal fields of the GSP, CT, and IX all enlarge after P30 so that the terminal field volumes are at least double the size of controls at adulthood. Establishing these developmental patterns in mice now allow us to ask more mechanistic questions about how and why terminal fields decrease with age in normally fed mice and what factors have a role in the late plasticity period that expresses itself when mice are restricted of dietary sodium at a very early stage of embryonic development.

Title: Postnatal development of sensory-evoked neuronal population activity in mouse barrel cortex

Authors: *A. VAN DER BOURG, F. HELMCHEN;
Brain Res. Inst., Zürich, Switzerland

Abstract: The mammalian neocortex is essential for high-level sensory processing, motor control and higher cognitive functions, yet the principles of neocortical circuit operation and their implementation in the developing brain remain poorly understood. The rodent whisker system is a widely adopted model for sensorimotor integration. However, the studies of developmental changes in the neuronal activity in somatosensory cortex S1 ('barrel cortex') are

scarce. Here, we investigated spontaneous and sensory-evoked neuronal population dynamics in layer 2/3 (L2/3) of the developing mouse barrel cortex (between postnatal day P10 and P30). Population activity was measured in anesthetized mice using *in vivo* two-photon calcium imaging following bolus-loading of the calcium indicator Oregon Green BAPTA-1. For precise stimulation of the principal whisker we used a newly developed multidimensional galvanometric stimulation system capable of moving single or multiple whiskers along their longitudinal and transversal axes at high temporal and spatial resolution, either simultaneously or independently. Longitudinal force exertion on the whisker follicle ('tapping') presumably is an important aspect of touch events but has been rarely employed so far. Between P10 to P30 spontaneous L2/3 activity markedly changed, showing increased sparseness, larger heterogeneity and progressive desynchronization. For principal whisker-evoked responses (either longitudinal, transversal, or both) we discovered a clear shift from highly synchronized unselective responses to sparse and stimulus-selective activity patterns. Whereas longitudinal and transversal stimulation activated the same sub-populations of neurons in young mice, two distinct groups could be identified in young adult animals implicating the emergence of tuning to specific whisker forces in L2/3. Stimulus-selective neurons emerged around P13 when overall neuronal population activity was starting to decrease significantly. At around P16 neuronal network activity already showed a highly selective and sparsified activity pattern comparable with evoked activity in young adult animals. Various mechanisms may underlie this functional maturation of L2/3 cortical circuitry, including changes in intrinsic excitability, formation of lateral connectivity, and maturation of the inhibitory network, warranting further examination. In the future, our findings may help to understand how maturation of sensory neocortical networks relates to emerging behaviors of young mice.

Title: Early postnatal development of synaptic input and intrinsic excitability in barrel cortex

Authors: *L. MURRAY, M. C. ASHBY;
Bristol Univ., Bristol, United Kingdom

Abstract: Cortical development is controlled by a combination of genetic factors, spontaneous activity and experience dependent plasticity. In mouse barrel cortex, by postnatal day (P) 4, the genetically encoded somatotopic whisker map in layer IV has been formed and marks the end of the critical period for gross structural plasticity. This coincides with the inside-out formation of cortical layers, with layer VI cells differentiating and arriving first in the cortex and subsequent layers migrating through deeper layers in turn. Migration of cells is complete by the end of the first postnatal week. However, the formation of functional cortical circuits undergoes a critical period of development between P4 and P10 that is primarily regulated by sensory experience and neuronal activity and does not follow the same structural maturation pattern. Using a combination of immunohistochemistry and whole-cell patch clamp electrophysiology, we have compared the development of synaptic input and intrinsic excitability of layer IV stellate and layer V pyramidal cells within barrel cortex slices throughout the functional critical period from P3 to P12. Current observations indicate a rapid maturation in action potentials and excitability, as well as significant changes in passive membrane properties across both layers. Postnatal development of intrinsic properties of neurons appears to be interrelated with synaptic modification, including a decrease in NMDA to AMPA receptor ratio. Interestingly, we observe that layer IV and V cells differ in their developmental profile, but all neurons appear tuned to respond to developmentally regulated synaptic inputs. Our results demonstrate some of the vast physiological changes which occur early in development, particularly during critical periods. Defects which alter the careful balance of synaptic and intrinsic properties early in postnatal growth may have long lasting effects of cortical processing.

Title: Developmental profiles of the intrinsic properties and synaptic function of auditory neurons in preterm and term baboon neonates

Authors: S. KIM[1], S. LEE[1], C. BLANCO[2], *J. KIM[1];
[1]Physiol., Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX; [2]Pediatrics, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: The human fetus starts to hear and undergoes major developmental changes in the auditory system during the third trimester of pregnancy. Although there are significant data regarding development of the auditory system in rodents, changes in intrinsic properties and synaptic function of auditory neurons in developing primate brain at hearing onset are poorly understood. We performed whole-cell patch clamp recordings of principal neurons in the medial nucleus of trapezoid body (MNTB) in preterm and term baboon brainstem slices to study the structural and functional maturation of auditory synapses. Each MNTB principal neuron received an excitatory input from a single calyx of Held terminal, and this one-to-one pattern of innervation was already formed in preterm baboons delivered at 67% of normal gestation. There was no difference in frequency and amplitude of spontaneous excitatory postsynaptic synaptic currents (PSCs) between preterm and term MNTB neurons. In contrast, the frequency of spontaneous GABAA/glycine receptor-mediated inhibitory PSCs, which were prevalent in preterm MNTB neurons, was significantly reduced in term MNTB neurons. Preterm MNTB neurons had a higher input resistance than term neurons and fired in bursts whereas term MNTB neurons fired a single action potential in response to suprathreshold current injection. The maturation of intrinsic properties and dominance of excitatory inputs in the MNTB allow it to take on its mature role as a fast and reliable relay synapse in which each presynaptic action potential results in a single and reliable postsynaptic action potential in the primate auditory system.

Title: A genetic fate map of the avian brainstem auditory nuclei

Authors: *M. LIPOVSEK, D. FRANCHINI, R. WINGATE;
MRC Ctr. For Developmental Neurobio., London, United Kingdom

Abstract: The auditory systems of birds and mammals have undergone separate evolution since these lineages shared their last common ancestor 320 million years ago. While the common origin of the auditory end organ is well established, there is no consensus as to whether the brainstem auditory nuclei of birds and mammals are developmentally homologous. However, both in birds and mammals auditory space coordinates on the horizontal plane are processed in similar ways. In both clades this is based on computing interaural time differences (ITD) using a similar circuit comprising brainstem auditory nuclei that nevertheless appear to arise from different axial developmental origins. The axial and cell lineage origin of the neurons involved has recently been elucidated for the mice nuclei. Here, we present data on the fate mapping of the analogous nuclei of chicken. We performed in ovo electroporations of enhancer-driven Cre-recombinase expression constructs, together with a Flox-pA-EGFP and -mCherry constructs, to label rhombic lip derived Atoh1+, or ventricular zone derived Ptf1a+ lineages. Electroporations were performed at embryonic day 2 (E2). Eggs were further incubated until E9-10. Hindbrains were dissected, fixed and processed for cryosectioning and confocal imaging. We used a combination of cell position and axon projections to identify different cell populations. Atoh1 expressing progenitors from the rhombic lip give rise to the glutamatergic neurons of the nucleus magnocellularis and at least two neuronal types of the nucleus angularis (radiate and vertical cells). The inhibitory neurons of the superior olivary nucleus originate from Ptf1a+ progenitors. The progenitors for the neurons that compose the nucleus laminaris, the coincidence detector for ITD, could not be identified within these genetic lineages. This suggests a divergence in evolutionary origins of the ITD circuit between mammals and birds.

Title: Dicer knockout affects the expression of vGluT1 in type Ia afferents

Authors: *M. M. FERRER SOCORRO, S. M. O'TOOLE, S. B. NELSON;
Nelson Lab., Brandeis Univ., Waltham, MA

Abstract: Proprioceptive feedback from type Ia sensory afferents is crucial for normal locomotion. Various transcription factors and signaling molecules are involved in the development and maintenance of these neurons and the targets they innervate. However much less is known about the role of post-transcriptional regulation by microRNAs (miRNAs) within type IA sensory neurons. miRNA biogenesis is dependent on the endoribonuclease Dicer. By conditionally ablating Dicer using a parvalbumin driven Cre we were able to impair miRNA biogenesis within type IA sensory neurons. Conditional knockout mice displayed severe ataxia, characterized by an uncoordinated gait and hyperextension of the limbs. Our behavioral analysis demonstrated that this deficit began at the middle of the third post-natal week. Immunohistochemical inspection of the muscle spindles revealed that intrafusal fibers were preserved and had intact overall morphology. Furthermore, Type IA sensory neurons continued to innervate the spindles as evidenced by the presence of characterstic annulospiral endings. However, we observed a near complete absence of vGluT1 staining, a marker of the spindle associated sensory endings (SSEs) within the peripheral sensory afferents. This observed drop in SSEs was statistically significant within both the gastrocnemius($p=5.41*10-5$) and tibialis anterior($p=0.03$) at post natal day 30 (p30). However, at p5 SSEs were largely intact when compared between knockout and control animals. Our findings place Dicer in a pathway that is vital for the maintenance of the type IA sensory neurons. Ongoing experiments will address the extent to which the innervation pattern and vGluT1 expression is affected in the spinal cord of Pvalb-cre Dicer condtional knockout mice.

Title: Coordinated changes in neuronal activity and vascular network properties in Wistar rat auditory brainstem during postnatal development

Authors: L. SHI[1], Q. BROWN[1], B. FU[2], *A. RODRIGUEZ-CONTRERAS[1];
[1]Biol., CCNY, CUNY, NEW YORK, NY; [2]Biomed. Engin., CCNY, CUNY, New York, NY

Abstract: Neurovascular coupling reflects the functional metabolic and signaling relationship between the blood vasculature and neural tissue. However, little is known about the developmental origins of neurovascular coupling. Recently, we found that the first postnatal week is important for cell proliferation and generation of astrocytes in the medial nucleus of the trapezoid body (MNTB) in the auditory brainstem of rats (Saliu et al., 2104. J Comp Neurol 522:971-985). Astrocytes are good candidates to modulate the development of neurovascular coupling because they interact simultaneously with synapses and blood vessels, but there is a paucity of data on the development of neuronal and vascular network properties in the MNTB. In this study we examined developmental changes in neuronal ensemble activity and vascular network structure and function in the MNTB of Wistar rat pups. All values reported here represent mean ± SD. To measure changes in the activity of MNTB neuronal ensembles we performed multi-electrode recordings in anesthetized pups. Mulit-unit activity (in spikes/s) increased from 1.1 ± 3.0 in the first postnatal week (n=9 pups) to 12.1 ± 20.2 in the second postnatal week (n=5 pups). To examine the development of the vascular network we used IB4 histochemistry to label blood vessels in 80 μm thick horizontal brainstem sections and obtained laser scanning confocal microscope z-stacks (512x512 pixels per image frame, 1 pixel = 0.581 μm). We performed semi-automated digital analysis of confocal stacks normalized to 10 μm thickness and found that vasculature density in the MNTB (in μm^3) increased from 30,199 ± 8313 in the first postnatal week (n=2 pups) to 47,690 ± 18,050 in the second postnatal week (n=2 pups). There was a similar trend in the number of branches per image stack from 7.5 ± 2.3 in the first postnatal week to 17.2 ± 8.8 in the second postnatal week. Finally, to quantify vascular function we injected the fluorescent solute TRITC-dextran (155 kD) via the carotid artery and quantified its permeability in individual capillaries or post-capillary venules in the MNTB of postnatal rats *in vivo* using two-photon microscopy. Our preliminary results show a decrease in the permeability of microvessels (in cm/s) from $2.9 \pm 1.1 \times 10^{-7}$ in one-week old rats (n=11 vessels) to $1.6 \pm 0.6 \times 10^{-7}$ in two-week old rats (n=5 vessels). Based on these preliminary results we propose that the first week of postnatal life could be important for coordinated changes in astrocytes, neurons, and the vascular network that might lead to the establishment of neurovascular coupling in neonate rats.

Title: c-Fos immunohistochemical study of vestibular activity in developing opossums, Monodelphis domestica

Authors: *F. LANTHIER, T. CABANA, J.-F. PFLIEGER;
Sci. Biologiques, Univ. De Montréal, Montréal, QC, Canada

Abstract: Even if they are born very immature, the newborn marsupials crawl, unaided, from the mother's birth canal to a nipple where they attach to pursue their development. In most species, the crawling is effected against gravity; the vestibular system is thus one of the sense organs thought to be involved in the guidance of the newborn to the nipple. Behavioral studies in which newborns were placed head down showed that they could revert themselves head up, but it was not ascertained if the vestibular system played a role in this reflex, their immobile hindquarters possibly acting as dead weight imposing the change in body orientation. Anatomical studies in opossum and wallaby have shown that even if the labyrinth is very immature, the macula (perceiving gravity) may be functional and innervated by vestibular afferents which distribute centrally in the vestibular nuclei. We recently showed that low intensity electrical stimulations of the brainstem where vestibulospinal cells are located induce forelimb movements in *in vitro* preparations of newborn opossums Monodelphis domestica. To additionnally test if the vestibular system may influence motor behaviors *in vivo*, immobilized but conscious opossums from the day of birth (P0) to P18 were subjected for 60 minutes either to sinusoidal acceleration along the three planes or to vertical angular displacement. Control animals were subjected to the same conditions, but without stimulation. The animals were then anesthetized by hypothermia, decapitated and the heads were fixed by immersion in paraformaldehyde to be sectioned. Sections were processed immunochemically to reveal c-Fos, a protein expressed in the karyon following sustained stimulation and used as a marker of neuronal activity. From P0 onwards, c-Fos labeled neurons were observed in different parts of the brainstem, such as the reticular formation or the solitary nuclei, but not in the vestibular labyrinth or nuclei. Labeling in the vestibular nuclei appeared at P15 and was more abundant at P18. No significant labeling was found in the vestibular sensory organs at any age examined. These results do not support an influence of the vestibular system in movement control of newborn opossums. However, c-Fos labeling in the vestibular nuclei appears slightly before the age at

which opossums start detaching from the mother and begin to use quadrupedal locomotion, albeit often returning to the nipple for several more weeks. It is likely that similar results would be obtained in other marsupial species.

Title: The developmental expression of PTEN in the spiral limbus of the mouse cochlea

Authors: Y. DONG[1,2], L. SUI[2], M. TOKUDA[2], *B. HU[1];
[1]Ctr. Hearing & Deafness, State Univ. Buffalo, Buffalo, NY; [2]Kagawa Univ. Fac. of Med., Kagawa, Japan

Abstract: Phosphatase and tensin homolog (PTEN) is a tumor suppressor gene that regulates diverse cell processes including proliferation, growth and synaptogenesis, as well as neural and glioma stem/progenitor cell renewal. PTEN also regulates the proliferation and differentiation of sensory cells in the developing inner ear. However, it is not clear whether PTEN plays a role in the development of the spiral limbus (SL). In this study, we examined the expression pattern of PTEN during the development of the SL in the mouse cochlea using RT-PCR, Western blotting, and immunohistochemistry. PTEN starts to express in the fibrocytes of the SL from the postnatal day (P) 4. At this time point, the expression also appears in the interdental cells (IDCs) when these cells begin to differentiate. Upon the maturation of the inner ear (P21), the expression of PTEN becomes undetectable in fibrocytes. However, PTEN expression persists in IDCs. Collectively, these results reveal a dynamic change in PTEN expression during inner ear development. Thus, our study suggests that PTEN plays a role in the differentiation of the SL in mouse cochlea.

Title: Crossmodal plasticity of intracortical connections in auditory cortex

Authors: *X. MENG, P. KANOLD;
Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Sensory systems do not work in isolation and interactions between auditory and visual systems have been shown during sensory loss. For example, cross-modal compensation in blind individuals leads to functional enhancement of the remaining senses, including enhanced frequency discriminations. However, the underlying mechanism for the compensation is not clear. Since our prior studies show that visual deprivations leads to improved frequency selectivity of neurons in primary auditory cortex (A1), we hypothesized that changes in visual experience can cause changes in the synaptic connections within A1. We investigated this hypothesis by comparing intracortical connections to Layer 2/3 neurons in dark-exposed mice to those from normally reared mice. We study the spatial pattern of excitatory and inhibition connections in acute slices of A1 using laser-scanning photostimulation (LSPS). We find that excitatory and inhibitory circuits related to layer 2/3 neurons are different in dark exposed mice than those from normally reared mice. The differences are characterized by the amount of input from different layers to L2/3 neurons and averaged maps. Our results show that visual experience can change circuits within A1 and these changes might contribute to enhanced auditory processing after visual deprivations.

Title: Developmental origin of axon initial segment-possessing olfactory bulb dopaminergic cells

Authors: *E. GALLIANO, A. N. CHAND, M. S. GRUBB;
MRC Ctr. For Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: Dopaminergic periglomerular neurons (DNs) in the olfactory bulb (OB) act at a crucial point in the early olfactory pathway, modulating information processing in OB glomeruli. DNs are extremely plastic cells, capable of regenerating throughout life, regulating their dopamine production levels in an exquisitely activity-dependent manner and undergoing structural plasticity of their dendrites. Previous work from our group has shown in an *in vitro* assay that only a subset of OB DNs has a specialised sub-compartment of the axon defined by local enrichment of the scaffolding protein ankyrin-G and voltage-gated sodium channels - an axon initial segment (AIS). Moreover, the AIS in OB DNs showed a surprisingly high degree of plasticity upon chronic changes in neuronal activity. In order to investigate if such plasticity also occurs *in vivo*, we firstly addressed the issue of which subset of DNs, if any, possesses an AIS in the intact organism. From a neurogenesis point of view DA neurons do not constitute a homogeneous population: while postnatally generated cells derive solely from precursors in the subventricular zone (SVZ), developmentally generated DNs are of different lineages. The majority of embryonically born DNs derive from neurogenetic areas outside the bulb such as the SVZ, the lateral ganglionic eminence (LGE) and the septum. Conversely, it has been recently shown that a small portion of DNs derives from a population of local bulbar precursors that, from as early as E13.5, generates very large DNs residing mostly at the border of glomerular and the external plexiform layers. Our preliminary results obtained in perinatally electroporated animals suggest that only this population of DA neurons derived prenatally from local precursors have an AIS, while the vast majority of small developmentally and postnatally born DNs do not possess this axonal specialisation. Future experiments will address whether these prenatally generated, AIS-possessing large DNs are the only source of OB short-axon cells, defined by their extensively ramifying axons that contact multiple glomeruli.

Title: Axon initial segment plasticity in olfactory bulb dopaminergic interneurons *in vitro* and *in vivo*

Authors: *A. N. CHAND, E. GALLIANO, T. RYAN, M. S. GRUBB;
MRC Ctr. for Dev. Neurobio., King's Col. London, London, United Kingdom

Abstract: The axon initial segment (AIS) is a specialised structure near the start of the axon that is a site of neuronal plasticity. Changes in activity levels can produce structural AIS changes that are linked to alterations in cellular excitability, which has previously been described in excitatory neurons. In the olfactory bulb (OB) inhibitory dopaminergic (DA) interneurons are particularly plastic, undergoing constitutive turnover throughout life, and regulating tyrosine hydroxylase (TH) expression in an activity-dependent manner. We investigated activity-dependent AIS plasticity in these inhibitory interneurons *in vitro* and *in vivo*. Dissociated cultures of rat embryonic day 18 and mouse postnatal day 3 (P3) OBs were immunolabelled for TH and for the AIS scaffolding protein Ankyrin-G. A +10mM K+ stimulus for 24 h produced an inward movement of the AIS in DA cells (~6 μm towards the soma) and an increase in AIS length. These counterintuitive changes, in the opposite direction to those previously reported in excitatory neurons, were not seen in rat OB principal cells, were fully reversed upon reinstatement of control conditions, and were dependent upon L-type calcium channels. To investigate the physiological effects of this 'reverse' AIS plasticity we cultured mouse OB cells from P3 TH:tdTomato mouse pups. Whole-cell electrophysiological recordings from tdT-positive DA cells suggested that inward AIS movement and increased AIS length were associated with increased excitability. Could these activity-dependent AIS changes contribute to homeostasis at OB circuit level? To address this question we manipulated OB activity in 4 week-old mice using 24 h unilateral naris occlusion or olfactory odour enrichment. In preliminary data a decrease in AIS length was observed in OBs deprived of sensory input using naris occlusion. This form of AIS plasticity in DA inhibitory neurons, which is the reverse of previously

observed AIS plasticity in excitatory cells, may therefore contribute to circuit-level adaptation in the OB allowing for consistent detection of odorant stimuli.

Title: Developing excitation in olfactory bulb projection neurons

Authors: ***A. S. MOBLEY**[1], M. A. TUSTY[2], C. A. GREER[2];
[1]Neurosci., Western New England Univ., Springfield, MA; [2]Neurosurg., Yale Univ., New Haven, CT

Abstract: Mitral cells, the olfactory bulb projection neurons, are born between embryonic (E) days 9-13, peaking at E11. Mitral cell dendrites receive odor input from olfactory sensory neurons that is then relayed by axon projection to higher cortical areas of the brain. We previously showed that the hyperpolarization-activated cyclic nucleotide-gated (HCN) channel in olfactory sensory neurons contributes to the specificity of axon targeting to the glomerular neuropil where they make the first synapse with mitral cell dendrites. To extend our analyses of the role(s) of HCN channels in the development of the olfactory bulb, we examined the expression of the four HCN channel subunits in developing mitral cells. The HCN1 and HCN2 subunits were widely expressed at E11 and colocalized with the mitral cell fate transcription factor Tbr1. Staining with the early progenitor marker Pax6 showed colocalization with HCN1 and HCN2. Such early expression suggests potential roles for HCN1 and HCN2 in fate choice, cue response or excitation in developing mitral cells. HCN3 and HCN4 expression was not observed until E15 when the developing layer of mitral cells is 5-6 cell bodies thick, co-localizing well with the later-onset mitral cell transcription factor Tbr2. By postnatal (P) day 0, when mitral cell layer development is complete (1-2 cell bodies thick), the subcellular localization of HCN1 shifted from the mitral cell somata to the dendrites which are located in the

glomerular layer. Colocalization of HCN1 and HCN2 with the mitral cell-specific marker vesicular glutamate transporter-1 indicates a postsynaptic role. HCN2 expression is also prominent in the glomerular layer, similar to HCN1. To test a functional role for HCN channels we transfected primary cultured mitral cells with shRNA targeting HCN2 and observed increased dendrite length. However, transfection with shRNA that targeted both HCN1 and HCN2 decreased dendrite length. These data suggest a role for HCN1 in neurite extension that is tempered by the presence of HCN2 with its slower kinetics and activation requirement of greater hyperpolarization. Thus far, the early onset of expression and subsequent distribution to sites of synaptic transmission suggest a role in developing mitral cell excitation and a functional contribution to developing morphology.

Title: Lamin B1 is required for olfactory sensory neuron maturation

Authors: ***C. M. WALL**[1,2], S. G. YOUNG[3], Y. ZHENG[2], H. ZHAO[1];
[1]Biol., Johns Hopkins Univ., Baltimore, MD; [2]Embryology, Carnegie Inst. of Washington, Baltimore, MD; [3]Med. and Human Genet., UCLA, Los Angeles, CA

Abstract: Disruption of the nuclear lamina, a protein network underlying the nuclear envelope, is linked to several human diseases; however, it is unclear how disruptions in a ubiquitous structure could produce a wide range of cell type-specific dysfunctions. The nervous system appears to be particularly sensitive to mutations in B-type lamins, major structural components of the nuclear lamina. To understand the role of B-type lamins in neuronal development, we investigated the differentiation of olfactory sensory neurons in the mouse olfactory epithelium, where local populations of progenitors are responsible for continuous replacement of neurons throughout adulthood. We used mouse genetics to knock out B-type lamins in an olfactory sensory neuron progenitor population (the horizontal basal cells) and then monitored differentiation after chemically-induced regeneration in adult animals. Lamin B1 mutant lineages

display a decrease in mature neuron markers, with no decrease in immature neuron markers or change in progenitor proliferation. These results suggest that Lamin B1 is not required for early stages of olfactory sensory neuron development, but may be necessary for neuronal maturation. This work aims to uncover a cell type-specific role for the nuclear lamina in the *in vivo* differentiation of a neuronal lineage.

Title: Self-generated movements with "unexpected" sensory consequences

Authors: *A. TIRIAC, C. DEL RIO-BERMUDEZ, M. S. BLUMBERG;
The Univ. of Iowa, Iowa City, IA

Abstract: Effective motor control demands that we distinguish sensations arising from self-generated movements (reafference) from those arising from other-generated movements (exafference). To make this distinction, reafferent signals are compared to motor copies (or corollary discharges). Recent findings in newborn rats demonstrate that myoclonic twitches, limb movements exclusive to REM sleep, trigger sensory responses throughout the brain, whereas wake-related limb movements do not. Here we tested the hypothesis that these differences result from state-dependent modulation of corollary discharge. While recording from the hindlimb region of primary motor cortex (M1), we evoked hindlimb movements using manipulations that differ with respect to their "expectancy" and, therefore, their presumed recruitment of corollary discharge. Only unexpected movements triggered M1 activity, thus supporting the notion that twitches, uniquely among all known self-generated movements, are processed as if they lack corollary discharge. This unique feature may be necessary for twitching to drive activity-dependent development of the sensorimotor system.

Title: Biochemical characterization and single particle electron microscopy of AMPA-Rs embedded in lipid nanodiscs

Authors: *T. NAKAGAWA, C. M. AZUMAYA;
Mol. Physiol. and Biophysics, Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Determining the molecular mechanism of AMPA-R modulation by auxiliary subunits remains a challenge. To conduct biochemical, biophysical, and structural studies it is advantageous to have a stable preparation in which the protein complexes are in a near native environment that resembles the cellular membrane. Biochemically isolated complexes made of AMPA-R subunits and auxiliary subunits such as TARPs and CNIHs dissociate by extended exposure to even a relatively mild detergent. To circumvent this problem, we reconstituted detergent solubilized recombinant AMPA-R subunits into lipid bilayers using a lipid nanodisc technology. In this method, purified AMPA-Rs are incubated with phospholipids and membrane scaffold protein (MSP), and subsequently the detergent is removed from the system so that a patch of lipid bilayer is formed within a disc surrounded by the MSP, embedding the AMPA-Rs. Single particle EM images of the reconstituted AMPA-Rs clearly demonstrate larger transmembrane density representing the lipid nanodisc. We have also investigated the global conformational change in response to the ligand glutamate. Particles exposed to glutamate adopt conformations in which the two N-terminal domain dimers were clearly separated, consistent with the previous observation using detergent extracted brain AMPA-Rs. The unliganded particles obtained by using nanodiscs have superior stability over conventional preparation in detergent. Because both the extracellular and cytoplasmic sides of the AMPA-R are accessible when embedded in nanodisc's lipid bilayer, this preparation also offers an opportunity to study molecular interactions and posttranslational modification of the cytoplasmic domain in the context of intact receptor complexes. We are currently extending this approach to incorporate auxiliary subunits into AMPA-R lipid nanodiscs and to investigate other membrane protein complexes in the synapse. Our progress in this area will be presented at this poster.

Title: Porcupine controls stability and composition of hippocampal AMPA receptors

Authors: ***H. YU**[1], N. HARMEL[1,2], T. YAMASAKI[3], S. TOMITA[3], D. S. BREDT[1]; [1]Johnson and Johnson, San Diego, CA; [2]Univ. of Düsseldorf, Düsseldorf, Germany; [3]Dept. of Cell. and Mol. Physiol., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Neuronal AMPA receptor complexes contain auxiliary subunits that modulate receptor trafficking and gating. In addition to well-studied transmembrane AMPA receptor regulatory proteins (TARPs) and cornichons (CNIH-2/3), recent proteomic studies identified a diverse array of additional AMPA receptor-associated transmembrane and secreted partners. We systematically surveyed this collection and found that PORCN and ABHD6 both increase GluA1 levels in transfected cells. Conversely, knockdown of PORCN in hippocampal neurons, which uniquely express it in high amounts, selectively reduces levels of GluA, TARP γ-2/8 and CNIH-2 proteins. Although PORCN is a membrane-associated O-acyl transferase, regulation of AMPA receptors is independent of its catalytic activity. PORCN knockdown decreases AMPA receptor currents and accelerates desensitization, and this is associated with depletion of TARP γ-8 from AMPA receptor complexes. These studies define novel roles for PORCN in controlling the level and composition of hippocampal AMPA receptor complexes. Hong Yu and Nadine Harmel contributed to this work equally.

Title: CPG2, a regulator of postsynaptic glutamate receptor internalization, directly links components of the endocytic machinery to the spine cytoskeleton

Authors: *S. LOEBRICH, M. BENOIT, J. KONOPKA, J. GIBSON, E. NEDIVI;
Picower Inst. for Learning and Memory, MIT, CAMBRIDGE, MA

Abstract: The nervous system has the remarkable capacity to adapt in response to altered sensory stimulation. Such plasticity is found on various organizational levels, including circuitry, single neurons and individual synapses, and is crucial for learning and memory. One mechanism of adjusting synaptic strength is the regulated display of glutamate receptors (GluRs) in the postsynaptic surface membrane. In response to neuronal activity, AMPA-type GluRs (AMPARs) can get internalized through Clathrin-mediated endocytosis (CME) in a specialized sub-compartment of dendritic spines, the endocytic zone. Candidate plasticity gene 2 (cpg2) is a brain-specific activity-regulated transcript from the Syne1 locus. It encodes a large protein that localizes to the endocytic zone and regulates AMPAR internalization through reversible association with the spine cytoskeleton. We have previously shown that CPG2 protein binds to F-actin through two coiled-coil domains in its C-terminus. Here, we investigate other CPG2 binding partners. Combining co-immunoprecipitation from synaptoneurosome preparations with mass spectrometry analysis we identified CPG2 interactions with multiple components of the endocytic machinery in brain, including Dynamin, Endophilin, the adaptor protein subunits AP2alpha, AP2beta, and the auxiliary endocytic factor HIP1. Using a yeast-2-hybrid approach to interrogate these interactors for direct binding, as well as heterologous expression in HEK cells for a structure-function analysis, we found that CPG2 binds directly to both AP2beta and EndophilinB2 via distinct protein domains. Further, CPG2 anchors components of the CME machinery at the spine cytoskeleton, directly linking the process of CME to F-actin. Our data suggest that CPG2 functions as a postsynaptic bridge that integrates second messenger signaling to instruct GluR internalization by linking components of the endocytic machinery to the spine cytoskeleton. These findings may have direct implications for neuropsychiatric disorder, since the human SYNE1 gene shows genome-wide significant association with Bipolar Disorder in regions homologous to rat cpg2.

Title: Multiple structural domains influence ampa receptor assembly

Authors: ***Q. GAN**[1,2], C. L. SALUSSOLIA[3], R. KAZI[3], L. P. WOLLMUTH[1];
[1]Neurobio. and Behavior, [2]Grad. Program in Neurosci., [3]Med. Scientist Training Program, Stony Brook Univ., Stony Brook, NY

Abstract: Ionotropic glutamate receptors (iGluR), including AMPA, kainate and NMDA receptors, are the major mediator of fast excitatory synaptic transmission in the vertebrate central nervous system. These ligand-gated ion channels function as tetrameric complexes consisting of four identical or similar subunits. Each iGluR subunit contains multiple structural domains: an extracellular amino-terminal domain (ATD), a ligand-binding domain (LBD), a transmembrane domain (TMD) consisting of three transmembrane helices (M1, M3 & M4) and a reentrant loop (M2), as well as an intracellular C-terminal domain. The assembly of iGluR subunits into tetrameric complexes is the pre-requisite for forward trafficking and synaptic insertion. To gain insight into the structural mechanisms underlying iGluR assembly, we investigated the contribution of each structural domain in the assembly of homomeric GluA1 AMPA receptors. We have found that while the ATD of GluA1 mediates the formation of dimeric intermediates, it is not required for the formation of a functional tetramer, nor does it affect the stability of the tetramer as assayed by titrating with incremental concentrations of SDS. In contrast, the TMD is the critical driving force behind tetramerization. Isolated TMD of GluA1 lacking both the ATD and the LBD still forms a tetramer. Previously we have identified a series of mutations in the M4 helix that prevent tetramerization in the full-length receptor or in the receptor lacking ATD. Interestingly, these mutations do not disrupt tetramer formation in the isolated TMD construct, although they still affect the stability of the tetramer. These results suggest that the LBD of

GluA1 negatively modulates the receptor tetramerization process. Consistent with this idea, disulfide cross-links introduced into the dimer-dimer interface of the LBD are able to partially rescue the tetramerization deficit of some M4 mutants. Elucidating how exactly the LBD confers the negative effect on AMPAR assembly will aid in the design of novel pharmacological agents that target this process to modulate the number and subunit composition of synaptic AMPARs.

Title: Photoinactivation analysis of synaptic AMPA receptors in PSD-95 knockout mice

Authors: *H. KAMIYA;
Dept. of Neurobio., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Hokkaido, Japan

Abstract: Various scaffold proteins determine dynamic localization of neurotransmitter receptors within the postsynaptic density (PSD). Among them, PSD-95 is one of the major proteins constituting a macromolecular complex of PSD in the central nervous system. It has been demonstrated that PSD-95 interacts with AMPA receptor subunits and play a key role in stabilizing AMPA receptors within the poststsynaptic membrane. In this study, synaptic delivery of AMPA receptors in PSD-95 knockout mice was examined using photochemical inactivation analysis using a photoreactive AMPA receptor blocker ANQX. Using acute hippocampal slices, field EPSPs were elicited by stimulation of Schaffer collaterals and were recorded from stratum radiatum in the CA1 region. Rate of synaptic delivery of AMPA receptors was evaluated by time course of recovery of EPSPs after photochemical inactivation of synaptic AMPA receptors using ANQX. Since ANQX forms crosslink and irreversibly blocks cell surface AMPA receptors, rate of recovery of EPSPs after photoinactivation is supposed to reflect rate of synaptic delivery of AMPA receptors from the intracellular pools. As described previously, photoinactivation persistently suppressed EPSPs in wild-type mice after a short period of recovery possibly due to washout of unbound photoproduct. In PSD-95 knockout mice, on the other hand, recovery of EPSPs was significantly accelerated than in wild-type. These results suggest that abundant

expression of PSD-95 in acute slice preparation may facilitate immobilization of AMPA receptors on the postsynaptic membranes in intact synapses. Molecular interaction between PSD-95 and AMPA receptors (or auxiliary subunits TARPs) critically limits the mobility of native synaptic AMPA receptors *in situ*.

Title: Acetylation of the AMPA receptor subunits GluR1 and GluR2 and the endoplasmic reticulum chaperone sigma-1 receptor: Implication for abuse of cocaine

Authors: *Y. YASUI, T.-P. SU;
NIH/NIDA, BALTIMORE, MD

Abstract: The sigma-1 receptor (Sig-1R) is an endoplasmic reticulum (ER) chaperone whose chaperone activity can be regulated by the ligands such as cocaine. We previously showed that cocaine causes behavioral and neuronal responses in mice by translocating the Sig-1R from the ER-mitochondrion contacts to interact with the potassium channel Kv1.2 on the plasma membrane (PM). Thus, Sig-1R has been implicated in the abuse of cocaine. AMPA receptor (AMPAR) trafficking and incorporation into PM play an important role in cocaine abuse. Post-translational modifications are key steps in the regulation of receptor functions. It has been reported that cocaine affects phosphorylation levels of GluR1 and GluR2 at the specific serine which contribute to the cocaine-induced changes of AMPAR. Acetylation is known to play key roles in the processing, trafficking, stabilization, and recycling of functional proteins. Recently it has been revealed that the PM proteins can also be regulated by acetylation. However, acetylation of AMPAR remains to be explored. In this present study we examined if Sig-1R may affect the AMPAR trafficking with a final goal of providing a potential mechanism on how cocaine may differentially regulate the PM contents of GluR1 and GluR2. We found that the Sig-1R physically associated with GluR1 and GluR2. The Sig-1R associated with p300/CBP-associated factor (PCAF) and GCN5 which are mammalian members of GCN5-related N-acetyltransferases and share about 73% of homology throughout their sequences. GluR1 and GluR2 also interacted with PCAF and GCN5. We found that GluR1 and GluR2 were acetylated

at the N-termini facing an extracellular space or the ER lumen, and that the acetylation levels were regulated by PCAF. Our immunocytochemistry data showed that these interactions occurred at the ER. Interestingly, our data showed that Sig-1R agonists, cocaine or PRE-084, could affect differently the acetylation levels of GluR1 and GluR2. Together, these results suggest that cocaine differentially regulates acetylation of GluR1 and GluR2 at the ER through Sig-1R, which may be a potential new mechanism underlying cocaine-induced dynamics of AMPAR subunits. Title: Dissecting the role of AMPAR subunit composition on synapse maturation in CGE-derived hippocampal interneurons

Authors: *G. AKGUL, E. BARKSDALE, K. A. PELKEY, C. J. MCBAIN;
Natl. Inst. of Hlth., Bethesda, MD

Abstract: Disrupting the excitatory synaptic recruitment of GABAergic inhibitory interneurons can promote excitation-inhibition imbalance within cortical circuits that can precipitate neurological diseases such as schizophrenia and epilepsy. In the hippocampus, two major lineages of inhibitory interneurons, derived from caudal ganglionic eminence (CGE) and medial ganglionic eminence (MGE), contribute distinct subgroups, which give rise to microcircuit complexity. The specific biophysical properties of excitatory input onto distinct interneurons strongly correlate with cellular lineage and dictate the circuit recruitment of discrete forms of feedforward and feedback inhibition. CGE-derived interneurons primarily express calcium impermeable AMPARs and exhibit relatively large NMDAR-mediated currents with slow kinetics due to prominent expression of GluN2B subunits throughout development. In contrast MGE-derived interneurons typically express GluA2-lacking calcium permeable AMPARs with smaller NMDAR-mediated currents that transit through a developmental GluN2B-GluN2A subunit switch. To investigate the role of AMPAR-mediated glutamatergic input on the

development of CGE- derived interneurons and maturation of their excitatory input, we created a knockout (KO) mouse line that eliminates the GluA2 subunit expression selectively in CGE-derived interneurons. KO mice have been tested for AMPAR and NMDAR activity in CGE-derived interneurons and compared with the activity in wild type (WT) CGE- and MGE-derived interneurons. KO CGE-derived interneurons display inwardly rectifying AMPAR-mediated EPSCs with fast kinetics that are sensitive to the calcium permeable AMPAR antagonist philanthotoxin confirming successful targeted loss of GluA2 within this interneuron cohort. Interestingly, despite this shift to an MGE-like AMPAR profile, CGE-KO interneuron NMDAR-mediated currents retained properties similar to WT CGE-derived interneurons. Thus, forcing CGE-derived interneurons to express calcium permeable AMPARs did not alter their basal developmental program for expression of NMDARs. Of interest, the frequency of spontaneous excitatory synaptic activity in CGE-KO interneurons is significantly lower than that observed in MGE and CGE-derived WT interneurons revealing a deficit in the circuit integration of KO CGE derived interneurons. We are currently investigating whether this decreased activity results from a change in presynaptic release probability, or a lower number of active synapses.

Title: Reduced kainate receptors at hippocampal mossy fiber synapse in PSD-95 knockout mice

Authors: *E. SUZUKI[1,2], H. KAMIYA[1];
[1]Dept. of Neurobio., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Hokkaido, Japan; [2] ＪＳＰＳ Res. Fellow, Tokyo, Japan

Abstract: PSD-95 is a major postsynaptic density (PSD) protein, and has been shown to play an important role in stabilizing AMPA receptors (AMPARs) as well as NMDA receptors (NMDARs) within the PSD. It has been reported that PSD-95 directly binds to GluK2 and GluK5 subunits of kainate receptors (KARs). However, it is still unknown whether this interaction regulates synaptic localization of native KARs. In this study, we examined a role of

PSD-95 in synaptic localization of native KARs using PSD-95 knockout mice. Acute hippocampal slices were obtained from wild type and PSD-95 knockout mice. KARs-mediated excitatory postsynaptic currents (EPSCs) were recorded from mossy fiber-CA3 synapses where KARs are densely expressed. EPSCs were evoked by the stimulation of granule cell layer of dentate gyrus. In wild type, 30 μM GYKI 53655, an antagonist of AMPARs, reduced both amplitude and charge transfer of EPSCs, and left small and slow components of EPSCs, as shown in the previous studies (amplitude: to 11.7 ± 0.9% of control, charge transfer: to 27.4 ± 2.5% of control, n = 16). These GYKI-resistant slow components were blocked by co-application of KARs antagonist, 1 μM ACET (amplitude: to 5.3 ± 0.6% of control, charge transfer: to 9.0 ± 1.8% of control). These data confirmed that slow components of EPSCs were mediated by synaptic activation of KARs. In PSD-95 knockout mice, KARs-mediated slow components were significantly reduced than those in wild type mice (amplitude: to 8.7 ± 0.7% of control, $P<0.05$, charge transfer: to 18.9 ± 2.0% of control, $P<0.05$, n = 8). These results suggest that PSD-95 is critical for synaptic localization of not only AMPARs, but also KARs at the hippocampal mossy fiber synapse.

Title: Genetic dissection of a defined neural circuit reveals the role of kainate and AMPA receptors in taxis behaviors

Authors: P. MALDONADO, *P. J. BROCKIE, J. GARDNER, J. E. MELLEM, D. M. MADSEN, A. V. MARICQ;
Dept. of Biol., Univ. of Utah, SALT LAKE CTY, UT

Abstract: Animals find sparsely distributed resources by navigating along gradients of sensory cues. For example, animals can associate temperature or chemical cues with favorable environmental resources and move towards those cues. The relatively simple nervous system of the nematode *C. elegans* has facilitated the identification of circuits that contribute to distinct

behaviors. For example, navigation along thermal and chemical gradients depends on a neural circuit that includes the RIA interneurons. RIA are the major integrating neurons of this circuit and receive glutamatergic synaptic inputs from several different sensory neurons. We have shown that the RIA neurons express both the AMPA and kainate classes of ionotropic glutamate receptors (iGluRs). Notably, the GLR-3 and GLR-6 kainate iGluR subunits are exclusively expressed in RIA. By coexpressing these subunits in heterologous cells, we have shown that they constitute the components of a heterologous iGluR that can be gated by both glutamate and kainate. To determine the role of GLR-3/GLR-6 iGluRs in taxis behaviors, we generated null mutations in both the *glr-3* and *glr-6* genes. *In vivo* electrophysiological analysis of these mutants showed that GLR-3 and GLR-6 are required for a kinetically distinct component of the excitatory glutamate-gated current in RIA. Furthermore, we determined that the remaining component is mediated by the GLR-1 AMPA-type iGluR. Interestingly, using optogenetic techniques, we have also shown that AMPA and kainate receptors mediate distinct components of the behavioral response to light activation of sensory neurons that provide synaptic inputs to RIA. Together, our results indicate that AMPA and kainate receptors are required for navigation along sensory gradients and together mediate behaviors critical for survival of the animal.

Title: Corticosteroid regulation of AMPA receptor mediated synaptic function

Authors: *H. XIONG[1], F. CASSÉ[2], S. MARTIN[2], M. JOËLS[3], H. KRUGERS[1]; [1]Swammerdam Inst. For Life Sci., Amsterdam, Netherlands; [2]Ctr. Natl. de la Recherche Scientifique, Inst. de Pharmacologie Moléculaire et Cellulaire, Valbonne, France; [3]Rudolf Magnus Inst. of Neurosci., Utrecht, Netherlands

Abstract: Corticosteroid hormones are released from the adrenal glands in large amounts upon exposure to aversive events. These hormones are lipophilic, cross the blood brain barrier and

bind to mineralocorticoid receptors and glucocorticoid receptors. Via these receptors, corticosteroid hormones exert rapid non-genomic and genomic effects on brain function. Behaviorally, corticosteroid hormones promote the consolidation of emotionally arousing information. The underlying mechanisms of these effects remain poorly understood. Mounting evidence suggests that corticosterone induces changes in glutamate neurotransmission in the prefrontal cortex and the hippocampus, which may underlie their effects on cognitive processing. We report that corticosterone regulates (i) AMPA receptor mediated synaptic function in an activity-dependent fashion, (ii) AMPA receptor mobility, (iii) AMPA receptor function via MRs and GRs in a time dependent manner, and (iv) these effects may underlie the effects on emotional memory formation.

Title: Chronic progesterone treatment increases the AMPA receptor-mediated neurotransmission via the activation of progesterone receptors

Authors: *S. JOSHI[1], K. RAJASEKARAN[2], C. PASSMORE[1], J. WILLIAMSON[1], J. KAPUR[1];
[1]Dept of Neurol., Univ. of Virginia, Charlottesville, VA; [2]Dept. of Neurol. & Neurotherapeutics, Univ. of Texas Southwestern Med. Ctr., Dallas TX, TX

Abstract: The effects of progesterone and its neuroactive derivative allopregnanolone on GABAA receptor (GABAR)-mediated inhibitory neurotransmission are well characterized. However the effects of prolonged progesterone treatment on glutamatergic transmission are not known. Chronic increase in progesterone levels could alter the AMPA receptor (AMPAR) expression via homeostatic mechanisms or through the activation of progesterone receptors (PR). Adult female rats were given PMSG (20 IU) followed 48 hrs later with β-HCG (10 IU). A separate set of animals were given a single dose of progesterone (50 mg/kg). The expression of

GluA1 and GluA2 subunits of AMPARs in the hippocampi was determined using standard Western blotting techniques. Surface expression of the GluA1 and GluA2 subunits was indirectly determined using a BS3 cross-linking assay. AMPAR-mediated sEPSCs were recorded from CA1 pyramidal neurons (PNs) of acutely isolated slices by whole-cell patch clamp technique. Progesterone levels increased in the animals treated with PMSG β-HCG (50.2 ± 5.9 ng/ml vs 20 ± 3.2 ng/ml, n=6, $p<0.05$). Chronic increase in serum progesterone enhanced the AMPAR current. AMPAR-mediated sEPSCs recorded from PNs were larger in PMSG β-HCG-treated animals (19.78 ± 3 pA, n=7 cells/3 animals vs 10.7 ± 0.4 pA, n=16 cells/3 animals, $p<0.05$). The expression of GluA1 and GluA2 subunits was also enhanced in the hippocampi of PMSG β-HCG-treated animals (174 ± 39% and 174 ± 24% of that in controls respectively, n=9, $p<0.05$). Further the ratio of intracellular to total expression of GluA1 (0.45 ± 0.17 vs 0.84 ± 0.28, n=10, $p<0.05$) and GluA2 (0.34 ± 0.07 vs 0.72 ± 0.15, n=9, $p<0.05$) subunits in PMSG β-HCG-treated animals was lower than that in controls, suggestive of increased cell surface expression. Progesterone treatment (50 mg/kg) for 2 days also increased the GluA1 and GluA2 subunit expression (134 ± 8% and 149 ± 17%, n=5, $p<0.05$). Preliminary studies found that blocking the PRs with RU-486 (10 mg/kg) prevented the increase in GluA1 and GluA2 subunit expression in progesterone-treated animals. Whether estrus cycle-associated fluctuations in progesterone levels influenced the AMPAR subunit expression was also determined. Using the cytology of vaginal smears obtained daily, the animals were monitored for one estrus cycle and hippocampi were isolated during the next cycle. The expression of GluA1 and GluA2 subunits was higher in the animals in estrus and diestrus stages than that in the animals in proestrus. Thus progesterone appears to increase AMPAR-mediated excitatory neurotransmission through the activation of PRs.

Title: Glutamate and GABA-A receptor mRNA levels in human brain co-vary homeostatically and low values characterize psychosis

Authors: *M. REIMERS, X. CHEN;
Virginia Inst. of Psychiatric and Behavioral Genet., RICHMOND, VA

Abstract: Inhibitory neurotransmission is crucial for brain function, and GABA-A receptors are thought to be critical for maintaining the balance between excitation and inhibition in the brain. Nevertheless an investigation into four human brain gene expression data sets (Kang et al, Nature, 2011, Gibbs et al PLoS Genetics, 2011, and two unpublished data sets) reveals consistently very large (at least 20-fold) differences across neurologically normal human brains in expression of the GABR genes coding for the main components of the GABA-A receptors. A comparative study of these four data sets indicates highly consistent estimates of GABR mRNA level variability, and highly consistent correlations among expression of different receptor components. Receptor components of the same type co-vary positively across samples, indicating that they cannot be substituting for one another to conserve function. Glutamate receptors vary less (at most ten-fold); nevertheless in all data sets the first PC of levels of Glutamate receptor mRNAs are highly correlated (>70%) with the first PC of GABR expression levels. In the Stanley Brain Series, aggregate GABR expression scores of more than half of the cortical samples from schizophrenic individuals were in the lowest 5% of the normal range (see Figure). Bipolar individuals also more commonly had lower scores. Similar results were obtained in an independent sample from hippocampus. These results confirms a variety of investigations suggesting lower inhibitory activity in psychosis.

Title: A methyoxypiperidine differentially interacts at αβ and αβγ GABAA receptors

Authors: *D. B. WILLIAMS, J. P. CLAVIJO, D. T. PARKER, J. J. KEITH;
Dept Life Sci., Winston-Salem St Univ., WINSTON SALEM, NC

Abstract: We previously reported a novel di-fluoride methoxypiperidine, WSS-2, that showed strong agonistic effects at α1β2γ2s GABAA receptors. At that isoform, WSS-2 could induce near maximal (1 mM GABA) current with nM EC50's in a two site model. We investigated if these properties would be affected by substituting the α1 subunit with the α2. We chose α2 because we were interested in treatments for cocaine addiction, and α2 may be important in such as it is highly expressed in the nucleus accumbens. We expressed α2β2γ2s receptors in Xenopus oocytes and measured GABA or WSS-2 induced currents using two-electrode voltage clamp at -60 mV. Compounds were applied for 30 s (or until peak current seen) and washed out with buffer for 3-5 min. At the α2β2γ2s isoform, WSS-2 also demonstrated nM affinity and a large maximal current in a two site model. The two site models of both the α1 and α2 isoforms gave extremely low Hill numbers; since the subunit mRNA was injected at a 1:1:1 ratio, we could have had a mixture of αβ and αβγ receptors. Therefore the dose response curves were repeated for both α1 and α2 containing forms, injecting α and β 1:1, and in different cells α, β, γ in a 1:1:5 ratio. At both α1β2 and α2β2 isoforms, WSS-2 induced a one site dose response curve, with EC50's near 5 nM. Maximal currents were about 99% for α1β2 and 68% for α2β2. Hill numbers were 2.27 and 2.64 respectively, more in line with reported piperidine responses. However, when the γ subunit was added at 5x the α or β, a biphasic effect was seen. The first effect was stimulatory, with EC50's approximately 1 nM, maximal currents estimated at 80%, and Hill numbers of 1.4 for both α1β2γ2s and α2β2γ2s. The affinity and maximal effect are stronger than seen with most GABA-acting piperidines. The second effect of WSS-2 at these 1:1:5 receptors was inhibitory; higher concentrations of WSS-2, such as 50 nM and 100 nM, caused the WSS-2 current to disappear, with IC50's of 52 and 14 nM for α1 and α2 containing receptors respectively. In general, WSS-2

had slightly higher affinities at α2 containing forms than α1 isoforms when γ was present. WSS-2 does seem to act on at least two sites, with the presence of a γ subunit causing WSS-2 to act antagonistically at one of those sites. Based in the differences in affinity with α1 and α2, and the antagonistic effect seen in receptors injected with 1:1:5 α:β:γ, we speculate that one of the sites WSS-2 binds could be the benzodiazepine site. A compound based in WSS-2 could form the basis of a high affinity GABA ligand, either a probe or drug, one that could target αβ receptors, or be used to differentiate αβ and αβγ receptors. It cannot yet be used as a treatment for drug addiction, due to these mixed GABA effects, and high affinity for the DAT.

Abstract: In vertebrate central nervous system, GABA acts as inhibitory neurotransmitter by binding to two general classes of receptors: chloride ligand-gated ion channels complex GABAARs and metabotropic GABABRs that are linked via trimeric G-proteins to potassium channels. However, in invertebrates GABA can activate inward cationic currents through an homo-oligomeric receptor as has been described in the nematode *C. elegans*, where the central ionic conduction pore corresponds to an amino acidic sequence that permits the cationic flux. Another kind of cation-selective heteromultimeric receptor formed by the combination of two ligand-gated channel subunits (LCCH3 and GRD) was described in the fruit fly D. melanogaster. Similarly, in the x-organ neurons of the crayfish Procambarus clarkii we have identified two

GABA-gated currents: an early transient inward current depending on the extracellular sodium concentration, and other one generated by chloride ions. Both currents are activated by muscimol and blocked by picrotoxin, while cis-aminocrotonic acid only activates the chloride current. A cDNA encoding an ionotropic GABAR subunit was isolated from these neurons and transiently transfected into HEK 239T cells. Pharmacologically this subunit forms an anionic ligand-gated GABAR activated by muscimol and cis-aminocrotonic acid, and blocked by picrotoxin but not by bicuculline. Clearly, it becomes necessary to find out which type of subunit could help us to explain the cation-dependent current.

Title: Modulation of GABA(A) receptors by dopamine

Authors: *P. HOERBELT, M. W. FLECK;
Ctr. for Neuropharm. and Neurosci., Albany Med. Col., Albany, NY

Abstract: GABA(A) receptors are pentameric chloride channels and targets for benzodiazepines, barbiturates and anesthetics. They are made of various combinations of 19 subunits (α1-6, β1-3, γ1-3, δ, ε, θ, π, and ρ1-3). Certain GABA(A)R subtypes have been shown *in vitro* to be directly activated or modulated by histamine. Related Cys-loop chloride channels in invertebrates are directly activated by histamine or other biogenic amines, including dopamine, octopamine, serotonin, tyramine, choline and acetylcholine. However, the extent to which biogenic amines can modulate the large class of GABA(A)R subtypes in mammals is underexplored. Based on homology to invertebrate receptors, we hypothesized that biogenic amines would directly activate or modulate GABA(A)R. We used whole-cell recording and fast perfusion in HEK 293 cells to study the effects of biogenic amines on common and uncommon assemblies of recombinant rat GABA(A)R subunits. Dopamine directly activated GABA(A)R currents (EC50 ≈ 700 μM), an effect that was concentration-dependent and blocked by the

GABA(A)R antagonist, bicuculline. Dopamine currents were consistently much smaller than GABA-evoked currents in the same cells, suggesting low efficacy. Dopamine activation was strictly linked to the presence of γ subunits, and was also seen in cells containing only β/γ subunits (which lacked α). Other tested biogenic amines (including epinephrine, norepinephrine, tyramine, choline and acetylcholine) did not activate GABA(A)R. In conclusion, dopamine directly and selectively activates γ subunit-containing mammalian GABA(A)R with low potency and efficacy. Whether such effects are present in brain receptors, are more pronounced with other biogenic amines, or are linked to mammalian behaviors, remain to be determined. Our results indicate that drug discovery and development efforts would benefit by considering GABA(A)R as potential targets for novel and selective dopamine-like drugs. The therapeutic potential includes treatment for epilepsy, anxiety, insomnia, Parkinson's disease, depression, schizophrenia, or other motivational/movement disorders.

Title: Ectopic expression of GABAA receptor subunits increases tonic inhibition in somatostatin neurons in the hilus of the dentate gyrus

Authors: Z. PENG[1], X. TONG[1], M. WALLNER[2], N. ZHANG[1], Y. CETINA[1], T. S. OTIS[1], *C. R. HOUSER[1];

[1]Dept. Neurobiol, David Geffen Sch. of Med. at UCLA, Los Angeles, CA; [2]Dept. Mol. and Med. Pharm, UCLA, Los Angeles, CA

Abstract: Somatostatin (SOM) neurons in the dentate hilus are highly vulnerable to excitotoxic damage, but the reasons for such vulnerability remain unclear. Our recent immunohistochemical studies have shown that hilar SOM neurons exhibit very little labeling for the δ subunit of the GABAA receptor (GABAAR), and subsequent electrophysiological studies have demonstrated that tonic inhibition is also very low in these neurons. As tonic inhibition is recognized as a key regulator of neuronal excitability, these observations have led to the suggestion that tonic inhibition could play a role in protecting such neurons from excitotoxic damage. The current studies tested the hypothesis that expressing exogenous GABAAR subunits, either the α6 subunit that is normally absent from the forebrain but mediates tonic inhibition in cerebellar granule cells or the δ subunit that mediates tonic inhibition in other regions of the dentate gyrus, could form functional receptors and increase tonic inhibition in hilar SOM interneurons. Utilizing SOM-Cre mice and Cre-dependent adeno-associated virus (AAV) vectors, we were able to deliver ectopic GABAARs α6 or δ subunit selectively to SOM neurons in the hilus. Cre-recombinase inducible GFP tagged GABAAR subunits (α6 and δ) were cloned into AAV vectors (AAV-DIO-GABRα6- or δ-EGFP) and assembled into AAV particles (Stanford vector core). One month following stereotaxic injections into the hilar region of SOM-Cre mice, confocal and electron microscopy demonstrated robust expression of GFP in hilar SOM neurons. Immunohistochemical studies with subunit-specific GABAAR antisera demonstrated strong labeling of either α6 or δ subunits in GFP-labeled hilar neurons. Tonic currents were measured in transfected hilar interneurons at 3 months of age (one month post transfection). We found a robust increase of tonic inhibition in both α6-Cre GFP and δ-Cre GFP transfected SOM hilar neurons (51.5 ± 7.9 pA, n=15; 27.8 ± 4.9 pA, n=16 respectively) compared to control hilar neurons (5.1 ± 1.5 pA, n=7 in non-injected SOM-Cre Ai9 mice; 3.0 ± 0.4 pA, n=13 in GFP virus delivered SOM-Cre mice, $p < 0.01$). Furthermore, we tested sensitivity to the δ subunit-selective agonist THIP (1 μM) and found that it induced larger inward current in both α6 and δ subunit transfected SOM hilar neurons relative to control (α6: -30.1 ± 4.3 pA, n=7; δ: -20 ± 2.4 pA, n=7; GFP: -4.2 ± 0.6 pA, n=6). Further experiments will determine how ectopic α6 and δ subunits of GABAARs in SOM hilar neurons affect hippocampal neuronal circuits and test the hypothesis that increased tonic inhibition might protect vulnerable neuronal subtypes that are lost during severe seizure activity or ischemic insult.

Title: Input-specific expression of the alpha5 GABAA receptor subunit in hippocampal interneurons

Authors: E. MAGNIN, O. CAMIRE, *L. TOPOLNIK;
CRIUSMQ, Laval Univ., Quebec, QC, Canada

Abstract: Synaptic expression of the alpha 5 GABAA receptor subunit (α5-GABAAR) has been reported in hippocampal CA1 inhibitory interneurons. However, the types of synapses that express α5-GABAAR and its functional role have not been investigated. Using a combination of whole-cell patch-clamp recordings, optogenetics and immunohistochemistry, we examined the synapse-specific expression of the α5-GABAAR and its modifications in the animal model of temporal lobe epilepsy (TLE). Our data showed that both the α5-GABAAR and its anchoring protein radixin exhibit a strong colocalisation with a vesicular GABA transporter in hippocampal CA1 oriens-alveus (O/A) interneurons. Moreover, inhibitory postsynaptic currents evoked in interneurons by selective activation of calretinin-positive (CR+) interneuron-specific cells in CR-Cre mice were decreased in the presence of the α5-GABAAR inverse agonists. Synaptic expression of the α5-GABAAR was revealed in different interneuron types, including oriens-lacunosum moleculare cells, bistratified cells, basket cells and oriens-oriens interneurons. Finally, a rapid decrease in the α5-GABAAR and radixin expression was observed in pilocarpine model of TLE, pointing to a significant disinhibition of O/A interneurons. Our data showed that the α5-GABAAR is expressed at inhibitory synapses formed at different types of interneurons by the local inhibitory input from CR+ cells. Moreover, the rapid decline of the α5-GABAAR in hippocampal interneurons during TLE may contribute to their disinhibition and hyperexcitability with consequences for network activity.

Title: RNF34 interacts with and promotes GABAA receptor degradation via ubiquitination of the γ2 subunit

Authors: *H. JIN, T.-T. CHIOU, C. P. MIRALLES, A. L. DE BLAS;
Univ. of Connecticut, Storrs, CT

Abstract: $GABA_A$ receptors ($GABA_A$Rs) mediate the majority of fast synaptic inhibitory neurotransmission in the brain. The efficacy of GABAergic synaptic inhibition depends on the number of functional $GABA_A$Rs localized in the postsynaptic membrane. It has been shown that GABAergic synaptic inhibition can be regulated by ubiqutination of the β3 or γ2 subunits in an activity-dependent manner (Saliba et al., 2007; Arancibia-Cárcamo et al., 2009). However, the specific E3 ubiquitin ligase(s) that mediate(s) this post-translational modification remains to be identified. We have found that RNF34, which is a RING-domain E3 ubiquitin ligase, specifically interacts with the γ2 subunit of the $GABA_A$Rs in the rat brain. The interaction occurs between the C-terminal RING domain of RNF34 and the large intracellular loop of the γ2 $GABA_A$R subunit (γ2IL), as shown by yeast-two-hybrid and *in vitro* pull-down assays. In brain extracts, RNF34 co-immunoprecipitates with assembled $GABA_A$Rs. A feature of the RING-domain E3 ubiquitin ligases is that they bind to the substrates that they ubiquitinate. Therefore, we investigated if RNF34 ubiquitinates and regulates the expression of the γ2 subunit and γ2-containing $GABA_A$Rs. In co-transfected HEK293 cells, RNF34 reduces the expression of the γ2 $GABA_A$R subunit by increasing the ratio of ubiquitinated/non-ubiquitinated γ2. Mutating several lysines of the γ2IL into arginines (γ2 8KR, 9KR, or 10KR) makes the γ2 subunit resistant to RNF34-induced degradation. RNF34 also reduces the expression of the γ2 subunit when the α1 and β3 subunits are co-assembled with γ2. This effect is partially reversed by Leupeptin or MG132, indicating that both the lysosomal and proteasomal degradation pathways are involved. Immunofluorescence of hippocampal neurons shows that RNF34 forms clusters and that a subset of these clusters is associated with GABAergic synapses. RNF34 is not expressed until the second postnatal week of rat brain development, being highly expressed in some interneurons. Overexpression of RNF34 in hippocampal neurons decreases both the density of γ2 $GABA_A$R clusters and the number of GABAergic contacts that these neurons receive. Knocking down endogenous RNF34 with shRNA leads to increased γ2 $GABA_A$R cluster density and increased GABAergic innervation. The results indicate that RNF34 i) interacts with and ubiquitinates the γ2 $GABA_A$R subunit promoting $GABA_A$R degradation and ii) regulates postsynaptic γ2

$GABA_AR$ clustering and the stability of GABAergic synapses. **Reference** 1, Arancibia-Cárcamo et al., (2009) Proc Natl Acad Sci USA. 106:17552-17557. 2, Saliba et al., (2007) J Neurosci 27:13341-13351.

Title: Synaptic pruning in the male hippocampus during adolescence: Reversal by knock-out of the GABAA receptor α4 subunit

Authors: *J. PARATO, S. SMITH;
SUNY Downstate, Brooklyn, NY

Abstract: Synaptic pruning during adolescence is a well-known phenomenon (Huttenlocher 1979; Yildirim et al., 2008). This decrease in spine density at puberty is thought to be important for normal cognition because it is abnormal in neurodevelopmental disorders such as autism and schizophrenia (van Spronsen and Hoogenrad, 2010). Although the mechanism which underlies this process is unknown, α4βδ $GABA_A$ receptors (GABARs) play a role in pubertal synaptic pruning in the CA1 hippocampus and dentate gyrus of the female mouse. NMDA receptor activation is known to maintain spine stability (Ultanir et al., 2007), and the presence of α4βδ GABARs, which increase expression on the dendritic spine of CA1 pyramidal cells at puberty, inhibits NMDA receptor activation by a shunting inhibition (Shen et al., 2010). Thus, in the current study, we tested the hypothesis that α4βδ GABARs also play a role in synaptic pruning in the CA1 hippocampus and dentate gyrus (DG) of male mice. To this end, we examined spine density at the onset of puberty (Pub, PND 35) compared to post-puberty (Post, PND 56) in male mice. Brains were processed using the Golgi method and spine counts obtained using a Nikon Eclipse Ci-L microscope. Our data show that, in the male mouse, spine density decreases across adolescence in the CA1 hippocampus (Pub, 1.2 spines/υm, Post, 0.6 spines/υm, $P<0.05$) as well as in the dentate gyrus (Pub, 1.7 spines/υm, Post, 1.2 spines/υm, $P<0.05$). Spine density in both regions was significantly greater in the post-pubertal α4-/- (CA1, α4-/-, 1.1 spines/υm, $P<0.05$;

DG, α4-/-, 1.8 spines/υm, P<0.05). These data suggest that α4βδ GABAR expression plays a role in adolescent synaptic pruning in the male as in the female. These findings may have relevance for neurodevelopmental disorders such as autism and schizophrenia where synaptic pruning is abnormal and abnormalities in the α4 gene are reported.

Title: The neurosteroid pregnanolone enhances actions of etomidate as a positive allosteric modulator of α1β2γ2L γ-aminobutyric acid type A receptors

Authors: *G. AKK, P. LI, J. BRACAMONTES, B. MANION, J. STEINBACH, A. EVERS; Dept Anesthesiol Res. Unit, Washington Univ. Sch. Med., St. Louis, MO

Abstract: Many neurosteroids are known to potentiate electrophysiological responses of the γ-aminobutyric acid type A ($GABA_A$) receptor to the transmitter GABA, and to amplify behavioral responses mediated by the $GABA_A$ receptor. We have examined the ability of neurosteroids to modulate electrophysiological and behavioral responses to the allosteric activator etomidate. Whole-cell electrophysiological assays were conducted on rat α1β2γ2L $GABA_A$ receptors expressed in HEK 293 cells. The sedative activity of etomidate was studied in *Xenopus* tadpoles and mice. The effect of neurosteroid on etomidate-elicited inhibition of cortisol synthesis was determined in human adrenocortical cells. The neurosteroid pregnanolone (3α5βP) potentiated peak currents from $GABA_A$ receptors activated by GABA or etomidate. Coapplication of 1 μM 3α5βP shifted the whole-cell macroscopic concentration-response relationship for direct gating by etomidate in the absence of GABA from 218 to 2.8 μM. Further, coapplication of 100 nM 3α5βP reduced the EC_{50} for potentiation by etomidate of currents elicited by 0.5 μM GABA from 2.0 to 0.7 μM. In behavioral studies, 1 mg/kg of 3α5βP reduced the dose of etomidate required to produce loss of righting in mice (ED_{50}) from 0.19 to 0.01 mg/kg. In *Xenopus* tadpoles, exposure to 50 and 100 nM 3α5βP shifted the EC_{50} for loss of righting from 2.1 to 1.0 or 0.4 μM, respectively. Finally, exposure to 3α5βP had no effect on inhibition of cortisol

synthesis by etomidate. We conclude that potentiating neurosteroids act similarly on orthosterically and allosterically activated $GABA_A$ receptors. Coapplication of neurosteroids with etomidate can significantly reduce dosage requirements for the anesthetic, and is a potentially beneficial combination to reduce undesired side effects.

Title: Extracts of Passiflora incarnata modulate the gamma-aminobutyric acid type A receptor

Authors: G. HAMERSKY, M. E. QUACH, T. MCKECHNIE, C. M. INGERSOLL, *J. A. TEISSERE;
Muhlenberg Coll, ALLENTOWN, PA

Abstract: The GABA-induced chloride current (I_{GABA}) of gamma-aminobutyric acid type A receptors ($GABA_ARs$) is sensitive to allosteric potentiation by benzodiazepine binding to a well-characterized high affinity site at the α-γ subunit interface of this receptor. Extracts of passionflower (Passiflora incarnata) provoke anxiolytic and hypnotic behavioral effects in vertebrates that are consistent with benzodiazepine-like allosteric modulation of the $GABA_AR$ and are available commercially as medicinal phytoextracts indicated for anxiety and sleeplessness. However, the specific molecular target(s) of Passiflora extract, as well as the putative identities of its pharmacologically active ingredients, remain unknown. We used two-electrode voltage clamping of Xenopus laevis oocytes expressing α1β2γ2 and α1β2 $GABA_ARs$ to demonstrate directly that Passiflora extracts potentiate I_{GABA} in a dose-dependent fashion. Bath application of the extract in the presence of EC_{15} concentrations of GABA elicited a dramatically potentiated response of I_{GABA} in comparison to GABA alone regardless of whether the γ2 subunit was assembled in the receptor complex. Applications of Passiflora extract in the absence of GABA demonstrated a robust GABA-mimetic ability of these extracts to directly gate the receptor. Co-application with gabazine, a competitive GABA-site antagonist, did not abolish the

ability of Passiflora extracts to directly activate the receptor. Last, gas chromatography-mass spectrometry (GC-MS) of the Passiflora extract demonstrated that the concentration of GABA contained in the extract was not sufficient to explain the robust potentiation of I_{GABA} we observed. Taken together, our results suggest that Passiflora extracts potentiate and directly activate $GABA_A$Rs in a manner distinct from benzodiazepines and GABA.

Title: $GABA_A$ receptor agonist activity and anxiolytic effects of organic acids

Authors: *Y. YAMADA[1], H. IZU[2];
[1]Dept of Biotech and Chem Fac of Engin. Kinki Univ., Higashi-Hiroshima, Japan; [2]Natl. Res. Inst. of Brewing, Higashi-Hiroshima, Japan

Abstract: γ-Amino butyric acid receptor ($GABA_A$ receptor) receptors are widely distributed in the central nervous system and were consisted with two α, β, and one of γ subunits. $GABA_A$ receptors can mediate inhibitory neurotransmission by hyperpolarizing the membrane of the postsynaptic neuron, resulting in an inhibitory postsynaptic potential that decreases the probability of firing. The chloride channels can be opened by GABA and are a target for a variety of important drugs such as benzodiazepine, barbiturate, neuroactive steroids, anti-convulsants and anaesthetics. Deficits in the functional expression of $GABA_A$ receptors are critical in epilepsy, anxiety disorders, cognitive deficits schizophrenia, depression and substance abuse. For improving these diseases, it is expected to develop therapeutic agents that are effective to the receptors. We have investigated the effect of some compounds in Japanese sake on the response of $GABA_A$ receptors which were expressed in *Xenopus* oocytes because it was known for long time in Japan that the sake has a relaxation effect. The sakes of six brands were fractionated to four fractions by ion-exchange chromatography. Fractionated samples were lyophilized for removing the alcohol and volatile compounds. One of four fractions (A fraction) contained various organic acids but not GABA showed the agonist activities of $GABA_A$ receptor. A fractions were analyzed by CE-TOFMS (Human Metabolome Technologies, inc., Tsuruoka,

Japan) and 64 compounds were identified. 13 out of 64 components showed $GABA_A$ receptor agonist activities. 3 (lactic acid, pyruvic acid and gluconic acid) out of 13 compounds showed high agonist activities and EC_{50} values of GABA, lactic acid, pyruvic acid, and gluconic acid were 65.1 μM, 16 μM, 210 μM, and 257 μM, respectively. The effects of intraperitoneal injection of $GABA_A$ receptor agonists on anxiety have been investigated by an elevated plus-maze test using mice. In the test, significant anxiolytic effects were observed in the presence of lactic acid, pyruvic acid, and gluconic acid. Our experiments suggest that the anti-anxiety influence of organic acid is in due to the effects of these compounds on $GABA_A$ receptor.

Title: The effects of early-life stress on nucleus accumbens $GABA_A$ receptor function and cocaine-mediated behaviour

Authors: *S. J. MITCHELL[1], E. P. MAGUIRE[1], B. G. GUNN[1], L. CUNNINGHAM[1], M. B. HERD[1], S. L. KING[2], D. STEPHENS[2], J. D. SWINNY[3], D. BELELLI[1], J. J. LAMBERT[1]; [1]Div. of Neurosci., Dundee Univ., Dundee, United Kingdom; [2]Sch. of Psychology, Univ. of Sussex, Brighton, United Kingdom; [3]Sch. of Pharm. and Biomed. Sci., Univ. of Portsmouth, Portsmouth, United Kingdom

Abstract: The nucleus accumbens (NAc) consists primarily of GABAergic neurons, and is an essential integration site within the natural reward-pathway, which is 'hijacked' by drugs of abuse. We have previously shown for accumbal medium spiny neurons (MSNs) that α2-subunit containing $GABA_A$ receptors (α2-$GABA_A$Rs), mediate phasic inhibition and that their genetic

inactivation ($\alpha2^{-/-}$) abolishes behavioural sensitisation to cocaine. Recently, linkage association studies in humans revealed a genetic association of GABRA2 haplotypes with cocaine addiction, which was evident only in individuals who had experienced childhood trauma. Collectively, these studies indicate an association of childhood trauma, drug addiction and the GABARA2 haplotype. Here, we have utilised a mouse model of early life stress (ELS) to investigate the impact of early-life adverse experiences on cocaine-induced behaviours and the putative role of NAc α2-$GABA_A$Rs in this interaction. A fragmented maternal care paradigm was implemented to produce ELS. Adult wild type (WT) control mice received a daily *i.p* injection of cocaine (10 mg/kg) for 10 days, which resulted in behavioural sensitization, manifest as enhanced cocaine-induced increase of locomotor activity *cf.* saline-injected controls. In contrast, adult ELS mice did not sensitise to cocaine, but exhibited a significantly increased acute locomotor response to a single cocaine injection (10 mg/kg) *cf.* WT control. Interestingly, but in contrast to a previous report, both features were exhibited by non-stressed $\alpha2^{-/-}$ mice. Whole-cell voltage-clamp recordings of NAc MSNs of adult mice, previously exposed to the ELS paradigm, revealed a significant reduction in the amplitude and frequency of miniature inhibitory post-synaptic currents (mIPSCs) *cf.* WT controls. Non-stressed $\alpha2^{-/-}$ mice exhibited similar alterations of mIPSCs properties *cf.* WT controls. Complementary immunohistochemical analysis revealed a significant and selective reduction of $GABA_A$R α2, but not α1 subunit staining in the NAc core of adult ELS *cf.* WT control mice, indicating that ELS selectively decreases α2-$GABA_A$R expression. In conclusion, ELS and $\alpha2^{-/-}$ mice share a selective α2-$GABA_A$R mediated reduction of inhibitory phasic transmission, which is accompanied under these experimental conditions for both models by an increased acute cocaine locomotor response and blunting of further behavioural sensitisation to cocaine. Collectively, these findings complement the human studies and suggest that such mouse models may prove useful in permitting a better understanding of the complex association of cocaine abuse, childhood trauma and the GABRA2 gene.

Title: Modulation of spinal motoneuron excitability by extrasynaptic ααalpha4/6 GABAA receptors

Authors: *R. DELGADO-LEZAMA[1], C. ANDRÉS[1], J. AGUILAR[1], R. GONZÁLEZ-RAMÍREZ[2], D. ELÍAS[3], R. FELIX[4];

Abstract: Motoneurons are provided with a repertoire of ionotropic and metabotropic receptors as well ion channels that contribute to modulate its excitability. Between the receptors expressed are the GABAA receptors which are known to mediate two types of inhibition in the mature nervous system, phasic and tonic, produced by synaptic and extrasynaptic receptors, respectively. In a previously we have shown that ambient GABA may activate tonically the extrasynaptic receptors in motoneurons producing a persistent inhibitory current. When these receptors were blocked by high concentration of picrotoxin or bicucullin, the EPSPS evoked in motoneurons and the monosynaptic reflex activated by dorsal root stimulation was facilitated. These results suggested that extrasynaptic GABAA receptors might have an important role in motor control. However, functional identification of the α subunits conforming GABAA receptors in spinal motoneurons is missing. In this work we investigated the expression and function of α4/6GABAA receptors in adult turtle motoneurons. By combining electrophysilogical, inmunohistological and molecular biology techniques with pharmacological tools we demonstrate that α4/6 subunit-containing GABAA receptors are expressed in these cells and produce a tonic inhibitory current that modulates their input resistance and excitability.

Title: Local impermeant anions establish the neuronal chloride concentration

Authors: *J. C. GLYKYS[1], V. DZHALA[1], K. EGAWA[1], T. BALENA[1], Y. SAPONJIAN[1], K. V. KUCHIBHOTLA[3], B. J. BACSKAI[1], K. T. KAHLE[2], T. ZEUTHEN[4], K. J. Hosp., Boston, MA; [3]Skirball Inst. for Biomolecular Med., NYU Sch. of Med., New York, NY; [4]Cell. and Mol. Med., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Neuronal chloride concentration $[Cl^-]_i$ is an important determinant of $GABA_A$ receptor ($GABA_AR$)-mediated inhibition and cytoplasmic volume regulation. Equilibrative cation-chloride cotransporters (CCC) move Cl^- across the membrane, but accumulating evidence suggests CCCs are not the sole determinant of $[Cl^-]_i$. To identify other factors, we tested the effects of pharmacological CCC blockade, osmotic challenge, extracellular matrix disruption and cytotoxic alteration of volume constraints on neuronal $[Cl^-]_i$ using two-photon imaging of brain slices from Clomeleon mice (genetically encoded ratiometric fluorophore sensitive to changes in $[Cl^-]_i$). Our results demonstrated that cytoplasmic impermeant anions ($[A]_i$) and polyanionic extracellular matrix glycoproteins ($[A]_o$) constrain the local $[Cl^-]$. In healthy neurons, CCC inhibition had modest effects on $[Cl^-]_i$ and neuronal volume, but substantial changes were produced by alterations of the balance between $[A]_i$ and $[A]_o$. NKCC1 inhibition reduced $[Cl^-]_i$ in pathological conditions, including seizure activity. In physiological conditions, CCC are important elements of Cl^- homeostasis, but local impermeant anions determine the homeostatic set-point for $[Cl^-]$, and hence, neuronal volume and the polarity of local $GABA_AR$ signaling.

Title: Assessing transcriptional and post-transcriptional mechanisms in fast spiking cell homeostatic plasticity

Authors: *S. M. O'TOOLE[1], P. T. TANEJA[2], S. B. NELSON[2];
[1]Brandeis Univ., Waltham, MA; [2]Brandeis, Waltham, MA

Abstract: Cortical neurons respond to changes in activity through multiple cellular and synaptic forms of homeostatic plasticity, and these plasticity mechanisms can operate differently for excitatory and inhibitory neurons. To study homeostatic mechanisms operating in fast-spiking (FS) interneurons, we crossed *Pvalb-IRES-Cre* mice to a cre-dependent reporter strain. We then generated organotypic slice cultures from these mice at post-natal day 9. From equivalent post-natal day 18 to 24 cultures were incubated in tetrodotoxin (TTX) to halt action potential firing across the slice. At this point we assessed the firing properties of the FS cells by measuring FI curves and examined the miniature excitatory postsynaptic currents (mEPSCs). TTX treatment led to a robust increase in mini frequency as well as a decrease in the firing threshold. It's known that homeostatic mechanisms in excitatory neurons rely on both transcriptional and post-transcriptional changes. To determine how fast spiking cells respond at the transcriptional level, labeled FS cells were manually isolated and their RNA was extracted, amplified and used for the construction of deep sequencing libraries. Our examination of the transcriptome within these cells revealed a robust response to activity deprivation (n=8). Amidst the largest expression changes we found that *Crhbp* (FC=-35.6, $p=3.0*10^{-7}$), *NPY* (FC=-7.85,$p=3.4*10^{-6}$) and *VGF* (FC=-7.85,$p=1.8*10^{-9}$) were significantly down regulated in TTX while *Pea15a* (FC=5.82,$p=5.4*10^{-11}$) and *Plk3R1* (FC=3.91,$p=1.6*10^{-9}$) were upregulated. All of these genes have been implicated or closely connected to epileptic disorders supporting the validity of the data set. Furthermore, we verified CRHBP's drop in expression through immunohistochemistry. To begin to address how post transcriptional mechanisms may be involved in the FS cell's response to activity deprivation, we crossed our *Pvalb-IRES-Cre* strain with a $Dicer^{flx/flx}$ line. Upon conditional ablation of Dicer small RNA biogenesis is impaired. We found that both the increase in mEPSC frequency as well the shift in the FI curve were *Dicer* dependent. Ongoing work will attempt to form a connection between the transcriptional and post-transcriptional mechanisms underlying homeostatic plasticity in FS cells.

Title: Target-cell dependent plasticity of inhibitory synapses in mammalian cortex

Authors: *Y. ESCOBEDO LOZOYA, Q. LEI, S. B. NELSON;
Brandeis Univ., Waltham, MA

Abstract: Homeostatic plasticity mechanisms are thought to promote proper balancing between cortical excitation and inhibition over neuronal circuit development and to maintain stable activity levels. Recruitment of homeostatic plasticity has often been studied after short-term (~24h) activity deprivation and has generally been found to be reversible. However, we were interested in investigating if prolonged activity deprivation (pAD) regimes might trigger irreversible recruitment of plasticity mechanisms which could possibly contribute to circuit disorders such as Epilepsy. Mouse coronal brain slices spanning somatosensory cortex were explanted at postnatal day (P)7-P10, placed on an interface culture chamber and allowed to develop *in vitro*. Previously, our work showed using simultaneous whole-cell recording of pyramidal (Pyr) neuron pairs in layer (L)5 of these slice cultures that 1) network activity spontaneously emerges after an age equivalent to P12; 2) activity is structured into a pattern of slowly alternating episodes (~0.1 Hz) reminiscent of 'Up' states seen in cortex during sleep or anesthesia 3)depriving activity by application of 0.4 μM TTX from EPD12 to 15 or EPD12-17 (pAD) increases average firing during 'Up' states and 'Up'-state frequency. These changes were not reversible within 5 days. Here, we focused on examining synaptic connectivity changes in Pyr and Fast-Spiking Parvalbumin-Expressing Interneurons (FS-I) by using mini excitatory or inhibitory post-synaptic current (mEPSC or mIPSC) recording. We found significant increases in the amplitude and frequency of mEPSCs received by L2/3 and L5 Pyr neurons in slice cultures subjected to pAD. We also found significant decreases in the amplitude and frequency of mIPSCs received by L5 Pyr. This suggests pAD promotes Pyr cell firing both by an increase in Pyr excitatory synaptic drive and a decrease on Pyr inhibitory synaptic drive, which might contribute to post-deprivation hyperactivity (PDHA). Next we investigated if FS-I firing and connectivity were also altered by pAD. Unlike the case for pyramids, FS-I firing frequency during 'Up-states' is not significantly increased after pAD. Most interestingly, mIPSC recordings on FS-I revealed that both mIPSC frequency and amplitude onto FS-I are largely increased by pAD. These results suggest that homeostatic plasticity rules for inhibitory synapses are different

depending on the post-synaptic target and suggest that an increase in inhibitory drive to FS-I might also contribute to PDHA. We are currently using histological methods to investigate if mEPSC and mIPSC frequency and amplitude changes reflect changes in synapse size or abundance.

Title: Reciprocal regulation of gephyrin-mediated clustering of GABA type A receptors by palmitoylation and S-nitrosylation

Authors: *B. DEJANOVIC[1], G. SCHWARZ[2];
[1]Dept. of Chem. and Ctr. for Mol. Med. Cologne, Inst. of Biochem., Cologne, Germany; [2]Inst. of Biochem., Univ. of Cologne, Cologne, Germany

Abstract: Gephyrin, the principal scaffolding protein at inhibitory synapses, is essential for the clustering of glycine and GABA type A receptors (GABAARs). We have recently shown that postsynaptic clustering of gephyrin, an essential process for the formation and homeostasis of GABAergic synapses, is mediated by palmitoylation (Dejanovic et al. PLOS Biology, 2014). Another posttranslational modification that regulates gephyrin function is S-nitrosylation (Dejanovic & Schwarz, J. Neurosci., 2014). Gephyrin association with neuronal nitric oxide synthase (nNOS) and subsequent S-nitrosylation decrease the size of postsynaptic gephyrin clusters. Here we report that gephyrin palmitoylation and S-nitrosylation occur on the same cysteine residues, suggesting reciprocal regulation of gephyrin-mediated clustering of GABAARs. We found that decreased palmitoylation augmented gephyrin S-nitrosylation and vice versa ultimately modifying the size of GABAergic synapses. Thus, we provide a new regulatory mechanism of GABAergic synaptic plasticity mediated by competitive post-translational modifications of gephyrin.

Title: Spike-timing dependent plasticity of fast-signaling inhibitory synapses in the input layers of auditory cortex

Authors: *E. D. VICKERS, R. SCHNEGGENBURGER;
BMI, EPFL, Lausanne, Switzerland

Abstract: In tonotopically organized auditory cortex, feedforward inhibition in thalamocortical input layers likely plays a critical role in controlling the window of temporal integration, frequency tuning, and gain of responses to sensory inputs. Feedforward inhibition largely relies on fast-spiking interneurons that express parvalbumin (PV-IN). *In vivo*, the delay between the arrival of excitation onto principal cells (PC), driven by glutamatergic thalamic afferents, and feedforward inhibition is only ~2 ms. Such a precise temporal relationship suggests that spike-timing dependent plasticity (STDP) could be present at inhibitory feedforward synapses. To test this idea, we performed paired whole-cell recordings of PV-INs and PCs in the input layers (L3/4) of mouse (P13 - 20) auditory cortex slices. PV-INs were identified by tdTomato fluorescence in PV-IRES-Cre / ROSA26-tdTomato mice. Brief current injection in presynaptic PV-INs triggered action potentials (APs), which evoked fast GABAergic IPSCs in PCs. These IPSCs had rapid rise times; high-frequency trains (10 - 50 Hz) caused depression, but IPSCs were reliably observed toward the end of trains, consistent with the previously described fast and reliable transmission properties of PV-IN output synapses. Connected pairs were subjected to an STDP induction protocol of 50 pre- and post-synaptic AP pairings at 0.2 Hz. We observed a robust STDP with potentiation of IPSCs (~60%) in the post- before pre- sequence, and depression in the pre- before post- sequence (~20%; absolute timing differences of 2 - 20 ms). Experiments with intracellular BAPTA showed that long-term potentiation of IPSCs (iLTP) depended on an increase in post-synaptic Ca^{2+}. Thus, iLTP may involve Ca^{2+} dependent release of a retrograde messenger. We speculate that STDP at inhibitory synapses in the input layers of the auditory cortex might initiate structural changes of inhibitory synapses, and thereby set the balance of excitation and inhibition in a fast feedforward circuit. This plasticity could contribute to sensory-experience dependent wiring decisions during critical periods of auditory cortex development.

Title: Compartment-specific regulation of interneuron connectivity

Authors: ***H. VOLKMER**, S. BEUTER, J. WUCHTER, S. KELLER, M. KRIEBEL;
NMI, Reutlingen, Germany

Abstract: Interneurons target different sub-cellular compartments of principal neurons. However, mechanisms that contribute to the compartmental stabilization of inhibitory synapses are poorly understood. In particular, different receptor tyrosine kinases are candidates for compartmental control via regulation of the postsynaptic scaffold protein gephyrin that is a crucial component of GABAA receptor clustering. We applied lentiviral shRNA expression combined with stereotactic injection into the dentate gyrus of adult rats to analyze the contribution of cell surface receptors to compartmental control of gephyrin clustering. Mechanistic insight is provided by Western Blot and histological analyis of hippocampal neurons. We show that EphA7 is implicated in the stabilization of GABAergic synapses in the perisomatic and proximal dendritic compartments of granular cells in the dentate gyrus. By contrast, stabilization of axo-axonic synapses relies on neurofascin that is connected to FGFR1 signaling. EphA7 signaling converges together with other signaling pathways induced by receptor tyrosine kinases on the activation of mTOR that is an interaction partner of gephyrin. Upon mTOR activation, gephyrin dissociates from mTOR and undergoes interaction with the GEF collybistin that is required for gephyrin translocation to the cell surface. In conclusion, compartmental control of GABAergic innervation on principle neurons might rely on the activity of specific receptor protein kinases that confer regulation of gephyrin clustering via mTOR.

Title: Excitatory GABAergic transmission impairs synaptic plasticity and memory in Down syndrome

Authors: *A. CONTESTABILE, G. DEIDDA, M. PARRINI, S. NASKAR, I. FERNANDEZ BOZARTH, L. CANCEDDA;
Neurosci. and Brain Technol., Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Down syndrome (DS) is the most frequent genetic cause of intellectual disability, with DS patients displaying low intelligence quotient, learning deficits, and memory impairment particularly in hippocampus-related functions. Trisomic mouse models of DS reproduce the main cognitive disabilities of the human syndrome. In particular, Ts65Dn mice show impaired synaptic plasticity (i.e., long-term potentiation, LTP) as well as learning and memory deficits. Increased GABAergic transmission through Cl^--permeable $GABA_A$ receptors ($GABA_AR$) largely determines these deficits in DS mice. Indeed, LTP and cognitive impairment can be rescued reducing the magnitude of GABA-mediated signaling by treatment with $GABA_AR$ antagonists. Nevertheless, the efficacy of GABAergic transmission has never been directly assessed in DS. Here, we show that GABAergic signaling is mostly excitatory rather than inhibitory and the reversal potential for $GABA_A$-driven Cl^- currents (E_{Cl}) is depolarized in hippocampi from adult DS mice. Accordingly, expression of cation/Cl^- importer NKCC1 is increased in the hippocampus of trisomic mice and DS patients. Notably, NKCC1 inhibition by the FDA-approved drug bumetanide restores E_{Cl}, synaptic plasticity and hippocampus-dependent learning and memory in DS mice. Our findings demonstrate that GABA is overall excitatory in DS adult mice, and identify a new and safe therapeutic approach to rescue cognitive disabilities of DS patients.

Title: Depolarizing GABA orchestrates inhibition in developing mouse neocortex *in vivo*

Authors: K. KIRMSE[1], M. KUMMER[1], Y. KOVALCHUK[2], O. W. WITTE[1], O. GARASCHUK[2], *K. HOLTHOFF[1];
[1]Hans-Berger-Klinik für Neurologie, Friedrich-Schiller-Universität Jena, Jena, Germany;
[2]Eberhard-Karls Univ. Tübingen, Institut für Physiologie II, Germany

Abstract: Whereas γ-aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the adult brain, a large body of *in vitro* evidence suggests that GABAergic transmission is partially excitatory during early development. The latter is supposed to result from a comparatively high intracellular chloride concentration in immature neurons that renders GABA(A)-receptor mediated responses depolarizing. At present, however, the mode of GABA action in the intact developing mammalian brain remains controversial. We here combine two-photon Ca2+ imaging and electrophysiological techniques in spontaneously breathing, head-fixed neonatal mice to address the mode of GABA action *in vivo*. We provide evidence that GABA depolarizes a substantial fraction of immature neurons in the upper cortical plate. Our data further reveal that GABA spatiotemporally constrains the generation of spontaneous network activity in the occipital cortex. Thus, our data identify GABA as a dual depolarizing-inhibitory neurotransmitter in the immature neocortex *in vivo*.

Title: Postsynaptic modulation of GABAergic synaptic transmission by Kainate receptors

Authors: *J. KANG;
Dept Cell Biol & Anat, New York Med. Col., VALHALLA, NY

Abstract: Presynaptic Kainate-type glutamate ionotropic receptors (KAR) have been reported to mediate either depression or facilitation of inhibitory transmission. Little attentions have been given to the postsynaptic modulation of GABAergic synaptic transmission by KARs. In the presence of the NMDAR antagonist, AP-5 (50 microM), AMPAR antagonist, GYKI53655 (50 microM), and TTX (1 microM), we tested the effect of the KAR antagonist, ATPA (10 microM), on $GABA_A$ receptor-associated channel-mediated Cl^- currents ($GABA_A$ current) in CA1 pyramidal neurons evoked by local application (puff) of GABA (50 microM). We found that activation of postsynaptic KARs reduced $GABA_A$ currents by desynchronizing $GABA_A$ channel openings and increasing intracellular [Cl^-]. ATPA attenuated desensitization of $GABA_A$ channels and prolonged the rise time and decay of dendritic $GABA_A$ currents. As a result, ATPA induced a sustained opening of dendritic $GABA_A$ channels activated by repetitively applied GABA. During LTP induction, postsynaptic KARs may be activated by tetanic stimulation-evoked synaptic release of glutamate and mediate the depolarizing shift in E_{Cl} and the prolongation of $GABA_A$ channel openings. In such way, the postsynaptic KAR plays a facilitating role in induction of LTP.

Title: The GABAergic circuits of the amygdala modulate the fear memory

Authors: *O.-B. KWON, J.-H. LEE, H.-J. KIM, S. LEE, H.-J. JO, J.-H. KIM;
Dept. of Life Sci., POSTECH, Namgu, Pohang, Korea, Republic of

Abstract: Excessive fear memory is one of major hallmarks of stress and post-traumatic disorder (PTSD). Possible molecular and cellular mechanisms for prevention of excessive fear memory toward non-salient stimuli should be understood to elucidate this fundamental aspect of memory and provide therapeutic intervention for emotion and anxiety disorders. Here we show that the neuronal activity of dorsal intercalated cell (ITCd) in the amygdala could effectively control the fear memory recall. To elucidate physiological features of ITCd, we assessed the synaptic plasticity before and after fear conditioning using *ex vivo* electrophysiology and optogenetics. ITCd neurons yielded long-term depression (LTD) with spike time dependent plasticity (STDP) stimulation protocol after fear conditioning. We also found that activation of dopamine D4 receptor (D4R) was sufficient in producing the physiological outcome that fear conditioning elicits, induction of STDP-LTD in naive mice ITCd. Moreover, selective inhibition of ITCd D4R *in vivo* induced excessive level of fear recall after mild-shock fear conditioning, suggesting that the D4R activation could be necessary for prevention of excessive fear responses and adjustment of emotional behavior in a moderate range. Combined, these data suggest that the fear engram can be modulated by local inhibitory networks and those networks are tightly regulated by dopaminergic signaling in the inhibitory network.

Title: Both H1 and H2 receptors are involved in histamine-dependent enhancement of GABAergic transmission in the entorhinal cortex

Authors: *N. I. CILZ, S. LEI;
Pharmacology, Physiology, & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: The entorhinal cortex reportedly expresses histamine (HA) receptors (H1R, H2R, and H3R) and receives input from the tuberomammillary nucleus, the only neuronal source for HA. Receptors for HA are G-protein coupled and enable a neuromodulatory action for HA. We focused on HA's neuromodulatory influence on inhibitory transmission in the EC and found that bath application of HA (30 μM) enhances GABAergic transmission. Whole-cell recordings from EC principal neurons display significant increases in the frequency of spontaneous inhibitory post synaptic currents (sIPSCs) in the presence of HA. A selective antagonist for the H1R, cetirizine, completely abolished the increase in sIPSCs whereas a selective antagonist for the H2R, rantidine, only blunted HA's effect. Experiments using selective agonists for both H1 and H2 receptors reveal that co-activation of both H1 and H2 receptors is required to fully mimic HA's effect. Inclusion of GDP-beta-S in the recording pipette does not block the HA-induced increases in sIPSCs, suggesting HA enhances GABAergic transmission via a presynaptic mechanism. Consistent with this hypothesis, presynaptic recordings demonstrate HA increases excitability of local GABAergic interneurons. HA elicits a moderate (~3-5 mV) depolarization of interneuron resting membrane potential in the presence of TTX. Similar to sIPSC experiments, activation of both H1R and H2R is necessary to induce significant depolarization and combination of both receptor antagonists is necessary to completely block HA-induced depolarization. A significant reduction in the input resistance accompanies HA-induced depolarization, suggesting the opening of a cation channel mediates this effect. Accordingly, replacement of extracellular NaCl with N-methyl-D-glucamine chloride significantly reduces the magnitude of HA-induced depolarization. Taken together, our results suggest that HA-induced increases in GABAergic transmission within the EC occur via presynaptic activation of both H1R and H2R leading to cation influx and depolarization of presynaptic interneurons.

Title: Epigenetic modifications of GABAergic synaptic plasticity and AKAP signaling after early maternal deprivation

Authors: *J. KODANGATTIL NARAYANAN, S. GOUTY, M. E. AUTHEMENT, B. M. COX, F. S. NUGENT;
Pharmacol., USUHS, Bethesda, MD

Abstract: Adverse early life experiences such as prolonged child neglect and abuse increases the risk of developing mental health disorders including substance abuse and psychiatric disorders in childhood, adolescence and adulthood. Pathological reward-dependent learning within the ventral tegmental area (VTA) and the subsequent dysregulation of dopamine (DA) signaling from the VTA seems to be central to the onset of addiction and stress-related disorders. A single 24h episode of early maternal deprivation (MD) in rodents is widely used as an animal model of severe early life stress. Studies using this model have provided a strong link between the dysregulation of DA signaling and a later propensity to develop stress-related disorders. However it is still unknown how early MD affects the reward learning processes in the VTA. Using immunofluorescence and whole-cell patch clamp recording in rat midbrain slices, we showed that MD per se induced long-term depression (LTD) at GABAergic synapses onto VTA DA neurons and impaired the capability of these GABAergic synapses to exhibit spike timing dependent plasticity (STDP) through epigenetic modifications of the postsynaptic scaffolding A-kinase anchoring protein 79/150 (AKAP79/150) signaling. Moreover, we found that the histone deacetylase (HDAC) inhibitor, sodium butyrate, rescued GABAergic STDP and AKAP signaling in MD animals. Understanding the effects of MD on neurons in the VTA will expand our knowledge of an important but neglected part of the cellular basis of child abuse and neglect. Consequently, we will identify novel mechanisms in the regulation of inhibitory plasticity and memory formation in the VTA that can be selectively targeted in a cell-type and circuit-specific manner in the period immediately following an episode of MD or other severe stress during early development. Title: Synapsin isoforms regulating GABA release from hippocampal interneurons

Authors: ***S.-H. SONG**[1], G. J. AUGUSTINE[1,2];
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technology(KIST), Seoul, Seongbuk-Gu, Korea, Republic of; [2]Lee Kong Chian Sch. of Med., Singapore 637553, Singapore

Abstract: Deletion of the three synapsin genes of mice causes substantial changes in behavior and synaptic transmission. These synaptic defects differ for excitatory and inhibitory synapses, indicating that synapsins have unique functions at different synapse types (J. Neurosci. 24:11368). Synapsin IIa is the main isoform involved in glutamate release and works by accumulating vesicles in a reserve pool (RP; J. Neurosci. 28:1085). Here we identify the synapsin isoform(s) that regulate GABA release by using lenti virus constructs to introduce individual synapsin isoforms into cultured hippocampal interneurons from synapsin triple knockout (TKO) mice. The amplitude of evoked IPSCs (eIPSC) was reduced in TKO neurons, compared to wild-type neurons (TWT) neurons, and could be rescued by introducing any synapsin isoform. During repetitive stimulation (50 Hz, 50 s), the rate of synaptic depression was similar in TKO and TWT neurons. This was also the case for TKO neurons expressing individual synapsin isoforms, aside from a more rapid rate of depression in neurons expressing synapsin llla. As previously reported (Nature Comm. 4:1512), synapsins influence the time course of GABA release: eIPSCs decay more slowly in TKO neurons than in TWT neurons. Deconvolution analysis indicates that this is due to a prolongation of the duration of GABA release following a stimulus. Each of the synapsin isoforms rescued this kinetic phenotype, except for the case of synapsin llla where the duration of transmitter release was still prolonged. Because synapsin llla slowed release kinetics and rescued the defect in IPSC amplitude, there was a 2-fold increase in the number of GABA quanta released in response to a stimulus in TKO neurons expressing synapsin IIIa. This presumably accounts for the more rapid rate of depression

in these neurons. Measurement of the cumulative amount of GABA released during a train of stimuli indicated that the size of the readily releasable pool (RRP) of GABAergic vesicles and the rate of mobilization of these vesicles from the RP to the RRP are unaffected by synapsins. In summary, at GABAergic terminals synapsins are responsible for controlling the synchronization of quantal discharge from the RRP. Synapsin IIIa is unable to synchronize GABA release but does enhance the total number of quanta released. This differs from the case for glutamatergic vesicles, where synapsins control the size of the RP and only one isoform (synapsin IIa) is capable of supporting the RP.

Title: Synaptic impairment of frontal cortical fast-spiking basket cells induces cognitive and behavioural deficits in mice with a Cacna1a loss-of-function mutation

Authors: *A. LUPIEN-MEILLEUR[1,2], I. RIEBE[2], L. DAMAJ[1,3], C. VANASSE[1], L. GAGNON[1], A. VAN DEN MAAGDENBERG[4], J.-C. LACAILLE[2], E. ROSSIGNOL[1,2]; [1]CHU Sainte-Justine, Montréal, QC, Canada; [2]Neurosciences, Univ. de Montréal, Montréal, QC, Canada; [3]Pédiatrie, CHRU Rennes, Rennes, France; [4]Human Genet. & Neurol., Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Loss-of-function mutations in the CACNA1A gene, which encodes the α1 subunit of voltage-gated CaV2.1 channels, result in episodic ataxia (EA2) and epilepsy in humans. These conditions are rarely associated with overt cognitive deficits. We investigated 15 patients from 4 non-consanguinous families carrying different CACNA1A loss-of-function mutations and revealed that the majority of them had moderate to significant neurocognitive impairment, which includes a spectrum of inattention, impulsivity, learning difficulties, working memory deficits, intellectual deficiency and autism. We recently demonstrated that a targeted deletion of Cacna1a causing an ablation of voltage-gated CaV2.1 Ca2+ channels selectively in forebrain GABAergic interneurons (INs) in mice leads to selective synaptic impairment of parvalbumin-positive (PV)

fast-spiking basket cells that is sufficient to induce generalised epilepsy. We therefore, propose that a selective impairment of perisomatic inhibition resulting from PV-INs synaptic dysfunction in neocortical orbitofrontal circuits might contribute to the cognitive deficits observed. To better understand the pathological mechanisms underlying these cognitive deficits, we studied the effects of CaV2.1 channel ablation in PV neurons that are thought to be critical for cognition. To this end, we generated mutant mice carrying a targeted heterozygous Cacna1a deletion restricted to PV neuronal populations (PVcre;Cacna1ac/+), which targets cortical PV-INs post-natally. Using an optogenetic approach (AAV-ChR2) to selectively activate PV-INs while recording inhibitory post-synaptic events (IPSCs) in orbitofrontal pyramidal cells (PC), we demonstrated that this selective mutation significantly impairs perisomatic inhibition of PC in the orbitofrontal cortex. We assessed the behavioural and cognitive abilities of these mutant mice in the Open Field, the Elevated Plus Maze, the T-maze, the Morris Water Maze and the Reversal Learning Task. These investigations revealed that the haploinsufficiency of Cacna1a in PV-INs leads to impulsivity, impaired working memory and reduced cognitive flexibility (impaired reversal learning) in PVcre;Cacna1ac/+ mutant mice. These deficits could be recapitulated by local AAV-Cre injections in the orbitofrontal cortex of Cacna1ac/+ mice. Our results demonstrate that haploinsufficiency of Cacna1a leads to significant cognitive and behavioural impairment in humans and in conditional mutant mice, and that this is partly attributable to disrupted perisomatic inhibition in orbitofrontal circuits.

Title: Adaptive wildtype GABAA receptor expression, distribution, mobility and seizure activity in Gabrb3+/- mice

Authors: *C.-Q. ZHANG[1,5], W. SHEN[1], C. ZHOU[1], Q. ZHANG[2], E. YANG[1], R. MACDONALD[1,2,3,4], J.-Q. KANG[1,4];
[1]Dept. of Neurology,, [2]Departments of Pharmacol., [3]Mol. Physiol. and Biophysics, [4]Vanderbilt Brain Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN; [5]Dept. of Neurosurg., Third Military Med. Univ., Chongqing, China

Abstract: Gamma-aminobutyric acid type A ($GABA_A$) receptors mediate the majority of rapid inhibitory synaptic transmission in the CNS. Mutations in the $GABA_A$ receptor 3 subunit and deletions of chromosome 15q11-13, which contain the 3 subunit gene *GABRB3* are frequently associated with epilepsy as well as other neurodevelopmental abnormalities like autism and Angelman syndrome. Deletion of 3 subunits in *Gabrb3* knockout mice results in ~90% neonatal lethality, and the surviving *Gabrb3* knock-out (KO) mice have been proposed to be both human Angelman syndrome and autism models due to their neurodevelopmental abnormalities and phenotypic presentations. The $GABA_A$ receptor 3 subunit is essential for pentameric $GABA_A$ receptor assembly and trafficking. Any alteration of 3 subunit expression would change $GABA_A$ receptor assembly, distribution and membrane diffusion in a neuronal milieu of multiple $GABA_A$ receptor subunits coexisting during brain development. We have characterized $GABA_A$ receptor expression, distribution and mobility in *Gabrb3*KO mice. Since all patients reported to harbor 3 subunit mutations are heterozygous, we characterized the expression of $GABA_A$ receptor subunits in both mouse brain and cultured neurons from heterozygous *Gabrb3*KO mice. We used live brain slice surface biotinylation, single Quantal dot labeling and whole cell recording in live hippocampal neurons.We demonstrated that both surface and total expression of 3 subunits were reduced in heterozygous KO mice. Additionally, 2 subunitswere reduced while 2 subunits were upregulated in the heterozygous mice. Using single quantal dot labeling, we found that hippocampal neurons cultured from heterozygous *Gabrb3*KO mice had altered mobility and a larger fraction of extra synaptic $GABA_A$ receptors. Whole cell recordings of hippocampal GABAergic interneurons from both heterozygous and homozygous *Gabrb3*KO mice had reduced current amplitudes and increased zinc inhibition. The heterozygous *Gabrb3*KO mice had absence-like seizures both behaviorally and electrographically. The study suggests that impairment in 3 subunit expression alters expression of other wildtype $GABA_A$ receptor subunits and alters membrane $GABA_A$ receptor distribution and diffusion dynamics during brain development, thus resulting in a complex neurobehavioral phenotype including epilepsy.

Title: A critical role for the ADHD associated protein, Cadherin 13, in inhibitory synapse formation and function

Authors: *M. M. SELTEN[1], O. RIVERO[2], S. M. KOLK[3], K.-P. LESCH[2], N. NADIF KASRI[1]; [1]Cognitive Neurosci., Dept. of Cognitive Neurosciences, Donders Ins, Nijmegen, Netherlands; [2]Div. of Mol. Psychiatry, Lab. of Translational Neuroscience, ADHD Clin. Res. Network, Dept. of Psychiatry, Psychosomatics and Psychotherapy, Univ. of Würzburg, Würzburg, Germany; [3]Dept. of Mol. Animal Physiology, Donders Inst. for Brain, Cognition, and Behaviour, Nijmegen Ctr. for Mol. Life Sciences, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Recently, genome-wide association studies have consistently identified the adhesion molecule Cadherin-13 (CDH13) as a risk gene for various neurodevelopmental and psychiatric disorders including ADHD. Although CDH13 has been well-characterized as an atypical adhesion protein in non-neuronal cells, surprisingly little is known about the function of CDH13 in neurons. Similarly, how CDH13 dysregulation impacts ADHD is currently unknown. Recently cadherins have emerged as critical players in the successive steps of synaptogenesis, suggesting a role in the changes in synaptic structure and function that underlie the neuronal circuitry changes observed in ADHD. Here we propose that CDH13, as an atypical member of the cadherin family, plays a critical role in the formation and function of inhibitory synapses onto CA1 hippocampal neurons. Using immunocytochemistry we show that CDH13 is highly expressed in the Stratum Oriens in the hippocampus, where it strongly overlaps with parvalbumin-positive (PV+, fast-spiking) GABAergic interneurons. At the subcellular level we find that CDH13 is specifically localized to the inhibitory pre-synaptic compartment in dissociated hippocampal neurons, suggesting for a pre-synaptic function at inhibitory synapses. Accordingly, using a Cdh13 knock-out mouse model and a knockdown approach we find a decrease in the frequency of miniature inhibitory postsynaptic currents on pyramidal cells in CA1, whereas no changes in excitatory synaptic transmission were observed. These results suggest that CDH13 is essential in the formation and function of synapses formed by PV+ interneurons in Stratum Oriens on excitatory CA1 pyramidal cells.

Title: Chronic fluoxetine treatment alters the structure, connectivity and plasticity of cortical interneurons

Authors: *J. S. NACHER[1], M. PEREZ-RANDO[2], R. GUIRADO[3], E. CASTREN[3];
[1]Univ. Valencia Esq4618001d, Burjassot, Spain; [2]Cell Biol., Univ. Valencia, Burjassot, Spain; [3]Neurosci., Univ. of Helsinki, Helsinki, Finland

Abstract: Novel hypotheses suggest that antidepressants, such as the selective serotonin reuptake inhibitor Fluoxetine, induce neuronal structural plasticity, resembling that of the juvenile brain, although the underlying mechanisms of this reopening of the critical periods still remain unclear. However, recent studies suggest that inhibitory networks play an important role in this structural plasticity induced by Fluoxetine. For this reason we have analyzed the effects of a chronic Fluoxetine treatment in the hippocampus and medial prefrontal cortex (mPFC) of transgenic mice displaying eGFP labeled interneurons. We have found an increase in the expression of molecules related to critical period plasticity, such as the polysialylated form of the neural cell adhesion molecule (PSA-NCAM), GAD67/65 and synaptophysin, as well as a reduction in the number of parvalbumin expressing interneurons surrounded by perineuronal nets. We have also described alterations in the perisomatic inhibitory puncta on pyramidal neurons and on eGFP interneurons in the mPFC. Finally, we have found that chronic Fluoxetine treatment affects the structure of interneurons in the mPFC, increasing their dendritic spine density. The present study provides evidence indicating that Fluoxetine promotes structural changes in the inhibitory neurons of the adult cerebral cortex, probably through alterations in plasticity-related molecules of neurons or the extracellular matrix surrounding them, which are

present in interneurons and are known to be crucial for the development of the critical periods of plasticity in the juvenile brain.

Title: Somatostatin neurons silence excitatory connections through presynaptic GABAb receptors

Authors: *J. URBAN CIECKO[1], A. L. BARTH[2];
[1]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA; [2]CMU, Pittsburgh, PA

Abstract: Somatostatin (SOM)-expressing inhibitory neurons represent one of the major sources of inhibition in cortical circuits, synapsing onto the distal dendrites of pyramidal neurons where they regulate excitatory transmission by fast, GABAa-mediated Cl- currents. SOM cells have also been implicated in state-dependent modulation and experience-dependent plasticity, and their spontaneous firing activity is regulated by neuromodulators. Here we provide evidence that SOM neurons regulate excitatory transmission at longer timescales through activation of presynaptic GABAb receptors. We show that spontaneous firing of SOM neurons suppresses excitatory synaptic transmission between connected pairs of L2/3 pyramidal neurons in primary somatosensory cortex. EPSP amplitude is reduced and EPSP failures rates are elevated when SOM neurons are active. Optogenetic suppression of SOM firing is sufficient to enhance EPSP amplitude and reduce failure rates, effects that were fully reversible. Our data indicate that SOM neurons suppress EPSP amplitude and enhance failure rates via presynaptic GABAb receptors, since GABAb antagonists occlude SOM silencing effects. Thus, SOM neurons can rapidly and reversibly modulate neocortical networks through synaptic silencing, and suggest a critical role for these neurons in gating perception and plasticity.

Title: KCTD12-induced desensitization of G-protein coupled receptor responses under physiological and pathophysiological conditions

Authors: *B. BETTLER[1], R. TURECEK[1], J. SCHWENK[2], T. FRITZIUS[1], K. IVANKOVA[1], G. ZOLLES[2], L. ADELFINGER[1], V. JACQUIER[1], V. BESSEYRIAS[1], M. GASSMANN[1], U. SCHULTE[2], B. FAKLER[2];

Abstract: G-protein coupled receptors and G-protein regulated ion channels represent important cellular signal transduction systems in the nervous system. Using a proteomics approach we recently identified the KCTD12 protein as an auxiliary subunit of native GABAB receptors (Schwenk et al., Nature 465, 2010). GABAB receptors assembled with KCTD12 subunits generate rapidly desensitizing K+ and Ca2+-channel responses. KCTD12 is a novel regulator of G-protein signaling whose mechanism of action, however, is unknown. We found that KCTD12 induces fast desensitization via a novel mechanism (Turecek et al., in press). This mechanism involves masking of the channel binding-site on the activated G-protein βγ-subunits and their subsequent uncoupling from effector channels. We show that KCTD12 can desensitize the responses of a variety of GPCRs *in vitro*. Quantitative proteomic analysis, however, reveals that virtually all KCTD12 protein in the brain is associated with GABAB receptors. Consistent with the proteomic data we find that neurons of KCTD12 knock-out mice selectively exhibit alterations in the kinetics of GABAB receptor-activated K+-currents. The KCTD12 subunit has

been associated with bipolar disorder, unipolar depression and schizophrenia. Our data predict that a down-regulation of KCTD12 protein will specifically alter GABAB receptor-mediated signaling while an up-regulation of KCTD12 may additionally alter the signaling of other G-protein coupled receptors.

Title: The inverse agonistic effect of Rimonabant is not mediated by CB1, GABAB, opiod and D2 dopamine receptors

Authors: A. PORCU[1], A. CASTI[1], F. SANNA[1], G. FLORIS[2], M. P. MASCIA[3], P. FOLLESA[2], M. MELIS[1], G. L. GESSA[1], *M. CASTELLI[4];

Abstract: The selective and potent cannabinoid CB1 antagonist Rimonabant at high micromolar concentrations behaves as an inverse agonist, i.e. decreases [^{35}S]GTPγS binding in rodent and human cerebral cortex and in Chinese hamster ovary (CHO) cells transfected with CB1 receptors. However, Rimonabant inverse agonism is CB1 receptor independent since is produced in CB1 receptor knockout (KO) mouse brain membranes and in CHO not expressing CB1 receptors. The present study was aimed at determining whether Rimonabant inverse agonism is mediated by $GABA_B$, opioid, or dopamine D2 receptors. We found that rimonabant decreased basal [^{35}S]GTPγS binding to cortical membranes of rats, wild type mice, CB1 receptor and GABAB KO mice. Rimonabant induced decrease of basal [^{35}S]GTPγS binding in rat or mouse cortical membranes was not prevented by CB1, $GABA_B$, opioid, and D2 receptor agonist and antagonists. Moreover, rimonabant attenuated the activation of [^{35}S]GTPγS binding to cortical membranes produced by the GABAB agonists baclofen and GABA, the μ agonist morphine, the

D2 agonist quinpirole, but failed to modify the stimulant effect on [^{35}S]GTPγS binding of the D1 receptor agonist SKF81293. Rimonabant suppressed both GABAB and D2 dopamine-activated inwardly rectifying potassium current in VTA dopamine and in CHO cells expressing D2 receptor. Our results suggested that Rimonabant inverse agonism in GTPγS binding is mediated by a multiple action on plurality of G protein coupled receptors (GPCRs) sharing the same Gi/o protein.

Title: K63-linked ubiquitination of GABAB1 sorts GABAB receptors to lysosomal degradation

Authors: ***K. ZEMOURA**, T. CLAUDIA, B. DIETMAR;
Inst. of Pharmacol. and Toxicology, Zurich, Switzerland

Abstract: The G protein-coupled GABAB receptors mediate slow and prolonged neuronal inhibition. The magnitude of GABAB receptor-mediated inhibition essentially depends on the amount of receptors in the plasma membrane. A main factor that determines receptor availability is regulated protein degradation. After internalization, GABAB receptors are recycled to the cell surface or degraded in lysosomes. The signal that sorts GABAB receptors to lysosomes is so far unknown. In present study we analyzed whether ubiquitination is the lysosomal sorting signal for GABAB receptors. We found that inhibition of lysosomal activity in cortical neurons increased total and cell surface GABAB receptors, confirming the constitutive degradation of GABAB receptors in lysosomes. In addition, blocking lysosomal activity considerably increased the amount of K63-linked ubiquitinated GABAB receptors. This observation indicates that K63-linked ubiquitination serves as the sorting signal. Indeed, mutational inactivation of four putative ubiquitination sites in the GABAB1 subunit significantly diminished K63-linked ubiquitination of GABAB1 and prevented lysosomal degradation of the receptors. Overexpressing a dominant-negative mutant of Rab7 to disrupt lysosome function increased the expression level of wildtype

GABAB receptors but not that of receptors containing the GABAB1 mutants. Finally, triggering lysosomal degradation of GABAB receptors by sustained activation of glutamate receptors down-regulated wildtype but not mutant GABAB receptors deficient in GABAB1 K63-linked ubiquitination. These findings indicate that K63-linked ubiquitination of GABAB1 at multiple sites is involved in sorting GABAB receptors to lysosomes for degradation.

Title: Effect of $GABA_B$ positive allosteric modulators in the DBA/2J mouse audiogenic seizure test: comparison to baclofen and utility as a pharmacodynamic screening model

Authors: *J. W. BROWN[1], S. TURNER[2], V. NIMMRICH[2], L. E. RUETER[1], E. VAN DER KAM[2], M. ZHANG[1];
[1]Abbvie, North Chicago, IL; [2]Abbvie, Ludwigshafen, Germany

Abstract: The GABAB receptor has been indicated as a promising target for multiple CNS-related disorders. Baclofen, a prototypical orthosteric agonist, is used clinically for the treatment of spastic movement disorders, but is associated with unwanted side-effects, such as sedation and motor impairment. Positive allosteric modulators (PAM), which bind to a distinct site apart from the orthosteric binding region, may provide an improved side-effect profile while maintaining baclofen-like efficacy. The identification of a validated preclinical pharmacodynamic assay can be a powerful tool for comparing drugs with related mechanisms of action and to help establish the relationship between target engagement and positive/negative effects. GABA, the major inhibitory neurotransmitter in the CNS, plays an important role in the mechanism and treatment of seizure disorders. Not surprisingly, baclofen is known to produce anticonvulsant effects in the DBA/2J mouse audiogenic seizure test (AGS), suggesting it may be a suitable pharmacodynamic endpoint. Little is known about the effects of GABAB PAMs, however. The studies presented here sought to validate the AGS test as a pharmacodynamic screening model for GABAB PAMs by comparing the profile of reference PAMs against baclofen. Rac-BHFF, GS39783, and CMPPE all produced robust, dose-dependent anticonvulsant effects; a similar profile was observed with baclofen, although it was more potent. Pre-treatment with the GABAB antagonist

SCH50911 completely blocked the anticonvulsant effects of baclofen and CMPPE in the AGS test, indicating such effects are mediated by the GABAB receptor. In addition to the standard anticonvulsant endpoint of the AGS test, video tracking software (SMART) was employed to assess potential drug-induced motoric side-effects during the acclimation period of the test. This analysis was sensitive to detecting drug-induced changes in total distance traveled, which was used to establish efficacy vs. side-effect margins (hypoactivity ED50 / anticonvulsant-tonic ED50) for each compound. Calculated margins for rac-BHFF, GS39783, and CMPPE were 2.51x, 1.76x, and 8.37x, respectively. The calculated efficacy vs. side-effect margin for baclofen was 0. The results presented here suggest the DBA/2J mouse AGS test is a potentially useful screening model for detecting pharmacodynamic effects of GABAB PAMs and can provide an initial read-out on target-related motoric side-effects. Furthermore, improved efficacy vs. side-effect margins were observed for PAMs compared to baclofen, particularly for CMPPE, indicating the PAM approach may be a viable therapeutic alternative to baclofen.

Title: Colocalization of interneuron markers with proteins involved in $GABA_B$ receptor mediated calcium current enhancement in neonatal hippocampus

Authors: D. P. VANDERHOEF, *M. MYNLIEFF;
Marquette Univ., MILWAUKEE, WI

Abstract: Previously, we demonstrated that activation of the G-protein coupled $GABA_B$ receptor ($GABA_BR$) modulates currents through voltage-gated calcium channels with an attenuation of N-Type calcium current mediated by a $G\alpha_{i/o}$ G protein. Our laboratory has also described enhancement of L-type calcium current mediated by a $G\alpha_q$ G protein and the α isoform of protein kinase C (PKCα). This enhancement peaks at postnatal day 7 and is expressed in only 10-20% of cells in the superior region of the hippocampus. Since a large percentage of the cells in the CA1 region are excitatory pyramidal cells, we hypothesized that enhancement of current is confined to one or more inhibitory interneuron subtypes and determining the subtype may provide insight into a physiological role for the L-type current enhancement observed. Studies have reported up to 21 different inhibitory interneuron subtypes. Sloviter et al. (*Neuropharm.*, 38(11), 1707-21, 1999) has demonstrated that in the CA1 region, interneurons expressing the neurochemical markers cholecystokinin (CCK), calbindin, neuropeptide Y, and somatostatin all express $GABA_BR$; making them possible candidates for the neuron(s) in which $GABA_BR$ mediated calcium current enhancement occurs. Interneurons that encompass these parameters are the CCK+ basket cells, Schaffer collateral associated cells, and quadrilaminar cells. In the present study, fluorescent confocal microscopy in the superior hippocampal region from 6-8 day old rats is utilized to determine colocalization of neurochemical markers used to identify interneuron subtypes with different components of the signaling pathway mediating calcium current enhancement. We hypothesized that the neuron of interest is a CCK+ basket cell, due to the morphology of the cell and similar localization as seen in preliminary data. The components of the signaling pathway of interest include $GABA_BR$, $G\alpha_q$, PKC_α and the two L-type calcium channel isoforms expressed in the brain, $Ca_V1.2$ and $Ca_V1.3$. The specific isoform of L-type channel enhanced by $GABA_BR$ activation has not been determined but the developmental expression and colocalization with $GABA_B$ receptors suggest that $Ca_V1.2$ is a component in the pathway. Preliminary data demonstrate a much higher colocalization of calbindin with $Ca_V1.2$ than CCK with $Ca_V1.2$. However, only 1.17% of the total cells counted in the CA1 region express both calbindin and $Ca_V1.2$ and thus, it is likely that enhancement of the calcium current by $GABA_B$ receptor activation occurs in multiple interneuron subtypes.

Title: Evaluation of multiple doses of GABA(B) ligands on learning and memory

Authors: *C. F. HEANEY, M. M. BOLTON, A. S. MURTISHAW, M. A. LANGHARDT, J. W. KINNEY;
Psychology/Neuroscience, Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: The inhibitory neurotransmitter, gamma-aminobutyric acid (GABA) acts on two main types of receptors, the ionotropic GABAA and the metabotropic GABAB. Evidence indicating a central role of GABAB in regulating oscillatory function suggests a prominent role of this receptor in cognitive processes. However, research has yielded mixed results regarding the extent to which altered GABAB receptor function impairs or enhances learning and memory performance. Previous data from our laboratory indicate that baclofen, a GABAB agonist, impairs learning and memory performance and phaclofen, a GABAB antagonist, improves learning and memory performance in the Morris water maze. In order to better characterize the effects of the GABAB receptor on complex behavior, we compared the effect of two distinct doses of these GABAB ligands on the performance of male Sprague-Dawley rats in the Morris water maze. Additionally, we examined the effect of co-administration of baclofen and phaclofen on performance. While the deficits due to baclofen followed an ascending concentration pattern, the effects of phaclofen were more interesting. The low dose of phaclofen improved learning and memory performance, but the higher dose did not impact learning. We then examined the effect of these ligands when co-administered utilizing the doses of the ligands that did not, by themselves, alter learning and memory. Interestingly, the co-administration of the GABAB receptor agonist and antagonist impaired performance in the Morris water maze. We also analyzed hippocampal tissue for alterations to numerous protein markers in order to link any changes to these neural targets with performance in the behavioral task. Our data indicate specific concentrations associated with both the agonist and antagonist that are capable of altering learning and memory. The data further indicate a limited range of effect of the GABAB receptor antagonist, which may contribute to some of the differences present in the literature. Finally, our data also indicate that co-administration of these two ligands impairs behavior.

These data suggest a potential interaction of the two ligands that may be possibly tied to pre- versus postsynaptic GABAB receptor mechanisms.

Title: 5HT6 receptor distribution in rat brain using agonist-induced FOS and antireceptor antibody immunocytochemistry

Authors: S. STEWART[1], L. DAILEY[1], A. HEFFERNAN[2], A. MITZEY[1], *M. S. BROWNFIELD[1];
[1]Dept Comp Biosci., Univ. Wisconsin, Madison, WI; [2]Vet. Clin. Sci., Univ. of Minnesota, Minneapolis, MN

Abstract: The 5-HT6 receptor is one of the most recently discovered serotonin receptors. This receptor appears to play a big role in cognition and memory, as evidenced by the paradoxical ability of both agonists and antagonists to have anti amnesic effects. Many brain illnesses that involve cognitive dysfunction, including schizophrenia and Alzheimer's disease, involve the 5-HT6 receptor. The 5-HT6 receptor has been found throughout the brain, primarily in the striatum, the dentate gyrus of the hippocampus, and the olfactory tubercle. Previous studies investigating the positioning of the 5-HT6 receptor, however, have been limited by the techniques they used, typically in-situ hybridization and Northern blotting. These techniques, which probe for mRNA associated with the receptor, can only tell us if the gene for the receptor is present; they cannot give any information on functionality. We have probed the entire rat brain for the 5-HT6 receptor using immunocytochemistry for the receptor protein. To do this, we generated an antibody to the 5-HT6 receptor in our laboratory (using the sequence LERPPGTPRHPPGPPLW-amide), and we used this antigen to affinity purify the antibody. We also looked at agonist-induced fos expression. Fos is the product of an intermediate early gene (IED) that is expressed when a neuron is activated; we gave rats a 5-HT6 agonist, EMD 386088, and observed where fos was expressed. We found the receptor in all the areas it had previously been suggested to be, as well as in several areas it has never been reported to be; these places

include, but are not limited to, neurons and fibers in the paraventricular nucleus of the thalamus, the lateral and medial, as well as central, nuclei of the amygdala, the habenula, and the subfornical organ. We found high concentrations of the 5-HT6 receptor throughout the hippocampus (CA1, CA2, CA3, dentate gyrus, and subiculum); the presence of the receptor in the hippocampus may mediate the 5-HT6 receptor's effect on memory.

Title: Interleukin 6 attenuates serotonin 2A receptor signaling through the JAK-STAT pathway

Authors: *J. J. DONEGAN[1,2], T. A. CHAVERA[1,2], M. S. PATTON[1,2], K. A. BERG[1,2], D. A. MORILAK[1,2], M. GIROTTI[1,2];

Abstract: Cognitive flexibility, the adaptive ability to modify behavior in response to environmental change, is impaired in psychiatric diseases, such as depression. Reversal learning is a type of cognitive flexibility mediated by the orbitofrontal cortex (OFC). We have shown that reversal learning is facilitated by both the serotonin 2A (5-HT2A) receptor and the cytokine, interleukin-6 (IL-6), in the OFC. In the current studies, we tested the hypothesis that 5-HT2A receptor- and IL-6-mediated signaling interact. We first determined if IL-6 signaling occurs in OFC neurons that also express 5-HT2A receptors. Rats were injected with an adeno-associated virus to over-express IL-6 and activate the downstream JAK-STAT pathway in the OFC. Dual-fluorescence immunohistochemistry was used to label 5-HT2A receptors and phosphorylated STAT3, a marker of pathway activation. Nearly 100% of 5-HT2A receptor-expressing cells show JAK-STAT activation in response to IL-6 over-expression, suggesting that there is the

potential for cross-regulation between the IL-6 and 5-HT2A receptor systems *in vivo*. To determine if IL-6 influences 5-HT2A receptor signaling in an *in vitro* cell model, we measured inositol phosphate (IP) accumulation in response to the 5-HT2 receptor agonist, DOI in the neuronal cell line, A1A1. In the presence of IL-6 (50 ng/ml), the maximal response to DOI was reduced from 45.96 ± 3.37% to 24.92 ± 3.58% above basal, suggesting that IL-6 regulates 5-HT2A receptor signaling. To identify the signaling pathway that mediates this effect, cells were pretreated with the JAK-STAT inhibitor, JSI-124 (50 μM), or the ERK inhibitor, PD-98059 (50 μM) and DOI-mediated IP accumulation was measured in the presence or absence of IL-6. The IL-6 effect on DOI-induced IP accumulation was abolished following treatment with JSI-124, but not PD-98059, suggesting that IL-6 acts through the JAK-STAT pathway to influence 5-HT2A receptor signaling. To determine if the effect of IL-6 generalizes to other Gq-coupled receptors, bradykinin (BK) B2 receptor-mediated IP accumulation in response to maximal concentrations of BK (100 nM) was measured in the presence or absence of IL-6. IL-6 had no effect on BK-mediated IP accumulation, suggesting that IL-6 may specifically attenuate 5-HT2A receptor signaling. Together, these findings suggest that the IL-6 and 5-HT2A receptor systems can interact, resulting in a functionally distinct outcome. Both IL-6 and the 5-HT2A receptor have been implicated in psychiatric disease. Therefore, further understanding of this interaction, and its functional effect on cognitive flexibility, may provide new insights into the treatment of psychiatric disease.

Title: Co-expression of 5-HT7 and 5-HT2 receptors in molluscan muscle

Authors: *D. R. MCPHERSON, J. A. LOVETT;
SUNY-Geneseo, GENESEO, NY

Abstract: Serotonin is a potent modulator of contraction in foot and buccal muscle of the marine gastropod *Aplysia californica*. Serotonin enhances the force of contraction and also increases the rate of relaxation from contraction. And in bivalve molluscs, serotonin is

responsible for release from the catch state of contraction in slow adductor muscles of the valves and in the anterior byssal retractor muscle (ABRM) of mussels such as *Mytilus edulis*. We have previously isolated and cloned a 5-HT_7 receptor that is expressed in *Aplysia* foot muscle (McPherson and Lovett, 2008, Soc. Neurosci. Abstr.). We have subsequently found that this receptor is expressed in the I-5 muscle of the *Aplysia* buccal mass, and that homologous receptors are expressed in foot tissue of the terrestrial gastropod *Helix aspersa* and in the ABRM of *Mytilus edulis*. More recently we have explored whether other serotonin receptors are expressed in the foot of *Aplysia,* and have discovered expression of a 5-HT_2 receptor. We are presently exploring whether co-expression of 5-HT_7 and 5-HT_2 receptors is a widespread feature of molluscan muscle organization.

Title: Localization and function of 5-HT6 receptor mutants to neuronal primary cilia in striatum

Authors: *M. BRODSKY, A. LESIAK, K. GARCIA NAKATA, J. SULLIVAN, J. NEUMAIER;
Univ. of Washington, Seattle, WA

Abstract: The 5-HT_6 serotonin receptor is an excitatory G_S-coupled metabotropic receptor which is found almost exclusively in the brain, is abundant in striatum, and is localizes to the primary cilia of neurons. These receptors are implicated in a variety of cognitive and emotional phenotypes including anxiety, depression, habitual behaviors and reward learning. The primary cilium is a sensory organelle stemming from the cell body of most mammalian neurons. The primary cilium is an antenna-like, microtubule-supported structure that receives both chemical and mechanical signals from other cells and the surrounding environment. Recently, neuronal primary cilia have become a major target of research as they play crucial roles in a variety of

disorders known as “ciliopathies”; they have also been implicated in Huntington’s and Alzheimer’s diseases. However, the role of primary cilia in normal cognitive functions is not understood, but there is evidence that impairments of ciliary signaling produce cognitive deficits. GPCRs that localize to cilia generally have a cilia targeting sequence (CTS) of conserved amino acids in the iC3 loop that has been hypothesized to be needed for intraflagellar transport, thereby permitting selective trafficking into primary cilia. Previous work has shown that the absence of a satisfactory CTS leads to default trafficking to the somatodendritic compartment of the neuron. We investigated whether manipulating 5-HT_6 receptor structure and expression levels alter their trafficking to neuronal primary cilia as well as their effects on cilia morphology and signaling. We introduced a set of discrete mutations to the iC3 loop of the 5-HT_6 receptor. Our results thus far suggest that some deletions and mutations to the CTS disrupt trafficking of the mutant receptor to cilia. Trafficking was, to some extent, altered by the extent of overexpression. Further, some of these mutations can interfere with the mutant receptor’s ability to activate adenylate cyclase (whether localized in the cilia or cell body). We are currently investigating whether an additional CTS in the C-terminal is necessary or sufficient for cilia trafficking. Our results suggest that regulation of cilia trafficking is strongly affected by the iC3 loop CTS, but additional features are likely to also be involved in 5-HT_6 receptor trafficking to neuronal primary cilia.

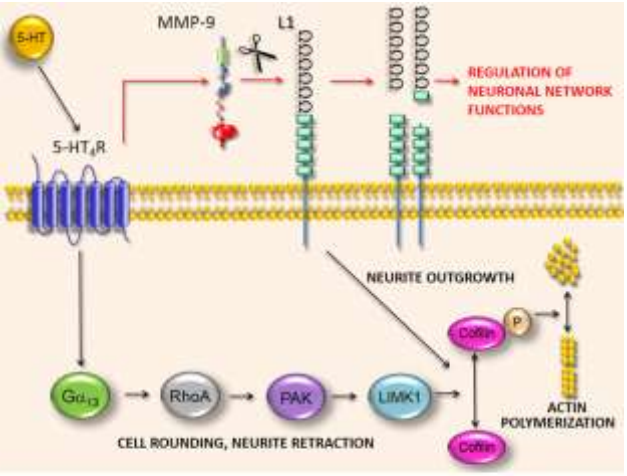
Title: New serotonergic pathway regulating neuronal morphology and functions via adhesion molecule L1

Authors: *D. GUSEVA[1], Y. SCHILL[1], M. BIJATA[2], J. WLODARCZYK[2], E. PONIMASKIN[1]; [1]Cell. Neurophysiol., Hannover Med. Sch., Hannover, Germany; [2]Nenski Inst., Warsaw, Poland

Abstract: Serotonin (5-HT) is an important neurotransmitter regulating a wide range of physiological and pathological functions including many aspects of neural development. Serotonin operates via the activation of multiple 5-HT receptors, whereby in the present study

we focused on the 5-HT4 receptor (5-HT4R). In the mammalian brain this receptor contributes to the regulation of learning and long term memory and is involved in various central and peripheral disorders, including neurodegenerative disease and depression. The 5-HT4R stimulation results in the activation of the small GTPase RhoA, leading to cell rounding and neurite retraction. Here we have demonstrated that this effect can be mediated by phosphorylation of cofilin, important mediator of the temporal and spatial control of actin filament organization. The neuronal adhesion molecule L1 is critically involved in axonal development and can contribute to stress-related disorders in humans. Noteworthy, L1-mediated neurite outgrowth is regulated by cofilin phosphorylation. Thus, cofilin may represent a common downstream effector for both 5-HT4R and L1. In present study we have shown that neuronal L1 can be proteolytically cleaved by the matrix metalloproteinase-9 (MMP-9). Interestingly that stimulation of 5-HT4R induces the release of enzymatically active MMP-9 from hippocampal neurons. Moreover, 5-HT4R and L1 are tightly co-localized at the synapses. Taken together, our results demonstrate that 5-HT4R might regulate L1 shedding in an MMP-9-dependent manner, and can thus represent a novel molecular mechanism by which serotonin can regulate the formation and plasticity of neuronal networks. From these investigations we hope to identify novel targets for pharmacological intervention into stress-related disorders such as depression.



Hypothetical model of the functional cross-talk between 5-HT$_4$R, MMP-9 and L1 signaling.

Title: Ryanodine receptor activation induces long-term plasticity of spine calcium dynamics

Authors: *F. W. JOHENNING[1], A.-K. THEIS[1], U. PANNASCH[1], M. RÜCKL[2], S. RÜDIGER[2], D. SCHMITZ[1];
[1]Charité Univ. Med. Berlin, Berlin, Germany; [2]Humboldt Univ., Berlin, Germany

Abstract: Dendritic spines compartmentalize signalling at excitatory synapses. Upon action potential firing, the majority of spines are subject to global backpropagating action potential (bAP) mediated Ca2+ transients (CaTsbAP). Here, we demonstrate that bAPs are electrochemically coupled to Ca2+ release from intracellular stores. We describe a new function of ryanodine receptor (RyRs) mediated spine intracellular Ca2+ release, the activity-dependent long-term enhancement of the CaTbAP. This form of plasticity is highly compartmentalized and independent of dendritic Ca2+ regulation. Further, this functional state change depends exclusively on bAPs travelling antidromically into dendrites and spines, without requirement for concomitant synaptic transmission. Induction, but not expression, of CaTbAP enhancement is a spine-specific function of the RyR Ca2+-nanodomain. We describe a new form of spine Ca2+ transient plasticity that constitutes a storage mechanism of neuronal suprathreshold activity patterns

Title: Heterosynaptic structural plasticity on local dendritic segments of hippocampal CA1 neurons

Authors: *L. K. PARAJULI, W. OH, K. ZITO;
Univ. of California, Davis, Davis, CA

Abstract: Competition between neighboring synapses contributes to activity-dependent refinement of the peripheral nervous system during development. However, it remains yet unknown if the local competition between synapses play a similar role during experience-dependent plasticity in the cerebral cortex. Here, we examined the role of activity-mediated competitive interactions in regulating dendritic spine structure and function on hippocampal CA1 neurons. We found that high-frequency glutamatergic stimulation at individual spines, which leads to input-specific synaptic potentiation, induces shrinkage and weakening of nearby unstimulated spines in the same dendrite. Heterosynaptic plasticity requires potentiation of multiple neighboring spines, suggesting that a local threshold of neural activity exists beyond which inactive synapses are punished. Notably, inhibition of calcineurin or IP3Rs blocked heterosynaptic shrinkage without blocking structural potentiation, and inhibition of CaMKII blocked structural potentiation without blocking heterosynaptic spine shrinkage, supporting a model in which activity-induced shrinkage signal, and not competition for limited synaptic resources, drives heterosynaptic structural and functional depression during neural circuit refinement.

Title: Wnt5a modulates the postsynaptic density of dendritic spines and the distribution of synaptic mitochondria in hippocampal neurons

Authors: *M. S. ARRÁZOLA, D. ORDENES, N. C. INESTROSA;
Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: Wnt signaling plays a key role in the development of the nervous system and participates in synapse formation. Wnt5a regulates the synaptic structure and function in hippocampal neurons and has shown postsynaptic effects stimulating dendrite spine morphogenesis and increasing glutamatergic neurotransmission through the up-regulation of the NMDA receptor-mediated currents, facilitating the induction of long-term potentiation (LTP). In agreement with the postsynaptic effects described, it has been shown that Wnt5a induces the clustering of PSD-95 in dendritic spines of cultured hippocampal neurons, which is associated with an increase in the density of dendritic protrusions. On the other hand, it has been reported that increasing dendritic mitochondrial content enhances the number and plasticity of spines, suggesting that dendritic distribution of mitochondria is essential for the support of synapses. In agreement with this idea, overexpression of the mitochondrial fission protein Drp1 increases the density of PSD-95 puncta, spines and synapses. By electron microscopy analysis from mouse hippocampal slices, we studied the effects of Wnt5a on the ultrastructure of the postsynaptic terminal. We observed a time-dependent increase in the length of the postsynaptic density (PSD) in dendritic spines in response to Wnt5a and a latter increase in the number of synaptic contacts. We also observed an increase in the percentage of dendritic spines that present segmented PSD, which has been associated with the dendritic spine changes in response to LTP induction and synaptic potentiation. Therefore, we evaluated whether these morphological changes were associated with the distribution of mitochondria at the synapse. We observed that Wnt5a induced an increase in the number of dendritic protrusions with mitochondria and in the number of mitochondria in dendritic spines. This redistribution of mitochondria at the postsynaptic terminal was correlated with a decrease in mitochondrial area and with the activation of the Drp1, which suggest that Wnt5a induces mitochondrial fission probably to support the morphological changes that occurs on the dendritic spines to produce new synapses.

Title: The role of metabotropic and ionotropic glutamate receptor signaling in activity-dependent spine shrinkage

Authors: *I. S. STEIN[1], W. OH[2], K. ZITO[1];
[1]Ctr. for Neurosci., UC Davis, Davis, CA; [2]Max Planck Florida Inst., Jupiter, FL

Abstract: Structural refinement of neuronal circuits is thought to underlie experience-dependent modification of brain function. Pruning of superfluous synaptic contacts during development as well as input-specific elimination of synapses in the adult have been correlated with behavioral performance. We are especially interested in the signaling mechanisms leading to shrinkage and elimination of dendritic spines, the principal sites of excitatory synaptic input in the mammalian cerebral cortex. Morphological changes in dendritic spines are closely linked to changes in synaptic strength and function; increases in synaptic strength through the induction of long-term potentiation (LTP) are associated with spine enlargement, while decreases in synaptic strength via the induction of long-term depression (LTD) are associated with spine shrinkage or loss. Work from our lab recently demonstrated long-lasting synaptic weakening and spine shrinkage following low-frequency glutamatergic activity at individual spines. This input-specific spine shrinkage required NMDAR activation and, intriguingly, was differentially regulated in small and large spines. In addition to NMDAR activity, the shrinkage of large spines also was contingent on group I mGluR activation and the downstream release of Ca2+ through IP3Rs. We are currently investigating more closely the role of metabotropic and ionotropic glutamate receptor signaling in this activity-induced spine shrinkage using subtype- and binding site-specific antagonists.

Title: Modeling spine dynamics in recurrently connected spiking networks

Authors: *J. HUMBLE[1], H. KASAI[2], T. TOYOIZUMI[1];
[1]Lab. for Neural Computation and Adaptation, RIKEN Brain Sci. Inst., Wako City, Japan; [2]Fac. of Med., The Univ. of Tokyo, Tokyo, Japan

Abstract: Cortical circuits rewire in an activity-dependent way. A major biological mechanism underlying this rewiring process is Hebbian plasticity. Hebbian plasticity is often regarded unstable in nature because of its positive feedback, e.g., as synapses become stronger, they are more efficient at driving their postsynaptic neurons and consequently get potentiated further. This kind of instability can manifest in a recurrently connected circuit with multiple loops of connections, which may cause non-physiological growth of neuronal activity and/or merge multiple patterns of stored memories unless a plasticity rule is finely tuned to provide stabilization and competition of synapses under a wide range of conditions. The biological mechanisms that achieve synaptic stabilization and competition under ongoing Hebbian plasticity are unknown. However, it was previously reported that intrinsic fluctuation of spine volume is roughly proportional to spine-size, and this fluctuation can gradually set the distribution of spine-sizes to a stereotypical shape in the absence of neural activity (Yasumatsu et al. 2008). In this study, we investigate the interaction of spike-timing-dependent plasticity (STDP) and fluctuations of synaptic strengths. Specifically, we demonstrate with a model of recurrently connected spiking neuron networks, that Hebbian (STDP) plasticity can be stabilized by intrinsic synaptic fluctuation, which increases linearly with synaptic strength. The model reproduces the previously reported distribution of synaptic strengths, with a fat tail, in the presence of ongoing Hebbian plasticity. Moreover, we show that persistent activation of arbitrary subsets of neurons forms independent cellular assemblies, which specifically and persistently elevate their firing rates and synaptic connections even after termination of the stimulus without causing synaptic instability or fusion of assemblies. Thus, memories of past stimuli are retained in our recurrent networks as cellular assemblies under noticeable fluctuations of synaptic strength.

Title: Myosin II ATPase activity mediates the biphasic movement of stable F-actin bound by drebrin A between dendritic spines and the parent dendrite in long-term potentiation

Authors: T. SHIRAO[1], T. MIZUI[1], N. KOGANEZAWA[1], H. SHIMIZU[1], *H. YASUDA[1], Y. SEKINO[1,2];
[1]Gunma Univ. Grad. Sch. Med., Maebashi, Japan; [2]NIHS, Tokyo, Japan

Abstract: The neuronal actin-binding protein drebrin A forms a stable structure with F-actin in dendritic spines. NMDA receptor activation causes an exodus of F-actin bound by drebrin A (DA-actin) from dendritic spines, suggesting a pivotal role for DA-actin exodus in synaptic plasticity. In the present study, we first used stochastic optical reconstruction microscopy (STORM) to reveal localization of drebrin in nanoscale. We prepared primary hippocampal neuronal culture from embryonic day-18 rat brain using Banker's method. For drebrin imaging, we fixed cultured neurons at 21 days *in vitro* (DIV) and immunolabeled drebrin with Alexa 568. The neurons were transfected with GFP to detect the neuron shape and it is also immunolabeled by anti-GFP antibody conjugated with Alexa 647 to do STORM analysis. Drebrin A is localized in the central region of dendritic spine heads at rest. We then quantitatively assessed the extent of DA-actin localization to spines using the spine-dendrite ratio of drebrin A in cultured hippocampal neurons, and found that (1) chemical long-term potentiation (LTP) stimulation induces rapid DA-actin exodus and subsequent DA-actin re-entry in dendritic spines, (2) Ca^{2+} influx through NMDA receptors regulates the exodus and the basal accumulation of DA-actin, and (3) the DA-actin exodus is blocked by myosin II ATPase inhibitor, but is not blocked by myosin light chain kinase (MLCK) or Rho-associated kinase (ROCK) inhibitors. These results indicate that myosin II mediates the interaction between NMDA receptor activation and DA-actin exodus in LTP induction. Furthermore, myosin II seems to be activated by a rapid actin-linked mechanism rather than slow MLC phosphorylation. Thus the myosin-II mediated DA-actin exodus might be an initial event in LTP induction, triggering actin polymerization and spine enlargement.

Title: The dynamics of interneuronal spines are regulated by N-methyl-D-aspartate receptors

Authors: *M. PEREZ-RANDO[1], E. CASTILLO-GOMEZ[1], R. GUIRADO[2], H. CARCELLER[1], J. NACHER[1];

Abstract: Dendritic spines are membranous protrusions specialized in receiving neuronal input. Although they have been typically studied on excitatory pyramidal neurons, they are also present in some populations of inhibitory interneurons, playing the same role. These neurons express plenty of neurotransmitter receptors, but glutamate N-methyl-D-aspartate receptors (NMDAR) are especially important. Despite extensively studied in order to understand learning and memory, little is known about their role on the structural plasticity of interneurons. In this study we try to unravel how NMDAR influence the spine dynamics of a subpopulation of interneuronal dendritic spines of hippocampus. In order to do so, we use the highly selective NMDAR antagonist MK-801 on organotypical entorhino-hippocampal cultures, performed on transgenic mice that express the enhanced green fluorescent protein (eGFP) under the promoter of the glutamic acid decarboxylase (GAD67) gene. This technique allows us to study either longitudinally or tangentially spine dynamics and the relative spine density. In the present study, we describe how the apparition turnover rate of interneuronal spines is rapidly decreased 4 hours after the antagonist treatment, remaining low 24 hours later. In addition, we report a decreased relative spine density 24 hours after the treatment. Since NMDAR hypofunction on inhibitory networks is the most accepted hypothesis explaining the molecular basis of schizophrenia, this study can also help to shed light on this important subject.

Title: A novel RhoGAP, ARHGAP12, interacting with F-BAR protein CIP4 regulates spine morphology and AMPA receptor function

Authors: *W. BA[1], J. VAN DER RAADT[2], M. M. SELTEN[1], L.-L. LI[3], M. BENEVENTO[1], A. R. OUDAKKER[2], H. VAN BOKHOVEN[2], M. J. COURTNEY[3], N. NADIF KASRI[1];

Abstract: Activity-dependent changes in the strength of excitatory synapses are thought to be key cellular mechanisms that contribute to the plasticity of neuronal networks underlying learning and memory. Key mechanisms for the regulation of synaptic strength are the dynamic change in size and number of dendritic spines and the synaptic incorporation and removal of AMPA-type glutamate receptors (AMPAr). As key regulators of the actin cytoskeleton the Rho subfamily of GTP-binding proteins play a critical role in synaptic development and plasticity. They shuttle between the active GTP- bound form and the inactive GDP- bound form under the regulation of dedicated guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs). More than 80 human GEFs and GAPs have been identified, most of which are expressed in the brain with a specific spatial and temporal expression pattern. Surprisingly, the cellular function of most GEFs and GAPs in the brain has not yet been elucidated. Here, we report the functional characterization of ARHGAP12, a RhoGAP that negatively regulates Rac1 signaling. ARHGAP12 is specifically expressed in the CA1 and dentate gyrus region of the hippocampus and its expression decreases after the first postnatal week, coinciding with the maturation process of excitatory synapses. At the cellular level ARHGAP12 localizes to the postsynaptic site of mature excitatory synapses. Via a direct interaction with the F-BAR-containing protein CIP4, ARHGAP12 bidirectionally regulates spine volume and the ratio of mature and immature spines of CA1 pyramidal neurons. Overexpression of ARHGAP12 in hippocampal neurons reduces the number of excitatory synapses and dramatically decreases the frequency and amplitude of AMPAr-mediated miniature excitatory postsynaptic currents. Conversely downregulation of Arhgap12 rapidly converted silent synapses to active synapses,

therefore enhancing AMPAr-mediated excitatory synaptic transmission. Together our data suggest that endogenous ARHGAP12 functions as a synaptic break during development and can bidirectionally regulate excitatory synaptic strength. Interestingly, Arhgap12 mRNA was recently identified as a target of Fragile X mental retardation protein, which regulates local protein translation during metabotropic glutamate receptor LTD. In accordance we found that ARHGAP12 is rapidly translated in response to mGluR activation in and is required for mGluR-LTD expression in hippocampal brain slices. Together our data show that ARHGAP12 is a novel synaptic RhoGAP that plays a critical role in regulating excitatory synaptic structure and function.

Title: NOS1AP regulates synapse formation and synaptic strength in rat cortical neurons

Authors: *K. HERNANDEZ[1], P. SWIATKOWSKI[1], N. R. DUDZINSKI[1], L. M. BRZUSTOWICZ[2], B. L. FIRESTEIN[1];
[1]Cell Biol. and Neurosci., [2]Genet., Rutgers Univ., Piscataway, NJ

Abstract: Proper neuronal circuitry is dependent upon the appropriate dendritic patterning of neurons as well as spine formation and maintenance. Schizophrenia is one of several neurodevelopmental disorders that are characterized by alterations in dendrite branching and spine density, resulting in the manifestation of the disease phenotype. NOS1AP (nitric oxide

synthase 1 [neuronal] adaptor protein) is a protein encoded by a schizophrenia susceptibility gene, and studies from the Firestein and Brzustowicz laboratories have shown that its expression is upregulated in the dorsolateral prefrontal cortex of patients with schizophrenia. In addition, our laboratory reported that NOS1AP negatively regulates dendrite branching in cultured rat hippocampal cells. The regulation of actin polymerization and depolymerization is important to the formation of new branch points and spines, which are small actin-rich protrusions, and thus, we studied the association of NOS1AP with actin. Using a co-immunoprecipitation assay, we found that the short isoform of NOS1AP (NOS1AP-S) associates with F-actin in adult rat brain, further strengthening a possible role for NOS1AP in actin dynamics. To elucidate NOS1AP's role in synapse formation and synaptic strength, we cultured rat cortical neurons exogenously overexpressing NOS1AP during the developmental time points of synapse formation and maturation. Both the short (NOS1AP-S) and long (NOS1AP-L) isoforms of NOS1AP increase spine density when overexpressed in cortical neurons from day *in vitro* (DIV) 14 to DIV 17. Using mutants of NOS1AP-L, we show that the PDZ-binding motif, which is present in both NOS1AP-S and NOS1AP-L, is necessary for mediating the effects of NOS1AP on spine density. The ability of NOS1AP to compete with PSD-95 for binding to NOS1 via its PDZ binding motif suggests that NOS1AP may sequester NOS1 away from NMDA receptors. The decoupling of NOS1 and NMDA receptors would prevent the activation of NOS1 and its downstream signaling pathways. To study the synaptic strength of cortical cells overexpressing NOS1AP, whole-cell patch clamping was performed. We find that NOS1AP alters the amplitude and frequency of excitatory postsynaptic currents (EPSCs). Our findings show that NOS1AP alters neuronal morphology as well as synaptic function.

Title: Juvenile rats exposed to environmental enrichment show increased densities of long-thin and filopodia spines, clustering of GluA2 and PSD-95 in the hippocampus and enhanced spatial learning

Authors: *A. AUBRY[1,2], A. ALLIGER[2], D. MUSHEYEV[2], J. AVILA[1,2], P. SERRANO[1,2]; [1]CUNY Grad. Ctr., New York, NY; [2]Hunter Col., New York, NY

Abstract: Environmental enrichment (EE) has been shown to increase synaptic plasticity and improve learning and memory. As a result of EE, many studies have identified increases in overall density of dendritic spines across various brain regions using traditional Golgi staining. Recent advances in both Golgi and imunnohistochemistry techniques now allow for the identification of specific spine types and the expression of synaptic proteins within these spines (Sebastian et al 2013, PLoS One, vol8, e79077). We focused on four distinct spine types (filopodia, stubby, long-thin, and mushroom) and two synaptic markers (GluA2 and PSD-95), which are found to cluster with protein kinase M zeta (PKMζ) during episodes of learning and synaptic plasticity. We therefore investigated the effects of 6 weeks of EE on spatial learning, spine morphology and the clustering of these synaptic markers in juvenile rats. Following 6 weeks of EE or standard housing conditions brains were prepared for Golgi-IHC. Spine morphology and the expression of GluA2 and PSD-95 were quantified with IMARIS software. Our results show that in the stratum radiatum of area CA1, EE increased the density of filopodia and the co-localization of GluA2 and PSD-95 within this spine type. In CA3, EE increased the density of long-thin spines, the expression of PSD-95 and the co-localization with GluA2. Filopodia and stubby spines in CA3 also reflected EE-induced increases in the expression PSD-95 and the co-localization with GluA2. Spatial learning was assessed during the 6th week of EE or standard housing treatment. For spatial learning assessment, animals were given 3 days of radial-8 arm maze training (10 trials per day/3d) where 4 of 8 arms were baited with sweetened oatmeal mash, which served as a food reward. We quantified daily acquisition performance as percent correct (number of correct arm entries divided by the total number of arm entries per trial). EE animals exhibited significantly higher percent correct scores compared to standard housed animals. Our results suggest that EE can increase immature spine types that are associated with improved learning. Together with the increase in the co-localization of GluA2 and PSD-95, EE may be acting to lower the threshold to induce morphological changes in the immature spine types resulting in larger, more stable spines (mushroom and long-thin) following learning. These morphological and neurochemical changes may reflect a mechanistic explanation for the increased acquisition of a spatial memory observed in rats reared in an enriched environment.

Title: Comparison of axospinous synapses onto glutamatergic and GABAergic forebrain neurons

Authors: *R. J. WEINBERG[1], E. KIM[3], A. C. BURETTE[2];
[1]Cell & Developmental Biol., [2]Cell Biol. & Physiol., Univ. North Carolina, CHAPEL HILL, NC;
[3]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: The dendrites of principal cells in the mammalian forebrain are covered with dendritic spines, which provide the main target for excitatory afferent input. These axospinous synapses exhibit a characteristic "asymmetric" morphology at the electron microscope, displaying a pronounced post-synaptic density. Accumulating evidence shows an important role for synaptic size: synaptic contacts with large surface area (typically between large presynaptic terminals and large postsynaptic spines) are stabler and express more AMPA receptor than small contacts, but it remains unclear whether there are other differences between the axo-spinous synapses on different types of principal cells in forebrain. The pyramidal cells of hippocampus and cortex are glutamatergic, whereas the medium spiny neurons (MSNs) of neostriatum are GABAergic, leading us to investigate possible differences in the structure and molecular organization of synapses onto these two basic cell types. The two classes of axospinous synapses have PSDs of similar length and thickness, but they appear to display different curvature: the postsynaptic membrane of spines on pyramidal cells typically exhibits a flat or convex curvature, whereas the postsynaptic membrane of spines on MSNs is often concave. Perhaps related to this, we find that the I-BAR protein IRSp53 lies preferentially at the center of the synapse in pyramidal cells, but is uniformly distributed along the synapse in MSNs. In contrast, our current evidence suggests only subtle differences in the organization of glutamate receptor subunits in these two types of synapses.

Title: Aberrant spine pruning in adolescence in a model of schizophrenia and related disorders

Authors: *S. K. BARODIA, J. R. MOORE, S.-H. KIM, A. SAWA, H. JAARO-PELED; Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Disturbances in glutamatergic synaptic connectivity underlie schizophrenia (SZ) and associated disorders. One major question is whether reduction of spine density frequently observed in autopsied brains from SZ patients occurs by excess synaptic pruning in adolescence or malformation of synaptic connection from early development. It is very difficult to address this question in human brains. Thus, animal models that represent SZ-relevant endophenotypes in behaviors, neurochemistry, and histology may provide an opportunity to address this question. Among multiple choices that satisfy these criteria of animal models, we chose a transgenic model expressing a putative dominant-negative DISC1 (DN-DISC1 Tg) (Hikida, Jaaro-Peled et al, PNAS 2007; Johnson, Jaaro-Peled et al PNAS 2013; Jaaro-Peled et al, Hum Mol Genet 2013). Involvement of DISC1 in synaptic dynamics has also been reported (Takagi-Hayashi et al, Nat Neurosci 2010; Brandon et al, Nat Rev Neurosci 2011). In the present study, we examined the spine change in the two regions of the prefrontal cortex in the time course from early adolescence to adulthood. Heterozygous line from DN-DISC1 mouse was crossbred with homozygous line of Thy-1YFP mouse to genetically label pyramidal neurons selectively in layer 5/6. Dendritic spine density was assessed at early adolescence (P28), late adolescence (P49) and adulthood (P90) in the medial prefrontal cortex and ventrolateral orbitofrontal cortex. We did not observe robust difference in the spine density at P28, whereas major spine loss existed at P90, between DN-DISC1 and control mice. Interestingly, dramatic difference between these two groups occurred between P28 and P49, but not between P49 and P90. This suggests the existence of pathological pruning in adolescence in DN-DISC1 model. It is under investigation how administration of PAK inhibitors in late adolescence can ameliorate the spine change and adult behaviors.

Title: Dendritic spine neck resistance measurements using voltage sensitive dyes

Authors: M. POPOVIC[1], N. CARNEVALE[1], B. ROZSA[2], *D. ZECEVIC[3];
[1]Yale Univ., New Haven, CT; [2]Inst. of Exptl. Medicine, Hungarian Acad. of Sci., Budapest, Hungary; [3]Dept Cell & Mol. Physiol, Yale Univ. Sch. Med., NEW HAVEN, CT

Abstract: Whether dendritic spines play an electrical role in signal processing based on hypothetical electrical isolation of the spine head from the parent dendrite by elongated spine necks is an open question. There is no direct information on the electrical resistance of the spine neck, the critical functional variable in this context. We investigated the transfer of unitary excitatory postsynaptic potentials (EPSPs) from synapses on spine heads across the spine neck to the parent dendrite using high resolution voltage sensitive dye imaging in the wide-field epi-fluorescence microscopy mode. L5 pyramidal neurons in mouse cortical slices were labeled by intracellular application of a membrane impermeable voltage-sensitive dye. To improve the signal-to-noise ratio in monitoring electrical events from individual spines we advanced the sensitivity of recording by: (a) using monochromatic excitation light from a laser at a near-optimal wavelength; (b) increasing the excitation light intensity to a level close to chromophore saturation; (c) by restricting the illuminated area to a small square region (18 x 18 μm) around the recorded spine and (d) briefly reducing the oxygen concentration in the extracellular medium during recording to minimize photodynamic damage. Unitary EPSPs were evoked by localized high-speed iontophoretic glutamate ejections from extracellular sharp electrodes onto individual spines. Alternatively, synapses were activated using focal 2-photon photolysis of caged glutamate with diffraction limited spot of 720 nm laser light. Somatic patch-electrode

measurements verified that the size and the kinetics of evoked excitatory postsynaptic currents (EPSCs) and potentials (EPSPs) were comparable to the spontaneously occurring events. Optical recordings of evoked subthreshold signals from dendritic spines showed that a temporal average of 9-25 trials was sufficient to record EPSPs that had somatic amplitude in the range of 0.3-0.8 mV with the S/N of >5. The ratio of recorded peak EPSP amplitudes in the spine heads/parent dendrites was close to 1. An attenuation ratio (EPSPspine/EPSPdendrite) of ~1 is in agreement with diffusion equilibration studies as well as with multicompartmental modeling (NEURON 7.2), indicating that the axial resistance of the spine neck is much smaller than the dendritic input resistance in most areas of the dendritic arbor. The time course of the signal from the spine head and from the parent dendrite was practically identical. This result indicates that the small membrane surface area of both the spine head and the dendritic compartment immediately below the spine provided negligible local capacitance.

Title: Morphological and Functional analysis of glutamatergic synapses in the dopamine neurons of the Substantia nigra pars compacta

Authors: ***M. JANG**, M. PARK;
Physiol., Sch. of Medicine, Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Midbrain dopamine neurons play critical roles in motivation and reward-based learning through glutamatergic signaling. Dopamine neurons of the substantia nigra pars compacta (SNc) are known to receive approximately 8,000 synaptic inputs and among them at least 30% are glutamatergic. However, little is known about the morphological and functional properties of glutamatergic synapses in the dopamine neuron dendrites. Here, using two-photon confocal microscopy we demonstrate morphological features of dendrites and typical structures of glutamatergic synapses in the dopamine neurons of the mouse SNc. The SNc dopmaine neurons in brain slices showed simple and low-branching dendritic arborizations, when

compared to those of CA1 pyramidal neurons. Interestingly, we found that there were three types of common dendritic spines in the SNc dopamine neurons; the thin, mushroom, and stubby spines, whose dimensions were similar to those of CA1 pyramidal neurons. However, the SNc dopamine neurons had a very low number of spines than CA1 pyramidal neurons. By analysis of PSD-95, GluR1 and GluN1 expressions with immunostaining and glutamate uncaging techniques, we identified functional dendritic spines for glutamatergic synapses in dopamine neurons which had a different AMPAR/NMDAR ratio to those in dendritic shafts. Therefore, we first provide a new piece of evidence showing the morphological and functional substrate for glutamatergic synapses in the SNc dopamine neurons.

Title: Repeated ketamine exposure during early development impairs learning-dependent dendritic spine plasticity in adulthood

Authors: L. HUANG, *G. YANG;
Anesthesiol., New York Univ. Sch. of Med., New York, NY

Abstract: General anesthetics are commonly used for surgical operations in infants and young children. Recent studies in rodents and monkeys suggest that repeated and prolonged anesthetic exposure, during early postnatal development, can lead to cognitive and behavioral impairments later in life. However, the mechanisms underlying anesthesia-related learning impairment remain unclear. Here, we have investigated motor learning and learning-dependent synaptic plasticity in adult mice that received repeated anesthetic exposure during development. We found that multiple ketamine (20 mg/kg)-xylazine (3 mg/kg) (KX) injections at early (postnatal days 7-18), but not late stage (postnatal days 21-25) of brain development, impair the animals' motor skill learning in a rotarod running task in adulthood. Using *in vivo* transcranial two-photon microscopy to track the formation and elimination of postsynaptic dendritic spines in the primary motor cortex, we observed no significant difference in either dendritic spine density or baseline

spine turnover rates between KX- and saline-treated mice. However, motor learning-induced formation of new dendritic spines is significantly reduced in adult mice with early KX treatments. Notably, enriched motor experience for ten days following anesthetic exposure ameliorates anesthesia-induced behavioral and synaptic deficits. Taken together, our study demonstrates that repeated exposure to ketamine-xylazine during early development impairs learning and learning-dependent dendritic spine plasticity in adulthood. Furthermore, these deficits can be reduced by environmental enrichment following anesthetic exposure.

Title: Very long-term memories may be stored in the pattern of holes in the perineuronal net

Authors: *V. LEV-RAM[1], E. A. BUSHONG[2], J. N. SAVAS[4], D. C. PRASHER[3], S. F. PALIDA[3], J. R. YATES, 3rd[4], M. H. ELLISMAN[2], R. Y. TSIEN[5];

Abstract: We are carrying out several experiments to test the hypothesis that life-long memories are stored as the pattern of holes in the perineuronal net (PNN) (R.Y.Tsien PNAS 2013). The PNN is a specialized form of extracellular matrix deposited around selected neurons during critical periods of development in specific parts of the brain, interrupted by holes where synapses occur. We postulate that the PNN is a long-lived structure and that new memories are created by cutting new holes in the PNN or expanding existing holes to enable formation of new synapses or to strengthen existing ones. There is much circumstantial evidence implicating the PNN in synaptic plasticity. If correct, the PNN would be something like an enormously convoluted punched card, with information continuously being stored in the location and size of

the interruptions in its coverage of the neuron - what we are calling holes. A basic premise of this hypothesis is that the card stock, i.e. the bulk of the PNN, should not undergo metabolic renewal from the first age at which memories are retained until senescence, whereas the active constituents of synapses i.e. membranes, receptors, channels, kinases, phosphatases, intracellular scaffolds, etc. turn over much more frequently and would therefore be poorer substrates for permanent information storage, unless they are equipped with incredibly accurate copying mechanisms. We are now testing this hypothesis using several experimental approaches: 1. The intertwining of PNN and synapses is being imaged by Serial Block Face Scanning EM to more fully reconstruct their 3D relationship. 2. Lifetimes of PNN proteins vs. intrasynaptic components are compared using mass spectroscopy and Stable Isotope Labeling in Mammals (SILAM). We grow mice on a ^{15}N spirulina diet until postnatal day 45, just beyond the final brain critical period and maturation of the PNN. Thereafter, the mice are fed a ^{14}N normal diet. At progressive times from the end of the ^{15}N pulse, different brain areas are prepared for Multidimensional Protein Identification Technology (MudPIT) to identify interesting proteins and those with the lowest turnover, i.e. $^{14}N/^{15}N$ ratio. 3. The role in very long-term plasticity of matrix metalloproteinase-9 (MMP-9), one candidate for cutting new holes or enlarging existing holes in the PNN, is tested in genetic knockouts and with pharmacological inhibitors during cued and contextual fear conditioning. We will present preliminary data from these three types of experiment to investigate the hypothesis that the PNN plays a role in life-long memory.

Title: Ultrastructural changes in hippocampal synaptic architecture caused by reduced food intake

Authors: *B. L. RACZ, R. B. BABITS, T. MAGYAR, D. NOVÁK-HAZAI, P. SÓTONYI; Szent Istvan Univ., Budapest, Hungary

Abstract: Neuronal mechanisms regulating food intake are a topic of current interest. Behavioral patterns of food intake involve learning and memory functions. The hippocampus plays a key role in encoding relationships between internal states (e.g. hunger) and action, providing a mechanism by which motivation and memory are coordinated to guide behavior. Learning paradigms can induce synaptic plasticity and physiological changes in the hippocampus, but it is unclear whether metabolic state can induce synaptic plasticity. Recent evidence shows that intestinal hormones (e.g. ghrelin) may initiate synaptogenesis in hippocampus. As activity-dependent 'morphing' of spines is linked to changes in synaptic efficacy, we studied spine-rich areas (CA1 and dentate gyrus) pivotal in long-term synaptic plasticity. Using quantitative electron microscopy we analyzed the effect of food restriction (FR) on the biophysical characteristic of hippocampal spines. We found that short-term FR induces significant ultrastructural changes in the architecture of hippocampal synapses. Interestingly, these changes were similar to those observed during long-term potentiation.

Title: Impermanence of dendritic spines in live adult CA1 hippocampus

Authors: *A. ATTARDO[1,2], J. E. FITZGERALD[1,3], M. J. SCHNITZER[1,2]; [1]Stanford Univ., Stanford, CA; [2]Howard Hughes Med. institute, Chevy Chase, MD; [3]Harvard Univ., Cambridge, MA

Abstract: The mammalian hippocampus is crucial for episodic memory formation and transiently retains information for ~3-4 weeks in adult mice and longer in humans. Although

neuroscientists widely believe neural synapses act as elemental sites of information storage, there has been no direct evidence hippocampal synapses persist for time intervals commensurate with the duration of hippocampal-dependent memory. Here we experimentally tested the prediction that the lifetimes of hippocampal synapses match the measured longevity of hippocampal memory. For this test, we monitored synapses by imaging dendritic spines, where most excitatory synapses have their post-synaptic structures and whose turnover dynamics are thought to reflect those of synaptic connections. By using time-lapse, two-photon microendoscopy we tracked CA1 pyramidal neurons' basal dendritic spines to investigate their dynamics over multiple weeks in live mice. Mathematical modeling revealed that, among a wide class of kinetic models, the data best matched models in which there is a single population of dendritic spines with a mean lifetime of ~1-2 weeks. This implies ~100% turnover in ~2-3 times this interval, a near full erasure of the synaptic connectivity pattern. Environmental enrichment did not alter these dynamics, whereas NMDA receptor blockade caused a temporary increase in spine loss. Together, these results quantitatively support the idea that the transience of hippocampal memory may directly reflect the turnover dynamics of the synapses that store these memories. Moreover, the turnover dynamics of CA1 dendritic spines appear distinct from those in neocortex, with a far greater fraction of spines undergoing turnover in hippocampus but with a slower time constant. These differences may reflect the different functional roles for hippocampus and neocortex in memory formation and storage. Our work also paves the way to visualization of synaptic dynamics in other deep brain areas and the cell biological mechanisms by which the brain encodes aspects of the external world and life experiences.

Title: Picomolar beta-amyloid modulates hippocampal synaptic plasticity via inhibitor of apoptosis protein regulation of caspase-3 activity and rho gdp dissociation inhibitor

Authors: M. PERO, E. M. RIBE, Y. Y. JEAN, *C. M. TROY;
Dept Pathol & Neurol, Columbia Univ. Medl Ctr., NEW YORK, NY

Abstract: Picomolar concentrations of beta-amyloid (Abeta) positively modulates hippocampal synaptic plasticity and memory, whereas nanomolar and higher concentrations lead to inhibition of long-term potentiation (LTP), loss of spines and eventually neuronal death. We have previously shown that the toxic effects of Abeta are mediated by activation of caspase-2, despite concurrent activation of caspase-3 (caspase-3 is neither necessary nor sufficient for toxicity). In the current work we examine the function of caspase-3 in the effects of pM Abeta. Treatment of primary hippocampal neurons with 300 pM Abeta leads to a rapid increase in spine density that is accompanied by a rapid increase in caspase-3 activity in purified synaptosomes. Effects are seen within 30 minutes of treatment of the cultures; injection of 300 pM Abeta *in vivo* also causes an increase in spine density. As this effect is rapid, we posited that the synapses contain cleaved (activated) caspase-3 that is inhibited by endogenous inhibitor of apoptosis proteins, IAPs. We found that the synaptosomal fraction contains cIAP1 and XIAP, and co-immunoprecipitation (co-IP) shows that there are complexes of cIAP1-cleaved caspase-3 and XIAP-cleaved caspase-3. Treatment of cultures with 300 pM Abeta induces a decrease in the cIAP1-cleaved caspase-3 interaction, but there is no change in the XIAP-cleaved caspase-3 interaction, suggesting that the increase in caspase-3 activity is modulated by cIAP1. Actin, the major component of spines, is a substrate of caspase-3, and we find that Abeta leads to an increase in cleaved actin (f-actin). siRNA knockdown of caspase-3 prevents the effects of Abeta and siRNA knockdown of cIAP1 potentiates the effects of Abeta on spine density. Surprisingly we found that siRNA knockdown of XIAP prevented the effects of Abeta. A recent study has shown that XIAP can bind to RhoGDI (Rho GDP dissociation inhibitor), leading to an increase in f-actin. Co-IP carried out in our lab shows that 300 pM Abeta increases the XIAP-RhoGDI interaction. Our data show that spine dynamics can be regulated by Abeta through both induction of caspase-3 activity by a decrease in cIAP1 levels and sequestration of RhoGDI by XIAP.

Title: Profilin isoforms as important modulators of structural spine plasticity and memory formation

Authors: K. MICHAELSEN-PREUSSE[1], S. ZESSIN[1], F. SCHARKOWSKI[1], J. FEUGE[1], *M. H. KORTE[2];
[1]Cell. Neurosci., TU Braunschweig, Braunschweig, Germany; [2]Tu Braunschweig, D-38106 Braunschweig, Germany

Abstract: Actin dynamics in neurons are equally important for structural stability, allowing proper signal transduction, and for plastic changes of neuronal structure. This tremendous task is fulfilled with the help of an ever increasing number of factors discovered to tightly regulate actin polymerization and F-actin structure in space and time. In our work, we concentrated on the neuronal profilin isoforms PFN1 and PFN2a regulating actin polymerization and known to be recruited to dendritic spines in an activity-dependent manner. Here, we were interested in the role of PFN1 and PFN2 for neuronal function and structure in murine hippocampal neurons. Fluorescence recovery after photobleaching (FRAP) using GFP-actin revealed alterations of spine actin dynamics in loss of function experiments in organotypic slices cultures using biolistic gene transfer of shRNAs against PFN1/ PFN2a. The loss of PFN1 led to an increase of the stable F-actin fraction in dendritic spines whereas shPFN2a had the opposite effect. As a next step, long-term potentiation (LTP) was induced via a chemical protocol in primary hippocampal cultures as well as in hippocampal slice cultures using Glycine. Calcium imaging experiments showed that synapses of PFN1/ PFN2a deficient cells were equally potentiated compared to control neurons. In contrast to this, PFN2a was found to be crucially involved in activity-dependent structural plasticity as spine head growth following LTP induction was prevented specifically in PFN2a deficient CA1 neurons. Finally, we investigated expression patterns of profilins following spatial memory formation in the Morris Water Maze (MWM) in the mouse model of the fragile X syndrome (FXS, Fmr1 KO mice). It was shown previously that the mRNA of the *Drosophila* homolog of profilin (chickadee) is bound by the fragile x mental retardation protein (FMRP). Interestingly, we found an impairment in spatial memory formation in Fmr1 KO animals together with a significant elevation of PFN1 expression levels in Fmr1 KO mice but not in WT littermates after spatial training. Most notably, PFN2a levels were not altered compared to WT littermates. This finding is in line with our results from co-immunoprecipitation studies where we could identify the mRNA of PFN1 but not PFN2a as a target of FMRP. Taken together our results indicate that both profilin isoform can perform even opposing roles - stabilizing versus destabilizing - on spine actin dynamics and that only the neuron specific isoform PFN2a is involved in activity-dependent structural plasticity. In addition, we could identify PFN1 but not PFN2a as part of the molecular mechanisms underlying FXS.

Title: Mechanism of Nogo-A action in regulating functional and anatomical synaptic plasticity

Authors: *M. ZAGREBELSKY[1], Y. KELLNER[1], S. KRAMER[2], M. E. SCHWAB[2], M. KORTE[1];
[1]Cell. Neurobio., TU Braunschweig, Braunschweig, Germany; [2]Brain Res. Inst. and Dept. of Hlth. Sci. and Technol., University of Zurich and ETH Zurich, Switzerland

Abstract: The functions of neural circuits in the adult brain are determined by the architecture of axons and dendrites and of the synaptic structures connecting them. Changes in synaptic connectivity - structural plasticity - have been correlated to functional changes at synapses - functional plasticity - and are thought to underlie learning and memory processes. Yet, long-term *in vivo* imaging in the adult brain reveals that the overall architecture of the neuronal network is remarkably stable. These observations suggest the need for a set of molecules regulating the balance between stability and plasticity of mature neuronal networks, ensuring the spatial and temporal specificity of plastic changes and preventing interference between different memory events. The myelin-associated neurite growth inhibitor Nogo-A and its receptors, Nogo-66 receptor 1 (NgR1) and sphingosine 1-phosphate receptor 2 (S1PR2) are expressed pre- and post-synaptically and have been shown to negatively modulate neuronal architecture and to control synaptic plasticity, by restricting long-term potentiation (LTP). However, whether Nogo-A regulates structural plasticity at a fast time scale and what the molecular mechanisms mediating this action are, is so far unknown. Here we addressed this question by combining time-lapse confocal imaging, Fluorescence recovery after photobleaching (FRAP) and calcium imaging with a series of loss- or gain-of-function approaches for Nogo-A and its receptors in mature hippocampal cultures. Our results show that Nogo-A signalling acutely modulates the spine actin cytoskeleton dynamics to control structural plasticity at dendritic spines at a fast time scale. Indeed, Nogo-A signalling loss-of-function experiments transiently increase F-actin stability within minutes and results in an increase in dendritic spine density and length. In addition, Nogo-A acutely restricts AMPA receptor (AMPAR) insertion and formation of new AMPAR clusters. Finally, calcium imaging reveals a role for Nogo-A in negatively modulating synaptic strength and number of active synapses at spines. Our data provide a cellular and molecular mechanism

mediating the role of Nogo-A signalling in controlling activity-dependent synaptic plasticity thereby maintaining the balance between the plasticity and stability of the neuronal circuitry in the mature central nervous system.

Title: The role of alpha2-chimaerin in dendrite morphogenesis and synaptic plasticity

Authors: *C. VALDEZ, A. A. BEG;
Neurosci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Neurons maintain a dynamic cellular morphology that can be modulated in response to synaptic activity. Dendritic spines are fine neuronal processes that can balance neuronal structure and function. These fine structural components localize biochemical signals and spatially restrict the recruitment of membrane receptors to activated synapses. The superfamily of Rho-GTPases have been shown to modulate cytoskeletal proteins that regulate dendritic arborization and spine shape. Importantly, these proteins can form activity-dependent complexes with signaling molecules that mediate surface levels and post-translational modifications of synaptic receptors. Our laboratory studies a Rac1 GTPase activating protein named alpha2-chimaerin. We have detected that alpha2-chimaerin is predominantly expressed during timepoints that coincide with developmental stages of synaptic connectivity. Our goal is to determine if the loss of alpha2-chimaerin results in long-term changes to dendritic morphology and synaptic transmission. We hypothesize that alpha2-chimaerin is important for neuronal development, and the subsequent loss results in long-term changes to dendritic morphology, synaptic function and behavior.

Title: Regulation of spine architecture by δ-catenin

Authors: *L. YUAN[1,2], E. SEONG[1], J. L. BUESCHER[1], J. ARIKKATH[1];
[1]Developmental neuroscience, [2]Pharmacol. and experimental neuroscience, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: The cadherin-catenin complex regulates multiple aspects of neural and synaptic development and plasticity. δ-catenin is a component of the cadherin-catenin complex and is predominantly expressed in the central nervous system. δ-catenin associates with cadherin at the juxtamembrane domain. We have previously demonstrated that loss or knockdown of δ-catenin leads to an increase in spine density and synaptic function. We now present evidence for a critical role for δ-catenin in regulating synaptic architecture. Loss or knockdown of δ-catenin leads to a decrease in spine headwidth and length in primary cultured rat neurons. The ability of δ-catenin to induce alterations in synaptic architecture is dependent on its ability to associate with cadherin. We are currently examining the molecular and cellular basis of how the cooperation between cadherin and δ-catenin contribute to the control of synaptic architecture and synaptic structural plasticity.

Title: Morphometric analysis of human pyramidal neurons of Brodmann Areas 39 and 40

Authors: J. C. ZINN[1], W. G. M. JANSSEN[2], J. EVANS[5], A. D. SHARAN[5], M. R. SPERLING[6], K. SIMONYAN[1], *P. R. HOF[3], J. H. MORRISON[2], F. HAMZEI-SICHANI[4,5]; [1]Neurol., [2]Neurosci., [4]Neurosurg., [3]Icahn Sch. of Med. At Mount Sinai, NEW YORK, NY; [5]Neurosurg., [6]Neurol., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Although previous studies have described geometric properties of human neurons, the quality of tissue has prevented reliable characterization of structure on the sub-micrometer scales that characterize crucial structures of neurons such as dendritic spines. Here, we present detailed, high-resolution analyses of layer II/III and layer V pyramidal neurons of two adult patients with epilepsy. Regions were identified as functionally normal via intracranial EEG and cortical mapping. High quality Lucifer Yellow filled neurons were selected and imaged at high magnification (63X, 1.4 N.A. 100 nm cubic voxel) using confocal laser scanning microscopy. Neuronal morphology was extracted from stacks of scanned images using a custom-designed algorithm (NeuronStudio). Morphometric analysis provided unbiased measurements of both local and global structure of the pyramidal neurons. In an effort to explore parameters of interest to electrotonic structure of neurons, spine volume and density were described as a function of spine type (mushroom or thin) and the parent dendrite (basal vs. apical). Gamma but not normal distributions were found to be more consistent with observed distribution of volumes of both types of spines in pyramidal cells of Brodmann areas 39 and 40. Nonparametric post-hoc analysis was therefore performed on spine volume measurements. Taken together, cells indicated significantly positive differences in mean volumes of basal and apical mushroom spines ($p < 0.001$, corrected). Basal mushroom spines were found to have average densities greater than both those found on apical dendrites ($p < 0.001$, corrected) and basal & apical spines ($p < 0.001$, corrected), using bootstrapped spine counts. In general, basal mushroom spines populated the neurons more densely than did thin spines ($p < 0.001$, corrected). The distribution of spine densities across type showed increases in density out to 100 micrometers away from the soma. Our preliminary findings offer insights into the functioning of healthy cells in Brodmann areas 39 and 40, which will prove useful for future modeling of human neocortical areas. In particular, differences in mushroom morphology as a function of position on basal or apical dendrites suggest specialization of basal/apical mushroom spines in neuronal signaling. Further study will

address other factors such as spine clustering and dendritic width that also affect eletrotonic structure of human neocortical pyramidal neurons.

Title: Involvement of Cadherin 13 in cocaine-related behaviors in mice

Authors: *J. DRGONOVA[1], D. WALTHER[1], O. RIVERO MARTIN[2], B. RANSCHT[3], K.-P. LESCH[2], G. R. UHL[1];
[1]Dept Mol Neurobiol, Natl. Inst. Drug Abuse, NIH, BALTIMORE, MD; [2]Univ. of Würzburg, Würzburg, Germany; [3]Sanford/Burnham Med. Res. Inst., La Jolla, CA

Abstract: Proper function of brain circuitry requires accurate expression and regulation of cell adhesion molecules (CAMs), including those of the calcium-dependent cadherin family. Cadherin-13 (CHD13; T-cadherin) is an atypical cadherin in that it lacks its intracellular domain and is localized to the plasma membraine via a glycosylphosphatidylinositol anchor. In mice, CDH13 is expressed in cerebral cortex, hippocampus, amygdala, striatum, ventral tegmental area, and other brain regions interesting in the context of drug addiction. Molecular genetic studies in humans associate variants in CDH13 with vulnerability to substance dependence and ability to quit smoking. In human postmortem frontal cerebral cortical samples, we found that levels of CDH13 mRNA expression correlated with CDH13 genotype. CDH13 knockout mice (CDH13-KO) provide a good model for possible behavioral and anatomical influences of variation at this gene locus. We now describe data from constitutive and conditional CDH13-KO mice which suggest that altered levels of CDH13 expression can influence cocaine reward as assessed by conditioned place preference test. These results are complemented by the data from

wild-type mice that show that levels of CDH13 mRNA variants are regulated by cocaine and strongly correlate with cocaine conditioned place preference and locomotor sensitization. These behavioral observations and the anatomical distribution of CDH13 are consistent with contributions of variants in this gene to human phenotypes in addiction. **Support:** NIH IRP (NIDA); NIH HD25938 (BR).

Title: Role of Cadherin-13 in interneuron function and hippocampal-related behavior

Authors: ***O. RIVERO**[1], S. SICH[1], S. POPP[1], L. BACMEISTER[1], D. NAGEL[1], C. GROSS[2], E. AMENDOLA[2], K.-P. LESCH[1];
[1]Universitätsklinikum Würzburg, Würzburg, Germany; [2]EMBL Monterotondo, Monterotondo, Italy

Abstract: Cadherin-13 (Cdh13) is an atypical cell adhesion molecule that has been recently associated with several neuropsychiatric conditions, namely attention deficit/hyperactivity disorder, autism, drug abuse and depression. Cdh13 has role as a regulator of neurite outgrowth and axon guidance during brain development and it also takes part in the formation of excitatory and inhibitory synapses in the hippocampus. In this study, we aimed to better understand the regional and cellular pattern of Cdh13 in the mouse brain. Our investigations showed that Cdh13 is found in regions that are important for cognitive control and attention, such as the prefrontal cortex (PFC), the reticular nucleus of the thalamus (TRN) and the hippocampus, among others. Especially enticing is the presence of Cdh13 in the TRN, a GABAergic nucleus known to regulate the activity of thalamocortical pathways. Indeed, double fluorescence studies proved that Cdh13 mRNA and protein are found in GABAergic interneurons of the TRN and the hippocampal stratum oriens. Coexpression studies of Cdh13 with different interneuron markers also showed that Cdh13 is located in distinct subpopulations of hippocampal interneurons, with

the higher coexpression levels found with Parvalbumin (PV) and Somatostatin (SOM). The presence of Cdh13 in GABAergic interneurons encouraged us to study the effects of Cdh13 deficiency in GABAergic and glutamatergic signaling. For this purpose, we compared gene expression levels via quantitative PCR in the hippocampus of knockout (Cdh13-/-), heterozygote (Cdh13+/-) and wildtype (Cdh13+/+) adult mice. Although the genes involved in glutamatergic signaling were unaffected, the expression of some GABAergic genes, such as Vgat, Gphn or some GABA-A receptor subunits, was significantly different in Cdh13-/- mice. Currently, we are also evaluating whether the number of PV- and SOM-positive interneurons are different in the stratum oriens of Cdh13-/- mice. Subsequently, an evaluation of different behavioral domains revealed that Cdh13-/- mice present increased locomotor activity as well as impaired spatial learning and contextual fear memory, two cognitive domains which are directly related to hippocampal function. Presently, we are also studying the effect of Cdh13 deficiency in attentional behavior. In summary, our study shows that Cadherin-13 has a role in the function of particular subpopulations of hippocampal GABAergic interneurons, reflected by changes in the expression of genes involved in the inhibitory synaptic machinery in Cdh13-/- mice. These molecular changes can be correlated with behavioral alterations in domains that involve hippocampal function.

Title: NrCAM regulates semaphorin 3f-induced spine morphogenesis in developing neocortex

Authors: V. MOHAN[1], G. P. DEMYANENKO[1], X. ZHANG[1], L. BRENNAMAN[1], K. E. S. DHARBAL[3], T. S. TRAN[4], P. B. MANIS[2], *P. F. MANESS[1];

Abstract: NrCAM (Neuron-Glial Related Cell Adhesion Molecule) is an Ig superfamily molecule implicated as a risk factor in autism spectrum disorders (ASD). NrCAM null mice display ASD-related impairment in sociability, reversal learning, and visual cortical responses. We found that NrCAM deletion in mice increases spine densities on dendrites of pyramidal neurons in visual cortex (V1) and other cortical areas.Spine density was specifically elevated on apical but not basal dendrites of star pyramidal cells, the principal target of thalamic inputs in layer 4 of V1. Whole cell recordings under voltage clamp in V1 slices showed that loss of NrCAM increased miniature EPSC frequencies in star pyramidal cells with no change in amplitude, consistent with an excess of functional excitatory synapses, which was confirmed by electron microscopy. NrCAM localized to postsynaptic sites on dendritic spines, and was co-expressed with Sema3F in layers 4, 6 of V1. In cortical neuron cultures, Sema3F-Fc fusion protein induced spine retraction on apical, but not basal dendrites of WT but not NrCAM null neurons. NrCAM co-immunoprecipitated with the Sema3F receptor complex, Neuropilin2 (Npn-2) and PlexinA3 from brain, as well as with synapse associated protein 102 (SAP102), a postsynaptic density scaffold protein. The binding site for Npn-2 was identified within the Ig1 domain of NrCAM (TARNER).Sema3F-induced spine retraction was rescued in NrCAM-minus neurons by WT NrCAM but not by mutants deleted in Npn2 or PDZ binding motifs. An *in vivo* genetic interaction test with heterozygotes demonstrated that Sema3F and NrCAM pathways interact to regulate cortical spine density. These findings reveal that NrCAM regulates postnatal spine remodeling in cortical pyramidal neurons, as an integral component of the Sema3F receptor complex, thus playing a vital role in establishing excitatory/inhibitory balance in cortical circuits. Altered expression of NrCAM may contribute to increased spine density and cortical hyperexcitability in ASD.

Title: Cadherin 13 (cdh13) gene knockout affects ethanol consumption

Authors: ***F. S. HALL**[1], S. O. GOLUB[1], A. M. MORROW[1], J. DRGONOVA[1], B. RANSCHT[2], G. R. UHL[1];
[1]Mol. Neurobio. Br., Natl. Inst. On Drug Abuse, IRP/NIH/DHHS, BALTIMORE, MD; [2]Sanford Burnham Med. Res. Inst., La Jolla, CA

Abstract: The gene for the cell adhesion molecule Cadherin 13 (CDH13) has been repeatedly associated with drug addiction, alcoholism, smoking and smoking cessation in genome wide association studies (GWAS). Furthermore, gene variants associated with addiction in the CDH13 gene are also associated with differences in the level of expression of CDH13 mRNA in human brain tissue samples post mortem. To model these differences in level of expression of the CDH13 gene on ethanol consumption we have used littermate CDH13 knockout mice (+/+, +/- and -/-). Mice were initially assessed for ethanol consumption using a home-cage two-bottle test (ethanol versus water) in which ethanol concentrations were varied over a period of 10 days. The initial concentration was 2% ethanol (vol/vol), and the ethanol concentration was raised every third day in the following progression: 2%, 4%, 8%, 16% and 32%. Subsequently, after 4 days without ethanol, 8% ethanol (and water) was made available on a limited access basis, 2 times per week for 24 hours. This "escalation" procedure was continued for 6 weeks. This procedure has been previously shown produce escalation of ethanol consumption over a period of 3 weeks. In the first procedure, CDH13 -/- mice were found to have elevated consumption of the highest ethanol concentration (32%). This effect was sex-dependent; consumption of this concentration was significantly increased in female but not male CDH13 KO mice, although male mice showed a similar trend. Escalation of ethanol consumption was observed in mice of all genotypes, but no differences between genotypes were observed. These experiments support a role for the CDH13 gene in ethanol consumption, and in particular consumption of high ethanol concentrations that may be more typical of alcoholics. Further experiments are needed to see if differences in ethanol consumption between these genotypes can be observed under other conditions, including escalation of intake for higher ethanol concentrations. Further experiments are also being conducted to determine if similar changes are observed for other drugs in CDH13 KO mice, including nicotine and methamphetamine. (**Support:** NIDA-IRP)

Title: cAMP signaling is involved in activity-dependent reduction of calcium responses in *Drosophila* mushroom body

Authors: *S. SATO[1], K. UENO[2], T. SAKAI[1];
[1]Tokyo Metropolitan Univ., Tokyo, Japan; [2]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: In the fruitfly, *Drosophila* melanogaster, behavioral and genetic studies have been extensively used to elucidate the molecular and neural mechanisms in learning and memory. In *Drosophila*, the mushroom body (MB), which is considered to be the memory center, receive olfactory information via the dendritic calyx mainly from the antennal lobe (AL). In cultured *Drosophila* brain, the simultaneous stimulation of the AL and ascending fibers of the ventral nerve cord (AFV) establishes long-term enhancement (LTE) in AL-induced Ca2+ responses. LTE at the AL-MB synapse is thought to be a cellular model for olfactory memory. In this current study, in an isolated cultured *Drosophila* brain, we report activity-dependent reduction of Ca2+ responses in the MB using electrical stimulation of AL (AL-stimulation). In wild-type, Ca2+ responses in the MB were reduced after repetitive-stimulation of AL (more than 40 bursts repeated with a 1 sec inter-burst interval, and 30 pulses at 100 Hz per burst). The reduction of Ca2+ responses induced by 40 repeated bursts was maintained for at least 30min. However, 30 repeated bursts were not sufficient to induce the reduction of Ca2+ responses. Therefore, to form the reduction of Ca2+ responses in the MB is required for intense and/or continuous neuronal excitation. One of the Ca2+/calmodulin-dependent adenylyl cyclase, Rutabaga (Rut), is expressed in the MBs and Rut-dependent cAMP production is required for short-term memory induced by olfactory conditioning. Thus, we next examined whether rut mutations affect activity-dependent reduction of Ca2+ responses. The reduction of Ca2+ responses induced by repetitive-stimulation of AL completely disappeared in rut mutant flies. In addition, targeted expression of wild-type rut in the MB in rut mutant flies restored rut mutant phenotype. These results suggest that activity-dependent reduction of Ca2+ responses is formed by postsynaptic Rut-dependent cAMP production in *Drosophila* brain.

Title: *Drosophila* WDR40A is critical for synaptic growth and neurotransmitter release at the neuromuscular junction

Authors: *L. A. PATRON, M. IMAD, K. NAGATOMO, K. ZINSMAIER;
The Univ. of Arizona, Tucson, AZ

Abstract: We conducted a forward genetic screen to identify novel genes regulating neurotransmitter release. Two of the isolated lethal alleles, B332 and B417, mutate the *Drosophila* gene CG3313, which encodes an ortholog of the mammalian WD repeat-containing protein 40A (WDR40A). WDR40A belongs to a class of WD40-repeat proteins that likely serve as substrate adaptor proteins for the DDB1-CUL4 E3 ubiquitin ligase complex. *Drosophila* WDR40A (dWDR40A) is expressed in the cytoplasm and nucleus of neurons and muscles. In neurons, dWDR40A is especially enriched in axons and axon terminals, where it is found in close apposition to the plasma membrane. In neurons, dWDR40A levels in the nucleus are low. However, in mitotically active muscles, dWDR40A is strongly expressed in nuclei and enriched in foci that depend on the presence of CUL4 and DDB1, suggesting that dWDR40A can interact with the CUL4 ubiquitin ligase complex. dWDR40A mutant neuromuscular junctions (NMJs) show a reduction in the number of glutamatergic type I boutons and display abnormal octopaminergic type II axonal innervation. In addition, dWDR40A mutants exhibit a severe impairment of evoked neurotransmitter release to 30% of control flies. The defects in evoked release are partially rescued by presynaptic expression of normal dWDR40A protein. At higher stimulation frequencies (10 Hz), dWDR40A mutants show an initial facilitation of release that is sustained for ~1 min. Thereafter, evoked release gradually depresses to less than 40% of the original value. These data suggest that dWDR40A is critically required for presynaptic function and likely an important component of the machinery that facilitates the probability of evoked release, as well as SV trafficking and/or recycling. The structural synaptic defects cannot explain the more severe functional defects. Therefore, we propose that dWDR40A has 2 mechanistically independent synaptic roles. Notably, postsynaptic dWDR40A is part of an unknown trans-synaptic signaling mechanism that controls presynaptic dWDR40A protein levels at the fly NMJ. RNAi-mediated KD of dWDR40A in the muscle reduces dWDR40A protein levels in both the

muscle and the presynaptic motor neuron. Similarly, RNAi-mediated KD of DDB1 or CUL4 in the muscle reduces presynaptic dWDR40A levels. Ongoing experiments aim to identify the biological significance of dWDR40A-mediated trans-synaptic signaling and how it may regulate neurotransmitter release and/or synaptic growth.

Title: Protocadherin 17 (Pcdh17), a common target of MEF2 and FMRP, is required for MEF2-dependent synapse pruning

Authors: ***C. F. HALE**[1,2], C.-W. CHANG[2], K. Y. HUNG[3], J. C. DARNELL[3], K. M. HUBER[2], C. W. COWAN[1];
[1]Harvard Med. School, McLean Hosp., Belmont, MA; [2]UT-Southwestern Med. Ctr. at Dallas, Dallas, TX; [3]The Rockefeller Univ., New York, NY

Abstract: Synapses are formed during early brain development, but neuronal activity also promotes the elimination of synapses to either prune excess synapses or to homeostatically maintain a steady-state number of synaptic connections. The myocyte enhancer factor 2 (MEF2) transcription factors were recently identified as important activity-dependent regulators of synapse elimination in the developing and adult brain, findings that have been correlated with a role for MEF2 in mediating various behaviors, including learning and memory. Recently, we found that Fragile X Mental Retardation Protein (FMRP) is required for MEF2-dependent excitatory synapse elimination, suggesting that MEF2 and FMRP function together to regulate common transcripts to induce elimination of excitatory synapses. To examine this hypothesis, we utilized high-throughput sequencing of RNA isolated by crosslinking immunoprecipitation (HITS-CLIP) of FMRP to identify MEF2-regulated gene targets whose transcripts associate with FMRP in neurons. We identified a large overlap in MEF2 target genes and RNAs associated with

FMRP, consistent with their shared roles in synapse elimination. More specifically, we observed that one FMRP-associated mRNA coding for Protocadherin 17 (Pcdh17) is upregulated upon activation of MEF2, and it exhibits differential binding to FMRP following MEF2 activation. Pcdh17 is partially enriched at excitatory synapses in postnatal hippocampus, and we find that it is required for MEF2-induced dendritic spine elimination of hippocampal CA1 pyramidal neurons. However, reducing Pcdh17 levels in the absence of MEF2 activation did not alter structural or functional glutamatergic synapses, suggesting that regulation of Pcdh17 is necessary, but not sufficient, for regulating MEF2-induced synapse elimination. Ongoing studies are examining the molecular and cellular mechanisms by which Pcdh17 mediates MEF2-dependent synapse elimination.

Title: EZH2 regulates learning and memory via controlling the synaptogenesis in mouse brain

Authors: *M. ZHANG[1], C. LIU[2], S. XXX[2], Z. JIAO[2], F. ZHOU[2];
[1]Orthopeadic surgury, Johns Hopkins Univ., Baltimore, MD; [2]Orthopaedic surgery, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Polycomb group protein Ezh2 is an essential epigenetic regulator of embryonic and adult neurogenesis in mouse brain, but its role in the neuronal morphogenesis during development is unknown. We generated a novel conditional knockout mouse line (NEX-EZH2) in which Cre, under the control of the NEX promoter, drives the deletion of EZH2 specifically in early postmitotic, excitatory neurons of the developing brain. Here we show that loss of EZH2 impairs the spatial learning and memory ability of mice. In addition, in a small portion of postnatal EZH2 mutant mice, they show abnormal cortical layer morphology, as well as abnormal dendritic morphology. We found a substantial change in the density of dendritic spines, which play critical roles in synaptic transmission and plasticity. Taken together, our

results suggest that EZH2 functions in modulating synaptic plasticity and long-lasting changes of neural circuits, which in turn regulates learning and memory.

Title: The effect of sustained vs. transient epochs of irregular conditioning on inhibitory synaptic plasticity in visual cortex

Authors: ***G. DAVIS**[1,2], D. KALIKULOV[2], Q. FISCHER, Ph.D.[2], M. FRIEDLANDER[2,1]; [1]Virginia Tech. Carilion Sch. of Med., Roanoke, VA; [2]Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: A better understanding of the role of excitatory and inhibitory synaptic plasticity can contribute to improved design of strategies for deep brain stimulation. Many studies of inhibitory synaptic plasticity in visual cortex have used conditioning with high-frequency stimulation (~50 Hz) with equal distributions of inter-stimulus intervals. We sought to examine more natural stimulation patterns by using a lower frequency (10 Hz), applied in sustained or transient epochs, and with a highly irregular interstimulus interval distribution with a coefficient of variation (CV) of 1.0. Glutamatergic signaling was blocked with bath-applied (in uM) 50 D-AP5, 25 CNQX, 1 LY341495, 10 MPEP hydrochloride, and 30 LY367385. Inhibitory field potentials (FPs) were evoked by stimulation in layer 4 and recording in layer 2/3 in visual cortical slices of 10-12 week old LE rats. Slices under pharmacologic glutamatergic blockade that received a conditioning epoch at 10 Hz, CV=1, with 9 sub-epochs of 100 stimuli each separated by 8 equal rest intervals (transient, n=8) had a mean post-conditioning/pre-conditioning FP peak amplitude ratio of 0.92 (±0.06), with no significant change in the majority of experiments (n=6) and significant long term depression (LTD) in the minority of experiments (n=2). Slices under glutamatergic blockade stimulated at 10 Hz, CV=1, for 900 pulses over 90 seconds (sustained, n=8) had a mean

post/pre FP peak amplitude ratio of 1.05 (±0.06), with variable plasticity outcomes ranging from significant LTD (n=3) to no significant change (n=2) to significant long term potentiation (LTP) (n=3). Response latency was measured as the time between the stimulus and the FP peak amplitude. The sustained stimulation group experienced no change, but the transient stimulation group underwent an increase in average response latency from 1.90±0.10 msec to 2.02±0.17 msec (post/pre ratio 1.05, p=0.32). In conclusion, synaptic inhibition between layers 4 and 2/3 in rat visual cortex responds with weak LTD to periods of spaced, transient synaptic conditioning with medium frequency and irregular interstimulus intervals. Sustained epochs of otherwise similar conditioning lead to greater and more variable long term synaptic plasticity. Such specific effects on long term plasticity may be useful in better predicting how downstream neural circuits respond to sustained deep brain stimulation directed at cortical pathways.

Title: *In vivo* morphine exposure generates silent synapses

Authors: ***N. M. GRAZIANE**[1], Y. HUANG[2], Y. WANG[3], O. SCHLUETER[4], Y. DONG[1]; [1]Neurosci., [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [3]The Univ. of British Columbia, Vancouver, BC, Canada; [4]Göttingen Grad. Sch. for Neurosciences, Biophysics, and Mol. Biosci., Gottingen, Germany

Abstract: Morphine addiction is a debilitating problem, likely initiated as neuroadaptations in the brain's reward circuit. Cascades of cellular and circuit alterations ultimately leading to addictive phenotypes in vulnerable populations may be triggered by initial neuroadaptations that occur during drug exposure. Here, we demonstrate a prominent initial neuroadaptation following exposure to morphine. We show that AMPA receptor-silent glutamatergic synapses are generated on medium spiny neurons in the nucleus accumbens ventromedial shell, a brain region involved in the acute reinforcing effects of abused drugs. Using electrophysiological approaches in brain slices we found that *in vivo* morphine exposure gradually generated silent synapses on

nucleus accumbens medium spiny neurons reaching significance after five days. Since a synaptic pruning-like phenomenon is observed one month following morphine administration (Robinson et al., 2002), we investigated whether morphine-generated silent synapses were initiated by AMPAR internalization and subsequent synapse degeneration. To do this we administered GluR2-3Y peptide in order to block activity-dependent AMPA receptor endocytosis (Brebner et al., 2005). Systemic GluR2-3Y administration blocked morphine-generated silent synapses, while the scrambled control peptide had no effect. Our results suggest that silent synapses are generated by AMPAR internalization following morphine administration. This morphine-generated silent synapse mechanism may lead to downstream neuroadaptations such as synaptic pruning and re-arrangement of excitatory circuits within the nucleus accumbens.

Title: Chronic administration of the antidepressant fluoxetine predisposes hippocampal network to elevated plasticity

Authors: *D. POPOVA[1], T. TAIRA[2], E. CASTREN[3];
[1]Neurosci. Ctr., Helsinki, Finland; [2]Vet. Biosci., Helsinki University, Fac. of Vet. Med., Helsinki, Finland; [3]Neurosci. center, Helsinki, Finland

Abstract: Recent studies demonstrate that chronic administration of the antidepressant fluoxetine (FLX) promotes neurogenesis, synaptogenesis and synaptic plasticity in the hippocampus, cortex and amygdala. In the present study we have further investigated the cellular and molecular changes associated with the FLX administration in the mouse hippocampus. After 21 days of FLX exposure in 8-11 week old mice recordings of field excitatory postsynaptic potentials (fEPSPs) evoked by stimulation of Schaeffer collaterals in the area CA1were done in acutely prepared hippocampal slices. We found that the basic synaptic transmission was upregulated after the FLX treatment as indicated by increased input-output curve of the fEPSPs. Moreover, FLX treatment increase Pair-pulse ratio of the fEPSPs and resulted in elevated level of long-term potentiation (LTP) thus indicating changes in short- and long-term synaptic

plasticity. Western blot analysis done in hippocampal slices after induction and maintenance of LTP revealed that the levels of expression of key synaptic proteins (synaptophysin, synaptotagmin, PSD 93/95, CaMKII, ERK and CREB) were altered after the FLX treatment. Thus, chronic FLX administration accentuates activity-dependent plasticity in the mice hippocampus paralleled by changes in the key marker proteins of synaptic plasticity.

Abstract: Loss-of-function mutations in the PTEN-induced kinase 1 (PINK1) gene have been linked to early onset Parkinson Disease (PD). Compound PINK1 heterozygous mutations have been proposed as a susceptibility factor contributing to the risk of developing PD. Accordingly, homozygous PINK1 null mice (-/-) exhibit bidirectional striatal synaptic plasticity impairment, whereas heterozygous mice show only subtle plasticity changes, associated to a significant

decrease of evoked dopamine (DA) release (Kitada et al, 2007; Madeo et al 2014). In this work we investigated if the exposure of mice carrying the heterozygous mutation of PINK1 gene to low-dose pesticides precipitates bidirectional striatal synaptic plasticity alterations, mimicking the homozygous condition, by a multidisciplinary approach. Chronic treatment with low doses of pesticides, rotenone and paraquat (i.p. for 7 days respectively), did not cause any nigral or striatal neurodegeneration. Moreover, basal levels of both striatal and nigral ATP, measured by ATP bioluminescence assay were normal after chronic pesticides treatment. Electrophysiological recordings, by means of conventional sharp and patch clamp techniques, of striatal medium spiny neurons (MSNs) from chronically treated (+/-) mice revealed the complete loss of bidirectional corticostriatal plasticity, whereas electrophysiological properties of nigral dopaminergic neurons were unaffected. A pre-treatment with amphetamine, a compound able to increase the DA availability in the synaptic cleft, restored the plasticity deficits in chronic treated (+/-) mice, similarly to the plasticity rescue previously showed in (-/-) mice (Kitada et al, 2007). Interestingly, a preventive treatment with Trolox, an antioxidant agent able to counteract the mitochondrial oxidative stress, determined a fully rescue of corticostriatal plasticity abnormalities in (+/-) mice chronically treated, as well as in (-/-) mice. Our experimental data suggest that synaptic plasticity disruption might represent an early hallmark in familial parkinsonism determined by the interaction between genetic predisposition and exposure to environmental factors.

Abstract: FK506, classified as an immunosuppressant, has shown the neurotrophic function *in vitro* and also neuroprotective effect on some neurological injuries. We observed long-term changes in synaptic efficacy following electrical and/or pharmacological manipulation of synaptic function by using electrophysiological and histological assays. Through optical imaging, we investigated the effects of FK506 on synaptic plasticity in organotypic hippocampal slice culture (OHSC). Hippocampal slices of 6-7 day-old rats were obtained using a tissue chopper which were placed on a membrane insert. Significant delayed neuronal death (18 hr after kainic acid (KA) treatment) was quantified by propidium iodide, NeuN, and TUNEL staining. The neuronal death was prevented significantly at 24 hr after 0.1 μM FK506 treatment. In our electrophysiology study, optical signals were observed by long-term potentiation (LTP) followed by the stimulation of the Schaffer collateral pathway. The improvement in amount of LTP was found in the FK506-treated group. These results suggest that FK506 may have a beneficial role in the recovery of synaptic efficacy following KA-induced neuronal injury. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning (NRF-2013R1A1A4A01009332).

Title: Effect of interstimulus interval regularity and mild traumatic brain injury (mTBI) on synaptic plasticity outcomes in adult rat visual cortex

Authors: *Q. S. FISCHER, D. KALIKULOV, M. J. FRIEDLANDER;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Typical protocols for inducing synaptic plasticity use stimulus patterns with constant interstimulus intervals (ISIs), while neurons *in vivo* receive synaptic input with irregular ISIs. A study of more physiologically salient stimulation patterns is important to understand the role that irregularity may play in determining synaptic plasticity outcome. Here we evaluate how stimulus regularity influences the induction of synaptic plasticity in visual cortex of normal and mTBI rats. We applied a defined pattern of stimulation to layer 4 in acute slices and made whole cell recordings of evoked postsynaptic potentials (PSPs) from 99 layer 2/3 pyramidal cells in 10-12 week-old rats (2-3 weeks after mTBI). Conditioning stimulation consisted of 900 pulses at 1Hz with 1 of 3 different patterns of ISI regularity defined by the coefficient of variation (CV): regular (CV=0), slightly irregular (CV=0.2), or highly irregular (CV=1). Averaged PSP amplitudes evoked by 0.1Hz stimulation were measured before and after conditioning stimulation, and their ratio used to assess plasticity outcome. In controls, LTD was observed in 68% of cells for regular stimulation (n=25) and 74% of cells for slightly irregular stimulation (n=19), but in just 44% of cells for highly irregular stimulation (n=23). Plasticity (LTP or LTD) did not occur in 16% of cells for regular or slightly irregular stimulation, increasing to 39% of cells for highly irregular stimulation (remaining cells showed LTP). Notably, the distribution of plasticity outcomes was significantly different for slightly vs. highly irregular stimulation (KS test, $P<0.05$). In mTBI rats, LTD occurred in 100% of cells for slightly irregular stimulation (n=8), 64% of cells for highly irregular stimulation (n=11), and 39% of cells for regular stimulation (n=13). Plasticity did not occur in 39% of cells for regular stimulation, and 27% of cells for highly irregular stimulation (remaining cells showed LTP). Importantly, the distribution of plasticity outcomes was significantly different for slightly irregular vs. regular stimulation (t-test, $P<0.05$). We also compared the half width, rise time, tau decay rate, and latency of PSPs before and after conditioning stimulation. In controls, slightly irregular stimulation induced a significant increase in rise time and latency (t-test, $p<0.05$), while highly irregular stimulation induced a significant decrease in half width and tau decay rate (t-test, $p<0.05$). In contrast, mTBI rats showed no change in these parameters for any stimulus pattern. Our results suggest that stimulus regularity modifies the efficacy of synaptic plasticity induction and that mTBI can alter this interaction.

Title: Novel form of depolarization-induced depression of GABAergic IPSCs in the Purkinje cells

Authors: *H. SATOH[1], F. SAITOW[1,2], H. SUZUKI[1,2];
[1]Pharmacol., Nippon Med. Sch., Tokyo, Japan; [2]Japan Sci. and Technol. Agency, CREST, Tokyo, Japan

Abstract: It is well known that the elevation of intracellular Ca^{2+} caused by depolarization can induce various forms of synaptic plasticity of inhibitory transmission at the cerebellar Purkinje cell (PC). These are rebound potentiation, depolarization-induced suppression of inhibition and depolarization-induced potentiation of inhibition. However, all these studies employed high Cl^- pipette solution which can record $GABA_A$ receptor-mediated current as an inward current. In this study, we attempted to observe depolarization-induced synaptic plasticity of inhibitory transmission under more physiological condition. We performed the whole cell voltage-clamp recording with low Cl^- pipette solution using young rat cerebellar slices. The direction of evoked IPSC (eIPSC) changed from outward to inward immediately after PC depolarization. Thereafter, the amplitude of eIPSC was depressed (Depolarization-induced Depression of Inhibition: DDI) for more than 20 min in spite of pharmacological blocking the well established depolarization-induced synaptic plasticity of inhibitory transmission. Exploring the biophysical properties revealed that the reversal potential of GABA-mediated current was positively shifted. Thus, $[Cl^-]_i$ of PC was increased by depolarization pulses. Furthermore, this phenomenon was abolished by BAPTA, CaMKII inhibitor, calcium-activated chloride channel (CaCC) blockers and cation-chloride cotransporter (CCC) inhibitors. Hence, CaCC and CCC were responsible to the elevation of $[Cl^-]_i$ via CaMKII activation. Finally, we examined the effects of DDI action on the spontaneous spikes of PCs. After the repetitive stimulation of climbing fiber to depolarize PC, 50% of observations showed weakened exogenous GABA-mediated inhibitory action on the spike generation. Altogether, our finding is distinct postsynaptic mechanism from well established depolarization-induced plasticity of the GABAergic transmission at the cerebellar PCs.

Title: Homogenous thalamic input across layer 5 corticospinal subpopulations becomes biased toward task-relevant neurons following motor learning

Authors: *J. BIANE[1], J. M. CONNER[2], M. SCANZIANI[2], M. H. TUSZYNSKI[2,3];
[1]UC San Diego, LA JOLLA, CA; [2]UC San Diego, San Diego, CA; [3]VA Med. Ctr., La Jolla, CA

Abstract: Layer 5 neurons of the neocortex receive direct and relatively strong input from the thalamus. However, the intralaminar distribution of these inputs and their capacity for plasticity in adult animals are largely unknown. Here, we examine the allocation of thalamic input to distinct subpopulations of layer 5 corticospinal neurons, and whether such input is modulated following acquisition of a skilled motor behavior. In young adult rats, channelrhodopsin (ChR2) was expressed in pyramidal neurons of the motor thalamus via focal injection of AAV2-ChR2 into VA/VL. Approximately three weeks later, we simultaneously recorded from pairs of corticospinal neurons associated with control of distinct motor outputs - distal forelimb versus proximal forelimb - in slices containing primary motor cortex (M1). Despite known differences in dendritic morphology and baseline spine density between recorded corticospinal subpopulations, activation of thalamic afferents in M1 produced equivalent responses in monosynaptic excitation, suggesting thalamic resources are evenly dispersed across layer 5 corticospinal neurons under baseline conditions. Following 10 days of skilled forelimb grasp training, however, thalamocortical input was biased toward the subpopulation of task-relevant corticospinal neurons associated with control of the distal forelimb, inducing a greater excitatory response in these cells compared to corticospinal neurons controlling the proximal forelimb. The

underlying synaptic mechanisms of this alteration are currently under investigation. These findings elucidate modifications in synaptic signaling between thalamus and layer 5 cortex that support learning during adulthood.

Title: Expression of endocannabinoid biosynthesizing enzyme mrna and protein in hippocampal stratum oriens neurons

Authors: *L. N. FRIEND, C. B. MERRILL, R. C. WILLIAMSON, S. T. NEWTON, Z. H. HOPKINS, J. G. EDWARDS;
Brigham Young Univ., Provo, UT

Abstract: The hippocampus is thought to mediate learning and memory by altering the strength of synapses within its circuitry. In many cases, this synaptic plasticity can be induced by signaling molecules. Lipid-based signaling molecules called endocannabinoids, have been shown to modulate synaptic plasticity among hippocampal pyramidal cells and stratum radiatum interneurons; however, the role of endocannabinoids in mediating synaptic plasticity among interneurons in the stratum oriens is still unclear and indeed what mediates some forms of plasticity, including one novel form of LTP in these interneurons, has yet to be characterized. Our goal was to determine whether stratum oriens interneurons have the machinery necessary for endocannabinoid production and, if so, whether this machinery is expressed in a cell sub-type specific manner and can potentially modulate oriens interneuron activity. Using patch-clamp electrodes to extract single cells we analyzed the expression of endocannabinoid biosynthetic enzyme mRNA using RT-PCR. In this analysis, we examined cellular expression of two interneuron markers, GAD65 and GAD67, as well as several calcium-binding proteins and

neuropeptides to determine interneuron subtype. We analyzed cellular expression of several endocannabinoid biosynthetic enzymes, including N-acyl phosphatidylethanolamine phospholipase D (NAPE-PLD), diacylglycerol lipase alpha, and 12-lipoxygenase, as well as type I mGluRs. In addition, our data suggests that stratum oriens interneurons coexpress mRNA necessary for endocannabinoid biosynthetic enzymes with type I mGluRs. We identified interneurons that coexpress mRNA for somatostatin and diacylglycerol lipase as well as parvalbumin positive basket cells coexpressing NAPE-PLD, suggesting that both basket cells and O-LM cells, or another somatostatin-positive interneuron subtype possess the enzymes necessary to produce various endocannabinoids. In addition, using immunohistochemistry, interneurons were identified to express NAPE-PLD, DAGLα, and mGluR5 to show that target mRNA is converted to protein and that the targets are co-localized to GAD producing interneurons. Currently we are performing whole-cell electrophysiological experiments to examine the potential involvement of endocannabinoids in modulating stratum oriens interneuron activity.

Title: Ventral tegmental area dopamine and GABA neurons: Physiological properties and expression of mRNA for endocannabinoid biosynthetic enzymes and type I mGluRs

Authors: *C. B. MERRILL, L. N. FRIEND, S. T. NEWTON, Z. H. HOPKINS, J. G. EDWARDS;
PDBio, Brigham Young Univ., Provo, UT

Abstract: The ventral tegmental area (VTA) is known to control the processing of rewarding and addictive behaviors. The VTA contains dopamine (DA) cells, which release DA to

downstream targets in response to rewarding stimuli, and GABA cells, which modulate DA cell activity. Therefore, both cell types are involved in associative reward learning. Synaptic plasticity plays an important role in adaptive reward signaling within the VTA. Endocannabinoids can mediate or modulate synaptic plasticity at several synapses within the reward circuit. However, the source of endocannabinoids within the VTA is not well understood. Therefore, our goal was to describe the distribution of endocannabinoid biosynthetic enzyme mRNA within VTA neurons. We extracted single VTA neurons via whole cell patch clamp and used single-cell real-time quantitative PCR to identify DA and GABA neurons based on mRNA expression of cell-type specific targets. DA neurons were identified by the presence of tyrosine hydroxylase and DA transporter mRNA, while GABA neurons expressed GAD65 and GAD67 mRNA. Additionally, electrophysiological properties such as action potential frequency and sag potential amplitude were examined between the two cell types. Concurrent with established observations, slower firing frequencies and larger Ih potentials were observed in DAergic neurons, however overlap was identified between these two cell types. VTA neurons were then probed for endocannabinoid/eicosanoid biosynthetic enzyme mRNA, such as N-acyl-phosphatidylethanolamine-specific phospholipase D (NAPE-PLD), diacylglycerol lipase α (DAGLα), and 12-lipoxygenase. We also probed for type I metabotropic glutamate receptor (mGluR) mRNA, as endocannabinoid synthesis requires mGluR activation in many cases. Our data demonstrate that endocannabinoid biosynthetic enzyme mRNA is expressed in both DAergic and GABAergic cells with concurrent expression of type I mGluRs. Next, to ensure mRNA expression was representative of protein content, slices were stained using immunohistochemistry for GAD67, DAGLα, NAPE-PLD and type I mGluRs. Positive labeling for these targets was observed in VTA neurons, supporting our RT-PCR results. Collectively, these data suggest DAergic and GABAergic cells of the VTA have the capability to produce endocannabinoids and potentially alter synaptic plasticity involved in reward and addiction.

Title: Endocannabinoids mediate autocrine inhibition of hippocampal principal cells

Authors: *V. STEMPEL[1], A.-K. THEIS[1], U. PANNASCH[1], A. WOJTALLA[2], A. ZIMMER[2], D. SCHMITZ[1];

Abstract: Endocannabinoids (eCBs) exert major control over neuronal activity by activating G Protein-coupled cannabinoid receptors (CBRs). The functionality of the eCB system is primarily ascribed to the well-documented retrograde activation of presynaptically located CBRs. We find that action potential-driven release of the eCB 2-arachidonoylglycerol leads to a long-lasting membrane potential hyperpolarisation in hippocampal CA3 pyramidal cells. The hyperpolarisation can be mimicked and occluded by CBR agonists. In contrast to depolarisation-induced suppression of inhibition, this mechanism occurred in a purely autocrine manner, as suggested by dual recordings from neighbouring cells. To conclude, we describe an auto-regulatory plasticity in the hippocampus that emphasises the importance of CBR function in the central nervous system.

Title: STED microscopy of filamentous actin in the visual cortex of adult mice

Authors: *K. I. WILLIG[1,2], H. STEFFENS[1], W. WEGNER[2], C. GREGOR[1], S. W. HELL[1];
[1]NanoBiophotonics, Max-Planck-Institute for Biophysical Chem., Göttingen, Germany; [2]Ctr. for Nanoscale Microscopy and Mol. Physiol. of the Brain, Göttingen, Germany

Abstract: Two-photon microscopy and less extensive also confocal microscopy are widespread techniques to visualize fluorescently labeled cells in tissue. However, the limit of this technique is the diffraction limited resolution of about half of the wavelength of light (~200-350nm). This barrier had been overcome by a whole family of superresolution microscopy or nanoscopy concepts such as STED, RESOLFT, PALM, STORM etc. They all rely on modulating the fluorescence emission so that adjacent features fluoresce sequentially in time. From all the superresolution microscopy techniques, STED microscopy stands out for its imaging capabilities in tissue: It is live-cell compatible, especially when using standard fluorescent proteins such as EGFP or EYFP, it is able to record 3D images from inside transparent tissue, and the imaging speed is fast compared to other superresolution methods. Recently, we have developed an upright scanning STED microscope to image the dynamics of dendritic spines in the molecular layer of the visual cortex in a living mouse. We implemented virus infection methods (Semliki Forest Virus and Adeno-associated virus) to label filamentous actin in the living mouse with Lifeact, an actin binding peptide, and the yellow fluorescent protein (EYFP). We recorded actin in dendritic arborisation and spines with a resolution of 50 - 70 nm at a depth down to 40 µm. Here we present the use of red fluorescent proteins for *in vivo* STED microscopy which has several advantages: Due to the red-shifted laser light compared to the previously used EYFP settings we were able to observe morphological changes of filamentous actin over a time scale of hours without any sign of photo toxicity and only limited by photo bleaching. The higher scattering length of the red light enables further a better penetration depth. With red fluorescent proteins we recorded morphological changes of actin over hours in the living mouse. These results show that STED microscopy becomes a valuable tool to study morphological changes in the living mouse brain.

Title: Disrupting PSD-95-mediated protein-protein interaction in neonatal rats impairs hippocampal neuronal function, learning, and memory

Authors: *O. FURMANSKI[1], C. LI[3], Y. YANG[2], Y. SATO[4], Q. CHEN[5], P. TANG[5], F. TAO[1], R. A. JOHNS[1];
[1]Anesthesiol. & CCM, [2]Kennedy Krieger Inst., Johns Hopkins Univ. Abstract: Introduction: Evidence from human and animal studies suggests that early postnatal anesthesia, using agents such as isoflurane (ISO), causes long-term impairment of learning and memory. These cognitive deficits in animals correlate with mitochondrial dysfunction, reduced neuronal complexity, and hippocampal cell death. However, the mechanisms of ISO toxicity remain poorly understood. Previously, we have shown via biochemical techniques that ISO inhibits N-methyl-D-aspartate (NMDA) receptor interaction with PSD-95 in a dose-dependent manner. We hypothesize that disrupting interactions between NMDA receptors and the PDZ2 domain of PSD-95 during development may impair cognition later in life. Methods: Male Sprague-Dawley rats were exposed to vehicle air (VA) control or 3.4% ISO for 4 hours on either postnatal day (PND) 7 or 60. Animals were tested for spatial and auditory memory in a fear conditioning paradigm. Animals were sacrificed 7 days later, and brains were processed for either electron microscopy or immunofluorescence. Acute hippocampal slices were prepared from animals exposed to VA or ISO and sacrificed 7 days later. Hippocampal long-term potentiation (LTP) was recorded at Schaffer collateral synapses on CA1 pyramidal neurons using whole-cell patch clamping. Finally, cultured hippocampal neurons were exposed to VA or ISO for 4 hours after either 7 or 14 days *in vitro* (DIV). Cultures were stopped on DIV15 for staining and microscopy. Results: ISO impaired hippocampus-dependent spatial fear memory and reduced cell proliferation in the hippocampi of rats treated on PND7, but not on PND60. Electron microscopy revealed that ISO reduced synaptic contacts and disrupted mitochondrial membranes on PND7 but not PND60. Western blotting showed that the actin-associated protein drebrin was reduced in the hippocampus after PND7 ISO, suggesting impaired postsynaptic spine development. To further examine the effects of disrupting NMDAR-PSD-95 interactions, recombinant PSD-95 PDZ domain 2 was conjugated to the cell-permeable Tat peptide (Tat-PDZ2). Tat-PDZ2 inhibited LTP in juvenile mouse hippocampal slices, and ISO in rats inhibited LTP after PND7 treatment but not after PND60. Recent data suggest that ISO and/or Tat-PDZ2 treatment in cultured hippocampal neurons rapidly and persistently reduced immunofluorescent staining for drebrin. Conclusions: These data show that PSD-95-mediated protein-protein interactions are important to the proper development and function of hippocampal neurons.

Disrupting PSD-95 binding to NMDA receptors is one possible mechanism by which ISO could impair synaptic function, synaptogenesis, and neurogenesis.

Title: Modulation of heterosynaptic plasticity by adenosine receptors in the rat neocortex *in vitro*

Authors: ***N. M. BANNON**, M. CHISTYAKOVA, M. VOLGUSHEV;
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Heterosynaptic plasticity can be induced in neocortical neurons by intracellular tetanization: bursts of spikes in the postsynaptic cell induced by depolarizing current pulses in the absence of presynaptic stimulation. Intracellular tetanization can result in potentiation, depression, or no change, depending on the initial paired-pulse ratio (PPR). Generally, synapses with a high release probability (low initial PPR) depress, while synapses with a low release probability (high PPR) potentiate. The dependence of the plastic change on the initial state of the synapse implicates a retrograde messenger which confers information about postsynaptic spiking to the presynaptic terminal. Adenosine is released from neurons and glial cells in an activity-dependent manner, modulating synaptic transmission by acting on pre and postsynaptic receptors. Because induction of heterosynaptic plasticity depends on release probability, we asked whether manipulation of adenosine receptors can modulate susceptibility of synapses for plastic changes. To test this, we made *in vitro* whole-cell recordings from layer 2/3 pyramidal neurons in slices of rat visual cortex and studied synaptic responses evoked with two pairs of stimulating electrodes placed in layer 4. After recording control EPSPs for 9-13 min, synaptic stimulation was stopped and intracellular tetanization applied to the cell, consisting of three trains (1/min) of ten bursts (1 Hz) of five pulses (5 ms, 100 Hz, 0.4-1.1 nA). The current intensity evoked 4-5 spikes per burst. Following tetanization, synaptic stimulation was resumed, and evoked EPSPs were recorded for 40-50 min. We compared the induction of heterosynaptic

plasticity under conditions of normal artificial cerebral spinal fluid, and with 20uM adenosine or 30nM of the selective A1R antagonist 8-Cyclopentyl-1,3-dipropylxanthine (DPCPX) added to the recording medium. Adenosine increased the median PPR during the control period, suggesting a reduction in release probability. The dependence of plastic changes on initial release probability, and a negative correlation between changes of EPSP amplitude and changes of the PPR were maintained on the background of adenosine. Under A1R blockade, inputs still showed potentiation, depression, or no change, but the dependence of changes on the initial PPR was abolished. This suggests that biochemical cascades activated by adenosine are not directly interacting with the mechanism by which long term changes are expressed and maintained, but rather adenosine receptor signaling serves a modulatory role, linking the initial state of the presynaptic input to the outcome of intracellular tetanization.

Title: Mechanisms underlying thalamocortical phase-amplitude switches due to the anaesthetic propofol

Authors: ***A. SOPLATA**[1], S. LEE[3], S. CHING[4], E. BROWN[5,6,7], P. PURDON[7,6], N. KOPELL[2]; [1]Grad. Program in Neurosci., [2]Mathematics, Boston Univ., Boston, MA; [3]Dept. of Neurosci., Brown Univ., Providence, RI; [4]Electrical and Systems Engin., Washington Univ. in St. Louis, Saint Louis, MO; [5]Dept. of Brain and Cognitive Sciences, MIT-Harvard Div. of Hlth. Sci. and Technol., MIT, Cambridge, MA; [6]Harvard Med. Sch., Boston, MA; [7]Dept. of Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: Thalamocortical dynamics display highly detectable signals associated with state changes of consciousness. Many different anesthetics can induce unconsciousness, and their spectral characteristics are often even more differentiated than those between the multiple stages of non-REM sleep. Propofol, a common anesthetic that acts as a GABA-A agonist and hyperpolarization-activated current (H-current) suppressor, has been shown to produce a

dynamic phase-amplitude coupling between alpha (8-14 Hz) and slow wave (0.1-1 Hz) rhythms (Purdon et al., 2013) in human EEG recordings. At approximately the time that the subject loses consciousness, "trough-max" coupling occurs, in which alpha power peaks at the trough of the thalamocortical slow wave (i.e., the cortical OFF state), while during full unconsciousness, there is "peak-max" coupling in which alpha power is highest at the peak of the slow wave (i.e., the cortical ON state). Building on previous models for alpha generation under propofol (Ching et al., 2010) that inherit from thalamic models (Destexhe et al., 1996), we have used a computational model to explore how propofol-induced changes in baseline voltage, the decay time of the GABA-A induced inhibition, and the maximal conductance of the H-current (gH) change the phase of the alpha rhythm in a cortically-generated slow-wave rhythm. We found that the predominant reason for the switch from trough-max to peak-max is the propofol-induced reduction of gH, as decreasing this current changes the interaction between the latter and the T-type Calcium bursting current, which is key for many thalamic oscillations (Destexhe et al., 1996). When the thalamus is hyperpolarized enough to burst, modeling an increase in the maximal conductance and time scale of decay of inhibition can increase the frequency of spontaneous thalamic bursting, but these, as well as direct hyperpolarization and modulation of potassium leakage strength, are all insufficient for generating the full range of the phase-amplitude coupling. The results of this model illustrate the level of complexity in the mechanisms by which anesthetics modulate brain interactions. Ching, S., et al. Thalamocortical model for a propofol-induced alpha-rhythm associated with loss of consciousness. PNAS December 13, 2010, doi:10.1073/pnas.1017069108 Destexhe, A., et al. (1996). Title: Layered architecture shapes context-dependent response and input integration of a cortical circuit

Authors: *M. HELMER[1,2], X.-J. CHEN[3], W. WEI[4], F. WOLF[1,2], D. BATTAGLIA[5,1]; [1]BCCN Goettingen, Goettingen, Germany; [2]Dept. of Nonlinear Dynamics, Max Planck Inst. for Dynamics and Self-Organization, Göttingen, Germany; [3]Psychology Dept., Brandeis Univ., Waltham, MA; [4]Ctr. for Neural Sci., New York Univ., New York, NY; [5]Inst. de Neurosciences des Systèmes, Aix-Marseille Univ., Marseille, France

Abstract: Lamination is a landmark feature of cortical architecture. But even if functional specializations of individual layers have been suggested (Raizada & Grossberg 2003; Hirsch & Martinez 2006), the role played by interlayer connections in shaping the dynamical responses of a cortical column has not yet been fully elucidated. Here, we analyze a mean-field model of a cortical column, embedding realistic interlayer connections (the one-column "connectome" of Binzegger et al. 2004). Systematically varying efficacy of excitation and inhibition in the model we find phase diagrams showing a great diversity of possible dynamical regimes. In particular, due to the presence of delayed inhibition and the interaction of layers, oscillations can be generated. Oscillations in different layers may be phase-locked or phase-precessing and have different frequencies. In some regions of the phase diagrams high frequencies (gamma-like) predominate in L23 while low beta-like frequencies predominate in L5. Remarkably, while this experimentally observed tendency is usually attributed to the different cortical sources to different layers, here it arises spontaneously in an isolated model column, resulting from the multilayer connectivity. The column is thus intrinsically predisposed to communication-through-coherence processes over multiple frequency bands. Furthermore, we find that horizontal or top-down currents, mediating perceptual context information, are non-linearly amplified and that vertical inter-layer interactions alone already contribute to contextual modulations of the column response, besides other interactions here not explicitly modeled. Our model predicts inter-layer competition behaviors which could be probed experimentally by selective optogenetic (in)activation techniques. Finally, the robustness of our findings is discussed by comparison with alternative wiring diagrams.

Title: Dynamics of cortical circuits lead to switching resting state functional connectivity

Authors: *V. K. JIRSA[1], E. HANSEN[1], A. SPIEGLER[1], G. DECO[2], D. BATTAGLIA[1,3]; [1]Faculté de Médecine, Inst. De Neurosciences Des Systemes, Marseille, France; [2]Univ. Pompeu Fabra, Barcelona, Spain; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: Functional connectivity opens a window on the interactions between different brain regions. Besides basic research, it is clinically relevant for applications in Alzheimer's disease, schizophrenia, presurgical planning, epilepsy, and traumatic brain injury. Simulations of whole-brain mean-field computational models with realistic connectivity determined by tractography studies enable us to reproduce average functional connectivity in the resting state with remarkable accuracy. Previous computational studies, however, did not address the prominent non-stationarity in resting state functional connectivity, which may result in large intra- and inter subject variability and thus preclude an accurate individual predictability. As we show here, this non-stationarity reveals a rich structure, characterized by rapid transitions switching between a few discrete functional connectivity states. We show that state-of-the-art computational models fail to reproduce these spontaneous state transitions and, thus, are not qualitatively superior to simplified linear stochastic models, which account for the effects of structure alone. We then demonstrate that a slight enhancement of the non-linearity of the network nodes is sufficient to vastly broaden the repertoire of possible network behaviors, leading to modes of fluctuations which are strongly reminiscent of some of the most frequently observed Resting State Networks. Because of the noise-driven exploration of this dynamical as well as functional repertoire, the dynamics of functional connectivity changes now qualitatively and displays non-stationary switching as in empirical resting state recordings. It thus bears promise to serve as a better biomarker of resting state dynamics.

Title: Spatio-temporal dynamics of low frequency oscillations in resting-state fMRI

Authors: *D. MASTROVITO, S. HANSON, C. HANSON;
Rutgers Univ., Newark, NJ

Abstract: Resting-state fMRI has been shown to capture intrinsic fluctuations in brain activity. These fluctuations are thought to mediate long distance neuronal synchronization and have a characteristic power spectrum dominated by low frequency oscillations (<.1 Hz). Using techniques such as correlation-based functional connectivity analysis, studies have identified structure in resting-state time series related to functional networks. However, functional connectivity analysis assumes temporal stationarity of the MRI time series and provides no indication of asymptotic convergence. Evidence suggests that functional connectivity changes over time, however few studies have attempted to characterize the spatio-temproal dynamics of resting-state functional connectivity. Those that have, employed techniques such as PCA or ICA that force constraints such as orthogonality or statistical independence on the data that may not be true of the underlying signals. The current study explores the dynamics of resting-state functional connectivity using state-of-the-art high temporal resolution multiband resting-state functional magnetic resonance imaging (rsFMRI) (TR = 645 msec). 63 lateralized regions of interest (ROIs) from the Montreal Neurological Institute (MNI) 2mm atlas were selected based on their high power in the low frequency band between .02 and .1 Hz as indicated by Fourier analysis. Temporal dynamics of the relationships between each of the 63 ROIs were explored using continuous wavelet transform. Wavelet analysis reveals changes in spectral power for each ROI over time, which were then mapped into an audible frequency range. Additionally, using these identified ROIs, sliding window correlations were used as an input similarity measure to map the ROIs into a 3 dimensional non-parametric multidimensional scaling (MDS-Kruskal-Shepard) space. A solution recovering 3 dimensions was able to account for 90 percent of the variation in the time series and provided a spatial visualization of the resting state network as it evolved over time. The resultant visualization of the ROI dynamics showed a highly structured

interplay between ROIs with periodic local collapse of ROIs towards the center of the space and subsequent expansion.

Title: Structural architecture supports local and global functional interactions in healthy aging

Authors: ***J. ZIMMERMANN**[1], R. MCINTOSH[1], P. RITTER[2], S. ROTHMEIER[2], M. SCHIRNER[2];
[1]Rotman Res. Inst., Toronto, ON, Canada; [2]Dept. Neurology, Charité - Univ. Med., Berlin, Germany

Abstract: Neuroscience research suggests that local and global functional interactions throughout the human brain are modulated by the underlying anatomical architecture. Age-related changes of anatomical tracts suggests a potential for concommitant changes in the structure-function relationship. We compared functional connectivity inferred from spontaneous BOLD fMRI with structural connectivity inferred from DTI among 49 participants between 18 and 82 years of age. Using multivariate Partial Least Squares analysis, we noted that the density of individual axonal tracts (r = .82, p <.01, 95% CI [0.77, .90]), and strength of functional interactions between regions (r = 0.54, p < .01, 95% CI [0.53, 0.82]) changed in the aging process. Although the direction of change was region-dependent, the majority of structural and functional connections decreased with age. Interestingly, we observed that structure-function correlations *(*individual participants: r = 0.19 to 0.36, and r = -0.40 to 0.66, for whole network and regionwise respectively), vary across the age spectrum*(r* = 0.69, p < .01, 95% CI [0.68, 0.83]), and that these differences varied by region. We also examined how the structural architecture upholds the functional modular organization, and whether this changes with age. First, the relationship between structure and function across modules was assessed with the participation coefficient function in the Brain Connectivity Toolbox (https://sites.google.com/site/bctnet/Home). The degree to which a region participates outside its functionally-defined module was significantly correlated with how structurally connected it was outside of its structural module (r = .32, p < .05). In a second analysis, we examined how

structure supports within-module function. We partitioned the structural network according to the modular organization of the functional network, and calculated the density (proportion of existing connections to all possible connections), and subsequently the Modularity Index (MI was quantified as the difference between density in the functionally defined structural partitions and the density across the entire structural network) of each region. MI's were significantly > 0 (t = 2.69, p < .01), such that regions were more densely connected within their functionally defined module, and MI's varied with age (r = 0.73, p < .01, CI [0.71, 0.85]) depending on region. For the first time, we provide a comprehensive view of how anatomical connectivity throughout the brain modulates regionwise functional interactions, intermodular integration, and community segregation changes in healthy aging.

Title: Brain state-dependent liquid information processing

Authors: *D. BATTAGLIA[1,2], P. QUILICHINI[1], C. BERNARD[1];
[1]INS, Univ. Aix-Marseille, Marseille, France; [2]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany

Abstract: How does information flow through cortical networks: via fixed and discrete internal pathways or via routes that are continuously dynamically reconfigured? Here we show, through information theoretical analysis of LFP and single unit recordings, that functional connectivity maps between entorhinal cortex neurons display dynamic reconfiguration between theta and slow oscillations *in vivo*. At the level of field potentials, the flow information follows fixed paths within and between cortical layers in a brain state-dependent manner. In contrast, at the single

cell level, the information flows in continuously reconfiguring networks, without changing the global amount of transferred information. We conclude that information processing operates differently at different scales: it is "liquid" at the neuronal scale, whilst it follows stable pathways at the network scale. Both modus operandi are brain-state specific, with theta oscillations being associated generally to enhanced information transmission between cortical layers.

Title: Functional connectivity of the claustrum during resting wakefulness

Authors: *D. H. RESER[1], S. C. KOLBE[2];
[1]Dept. of Physiol., Monash Univ., Clayton, Australia; [2]Anat. and Neurosci., Univ. of Melbourne, Melbourne, Australia

Abstract: Despite widespread connectivity with sensory and motor control areas of the cerebral cortex, the role of the claustrum in normal and pathological brain function remains unclear. We have recently proposed that the claustrum may be involved in regulation or transition among functional networks of the cerebral cortex. Here we examined the resting state functional connectivity (FC) of the left and right claustrum using voxelwise correlation analysis seeded from regions of interest (ROIs) in 13 right handed healthy subjects (6m/7f, mean ± SD age = 32 ± 4.7yrs). Subjects were scanned at 3T (Skyra, Siemens, Erlangen) while viewing a blank (grey) screen with eyes open. Regions of interest were manually drawn on high-resolution T1-weighted scans of each subject and linearly registered to each subject's functional MRI scans using FLIRT (FMRIB, Oxford). Seed-based connectivity maps of the whole brain were calculated for each subject and non-linearly transformed to the MNI atlas using ANTs (PICSL, UPenn) to create a group average connectivity map. Analysis of the average resting state connectivity of the claustrum yielded a pattern of bilaterally symmetrical connectivity with areas of peak correlation

in sensory cortices (visual, auditory and somatosensory), spatial attention areas (frontal eye fields, parietal cortex), supplementary motor areas, dorso-lateral prefrontal cortex, insula, and medial thalamus. Overall, connectivity was stronger in the hemisphere ipsilateral to the seed. However, the patterns of connectivity from left and right claustrum were highly consistent between hemispheres. The resulting connectivity maps coincide well with recent descriptions of the FC between visual cortex and the salience network as measured during the eyes open condition (Riedl et al., J. Neurosci. 2014. 34(18):6260-6266). Our data indicate that the claustrum may be a ripe target for analysis of FC in resting state networks, and indicate the need to differentiate activity in the claustrum from that of surrounding structures in future imaging studies.

Title: Targeted enhancement of hippocampal brain networks and associative memory with transcranial magnetic stimulation

Authors: *J. X. WANG[1,2], K. L. BRANDSTATT[1,2], E. Z. GROSS[1,2,4], A. J. RYALS[1,2], L. M. ROGERS[5], M. DOKUCU[3], M. S. HERMILLER[2], J. L. VOSS[1,2];

Abstract: Few findings substantiate the influential notion that the hippocampus supports associative memory by binding together elements of experience that are individually processed by distributed brain regions. We explored the causal role of hippocampus by using noninvasive electromagnetic stimulation of human hippocampal brain networks to identify changes in associative memory caused by enhancing the interactivity of hippocampus with distributed

regions. Individualized measures of intrinsic functional connectivity of hippocampus were used to locate subject-specific stimulation targets. A total of 16 subjects participated in our experimental design that counterbalanced one week of treatment stimulation with one week of sham control stimulation. Target sites were stimulated with repetitive transcranial magnetic stimulation (rTMS) for a total of five daily sessions. Stimulation increased functional connectivity within hippocampal networks versus the sham condition, and this was associated with selective improvements in associative memory performance that outlasted the period of stimulation by ~24 hours. Furthermore, treatment-induced changes in seed-based connectivity with respect to hippocampal targets were spatially selective to individual target locations. No improvements were identified for tests of attention, language, and perceptual functions. These findings demonstrate that hippocampal brain networks and associative memory can be enhanced in humans using noninvasive stimulation, providing direct evidence that hippocampal interactivity with distributed regions plays a causal role in associative memory.

Title: Origin of resting state slow spontaneous neuronal oscillations in brain networks

Authors: ***G. P. KRISHNAN**[1], O. GONZALEZ[2], M. BAZHENOV[2];
[1]Univ. of California, Riverside, Riverside, CA; [2]Univ. of California, Riverside, CA

Abstract: Resting or baseline brain activity occurring at very low frequencies (0.01-0.1 Hz) has been observed in fMRI and EEG recordings. These oscillations were found to be correlated across brain regions and are thought to reflect functional connectivity between interacting areas of the brain. Here, we used a biophysically realistic, conductance based cortical network model

to show that spontaneous very slow oscillations (less than 0.1 Hz) may rise from the ion concentration dynamics. The model included ion concentration dynamics for intra- and extracellular K+ and Na+ and intracellular Cl-, Na+/K+ exchange pump, and KCC2 pump. A random Poisson input was applied to each neuron to mimic *in vivo* conditions. Our study revealed that network oscillation around 0.01-0.05 Hz arises from progressive slow accumulation of extracellular [K+] and its removal. The network oscillations were more prominent in larger network as compared to the smaller networks, and the amplitude of oscillations depended on the random input to the network. While K+ dynamics and diffusion contributed to the local synchrony, long-range synaptic connectivity provided correlated activity between distinct populations of neurons. This finding may explain observation that long-range synaptic connectivity influences the correlation between locally generated oscillations in remote cortical regions. We conclude that the ion concentration dynamics and long-range connections may originate the very slow large-scale spontaneous fluctuations of brain activity found with fMRI recordings.

Title: Correlated variability in a network model of primary visual cortex

Authors: *R. MEYER[1,2], K. OBERMAYER[1,2];
[1]Fakultät IV, Technische Univ. Berlin, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci. Berlin, Berlin, Germany

Abstract: Cortical neurons are organized into functional columns, where individual cells share many common inputs. Correlated trial-to-trial variability among the activity of cortical neurons is believed to be influenced by the functional and anatomical connectivity of a cortical circuit. There is experimental evidence that correlated variability varies between different layers of primary visual cortex [1]. Here we investigate the hypothesis that correlations of trial-to-trial variability depend on the topology of a neural network as proposed by [1]. We simulate a

network of inhibitory and excitatory Hodgkin-Huxley neurons receiving tuned afferent stimulus input as in [2]. We measure correlated trial-to-trial variability and systematically vary the recurrent connectivity spread as well as recurrent synaptic strengths. Our findings suggest that besides the connectivity profile, correlated trial-to-trial variability is most strongly modulated by the recurrent connectivity strength of a network. As previously shown, balance of excitatory and inhibitory recurrent activity can actively decorrelate neural responses [3]. Accordingly, we observe correlated activity in network regimes where the balance between excitation and inhibition is broken and excitatory recurrent activity is slightly stronger than the inhibitory one. Moreover, networks operating in regimes with correlated responses undergo a substantial change in behaviour where individual neurons show fast spiking variability and slow changes in rate dynamics where average activity oscillates, comparable to findings in [4]. Title: Are spontaneous oscillatory brain dynamics impacted by the gastric slow-wave? An investigation of cerebro-gastric coupling

Authors: *C. G. RICHTER[1], M. BABO-REBELO[1], A. DUCORPS[2], C. TALLON-BAUDRY[1]; [1]Lab. de Neurosciences Cognitives, L'Ecole Normale Superieure, Paris, France; [2]CENIR - Ctr. de Neuroimagerie de Recherche, Paris, France

Abstract: Spontaneous brain activity is highly structured in space, time and frequency, and impacts both neural processing and behavior. It is usually considered that the structure of spontaneous brain dynamics derives solely from constraints intrinsic to the brain. Here, we examine an alternative view: spontaneous brain dynamics could also be influenced by an extra-cerebral pacemaker. The stomach wall contains cells (interstitial cells of Cajal, or ICCs) that have an intrinsic pacemaker activity giving rise to a stable ~ 0.05 Hz electrical oscillation (the gastric slow-wave) in healthy adults. Because the ICC matrix and brain are anatomically densely interconnected via ascending and descending neural pathways, we hypothesized that the low frequency activity originating in the stomach may be functionally coupled with spontaneous brain dynamics. Indeed, it is known that the amplitude of brain rhythms, in particular in the alpha (8-12 Hz) and beta (14-30 Hz) ranges, spontaneously waxes and wanes very slowly. We test here whether the infra-slow modulation (0.01-1Hz) of brain rhythms is coupled to the stomach pacemaker. To assess this coupling we simultaneously recorded the electrogastrogram (EGG) from electrodes placed over the abdominal surface and magnetoencephalogram (MEG) in 18 healthy human subjects (9 females) during 12 minutes of resting fixation. The gastric-slow wave was identified from the EGG of each subject (mean frequency, 0.046 Hz ± 0.001 s.e.m.). We then assessed phase amplitude coupling (PAC) between the amplitude envelopes of MEG activity in the 1 – 15 Hz range, and the EGG phase, using the coefficient of variation as a modulation index over each MEG sensor, envelope frequency, and subject. Using a cluster-based randomization procedure, we tested for a group effect by comparing these values to the median values obtained from a surrogate distribution produced via rotating the relationship between the EGG and MEG data by a value greater than +/-3 cycles of each subject's gastric slow-wave peak frequency. This resulted in a significant cluster (cluster statistic = 86.21, p = 0.004) of EGG-MEG modulation of 10 - 11 Hz oscillatory activity, lateralized to the left-hemisphere. These results indicate that cerebro-gastric coupling is a significant contributor to alpha rhythm amplitude variability.

Title: Extracellular field contributions to a globally conscious brain

Authors: *E. TOGNOLI[1], J. KELSO[2,3];
[1]Ctr. for Complex Systems & Brai, Boca Raton, FL; [2]Ctr. for Complex Systems & Brai, Florida Atlantic Univ., Boca Raton, FL; [3]Intelligent Syst. Res. Ctr., Univ. of Ulster, Derry, United Kingdom

Abstract: Brain function depends on the rapid exchange of information across spatially-dispersed neural ensembles. It is well established that information is communicated proximally by virtue of synaptic connections: one neural structure -the dendrite- receives the information that another- the axon- emits. In this scenario, information exchange between distant neural groups suffers delays of tens of milliseconds. Here, we raise the theoretical possibility that some neurons attune themselves to extracellular brain fields, such that local neural ensembles are near instantaneously informed of the global pattern of brain activity. On the extracellular side, dendrites are exposed to a local ionic environment that changes over time under the influence of proximal synaptic release and global activity-dependent electromagnetic fluctuations. Fluctuations arising from local synapses have the largest magnitude and as such have received most experimental attention. Nevertheless, fluctuations of extracellular fields driven by the activity of distant neural populations have the potential to convey information. We explore the possibility that neurons are directionally tuned to remote neural populations, by sampling extracellular field gradients with their tridimensional -spatially extended- dendritic arborescence. Recent empirical evidence (ephaptic coupling, dendritic computation, extracellular volume/consciousness connection) renders this hypothesis plausible, with implications for both empirical and theoretical neuroscience. In particular, it is argued that the Extracellular Field hypothesis has potentially profound consequences for artificial neural networks and for brain in silico: for both implementations, the spatial arrangement of neural populations, distance and orientation, have yet to be included as key variables. This hypothesis may also shed new light on spatial transformations occurring in the evolving and developing brain: a directionally favorable arrangement of neural ensembles may help explain idiosyncrasies in human performance.

[5]Macau Inst. Applied Res. in Med. and Hlth., Macau Univ. of Sci. and Technol., Macau SAR, China

Abstract: Effects of anesthetics on tau phosphorylation have received increasingly attention in these years. Most of the studies have shown that anesthetics-induced hypothermia is a key factor for inducing hyperphosphorylation of tau. Among different anesthetics, dexmedetomidine is widely used in different types of surgery and as sedative in Intensive Care Unit. It is not a conventional anesthetic agent in which its action is independent of GABA receptor. Its action mechanism is via the alpha-2 adrenergic receptor. However, it is unclear of whether dexmedetomidine can also trigger phosphorylation of tau. The major purpose of this study is to investigate its effects on tau phosphorylation in neurons. We hypothesize that dexmedetomidine can promote tau phosphorylation. We had established both *in vitro* and *in vivo* experiments for this study. Primary culture of cortical neurons established from Sprague-Dawley (SD) rat embryos were exposed to dexmedetomidine for 1 or 6 h; and the levels of tau phosphorylation at the AT8, AT180 and S396 sites were assessed by Western-blot analysis. To assess and compare their relative *in vivo* effects, the same agent was administered intravenously to 8 - 10 week-old male SD rats and titrated to the loss of the righting reflex for 2 h. After 1 h of recovery, the rats were euthanized and tissues from the cortex and hippocampus were harvested for Western-blot and immunohistochemical analysis. The *in vitro* studies revealed significant phosphorylation only at the S396 site; but such changes returned to normal level at 6 h. With temperature control, dexmedetomidine significantly induced increase in phosphorylation at AT8 site in the cortex and hippocampus and at AT180 in the hippocampus. The direct effect of anesthetic agents on differentiated cortical neurons was epitope specific and short lived. Its effects in rats were more complicated and depended not only on the phosphorylation site but the regions of the brain. While hypothermia has been considered to play important roles in inducing phosphorylation of tau, our findings suggest that dexmedetomidine can induce tau phosphorylation under normothermic conditions. Further studies are warranted to determine the long-term impact of this anesthetic on tau pathology and even cognitive functions.

Title: Tau accumulation is regulated by RNA translation: A role for stress granules in tauopathies

Authors: *D. APICCO, T. VANDERWEYDE, P. ASH, B. WOLOZIN;
Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

Abstract: Pathological accumulation of microtubule associated protein tau is a key feature of various neurodegenerative disorders, including Alzheimer's disease (AD) and frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), which are collectively referred to as tauopathies. However, the cellular processes that regulate tau accumulation in disease remain unclear. Here, we demonstrate a role for RNA binding proteins (RBPs) associated with stress granules (SGs) in promoting tau pathology. SGs are cytoplasmic complexes of RNA and protein that form in response to stress-induced inhibition of RNA translation. Immunohistochemistry showed that SGs are highly prevalent in AD, FTDP-17, and rTg4510 transgenic mouse cortical tissues compared to control tissues, and that RBPs associated with SGs, particularly T cell intracellular antigen 1 (TIA-1), strongly co-localize with phosphorylation and conformational tau epitopes associated with disease (recognized by PHF1 and MC1 antibodies, respectively). In immortalized hippocampal neurons, overexpression of TIA-1 led to co-localization of TIA-1 with MC1-positive tau and increased the number and size of MC1-positive tau inclusions. The effect of TIA-1 was attenuated by expression of a tau construct with 14 serine/threonine residues mutated to alanine, indicating that phosphorylation of tau is required for the interaction with TIA-1. A kinase inhibitor screen of tau kinases associated with AD identified p38 MAPK as a critical regulator of the association of tau with SGs. Since SG formation requires translational inhibition, we investigated the effect of modulating RNA translation on tau using two translation inhibitors with distinct mechanisms of action: puromycin, which causes premature chain termination leading to SG formation, and cycloheximide, which blocks chain elongation but does not induce SGs. Interestingly, puromycin treatment increased the level of total and MC1-positive tau while cycloheximide had no effect on tau levels. In contrast, stimulation of RNA translation by GADD34 overexpression reduced tau levels. These results show that tau accumulation is regulated by the translational machinery and suggest that

the disease-associated phosphorylation of tau contributes to a biochemical pathway that regulates the response of RBPs to stress, highlighting a central role for SG signaling pathways in the progression of tauopathies.

Title: Neuron-to-neuron propagation of high-molecular-weight tau species derived from tau-transgenic mouse and human Alzheimer's disease brain

Authors: *S. TAKEDA[1], S. WEGMANN[1], H. CHO[2], A. D. ROE[1], C. COMMINS[1], D. IRIMIA[2], B. T. HYMAN[1];

Abstract: Tau pathology is known to spread in a predictable pattern in Alzheimer's disease (AD) brain and accumulating evidence suggests a trans-synaptic mechanism of tau transfer between neurons. However, it remains controversial which tau species are involved in neuron-to-neuron propagation. To identify specific tau species responsible for propagation, we compared uptake and propagation properties of different tau species derived from tau-tg mice and human AD brains. First, we prepared two different brain extracts from rTg4510 mice (PBS-soluble, 3k g or 150k g ext.), incubated them with mouse primary neurons, and assessed tau uptake immunohistochemically. After 2 days incubation, significant uptake of human tau occurred from the 3k g brain extract, which contains high-molecular-weight (HMW) tau species. The involvement of HMW tau in neuronal uptake was confirmed by separating the same brain extract by SEC and incubating each fraction with primary neurons. The most extensive uptake was observed in HMW fractions, suggesting that HMW tau species were responsible for uptake. Brain extracts from rTg21221 mice, which overexpress WT human tau, did not contain these

HMW tau species, and no tau uptake was observed into neurons. Importantly, brain ISF, collected from rTg4510 using a large pore microdialysis probe (1,000kDa MWCO), contained extracellular HMW tau, which was taken up by neurons, demonstrating that transmissible tau species are present in the extracellular space. We studied the transfer of tau between neurons inside a new microfluidic neuron culture platform. The design of the platform included three distinct chambers connected through arrays of channels such that the growth of axons and the formation of synaptic connections are precisely controlled between neurons in different chambers. rTg4510 brain-derived tau was taken up and propagated between neurons in the device within a week. Notably, human tau taken up by the 1st chamber neuron was propagated to the next chamber neurons even after washing out the human tau from the medium. HMW tau species extracted from AD brain were highly phosphorylated and also taken up by primary neurons. On the other hand, HMW tau species extracted from control brain or prepared from recombinant tau were not taken up by neurons. Further biochemical analysis showed that the HMW tau species appear to be complexes containing both human mutant and mouse endogenous tau, suggesting an interaction between these tau species in the brain. These findings suggest that PBS-soluble HMW p-tau species, present in the extracellular space, are involved in propagation and could be a target for therapeutic intervention and biomarker development.

Abstract: In Alzheimer's disease, tau protein is the major constituent of paired helical filaments, and undergoes several post-translational modifications (hyperphosphorylation and truncation). It has been reported that the main function of tau is to stabilize microtubules and promote the movement of organelles through the axon of neurons. However, little is known regarding other functions in which tau protein might be involved. We performed double and triple immunolabelling for a variety of tau markers in non-differentiated SHSY-5Y cells and analyzed them using confocal microscopy. We detected phosphorylated tau protein in the cell nucleus in small dense dots, which colocalize with intranuclear structures known as speckles. We observed that tau phosphorylated at Thr231 is closely associated with cell division. It appears that different phosphorylated forms of tau protein are associated with specific functions during mitosis. Our results suggest that the presence of tau might be involved in the separation of sister chromatid during anaphase, that it maintains the integrity of DNA throughout the prophase and protects chromosomes during cell division.

Abstract: Abnormal intracellular aggregation of tau protein is a pathological condition leading to neuronal death in Alzheimer´s disease (AD). Fibrillar and nonfibrillar aggregates of tau protein alter the normal functioning of neurons by disturbing the organization of distinct membranous organelles including the mitochondria and nucleus. However, the mechanism by which tau produces these alterations is still under investigation. In this study we evaluated whether full-length tau protein and its acid aspartic^{421}-truncated variant (D^{421}-truncated tau) also produce alterations in the normal organization of the cytoskeleton and plasma membrane (PM) when expressed in cultured glial cells. We transiently transfected the glial C6 cell line with plasmids (pcDNA3.1Zeo(-)) containing the sequence for either full-length tau protein (hTau40) or D^{421}-truncated tau. After transfection, cell viability and alteration in the normal organization of the cytoskeleton and PM were evaluated by multilabeling-immunofluorescence and confocal microscopy. After 48 hours of transfection, the radial microtubule lattice emerging from microtubule-organization centers in glial C6 cells was changed to more pericentric and cortical arrays of thick microtubule bundles. This effect was produced by both hTau40 and Asp^{421}-truncated tau molecules. Moreover, both tau variants induced severe alteration in the glial morphology by producing extensive blebbing along the PM. The formation of these PM blebs was closely associated with remodeling of the actin cytoskeleton. When tau-transfected cells were incubated with drugs that depolymerize the actin cytoskeleton the PM blebbing was reverted. Moreover when glial cells showing tau-induced PM blebbing were incubated with inhibitors of the Rho-GTPase-Rho-associated kinase (ROCK) signaling pathway, the formation of these abnormal membrane blebs was avoided. Interestingly, under this condition the actin cytoskeleton underwent a new organization in close association with the rings of abnormally formed microtubules bundles. These results are new evidence about alterations of the actin cytoskeleton, indirectly produced by the expression of tau protein. This effect may represent a new mechanism of tau toxicity, in which activation of the Rho-GTPase-ROCK pathway mediating the remodeling of cortical actin and MP blebbing is produced by tau-induced microtubule bundling. In the disease, this tau-induced blebbling of the PM may occur and contribute to the impairment of glial activity

Title: Model of tau pathology in induced pluripotent stem cell-derived human neurons

Authors: *M. USENOVIC, S. NIROOMAND, M. COSDEN, B. VOLETI, J. J. RENGER, S. PARMENTIER-BATTEUR;
Neurosci., Merck & Co., West Point, PA

Abstract: The pathology of neurodegenerative disorders, like Alzheimer's disease (AD), may spread throughout the brain via transcellular propagation of misfolded aggregated proteins. Abnormal accumulation of tau protein into intracellular hyperphosphorylated aggregates is a pathological hallmark of AD. The principle of tau transmission in AD has emerged due to spatial and temporal progression of tau pathology observed in AD patients' brains, as well as evidence showing that tau misfolded proteins gradually propagate from one brain region to another in animal models. However, the molecular and cellular mechanisms of tau transmission still remain unknown. We developed a novel clinically relevant cellular model to study tau aggregation and transmission using induced pluripotent stem (iPS) cell-derived human neurons. We seeded these neurons with full length human tau monomers and oligomers. The effects of tau seeding were examined for 4 weeks. Using high content imaging and a microfluidic device that enables the separation of neuronal soma and axon in two compartments, we showed that tau oligomers were internalized and transported along the axons. Also, oligomer-treated neurons exhibited an increase in aggregated and phosphorylated pathological tau. Interestingly, these effects were associated with progressive changes in neuronal morphology with neurite retraction and loss of synapses in time dependent manner. We did not observe any changes in neurons treated with tau monomers. Taken together, our data provide support for the pathological tau propagation hypothesis in a new human neuronal model for studying mechanisms involved in tau pathology to identify novel therapeutic targets.

Abstract: Our aging society is confronted with a dramatic increase in patients suffering from Tauopathies, such as Frontotemporal dementia (FTD) and Alzheimer's disease (AD). These disorders are characterized by neuropathological lesions including Tau hyperphosphorylation and aggregation and massive cortical cell death. No mechanism-based cures are currently available. Animal models, although useful for understanding aspects of Tau pathology, do not capture key aspects of the disease process and have been of limited use in developing treatments. Furthermore, certain aspects of Tau biology, such as isoform expression, differ between rodents and human. A human Tauopathy model that reproducibly develops disease-relevant molecular pathology in cortical neurons would enable functional studies and serve as an improved screening platform for drug development. Recent advances in stem cell research have allowed reprogramming of mutant patient-derived cells to induced pluripotent stem cells (iPSCs) and subsequent differentiation into cortical neurons. Although the first studies using this approach have shown promising results for AD and atypical Tauopathies, no human model of FTD has been described. Moreover, early studies lacked appropriate isogenic controls to confirm phenotype specificity. Newer studies have used isogenic controls generated by zinc finger nuclease-mediated genome editing, but these are very difficult to assemble in non-expert labs. We have generated iPSC lines from patients carrying different FTD-causing mutations affecting several aspects of Tau biology, such as splicing, microtubule binding or aggregation. Using TALENs and CRISPR genome-editing tools, we (1) have generated multiple isogenic control lines, (2) knocked out genes to study aspects of normal and disease-associated Tau biology, and

(3) are inserting transgenes in safe-harbor genomic loci to label cells, characterize phenotypes and introduce disease-modifiers. The splice mutant neurons show altered isoform expression. Other disease-relevant phenotypes, such as Tau phosphorylation, aggregation and cell death, are under investigation. An update on these phenotypes will be presented at the meeting.

Title: Optimization and utilization of hybrid culture between rat and fly primary neurons

Authors: K. L. KRAUS, *R. A. COLVIN, C. QIAN, D. LEE;
Dept Biol. Sci., Ohio Univ., Athens, OH

Abstract: Various *Drosophila* lines provide strong genetic models of human neurological disorders that can be efficiently produced at low cost; however, fly cultures less closely model the development, synaptic organization and neurotransmitter utilization of the human brain with respect to rodent primary neuronal cultures. A multidisciplinary approach to culturing neurons *in vitro* can be utilized to create a hybrid culture model consisting of both rodent and *Drosophila* primary neurons that amplifies the selective benefits of culturing each type of neuron. With clearly distinguishable pre- and post-synaptic targets, a hybrid model will be useful in studying various aspects of synaptic physiology, such as pre- and post-synaptic mechanisms and the cell-to-cell propagation of proteins. Preliminary data have demonstrated that fly and rat neurons can co-exist in primary culture and have the potential to establish cross-species contacts. Fly embryonic neuroblast cells were added to established rat (Sprague-Dawley) cortical neurons prepared from E18 embryos and the resulting hybrid culture was incubated at 24°C. Fly and rat neurons in mass culture were distinguished through their distinct morphological differences and the use of a transgenic fly line that selectively expresses GFP in cholinergic neurons. The fully established, self-organized hybrid neural network was then investigated for functional cross-

species contacts using a vertebrate nicotinic acetylcholine receptor (nAChR) antibody (mAb270 from DSHB). In pure primary rat cortical culture, nAChR expression is negligible. However, the rat neurons in close proximity to the fly neurons in the hybrid culture expressed significant levels of nAChR, indicating the possibility of functional cross-species interactions. The next step will be discovery of optimal long-term survival culture conditions (media composition, temperature, etc.). Using innate species differences in major excitatory neurotransmitter utilization and whole-cell patch clamp techniques to measure excitatory post-synaptic currents, it will be possible to definitively demonstrate cross-species functional contacts, and thus the potential applications of the hybrid model. Many neurodegenerative diseases, such as Alzheimer's disease and Parkinson's disease, are believed to involve the cell-to-cell propagation of characteristic misfolded proteins. The novel development of an *in vitro* hybrid model of neurodegenerative disease would permit the study of trans-synaptic protein propagation under controlled conditions with clear pre- and post-synaptic targets.

Title: Disruption of intraneuronal tau by extracellular tau oligomers containing individual or mixed tau isoforms

Authors: E. M. SWANSON, L. MCMAHON, S. SOM, *G. S. BLOOM;
Univ. of Virginia, Charlottesville, VA

Abstract: Tau is microtubule-associated protein enriched in the axons of neurons of the central nervous system, where its functions include direct binding and stabilization of microtubules and regulation of axonal transport. Tau is found in the CNS in six isoforms produced by the alternative splicing of a single tau gene, MAPT, with these isoforms characterized by the presence of zero, one or two N terminal inserts, and three or four C-terminal microtubule binding

repeats. Neuronal inclusions composed of hyperphosphorylated tau are a major histopathological feature of a series of neurodegenerative disorders known collectively as tauopathies, the most common and well-known of which is Alzheimer's disease (AD). While the clinical and histological presentation of these disorders is heterogeneous, a majority share the following hallmarks: loss of the normal axonal distribution of tau; accumulation of insoluble, fibrillar tau aggregates in neurites and perikarya; synaptic dysfunction; and eventual neuron death. There is also evidence that the majority of these disorders spread through the brain by a prion-like mechanism, in which pathologically misfolded tau is taken up by neurons, confers this pathological phenotype to the endogenous "normal" protein through direct protein-protein contact, and is eventually released by the cell, perpetuating the cycle. Some evidence points to short tau fibrils as being prion-like, but scant attention has been paid to small tau oligomers. Using a new morphometric method for rigorously quantifiying tau distributions in cultured neurons, we now demonstrate that externally applied tau oligomers are much more effective than tau monomers or fibrils at disrupting the normal tau distribution in primary cortical neurons, that oligomer potency varies according to tau isoform, and that oligomers made from mixtures of all six CNS tau isoforms are much more potent than oligomers made from individual isoforms. These results raise the possibility that soluble, pre-fibrillar oligomers of mixed tau isoforms account for the prion-like spread of tau pathology *in vivo* in AD and non-Alzheimer's tauopathies.

Title: Differential oligomer formation and phosphatase-activating domain exposure in tau isoforms

Authors: ***K. K. COX**[1], D. S. HIMMELSTEIN[2], N. M. KANAAN[1];
[1]Dept. of Translational Sci. & Mol. Med., Michigan State Univ., Grand Rapids, MI; [2]Dept. of Cell and Mol. Biology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: Tauopathies represent a collective group of neurodegenerative diseases where the microtubule-associated protein tau is abnormally modified and forms pathological inclusions in neurons and glial cells. There are six tau isoforms in the adult human CNS and different tauopathies are characterized by the pathological accumulation of various tau isoforms. Recently, our group identified a potential mechanism of tau toxicity. Specifically, disease-related modifications of tau expose a signaling motif in the amino terminus of tau called the phosphatase-activating domain (PAD). PAD exposure leads to activation of a protein phosphatase 1/glycogen synthase kinase 3 signaling cascade that ultimately impairs axonal transport. The formation of tau oligomers is one mechanism by which PAD becomes exposed during disease pathogenesis. Little is known about whether different tau isoforms exhibit a differential ability to form oligomers and whether PAD exposure is different among aggregated tau isoforms. Using a combination of *in vitro* aggregation assays, we investigated the propensity of different tau isoforms to form oligomers and the extent to which PAD is exposed in aggregates composed of each tau isoform. Oligomer formation was determined by using our tau oligomer-specific monoclonal antibody (TOC1) and PAD exposure was measured using our PAD-specific antibody (TNT1). Different tau isoforms create distinct forms of aggregates under identical polymerization conditions. For example, electron microscopy data suggest that 4 microtubule-repeat (4R) isoforms tend to form oligomers and a mixture of short, intermediate and long filaments, while 3 microtubule-repeat (3R) isoforms form only oligomers and long filaments. In general, immuoblot results suggest that the aggregated forms of each tau isoform exhibit increased TNT1 reactivity (i.e. PAD exposure) and TOC1 reactivity (i.e. presence of oligomers) compared to monomeric proteins. Preliminary quantitation of immunoblotting for TOC1 suggests that the relative proportion of oligomer formation is greater in 4R isoforms compared to 3R isoforms. Ongoing studies will determine whether aggregates from each tau isoform are toxic to cells in culture. Collectively, this work will help distinguish important differences among tau aggregates composed of each tau isoform and help identify the most toxic isoforms of tau.

Title: Tau oligomer formation and phosphatase-activating domain exposure in disease-related forms of tau

Authors: *C. T. TIERNAN[1], D. HIMMELSTEIN[3], S. E. COUNTS[1,2], N. M. KANAAN[1]; [1]Translational Sci. and Mol. Med., [2]Family Med., Michigan State Univ., Grand Rapids, MI; [3]Cell and Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: Tau is a microtubule-associated protein that is believed to contribute to neuronal loss and cognitive decline in Alzheimer's disease (AD) and other tauopathies. Despite our growing understanding of tau mutations, conformational changes, and aggregation, the toxic tau moiety remains elusive. Tau is the predominant protein found in neurofibrillary tangles (NFTs), and therefore it was presumed that aggregation of tau monomers into NFT-related filaments was causal in AD pathogenesis. However, tau oligomers appear prior to NFT formation and are accompanied by abnormal unmasking of the tau amino terminus [i.e., the phosphatase-activating domain (PAD, aa 2-18)]. PAD exposure activates a signaling pathway that impairs anterograde axonal transport, suggesting that prefibrillar tau oligomers and associated PAD exposure mediate tau toxicity upstream of NFT formation. The present investigation sought to characterize the effects of two posttranslational modifications in the tau protein that are hypothesized to produce toxic forms of tau by facilitating oligomer formation and subsequent PAD exposure. Phosphorylation of serine 422 (pS422), which modulates caspase proteolysis at aspartic acid 421 (D421), is an early event in tangle evolution that correlates with cognitive decline. In contrast, caspase cleavage of tau at D421 is a later pre-tangle event in the evolution of tau pathology in AD. Preliminary data indicate that *in vitro* aggregation of recombinant tau pseudophosphorylated at S422 (S422E) produces more oligomeric species of tau as compared to full-length wild-type tau. These results corroborate *in situ* data demonstrating that the appearance of pS422 tau correlates better with cognitive decline than D421 tau during the progression of AD, and suggest the existence of a separate toxic pool of oligomeric tau that is independent of NFT formation. Ongoing studies will compare the extent of oligomer formation and PAD exposure in recombinant D421 and S422E tau aggregates formed *in vitro*. Our tau oligomer-specific monoclonal antibody (TOC1) will be used to measure oligomer formation and our PAD-specific antibody (TNT1) will be used to measure PAD exposure. Finally, S422E and D421 aggregate toxicity will be determined in cultured cells. Collectively, these experiments will provide a link between two important disease-related modifications of tau, oligomer formation, PAD exposure and tau-mediated toxicity.

Title: Characterization of tau aggregation induced by arachidonic acid and eicosanoids

Authors: *B. COMBS[1], A. S. ALBERTS[2], N. M. KANAAN[1];
[1]Col. of Human Medicine, Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI; [2]Van Andel Inst., Grand Rapids, MI

Abstract: Aggregation of the tau protein is a predominant pathological marker of tauopathies, a group of neurodegenerative disorders including Alzheimer's disease (AD). Tau aggregates are closely linked to toxicity and neuronal pathology in these diseases. Recent evidence suggests that smaller aggregates, known as oligomers, may be particularly toxic. Despite its clear role in the propagation of these diseases little is known about the initiation of tau aggregation *in situ*. Unmodified tau is normally soluble and resistant to aggregation but changes in the conformation can enhance the propensity for aggregation. Phosphorylation of tau is commonly found in tau aggregates but it does not appear to be sufficient to induce aggregation and the possibility remains that a cofactor or inducing agent may be involved. For many years, investigators have used arachidonic acid (ARA) to induce tau aggregation *in vitro*, but whether ARA or ARA metabolites (i.e. eicosanoids) are the physiological inducers of tau aggregation *in situ* is unknown. Eicosanoids are naturally occurring metabolites of ARA and are mediators in inflammatory and other signaling pathways. Alterations in the levels of particular eicosanoids have been noted in many tauopathies, including AD and traumatic brain injury. Therefore, it is possible that changes in endogenous levels of ARA or eicosanoids could lead to increased direct interactions with tau that induce its aggregation and promote a neurodegenerative cascade. This study is aimed at testing ARA and eicosanoids as potential inducers of tau aggregation both *in vitro* and in cultured cells. We tested several eicosanoids to determine their relative abilities to induce tau aggregation *in vitro* and characterize the aggregates. Unmodified ARA was clearly the most potent aggregation inducer of any of the tested molecules. Ongoing studies are using microinjection to deliver ARA and eicosanoids directly into cultured cells expressing tau in order to characterize its effects in a cellular environment. Ultimately, this work may help to identify

whether modifying ARA production/metabolism represent a viable strategy aimed at mitigating the aggregation of tau in the brain.

Authors: *H. YOSHIDA;
Natl. Ctr. For Geriatrics and Gerontology, Obu, Aichi, Japan

Abstract: Alzheimer’s disease and other tauopathies are pathologically characterized by intracellular filamentous inclusions of abnormally hyperphosphorylated tau. Recent work suggests that tau pathology is likely to spread in a prion-like manner. Some experimental models of this hypothesis using cultured cells and mouse indicated that primary seeds of the identical isoform are required and trigger the formation of the inclusions and following propagation of them. However, it is unclear what actually induces tau pathology in tauopathy and that the characteristics of tau inducing the following chain propagation of tau pathology in the model systems. In this study, extracellular tau, which is thought to be one of the candidates to mediate or induce the propagation, was identified in conditioned media of cells stably expressing human tau and fractions collected by mouse brain microdialysis, and then biochemically characterized. Tau was detected in both conditioned media of SHSY5Y cells expressing human tau and fractions collected by mouse brain microdialysis on immunoblot. It was also labeled by phosphorylation-dependent anti-tau antibody AT270, indicating phosphorylation at T181. In addition, tau in these fractions was present as multiple sizes of oligomer, while tau in the cell and mouse brain extracts as relatively smaller sizes of oligomer. These results indicated the presence

of extracellular tau as multiple sizes of oligomer, and suggest a significance of contribution of oligomer formation of tau to produce extracellular tau.

Title: Tau pathology regulated by membrane lipid

Authors: *A. SUMIOKA, A. GOTO, Y. SOEDA, A. TAKASHIMA;
Dept. of Aging Neurobio., Natl. Ctr. for Geriatrics and Gerontology, Obu-City, Aichi, Japan

Abstract: Alzheimer's disease (AD) is one of the most common forms of dementia. It is required to establish their therapy. Senile plaques and neurofibrillary tangles are pathological features of AD. Neurofibrillary tangles formation is well involved with AD development (Braak staging). A major component of neurofibrillary tangle is aggregate of hyper-phosphorylated Tau protein. So aggregation of Tau protein would be one of the causative factors of AD and it is important to elucidate their molecular mechanism. Interestingly, purified recombinant Tau protein is known to be stable, and heparin as an anionic inducers, is required for *in vitro* Tau aggregation. These finding suggest an endogenous regulator for Tau aggregation in brain. In this study, we addressed a role of membrane lipid for Tau aggregation. We examined an interaction between Tau and lipids. We found lipid X1 as a specific interactor of Tau protein and confirmed their interaction on lipid bilayers by liposome floatation assay. Then we examined a mechanism of the interaction. We identified a specific region of Tau protein as a lipid interacting domain by using Tau deletion mutants. Furthermore we examine the effect of lipid X1 on Tau aggregation. We will discuss recent progress in its roles.

Title: Temporal sequence of TBI-dependent post translational modifications of Tau in a mouse model of concussion

Authors: *R. C. PELOT[1,2,3], J. REED[1,3], G. CRYNEN[1,2], C. BACHMEIER[1,2,3], J. EVANS[1], L. ABDULLAH[1], F. CRAWFORD[1,2,3];
[1]Roskamp Inst., Bradenton, FL; [2]The Open Univ., Milton Keynes, United Kingdom; [3]The Veteran's Admin., Tampa, FL

Abstract: Traumatic Brain Injury (TBI) is a condition that has recently come to the forefront of the media's attention due to the prevalence of mild to severe head injury in combat veterans and athletes. In the United States alone, there are between 1.6 -3.8 million mild to moderate TBIs per year in connection with organized sport and recreation. In the TBI condition Chronic Traumatic Encephalopathy CTE (formerly dementia pugilistica) there appears to be a key role for the microtubule associated protein tau, but the nature of tau's role in this neurodegenerative process is as yet unknown. The use of quantitative proteomics in the characterization of disease states by Mass Spectrometry (MS) is becoming widespread, but has not yet been fully applied to tau biochemistry. While analysis of tau by western blot utilizes several well known antibodies to identify pathology, it cannot cover the entire range of PTMs, even when trying to identify phosphorylation alone. In this study, we present an MS based characterization of tau pathobiology following repetitive mild TBI in hTau mice. Mouse brain tissue was analyzed at 24hr, 1 week, 1 month, & 3 months post injury using quantitative mass spectrometry to map as many PTMs as possible, including Phosphorylation, O-GlcNAc, Deamidation, Acetylation, & Methylation. To determine the TBI-dependent changes in tau PTM status we used XCMS to measure the differences in peak area against the total ion current in injured versus sham mice over time. We have thus established a protocol to quantitatively determine the level of modification of several types of PTMs on tau, which may be further exploited to investigate pathological changes in many different tauopathies.

Title: Calorie restriction, age, and genotype modulate the intestinal microbiota in a mouse model of Alzheimer's disease

Authors: *L. M. COX[1], M. J. SCHAFER[2,4], S. D. GINSBERG[3,4], M. J. BLASER[1,5]; [1]Departments of Med. and Microbiology, [2]Dept. of Cell Biol., [3]Departments of Psychiatry and Physiol. & Neurosci., NYU Langone Med. Ctr., New York, NY; [4]Ctr. for Dementia Res., Nathan Kline Inst., Orangeburg, NY; [5]New York Harbor Dept. of Veterans Affairs Med. Ctr., New York, NY

Abstract: Alzheimer's disease (AD), a late onset neurodegenerative disorder, is associated with accumulation of β-amyloid in senile plaques and tau in neurofibrillary tangles. Animal model studies indicate that AD-like pathology can be influenced by changes in diet, metabolism, and immunity, indicating that factors distant from the brain play a role in AD pathogenesis. The intestinal microbiota, composed of trillions of microbial cells, influences host metabolism, immunity, and cognitive function, and has been hypothesized to be linked mechanistically to AD pathobiology, but it's role remains to be adequately tested. We sought to determine whether there

were specific microbial signatures associated with calorie restriction (CR)-mediated protection against AD pathology in the well-established mouse model of cerebral amyloid overexpression, the Tg2576 mouse, which exhibits age-dependent increases in Aβ plaque load and concomitant memory deficits driven by overexpression of a human APP variant (APPswe) responsible for early-onset AD. To determine whether intestinal microbiota changes occur in Tg2576 mice, and whether or not they are responsive to CR, wild-type or Tg2576 mice were randomized to ad-libitum (AL) or CR dietary regimens, with 30% carbohydrate reduction starting at 3 months of age. As we have previously shown, CR significantly reduced amyloid plaque burden in Tg2576 mice at 15 months of age, particularly in females. Fecal microbiota samples were collected 2 months and 1 year after the dietary intervention was begun, and microbial communities were surveyed by sequencing the 16S rRNA gene V4 region, with a mean (± standard deviation) depth of coverage of 30,148 ± 4,933 sequences per sample. Both CR and mouse genotype alter the microbiota early (at age 5 months) and late (at age 15 months), with progressive changes over time. CR selected for particular bacterial taxa previously associated with prolonged longevity and reduced systemic inflammation, including Lactobacillus and Allobaculum, and the effect was greatest in the aged Tg2576 mice, suggesting that in this model system, CR may have therapeutic value with potential translational benefits. This study characterizes key taxonomic changes and identifies particular intestinal microbiota as modifiable therapeutic targets for AD. Further investigation of the interaction between the intestinal microbiota and age-related neurodegenerative disorders in animal model systems is warranted to provide mechanistic insight into AD pathology, and to reveal novel therapeutic approaches for preventing and treating AD and related dementing disorders.

Abstract: The microtubule-associated protein tau is the main component of neurofibrillary tangles (NFTs). Six distinct isoforms of tau are produced in the adult human brain via alternative mRNA splicing. Three isoforms contain 3 microtubule binding domain tandem repeats {3-repeat tau (3Rtau)} with amino terminus inserts (0 inserts, 1 insert, or 2 inserts) termed 3R0N, 3R1N, and 3R2N, respectively. Similarly, three isoforms contain 4 microtubule binding domain tandem repeats {4-repeat tau (4Rtau)} with amino terminus inserts (4R0N, 4R1N, and 4R2N). Assessment of the mRNAs encoding the 6 isoforms of human tau have been difficult to determine unequivocally due to their high sequence homology. Therefore, specific alterations within individual tau isoforms have remained elusive, notably in vulnerable regions and cell types within the brain where tauopathic processes are thought to be initiated. We have developed a qPCR-based assay with associated computational methodology to quantitate the 6 isoforms of tau using human postmortem brain tissues as sources of input RNA. Combinatorial pairs of qPCR primers are employed to detect 3Rtau (3R0N, 3R1N, or 3R2N) and 4Rtau (4R0N, 4R1N, or 4R2N), either directly or via computational analysis. Individual tau isoform expression is represented relative to the total expression of all 6 isoforms. This experimental design allows for statistical comparisons of each tau isoform in AD and age-matched normal controls. Preliminary results from entorhinal cortex of normal control subjects indicate that 3N0R and 4R0N are most abundant, accounting for approximately 45% and 27% of the total expression of tau isoforms, respectively. 3R1N (~15%) and 4R1N (~10%) and the 2 insert tau isoforms 3R2N (~2%), and 4R2N (~1%) are expressed at lower concentrations. Preliminary qPCR assessment in AD brains (n = 14) and nondemented age-matched control (CTR) subjects (n = 11) indicate selective changes within individual tau isoforms. Specifically, downregulation of 3Rtau isoforms 3R1N and 3R2N was observed concomitantly with upregulation of the 4Rtau isoform 4R0N, indicating a complex alteration of tau isoforms in AD within an early vulnerable area. These preliminary assessments will be validated in a larger cohort of AD and CTR subjects along with additional regional evaluations including frontal cortex, hippocampus, and brainstem. Additional evaluation of AD cases as well as subjects with mild cognitive impairment (MCI) and tauopathies is being

performed to test the hypothesis of differential vulnerability of specific tau isoforms, as well as assessing whether the ratio of 3Rtau/4Rtau expression changes in neurodegenerative disorders.

Title: Characterization of tau and phosphorylated tau (ptau) in brains from human Alzheimer's disease and tauopathy subjects

Authors: ***S. SANKARANARAYANAN**[1], L. YANG[1], N. HOQUE[1], G. CADELINA[1], D. BARTEN[1], C. F. ALBRIGHT[1], J. B. TOLEDO[2], K. BRUNDEN[2], V. M. Y. LEE[2], J. Q. TROJANOWSKI[2], M. AHLIJANIAN[1];
[1]Neurosci. Biol., Bristol-Myers Squibb, Wallingford, CT; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Alzheimer's disease (AD) and related tauopathies are associated with an increase in brain insoluble tau and ptau based on post-mortem biochemical and histological analysis. In this study, we utilized a panel of tau and ptau ELISA assays, spanning the entire tau sequence, to systematically evaluate changes in tau levels from extracts derived from brains of multiple neurodegenerative disorders. Brain samples were provided by the Center for Neurodegenerative Disease Research (CNDR) at the Perelman School of Medicine of the University of Pennsylvania. We compared soluble and insoluble brain extracts from AD, Corticobasal Degeneration (CBD), Pick's disease (PiD), Progressive Supranuclear Palsy (PSP), Parkinson's disease (PD), Frontotemporal Lobar Degeneration with TDP-43 pathology (FTLD-TDP) and age-matched control subjects (n=10/group). A panel of 5 total tau assays, which interrogate the mid-domain, amino-terminal, microtubule repeat domain and carboxy-terminal regions of tau

and 6 different ptau assays (pT181, pS202-pT205, pT231, pS396, pS404 and pS422) were used to assess disease-specific changes. In AD and CBD subjects, significant increases in amino-terminal and carboxy-terminal tau levels were evident in brain insoluble extracts, without any change in mid-domain tau. Interestingly, brain soluble tau levels were unchanged across this panel of tau assays. In contrast, brain ptau levels were significantly elevated in AD and tauopathies, in both soluble and insoluble extracts with a rank order of AD > CBD > PiD > PSP. PD and FTLD-TDP brains did not show any tau changes compared to controls. A similar pattern of tau and ptau changes was evident in mouse models that overexpress mutant tau - both aged (6-8 month) Tg4510 mice and in PS19 mice injected intra-cerebrally with preformed synthetic tau fibrils. Taken together, the results confirm that in human disease and tau overexpression models, tau pathophysiology is associated with an increase in ptau levels. In addition, these data demonstrate greater antibody accessibility of the amino and carboxy-terminal regions of tau suggesting a change in the conformation of these epitopes when tau becomes misfolded and aggregated. These studies provide novel hypothesis with respect to tau aggregation and identify targets for tau immunotherapy.

Title: Cross-talk between PI3K/AKT/GSK-3beta and PP2A pathways determines tau hyperphosphorylation

Authors: *F. LIU[1,2], Y. WANG[2], R. YANG[2], X. YIN[2], J. GU[1,2], N. JIN[1,2], K. IQBAL[1], C.-X. GONG[1], C. CHENG[2];
[1]New York State IBR, Staten Island, NY; [2]Nantong Univ., Nantong, China

Abstract: Intraneuronal aggregation of abnormally hyperphosphorylated tau is a hallmark of a family of neurodegenerative diseases called tauopathies. Hyperphosphorylation of tau disrupts microtubules and promotes its self-assembly into paired helical filaments. Thus, hyperphosphorylation of tau is crucial for tau pathology in Alzheimer's disease and related tauopathies. Glycogen synthase kinase-3β (GSK-3β) and protein phosphatase 2A (PP2A) are the major regulators of tau hyperphosphorylation. Both enzyme activities are regulated by post-translational modifications. GSK-3β is phosphorylated and inactivated by activation of PI3K/AKT pathway, whereas Leu309 methylation of PP2A catalytic subunit (PP2Ac) is required for its phosphatase activity toward tau. The relationship between these two enzymes and its impact on tau hyperphosphorylation are not well understood. In the present study, we determined the cross-talk between PI3K/AKT/GSK-3β and PP2A pathways. We found that former PI3K signaling regulated the methylation of PP2Ac via GSK-3β. Up-regulation of GSK-3β led to an increase in the methylation and activity of PP2Ac through phosphorylation of leucine carboxyl methyltransferase 1 (LCMT-1) and suppression of protein phosphatase methylesterase-1 (PME-1) expression, two enzymes maintaining PP2Ac methylation. PP2A also regulated GSK-3β phosphorylation. Down-regulation of PP2A enhanced Ser9 phosphorylation of GSK-3β and inhibited its kinase activity. Thus, GSK-3β and PP2A regulate each other and control tau phosphorylation both directly and indirectly through each other. Reduction of tau phosphorylation by inhibition of GSK-3β may be more than offset by inhibition of PP2A through

a shift in PME-1/LCMT-1 balance; PP2A regulates phosphorylation of tau at Ser262/356, a required site for tau pathology. These findings suggest targeting PP2A and not GSK-3β to inhibit tau pathology.

Title: Effects of methylene blue and another oxidant on human tau transgenic fly models

Authors: S. SHEIK MOHIDEEN[1], Y. YAMASAKI[1], Y. OMATA[2], L. TSUDA[1], *Y. YOSHIIKE[1];
[1]NCGG CAMD, Obu, Aichi, Japan; [2]Occup. and Envrn. Hlth., Nagoya Univ., Nagoya, Japan

Abstract: Objective: Neurofibrillary tangles (NFT) formed by aggregation of tau are one of the pathological hallmarks of Alzheimer's disease. Methylene blue (MB) has been reported to suppress tau aggregation *in vitro* by oxidizing cysteine residues of tau. Expression of human wild type tau (2N4R) in neurons of *drosophila* causes phenotypic abnormalities such as climbing deficits "without" NFT. We investigated the effects of MB and another compound that promotes oxidization by the common mechanism on tau fly models. Methods: Human tau-expressing flies were treated with 1mM compound for one month. In prior to biochemical examination of tau accumulation in fly heads, their climbing activity was analyzed. Results: Although it is known that no NFT is formed in tau flies, we were able to detect tau in the sarkosyl insoluble fraction of the fly heads. As a result of 1-month MB treatment, the sarkosyl insoluble tau was reduced. We also found that MB treatment had reduced not only tau in TBS soluble fraction but also the total concentration of TBS soluble proteins. These results suggest that MB may not simply work as a tau aggregation inhibitor but may play other roles for reducing tau accumulation. MB treatment on flies expressing tau in neurons ameliorated their climbing deficits. We also found that those

flies that were able to climb high had less sarkosyl-insoluble tau than those flies that did not climb high, suggesting a correlation between the climbing deficits and the insoluble tau accumulation. Interestingly, the median survival rate of the flies treated with MB decreased to almost half of the control. In search of a compound that may work similarly as MB without substantial aversive effects, we looked for one that has a common oxidizing property with good safety profile. Treatment of tau flies with this compound resulted in the reduction of tau accumulation as well as improvement of climbing activity even though the extent of these efficacies was smaller than MB. Unlike MB, no significant effect on fly lifespan was observed by treating with this compound. Conclusion: Treatment with MB or another oxidizing compound reduced tau accumulation in human tau-expressing fly models and improved their climbing deficits.

Abstract: Background Alzheimer Disease (AD) is a neurodegenerative disorder characterized by progressive cognitive decline, with the pathology progressing from the entorhinal cortex to hippocampal subregions and the cortical area via anatomical connections. The process involved in disease progression is still poorly understood. However, the spreading of the pathology through neuronal pathways can be evaluated using microdialysis. The present study monitors the different forms of beta-amyloid, tau, monoamine, acetylcholine and amino-acid levels in the

interstitial fluid (ISF) of two different transgenic mice strains considered representative of the pathology. **Method** Male TauPS2APP ($APP^{695\ (K670N-M671L)}$/ $PS2^{N141I}$/ Tau^{P301L}**)** and TASTPM ($APP^{695(K670N-M671L)}$/ $PS1^{M146V}$) mice were obtained via the PharmaCog consortium and evaluated between 3 and 23 months. A 2mm, 300kDa, cut off membrane, (Brainlink, Netherland) was stereotaxically implanted (Lat, -0.4, AP, +2.0, DV, -3.0) in the frontal cortex under a ketamine/xylazine anaesthesia. Two days later, freely-moving mice were perfused at a flow rate of 0.5µl/min with a Ringer solution and samples collected during 7 hours. For whole brain extracts parallel cohorts were evaluated. Simultaneous ELISA quantification of $Abeta_{1-40}$ and $Abeta_{1-42}$ as well as total tau was performed in ISF and brain extract samples using MesoScale Discovery's electrochemiluminescence detection. **Results** Frontocortical ISF levels of total tau increases with age in both strains. $Abeta_{1-40}$ and $Abeta_{1-42}$ ISF levels rapidly increase in the TASTPM mice whereas the increase seems to be delayed in the TauPS2APP mice. Brain tissue levels of soluble and insoluble $Abeta_{1-40}$ and $Abeta_{1-42}$ showed an increase in both strains, whereas no change in total tau was noted. The increase observed in TauPS2APP mice was in favour of the $Abeta_{1-42}$ form. No significant differences were observed in the levels of the neurotransmitters tested in either strain. **Conclusions** Monitoring beta-amyloid, tau, monoamine, acetylcholine and amino-acid levels using microdialysis provides a useful tool to assess the spreading of the AD pathology and neuronal dysfunction *in vivo*. The research leading to these results was conducted as part of the PharmaCog consortium funded by the European Community's Seventh Framework Programme for the Innovative Medicine Initiative under Grant Agreement n°115009. All procedures using these animals conformed to international European ethical standards (86/609-EEC) and the French National Committee (décret 87/848) for the care and use of laboratory animals.

Title: Targeting Tau-SH3 Interactions in Alzheimer's Disease

Authors: *J. COCHRAN[1], P. DIGGS[1], M. NEBANE[3], T. RUSH[1], J. YAN[3], I. PADMALAYAM[3], L. RASMUSSEN[3], E. CAPRIOTTI[2], B. BOSTWICK[3], L. WHITE[3], J. MADDRY[3], M. SUTO[3], E. D. ROBERSON[1];
[1]Ctr. for Neurodegeneration and Exptl. Therapeut., [2]Pathology Informatics, Univ. of Alabama at Birmingham, Birmingham, AL; [3]Southern Res. Inst., Birmingham, AL

Abstract: New therapies for Alzheimer's Disease (AD) are critically needed. Many therapies have focused on Aβ, which is an important cause of AD. However, Tau is a critical mediator of the detrimental effects of Aβ and Tau abnormalities can propagate independently of Aβ. Because of this, Tau-directed therapies will be an important complement to Aβ-directed therapies for AD. After showing robust benefits of Tau reduction in multiple AD models, we began investigating how Tau reduction may provide benefit in order to identify druggable targets. A variety of evidence from our lab and others implicates Tau-Fyn interactions in the pathogenesis of AD. Preventing the Tau-Fyn interaction, either by removing Tau, removing Fyn, or expressing a dominant negative Tau, has strong beneficial effects in models of AD. Because of this, we conducted a high-throughput screen and identified a variety of chemically tractable small molecule inhibitors of the Tau-Fyn interaction. We are continuing development of Tau-Fyn interaction inhibitors by analog development and screening in a variety of secondary and liability assays. As SH3 domains are enriched at the synapse compared to overall proteomic prevalence, we are investigating other Tau-SH3 interactions using both candidate and unbiased approaches using techniques in animal tissue, in reductionists assays, and in silico. These efforts will allow us to identify both liability SH3 domains and SH3 domains that may serve as other mediators of Aβ-induced synaptic abnormalities. These ongoing efforts highlight the importance of Tau-SH3 interactions as potential mediators of Aβ-induced abnormalities which are therapeutically targetable.

Title: Tau: an interactor and substrate for protein tyrosine phosphatase SHP-2

Authors: Y. KIM, M. B. FRANCIS, C. J. LEUGERS, *G. LEE;
Univ. Iowa, Iowa City, IA

Abstract: The microtubule-associated protein tau is involved in regulating microtubule assembly and function in neurons. During early brain development, tau is normally phosphorylated at several serine/threonine residues such as Thr231, with phosphorylation levels decreasing in adult. Previously, Leugers and Lee reported that in NGF-induced differentiation of PC12-derived cell lines, MAPK activation was potentiated by tau and that phosphorylation at Thr231, which reduces its affinity for microtubules, was required. To investigate the mechanism by which tau enhances the NGF-stimulated MAPK activity in PC12 cells, we examined immunoprecipitates of phospho-Thr231-tau, looking for associated proteins. We found SHP-2, a protein tyrosine phosphatase that is also required for NGF-induced MAPK activation during PC12 cell differentiation. The interaction was confirmed in COS7 cells, where tau, expressed by transfection, co-immunoprecipitated with endogenous SHP-2. To determine if phosphorylation at Thr231 of tau was required for the association with SHP-2, we expressed T231A-tau and found an association with SHP-2, suggesting that phosphorylation on Thr231 was not required for the association with SHP-2. We found that other Ser/Thr to Ala tau mutants also co-immunoprecipitated with SHP-2. However, when tau was immunoprecipitated by antibodies that did not bind to highly phosphorylated tau, SHP-2 did not co-immunoprecipitate. This suggests that tau phospho-sites other than those tested may be important for the association with SHP-2. In addition, *in vitro* phosphatase assays, using either full-length tau or tau peptide, showed that SHP-2 dephosphorylated phospho-Tyr18-tau, suggesting that phospho-Tyr18-tau was a substrate for SHP-2. Taken together, our data suggest that tau associates with SHP-2 and is a potential substrate for SHP-2 in cells. The role of the tau-SHP-2 interaction in NGF-induced MAPK activation remains to be shown. Given the regulation of phospho-Tyr18-tau seen in Alzheimer's disease (AD) brain, SHP2 might be active during neurodegeneration. Also, since MAPK activity is augmented in AD and SHP-2 is critical for MAPK activation in developing neurons, this also suggests that SHP-2 may have a role in AD.

Title: Critical role of death-associated protein kinase 1 in regulating tau protein accumulation in Alzheimer’s disease

Authors: ***T. LEE**, M.-H. YOU, B. KIM;
Harvard Med. School/BIDMC, Boston, MA

Abstract: Background The neuropathological hallmarks of Alzheimer’s disease (AD) are intracellular neurofibrillary tangles made of hyperphosphorylated tau and extracellular senile plaques consisted of Aβ deposits. Interestingly, the formation of neurofibrillary tangles in AD is preceded by increased phosphorylation of tau and other proteins on specific serine or threonine residues. However, it is not fully understood how these aberrant tau phosphorylation events lead to neurodegeneration and how to prevent this phosphorylation-induced neurodegeneration in AD. Death-associated protein kinase 1 (DAPK1) is a Ser/Thr kinase and functions as a positive mediator of apoptosis and is genetically linked to AD. However, the association between DAPK1 and late onset AD has not yet been explored since little is known about the downstream targets of DAPK1 involved in AD. In this study, therefore, we aimed to elucidate the mechanisms of DAPK1 action on tau protein regulation and tau pathology using various cell lines and mouse model. Methods We investigated the effects of DAPK1 on tau protein regulation by examining tau protein stability and phosphorylation status using comprehensive approaches, including gene knockout, knockdown in cell culture models and mouse, and human patient tissues. Moreover, since DAPK1 inhibits the catalytic activity of Pin1 by phosphorylating Ser71 residue, we also assessed the correlation of DAPK1 expression and Ser71 phosphorylation of Pin1 and assessed the involvement of Pin1 inhibition in DAPK1 action. Results We

demonstrated that DAPK1, but not kinase dead mutant form DAPK1 K42A, significantly enhance tau protein stability using cycloheximide chase experiment. DAPK1, but not K42A, also triggered tau phosphorylation in cell lines and DAPK1 knockout reduced tau phosphorylation in mouse model. We also demonstrated that DAPK1 knockout significantly reduced total expression and phosphorylation of tau in sarkosyl-insoluble fraction in an age-dependent manner in mouse brains. Moreover, the expression of DAPK1 was increased more than 2 folds in hippocampus of AD patients compared to normal alone with tau hyperphosphorylation. In addition, Ser71 phosphorylation of Pin1 was increased in DAPK1-expressing neuroblastoma cells. Moreover, DAPK1 did not exert its effect on tau protein regulation in Pin1 knockout MEF cells, and did not affect T231Atau protein stability. Conclusions These results indicate that DAPK1 regulates protein stability and phosphorylation status of tau and might regulate tau-related pathology. Our results also suggest that Pin1 inhibition is critical in DAPK1-mediated tau regulation.

Title: Removal of tau oligomers by immunotherapy decreases Aβ56* and improves cognition in an AD mouse model

Authors: *D. L. CASTILLO[1], M. J. GUERRERO-MUÑOZ[2], U. SENGUPTA[2], C. HERNANDEZ[2], K. DINELEY[2], R. KAYED[2];
[2]Neurol., [1]UTMB, GALVESTON, TX

Abstract: **Background** In Alzheimer’s disease (AD) the misfolding of functional tau monomer seems to be coupled upstream to the aggregation Aβ a more potent amyloidogenic peptide. Soluble Aβ oligomeric species can drive the formation of neurotoxic tau oligomers *in vitro* and *in vivo*. However, the relationship between these two proteins and neuronal loss lacks a mechanistic explanation. Furthermore, evidence from animal models suggests that amyloid beta toxicity is mediated by tau]. We hypothesize that tau oligomers formation plays crucial role in

driving AD pathogenesis. Thus, tau oligomers represent an ideal therapeutic target for the treatment of AD. In order to study the removal of toxic tau assemblies in an animal model of AD (Tg2576), we generated a tau oligomer specific antibody (TOMA). This antibody does not recognize the functional monomeric tau or oligomers from other amyloidogenic proteins. **Methods** Here we used the Tg2576 mouse model which overexpress the human APP with the Swedish double mutations (K670N, M671L) under the control of a hamster prion protein promoter.14-month old Tg2576 mice, received a single iv injection of 30 µg of the TOMA antibody. Control group received 30 µg of non-specific IgG. Cognitive function was assessed by novel object recognition test, 15 days after injection. In addition, western blot, ELISA and Immunostaining were performed to evaluate the response to treatment. **Results** Our results indicate that single iv-injection of the TOMA antibody, reduce endogenous tau oligomers and improve cognition in the Tg2576 mouse. Interestingly, removal of tau oligomers by immunotherapy decreases amyloid beta-56* and increases deposition of plaques in immunized mice. **Conclusion** Our results support the findings that tau oligomers mediate Aβ toxicity *in vivo*. Moreover, removal of tau oligomers by immunotherapy may induce Aβ aggregates to assembly into inert and perhaps protective plaques. Thus, targeting tau oligomers by immunotherapy may represent a novel strategy for the treatment of AD and other neurodegenerative tauopathies.

Title: Bexarotene reduces intraneuronal APP/Aβ and neuronal loss in 5XFAD mice

Authors: *M. HOLLEY, T. JAY, B. CASALI, T. MALM;
Case Western Reserve Univ., Cleveland, OH

Abstract: Alzheimer’s disease (AD) is the most common form of dementia, and is characterized by accumulation and deposition of soluble forms of amyloid beta (Aβ), gliosis, and extensive neuronal loss. We have recently demonstrated that an agonist of the nuclear receptor RXR bexarotene (bex), promoted the clearance of amyloid from the brain and improved cognition in

several amyloidogenic AD mouse models. To extend this work we chose to examine 5XFAD mice, a mouse model that exhibits neuronal loss. 5XFAD mice exhibit intraneuronal amyloid deposition at 1-2 months of age, mild cognitive deficits at 4 months, and extensive neuronal death. The first wave of neuronal death occurs in the subiculum between 2-4 months of age, and the second wave occurs in layer V of the cortex between 6-8 months. Therefore, we hypothesized that bex treatment in 5XFAD mice will improve cognition before and after neuronal loss and attenuate neuronal death through reduction in soluble Aβ and insoluble Aβ. We treated 4 and 8 month 5XFAD mice with bex for 14 days. Bex treatment increased ApoE, Abca1, and Abcg1 levels in 5XFAD mice at all ages indicating increased lipidation of ApoE. Although bex treatment significantly reduced amyloid plaque burdens, bex treatment did not significantly reduce soluble or insoluble Aβ. Importantly, in both 4 and 8 month 5XFAD bex treated mice, intraneuronal APP/Aβ was reduced in the cortex. The reduction in intraneuronal APP/Aβ, in bex treated mice, correlated with a significant preservation of subicular and cortical neurons during their respective die-off periods. Moreover, bex treatment improved long term memory in fear conditioned mice aged 4 and 8 months, and improved olfaction cross habituation in 8 month 5XFAD mice. There is evidence that autophagy and lysosomal acidification are impaired in 5XFAD mice. Western analysis indicates that bex treatment alters protein expression of Beclin-1 and LC3II which are critical for initiation of autophagy and autophagosome formation, respectively. Collectively, we provide evidence that Bex treatment reduces amyloid species and improves behavior in an aggressive model of AD which exhibits neurodegeneration.

Abstract: In many neurodegenerative disorders including Alzheimer's disease (AD), oligomeric forms of amyloid proteins are believed to be the principal bioactive species. However, our understanding of these disorders is currently limited by insufficient knowledge about the specific molecular pathways activated by different assemblies. Here, we demonstrate that the amyloid-β (Aβ) oligomer Aβ*56 associated with preclinical AD forms a complex with NMDA receptors (NMDAR) resulting in an aberrant increase in intracellular calcium, driven by synaptic NMDARs, and the specific activation of the Ca2+-dependent calmodulin kinase CaMKIIα. Active CaMKIIα induced selective pathological changes in tau *in vivo* and *in vitro*, involving phosphorylation and missorting. Importantly, other forms of endogenous Aβ oligomers did not trigger these effects. Our results indicate that distinct Aβ oligomers activate neuronal signaling pathways in a highly selective manner, leading to AD pathology, and suggest a general strategy for dissecting the molecular events caused by endogenous oligomeric misfolded proteins.

Title: Chronic exposition to ozone produces β amyloid 1-42 accumulation in mitochondria of rat hippocampal neurons

Authors: *L. F. HERNANDEZ, E. RODRÍGUEZ MARTÍNEZ, S. RIVAS-ARANCIBIA; Phisiology, UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, Mexico, Mexico

Abstract: Oxidative stress is a major risk factor for Alzheimer´s Disease that has been suggested to be the trigger of AD pathology. However, whether oxidative damage precedes and contributes directly to the intracellular accumulation of beta amyloid 1-42 peptide is still a matter of debate. Nevertheless, it has been recently shown that free radicals cause exacerbation of the amyloid pathology in AD. Environmental, dietary and pathological factors have been related with oxidative stress generation. The chronic exposure to low doses of ozone similar to a day of high pollution in México City causes a state of oxidative stress producing progressive neurodegeneration in hippocampus of rats exposed to this gas. Several reports have demonstrated that mitochondria are one of the first organelles affected by oxidative stress and beta amyloid 1-42 toxicity. However the mechanisms related with neurodegeneration process and mitochondrial damage under chronic exposure to low doses of ozone have not been demonstrated. The aim of this study was to analyze the effect of ozone chronic exposure on the changes in the accumulation of beta amyloid 1-42 peptide in mitochondria of hippocampal neurons of rats exposed to low doses of ozone. Method: each group of 10 rats received one of the following treatments; control group received only air, and groups 2, 3, 4, 5 y 6 received ozone doses of 0.25 ppp. for 4 h daily, during 7, 15, 30, 60 and 90 days respectively. Groups were processed for immunohistochemical and double immunofluorescence analysis against the following proteins: beta amyloid 1-42 peptide and cytochrome C. Cellular fractionation of hippocampal cells for recover mitochondrial fraction was performed and mitochondrial protein extract was analyzed also by gel electrophoresis and Western Blot to detect beta amyloid 1-42. The results show a significative accumulation of beta amyloid peptide in 30, 60 and 90 days of ozone exposition. This indicates that there is a correlation between the time of exposure to ozone and accumulation of beta amyloid peptide 1-42 in mitochondria of hippocampal neurons of rats. Conclusions: Accumulation of beta amyloid 1-42 peptide may promote mitochondrial dysfunction and cell death. Although our findings do not explain all components of the puzzle regarding how amyloid beta causes neuronal damage, they do provide another potentially important pathogenic mechanism that may contribute to the onset and progression of AD. Finally, all this indicates that the chronic state of oxidative stress induces the neurodegeneration process probably through of beta amyloid 1-42 accumulation in mitochondria.

Title: Gsk antisense improves learning and memory and reduces active gsk in samp8 mice

Authors: *S. A. FARR[1], V. B. KUMAR[1], K. WITT[2], K. E. SANDOVAL[2], J. E. MORLEY[3]; [1]Geriatrics/GRECC, St. Louis University/VA Med., St Louis, MO; [2]Pharm., SIUE, Edwardsville, IL; [3]Geriatrics/Endocrinology, St. Louis Univ. Sch. of Med., St. Louis, MO

Abstract: Glycogen synthase kinase (GSK) -3β is involved in the phosphorylation of Tau and binds and phosphorylates presinilin-1 (PS-1). Human brains from Alzheimer's patients have increased GSK-3 associated with neurofibrillary tangles, neurodegeneration and increased tau phosphorylate. The SAMP8 have a natural mutation which results in age-related impairment in learning and memory, elevated Aβ, oxidative tissue damage and elevated hyperphosphorylated Tau. We have previously shown that reducing Aβ in 12 month old SAMP8 mice with an antisense directed at APP improves learning and memory. Here, we examined the effect a phosphorothionated GSK-3β antisense in SAMP8 mice on learning and memory in T-maze foot shock avoidance. The GSK-3β antisense had a sequence that orresponds to 94-113 nucleolides downstream from the initiation codon of GSK-3 mRNA. This is an internal sequence with high probability of being away from any loop formation in the mRNA. As an internal site it should not block 100% of GSK mRNA. SAMP8 mice were injected IV with GSK antisensen 5 times at one-week intervals. Acquisition was tested 5 days after the third injection in an aversive T-maze. Retention was tested one-week later. The day after T-maze retention testing mice were tested in novel object recognition with a 24 hour retention delay. Anti-GSK improved T-maze acquisition and retention and novel object recognition retention in 12 month old SAMP8 mice compared to the mice that received a random antisense. The 12 month-old SAMP8 mice that received anti-GSK took significantly fewer trails to reach criterion of one avoidance (10.1±0.57) compared to the 12 month-old SAMP8 mice which received random antisense (112.56±0.50). On the one week retention test mice which received anti-GSK took significantly fewer trails to reach criterion of 5 avoidances in 6 consecutive trials (8.5± 0.76) compared to the mice which received random antisense (15.88±2.2). On the 24 hour retention test, the mice that received GSK antisense spent significantly greater amount of time with the novel object (63.89±2.44) than the mice that received random antisense (52.86 ± 3.45). Assays of brain tissue indicate that GSK antisense significantly reduced active GSK compared to the mice that received random antisense.

GSK-3 is thought to play a role in amyloid-β effects in the brain. Here we demonstrate that reducing GSK-3 with a phosphorothinoated GSK-3β antisense improves learning and memory. GSK-3β antisense is a potential treatment for Alzheimer's disease.

Title: Comparative study of biochemical markers in cerebrospinal fluid in dog after intracerebroventricular injection of streptozotocin

Authors: *G. KIM, H. OH, M. KIM, Y. JO, J. CHOI, B. LEE;
Theriogenology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Dogs naturally develop to cognitive dysfunction like Alzheimer disease (AD) in human. Several studies indicate that cerebrospinal fluid (CSF) composition depends on the disease stage and reflects the brain pathology in AD patients. The goal of this study is to investigate the concentration of various biochemical markers in CSF of dogs after icv-STZ to propose a new AD animal model. In icv-STZ group, STZ was injected into CSF via the cerebro-medullary cistern using 25G needle on day 1 and 7 under general anesthesia. They received a

single infusion of various doses of STZ (0.5 mg/kg, 1 mg/kg or 1.25 mg/kg). In the control group, same volume of saline solution was injected. CSF drainage was also performed at pre-injection (day 1) and on days 7, 14 and 21. Collected CSF was used for analysis of glucose, sodium, chloride, potassium, pyruvate and lactate concentrations. After the procedure, dogs were replaced on a cage at room temperature and were carefully observed until recovery from anesthesia. After 1 and 7 days of STZ injection, there was no significant change in the biochemical markers among the dogs infused with all varius doses of STZ compared to control dogs. However, 14 days after STZ injection, icv-STZ dogs that was injected with 1.25mg/kg showed significant high concenetrations of lactate, pyruvate and potassium in CSF samples ($P < 0.05$) compared to other dogs with doses of 0.5 mg/kg and 1mg/kg. After 21days, icv-STZ dogs injected of 1mg/kg and 1.25 mg/kg had higher concentration of lactate, pyruvate and pottasium ($P < 0.05$) than those of control and 0.5mg/kg. No significant differences in the levels of sodium, chloride and glucose of all treated groups were observed. These biochemical markers alteration in icv-STZ dogs is similar to those observed in human AD patients. These result suggests the possibility of using icv-STZ dogs as human AD models because of alterations in CSF composition after icv-STZ.

Title: The effects of agmatine on alzheimer’s disease induced by brain insulin resistance

Authors: S. KANG[1,2], *J. SONG[1], W. LEE[1], K. PARK[1], J. LEE[1,2];
[1]Anat., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]BK21 Plus Project for Med. Science, and Brain Res. Inst., Seoul, Korea, Republic of

Abstract: Type 2 diabetes mellitus (T2DM) has detrimental effects in various organs including the brain. Many studies reported that patients with T2DM suffer from cognitive decline and

severe process of Alzheimer's disease due to brain insulin resistance. Insulin, the hormone secreted from beta-cells in pancreas, regulates glucose uptake in peripheral tissues and modulates also cognitive and memory dysfunction in brain. Agmatine is an endogenous aminoguanidine compound made from arginine producted by arginine-decarboxylase (ADC) gene. It shows positive effects on a variety of diseases including diabetes, stroke, Alzheimer's disease, depression. In present study, we investigated the agmatine's neuroprotective effect in type 2 diabetes induced Alzheimer's disease mouse model. Male ICR mice were fed a 60% high fat diet (HFD) for 8 weeks and intraperitoneally injected streptozotocin (100mg/kg) at 4th week. Then, mice were intraperitoneally administered with agmatine (100mg/kg) for 2 weeks. Following agmatine injection, mice were subjected to perform Morris Water Maze for identify their cognitive decline and its recovery. After that, mice were sacrificed and brains were prepared for immunohistochemistry (IHC) and western blot assay. To determine biochemical changes, we checked blood glucose level, body weights once a week, and serum insulin level at the end of experiment. For confirm insulin resistance state, we conducted glucose tolerance test and insulin tolerance test, and calculate the HOMA-R index using blood glucose level and serum insulin level. The treatment of agmatine alleviated insulin resistance and improved cognitive decline in Alzheimer's disease mouse model induced by high fat diet. Thus, we concluded that agmatine may alleviate the pathologies of Alzheimer's disease through improving the insulin resistance in brain.

Title: Intra-cerebro-ventricular erythropoietin reverses morphological and cognitive deterioration in a streptozocin-induced Alzheimer's disease rat model

Authors: ***G. O. PEKER**[1], V. SOLMAZ[2], T. CAVUSOGLU[3], G. YIGITTURK[3], O. ERBAS[4]; [1]Physiol., [2]Neurol., [3]Histology-Embryology, Ege Univ. Fac. of Med., Izmir, Turkey; [4]Physiol., Osmangazipasa Univ. Fac. of Med., Tokat, Turkey

Abstract: Background & Aim: Alzheimer's (AD) is the most devastating disease with highest prevalence rate in late middle-old aged population universally. Progressive aggregation of amyloid plaques and neuro-fibrillary tangles, and resultant neuronal death characterize this incurable, but poorly and only palliatively manageable disease. Erythropoietin (EPO) is the essential tropic/local hormone stimulating primarily red blood cell generation and maturation, and overall blood cellular elements plus several other tissues. We aimed to simulate AD in relatively older adult rats by inducing "acute brain diabetes" using intra-cerebro-ventricularly (ICV) administered streptozocine (STZ) and then comparing shuttle box performance of those chronically treated with and without systemic EPO (Epprex, Janssen). Material & Methods: With the approval of the Ege University Experimental Animal Ethics Committee, we handled 24 male (16 m.o.) Sprague Dawley rats; then, administered 12 rats STZ (3mg/kg in saline, total V=5µL, ICV, bilaterally); administered 6 rats saline (Group III) in equal V, through the same route; and spared 6 rats as naive controls (Group IV). Twelve STZ rats were then distributed randomly as Group I and Group II (n=6, each). Group I received EPO (5000IU/kg/d, ip) and Group II (placebo) received saline (1ml/kg/d,ip) for 15 days. Passive avoidance learning (PAL) task and endurance of its memory were assessed (as described in the authentic literature) in every rat starting from the 16th day on. On the 18th day, all rats were euthanized, and their brains were fixed and sectioned for Nissl staining for neuronal counts, especially in their respective, corresponding CA1 and CA3 hippocampal regions and levels. Findings & Results: Both hippocampal CA1 and CA3 neuronal counts and PAL task and memory scores showed very significant ($p<0.000$) differences between the STZ-treated (Groups I and II) and saline-treated (Group III) and naive control (Group IV) rats. STZ + EPO-treated Group I showed significant ($p<0.05$) improvements both histologically and behaviorally, compared to STZ + saline-treated Group II. Conclusion & Future Plan: Our "acute brain diabetes" model has worked out. ICV EPO has definitely favored histology, at least in the quantity and gross outlook of the neurons of interest, and more importantly, the PAL paradigm which is an index of a simple behavioral homeostasis-related cognitive function. We foresee enlightening differentially and more specifically whether this remarkable neuro-protective/neuro-restorative effect of EPO has been direct (genomic), indirect (metabolic) or both.

Title: Interactive effects of high fat diet and testosterone on neuroinflammation and Alzheimer's-related pathways

Authors: *V. A. MOSER, A. JAYARAMAN, J.-W. LEE, C. J. PIKE;
Andrus Gerontology Ctr., USC, Los Angeles, CA

Abstract: Despite the complex etiology of Alzheimer's disease (AD), a number of risk factors for the onset and progression of this neurodegenerative disorder have been identified. Among these are obesity and age-related decline in testosterone levels in men. Interestingly, obesity and testosterone are reciprocally interactive, with low testosterone promoting obesity and vice versa. Although both of these risk factors have been independently linked with AD, their potential interactions in regulating AD pathogenesis and the underlying mechanisms have thus far not been explored. A pathway common to both obesity and testosterone that is also associated with AD is inflammation. Thus, the goal of the current study was to examine the independent and combined effects of testosterone and obesity on AD outcomes and to explore neuroinflammation as a potential mechanism underlying these effects. To this end, we experimentally manipulated testosterone and obesity in both wild-type rodents and a mouse model of AD, then evaluated indices of inflammation and AD-related pathways. Male mice were maintained on either a control or a high fat diet for four months under varying levels of testosterone: sham orchidectomized (ORX), ORX, and ORX + testosterone replacement. Mice on high fat diet developed metabolic syndrome, as indicated by insulin and glucose resistance, had significantly higher levels of soluble β-amyloid, and also showed a marked increase in gene expression of pro-inflammatory cytokines. Moreover, the effects of high fat diet were exacerbated under conditions of testosterone depletion, whereas testosterone replacement therapy improved AD and neuroinflammatory outcomes, in both the presence and absence of high fat diet. In summary, we find that testosterone and diet-induced obesity independently and cooperatively impact metabolic, inflammatory, and AD-related endpoints, suggesting that neuroinflammation may be an important underlying mechanism in the process of these diseases.

Title: *In vivo* imaging of smooth muscle cell loss during the progression of cerebral amyloid angiopathy

Authors: M. ARBEL-ORNATH[1], A. KIM[1], J. RAMOS-RODRIGUEZ[2], L. ZHAO[1], M. GARCIA-ALLOZA[2], S. M. GREENBERG[1], M. P. FROSCH[1], *B. J. BACSKAI[1]; [1]Dept Neurol., Mass Gen. Hosp., CHARLESTOWN, MA; [2]Biomedicine, Inst. of Biomolecules (INBIO), Univ. of Cadiz, Cadiz, Spain

Abstract: Cerebral amyloid angiopathy (CAA) is an age-related disease that frequently co-occurs in Alzheimer disease (AD) patients. Like the senile plaques of AD, the cerebrovascular deposits in CAA are comprised primarily of the β-amyloid peptide. The pathological manifestations of CAA include vascular smooth muscle cell (VSMC) degeneration and hemorrhagic and ischemic stroke. CAA-related hemorrhages are not readily preventable, and represent a serious and debilitating outcome in affected patients, highlighting the need to understand the vascular components of amyloid deposition. The concomitant accumulation of amyloid deposits along arteries and VSMC loss is established and play a crucial role in the collapse of the vessel wall and subsequent hemorrhage; however the temporal and spatial relationship between the two phenomena remains poorly understood. This is largely because the meningeal vessels, which are the ones affected by CAA in the available mouse models, are difficult to study post mortem. To better understand the close interaction between accumulation of amyloid at the arterial wall and degeneration of VSMC we established a colony of AD mouse model (APPSW/PS1dE9) in which the VSMC express EGFP (smMHC/Cre/eGFP)and took advantage of advanced imaging techniques to perform longitudinal *in vivo* imaging during the progression of CAA. This methodology allowed us to closely inspect individual VSMC over months and ask how the amyloid insult affects their structure/presence. Longitudinal *in vivo* imaging of the cerebrovasculature of these mice along CAA progression revealed an overall age-dependent loss of VSMC which correlated with the amyloid progression rate. Importantly, wild type littermates showed preserved VSMC viability. A closer inspection of both VSMC and CAA in the APP/PS1 mice at small vessel segments showed that amyloid burden itself does not correlate with VSMC loss and cannot be used to predict cell loss. This can be due to unknown factors that affect VSMC in these animals or that vessel physiology may be affected by CAA up- or downstream to it and not necessarily by this within the segment itself. Altogether, amyloid deposition on vessel walls, and the subsequent loss of VSMC may contribute to the arteries

thickening, decreased contractility and eventual collapse of the vessel wall and hemorrhage evident in CAA brains. Understanding the intimate interaction of amyloid deposition and VSMC loss and vessel dysfunction throughout the course of the disease may elucidate novel underlying mechanisms. Moreover, the ability to quantify VSMC loss during CAA progression highlights the potential of this model for evaluation of therapeutic interventions.

Title: Comparative genome-wide analysis of RXR binding and expression profiling in Bexarotene treated APOE4 mice

Authors: *D. GEORGIEV, A. MOUNIER, K. NAM, N. F. FITZ, A. A. CRONICAN, I. LEFTEROV, R. KOLDAMOVA;
Dept. of Envrn. & Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Retinoid X receptors (RXRs) are ligand-activated transcription factors that form permissive heterodimers with Liver X Receptors (LXR). Recently we have shown that RXR ligand Bexarotene improves memory and Aβ clearance in amyloid precursor protein (APP) mice expressing human apolipoprotein E (APOE) isoforms. To identify direct RXR targets genome-wide we applied chromatin immunoprecipitation followed by high-throughput sequencing

(ChIP-seq). We chose mice expressing endogenous APP to avoid possible effects of Aβ pathology on transcription factor binding. Since we were particularly interested in determining the effect of RXR binding in APOE4 and APOE3 expressing mice we chose 6 months old targeted replacement mice (WT/E4). Functional annotation clustering using Database for Annotation, Visualization and Integrated Discovery (DAVID) revealed unique Biological Process (BP) Gene Ontologies that were significantly enriched in samples from Bexarotene treated animals. The highest significantly enriched clusters in Bexarotene treated samples only were transcription regulator activity, vascular development and neuron differentiation. To determine how Bexarotene affects mRNA levels and potentially gene expression in brain, we applied high-throughput mRNA-seq technology with RNA isolated from cortices of the same mice. We identified 1440 differentially affected genes. Of those, 1020 were up- and 420 down-regulated. Among the up-regulated genes the first BP categories identified as significantly enriched were: ion transport, neuron differentiation and intracellular signaling cascade; among the down-regulated: neuron differentiation, regulation of transcription from DNA and RNA polymerase. By comparing the list of genes identified by ChIP-seq as unique binding sites in Bexarotene treated mice (27 genes) and genes differentially affected as identified by RNA-seq (55 genes; GO:0030182~neuron differentiation) we revealed differentially affected genes which are direct RXR targets. We further validated the effects of RXR-specific ligand treatment on neuron differentiation/neurogenesis in cell culture systems and *in vivo* using Next Generation Sequencing and immunohistochemistry. Conclusion: these preliminary data demonstrate the applicability of new and powerful sequencing technologies for research in Alzheimer's disease model mice and for addressing questions with significant therapeutic implications.

Title: Chronic sucrose intake is related with early cognitive impairments in 3xTg-AD and non transgenic mice

Authors: *K. R. GUZMAN-RAMOS[1,2], L. AYALA-GUERRERO[1], P. GARCIA-DELATORRE[3], F. BERMUDEZ-RATTONI[1], G. PACHECO -LOPEZ[2];

Abstract: High sugar diets are among the most popular within the western societies and their consumption have produced health detriments at the central nervous system level. It is known that high caloric diets and type 2 diabetes are risk factors for the development of dementias, and particularly Alzheimer's Disease (AD). However, the molecular and metabolic events that lead to cognitive impairments are not clear. We studied the effect of a sucrose rich diet in two types of mice: a murine model of AD harboring three mutations related to the amyloid beta and p-tau accumulation (3xTg-AD) and non-transgenic strain where the transgenic was developed (WT). As a consequence of high sucrose diet, we found an early deterioration of object and taste recognition and spatial memories in the 3xTg-AD mice that underwent sucrose diet for 5 months (7 months of age at the time of tests), comparable to the deterioration found in the 12 months-old 3xTg-AD mice group that had a normal diet. Additionally, the high sucrose diet induced in the WT mice a cognitive impairment in the taste recognition and spatial memories also comparable to 12 month-old 3xTg-AD mice. Metabolic and molecular dysfunctions of glucose biochemistry are also related to the cognitive performance of the affected groups. This data suggest that an early exposure to high caloric food has a powerful impact on the acceleration or production of cognitive impairments.

Title: Learning and memory is largely intact in an idiopathic rat model of Alzheimer's Disease that pairs Aβ injections with either stress or cholinergic depletions

Authors: *S. H. DEIBEL, N. S. HONG, R. J. KEELEY, R. J. BALOG, C. M. BYE, S. MACINNIS, S. M. HIMMLER, R. J. MCDONALD;

Abstract: Alzheimer's disease (AD) is likely a disease of complex etiology, which involves multiple risk factors. When these risk factors are presented concomitantly, cognition and brain pathology are more severely compromised than if those risk factors were presented in isolation. Reduced cholinergic tone, stress, and elevated beta-amyloid (Aβ) load are all risk factors for AD. The present studies sought to investigate alterations in learning and memory in a variety of tasks when Aβ was paired with either stress or cholinergic depletions. Male Long-Evans rats received either sham surgeries, stress (2 week variable stress paradigm), cholinergic depletions of the medial septum, Aβ25-35 injections, both cholinergic depletion and Aβ25-35 injections (Aβ + ACh group), or both stress and Aβ25-35 injections (Aβ + stress group). Both the Aβ + ACh and Aβ + stress rats had impaired acquisition in the standard version of the Morris water task during the first half of training but displayed normal retention and no impairment in acquisition of a novel platform location during a single massed training session. Similarly, the Aβ + ACh and Aβ + stress rats were not impaired in the discriminative fear-conditioning to context task or the stimulus-response radial arm maze task. Despite minor cognitive deficits, the Aβ + ACh rats had reduced cholinergic tone in the hippocampus as indicated by a reduction in dorsal hippocampal acetylcholinesterase staining. These data suggest that certain components of memory in the Morris water task are impaired by pairing Aβ with either cholinergic depletions or stress, when behavioural testing is conducted shortly after the presentation of these factors. The pattern of effects also suggests that only subcircuits of the hippocampus are dysfunctional.

Abstract: The accumulation of amyloid-β peptide (Aβ) in the brain plays a central role in the pathogenesis of Alzheimer's disease (AD). The balance between Aβ generation and elimination determines the steady-state concentration of Aβ in the brain. Human studies strongly suggest that a key factor leading to Aβ accumulation is a defect in clearing the peptide from the brain. Several mechanisms involved in Aβ clearance have been identified, and some of these mechanisms may be fast-acting and are unavailable to measure using currently available tools. We have recently developed a novel microimmuno-microelectrode (MIE) to detect brain ISF Aβ every 30-60 seconds in living mice, using square wave voltammetry. This new technique provides the temporal resolution necessary to assess very rapid changes in Aβ elimination in living mice. In our design, specificity is achieved by using anti-Aβ antibodies immobilized to the electrode surface. Anti-Aβ antibodies capture/bind Aβ molecules to the MIE surface and decrease the electron tunneling distance between the electrode and Aβ molecules. MIEs are prepared similar to our previously described methods (Prabhulkar et al., 2012). Activation of carboxylic groups on the carbon fiber surface is achieved by application of EDC/NHSS to form a semi-stable reactive amine NHS ester. The activated microelectrodes are placed in a solution of anti-Aβ antibody. Following antibody attachment, MIEs are incubated with 0.1 % ethanolamine to block reactive NHS sites then 0.15% BSA to block any non-specific protein binding sites. We are using MIEs to determine the rapid kinetics of protein elimination in mice that have suppressed clearance mechanisms. By using a combination of pharmacological and genetic inhibition of proteases and transporters we can assess how these different clearance pathways act in synergy on Aβ. Using the MIEs, we can demonstrate that the elimination half-life of ISF Aβ *in vivo* is very short ($t_{½}$ = 37.5 minutes). This tool can be used to assess the fast-acting clearance mechanisms in the brain of living AD transgenic mice. This study was funded by: NIH R01 AG042513, P01 NS074969, R21 AG045691, and the Knight Alzheimer's Disease Research Center at Washington University.

Title: Restoration of cognitive function in the triple transgenic mouse model of Alzheimer´s diseases by the LXR agonists GW3965: Potential molecular mechanism

Authors: *A. G. SANDOVAL HERNANDEZ, SR[1], G. P. CARDONA-GÓMEZ[2], G. ARBOLEDA[1];
[1]Cundinamarca, Inst. De Genetica - Univ. Nacional Sede Bogota, Bogota D.C., Colombia; [2]Area de Neurobiología Celular y Molecular. Grupo de Neurociencias de Antioquia. Univ. de, Medellin, Colombia

Abstract: Alzheimer's disease (AD) is the major cause of dementia. The pharmacological activation of nuclear receptors (Liver X receptors: LXRs or Retinoid X receptors: RXR)has been showed to induce overexpression of the ATP-Binding Cassette A1 (ABCA1) and Apolipoprotein E (ApoE), changes that are associated to the improvement in cognition, reduction of neuroinflammation. This treatment has showed to increase the clearance of amyloid load soluble and insoluble in some specific AD models, but the mechanism on cognitive improvement is not completely understood yet. Our may aim is to analyze the potential mechanism of LXR activation involved in the improvent of the cognitive function in old 3xTg-AD mice model. We used de LXR agonist GW3965 (33mg/kg/day) administered i.p. during 12 weeks (long-term treatment) in 3xTg-AD mice at 12 months of age. We realized spatial learning and memory analysis by Morris Water Maze test, evaluated amyloid load by immunohistochemistry and soluble Aβ by ELISA. Also, we used ApoE immunoreactivity and its correlation with Glial Fibrilary Acidic Protein (GFAP), Neuronal Stem Cells marker Nestin and proliferating cells Phospho histone H3, neurons markersNeuN and Doublecortin (DCX), oligodendrocytes markers (O1 and O4) and myelin marker myelin Basic Protein (MBP) by Laser Confocal Microscopy. Our finding confirmed that LXRs agonist GW3965-treated 3xTg-AD mice showed better performance in the learning and memory tasks, correlated whith an increase in the ApoE and ABCA1 immunoreactivities in the hippocampus and cerebral cortex of 3xTgAD treated mice. Soluble and insoluble amyloidosis labeling did not present any changes. Novelty, we found that ApoE overexpressing are mostly localized in neurons (86±12%) particularly in the GCL of hippocampus and entorhinal cortex of GW3965-treated 3xTg-AD mice, accompanied by an

increase in the number of stem and proliferating cell, a significant increase in oligodendrocytes markage (O1 and O4) and myelin markers in the Dentate Gyrus without changes in mature neurons and a significant reduction of astrogliosis (GFAP+). Together our data suggest an alternative molecular mechanism by which LXRs agonist could exert control on lipid transport in neurons, generating neuroprotection, neurogenesis and remyelinization, changes that are of potential benefit as a therapeutic strategy against AD.

Title: Rat P3 ERP in behavioral chains as a function of cue duration, inter-event interval, and predictability of reinforcement

Authors: *W. D. KLIPEC[1], A. PAJSER[2], R. LEWIS[1], T. GRAY[1], K. ELDER[1];
[2]Psychology, [1]Drake Univ., Des Moines, IA

Abstract: The human P300 Event Related Potential (ERP) is a time locked, averaged EEG to task relevant stimuli. Previous research in our laboratory has shown that a robust P3 ERP, recorded in freely behaving rats, is decremental function of its proximity to the primary reinforcer in backward chaining, suggesting that the P3 ERP is a correlate of conditioned reinforcement. Because many of the stimuli in behavioral chains occur in close temporal proximity, the ERPs may overlap and interfere with each other. Previous research in our laboratory has established the optimal delays for lever insertion and food delivery. In this paradigm, a 4.0 kHz, 80 dB tone cues the insertion of a lever, following a 1-sec delay. Responding on the lever delivers reinforcement on a VR-6, schedule of reinforcement, cued by a 5.5 kHz, 80 dB tone where food reinforcement is delivered after a 1.3-sec delay. As a control, a random non-target 2.5 kHz, 80 dB tone was presented on an 8:1 non-target to target ratio. Here we manipulated tone duration and found that the P1, P2 and P3 ERP latencies were a function of tone onset and unaffected by tone duration. We found no systematic changes in amplitude. By triggering lever insertion and pellet delivery by tone offset, we found that P3 ERP latencies to lever insertion and food delivery moved proportionate to the tone duration, confirming that these

P3 ERPs were a function of those events. While holding tone duration constant we manipulated the density and predictability of the reinforcers by using fixed (FR) and variable (VR) ratio schedules of reinforcement. Here we found that the P3 amplitude was greater when the reinforcer was unpredictable (VR) compared to predictable (FR). This suggests that the P3 ERP is dependent on the informational value of the tone cue rather than just the occurrence of, or effort to produce the reinforcer. The data replicated the finding that P3 ERP amplitude is a decremental function of its proximity to the primary reinforcer in backward chains. We have now established the optimal parameters in this paradigm for producing a robust and reliable P3 ERP in rat model of the human P300 ERP paradigm. Our data strongly suggest that the rat P3 ERP is the equivalent of the human P300 ERP. Accordingly, this animal model of the human P300 ERP would be an excellent tool for conducting pharmacological investigations on the substrates of the P300 ERP. Moreover, since alterations in the human P300 ERP are trait markers for schizophrenia and early onset Alzheimer's disease, and since rat models of schizophrenia and Alzheimer's disease exist, the rat P3 ERP may also be a useful tool for research on these diseases.

Title: NMR analysis of cerebrospinal fluid: Animal model of Alzheimer disease

Authors: *E. MUGANTSEVA, S. PASKEVICH, M. MOLCHANOV, M. TIMCHENKO; Inst. of Theoretical and Exptl. Biophysics RAS, Pushchino, Russian Federation

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive loss of cognitive functions. According to the amyloid cascade hypothesis, the aggregated forms of the amyloid-beta peptides initiate pathological processes in neurons of the

hippocampus, the cortex, and some other structures of the brain. Finding biomarkers for diagnosis of Alzheimer's disease in early stage is one of the most important neuroscience problems. The aim of this study was to investigate metabolite profiles of cerebrospinal fluid using NMR-spectroscopy. In the present work, Aβ25-35 or vehicle was bilaterally injected into the cerebral ventricles of rats. The concentrations of main metabolites in cerebrospinal fluid (CSF), hippocampus, frontal cortex in control rats and rats with administration of beta amyloid were received. We studied over 30 metabolites. Adenosine triphosphate level in CSF was decreased. Glucose level reduced as well as pyruvate and creatinine concentration. Decreased levels of N-acetyl aspartate have been interpreted to indicate neuronal/axonal loss, or compromised neuronal metabolism. NMR analysis of the brain and spinal fluid major metabolites revealed altered metabolic profile.

Title: Allopregnanolone rescues rotenone induced cognitive impairment in mice with apoe4 domain interaction

Authors: *J. WANG, X. HOU, S. ADEOSUN, Q. ZHANG, B. ZHENG;
Dept. of Pathology, Univ. Mississippi Med. Cent, Jackson, MS

Abstract: Although the causes of Alzheimer’s disease (AD) are not fully understood, it is accepted that AD is caused by multiple risk factors rather than a single one. Besides the greatest risk factor of advancing age, several known genetic variations and environmental toxins contribute to the development of AD. These include the apolipoprotein E4 (ApoE4) allele, which is the major genetic risk factor for sporadic Alzheimer’s disease (AD), due to the higher prevalence and earlier onset of AD in apoE4 carriers. Our previous works and those of others

indicated that the interaction between the N- and the C-terminal domains in the protein may be the main pathologic feature of ApoE4**.** Rotenone, a wildly used broad-spectrum pesticide, is reported a potential neurotoxin for some neurodegenerative disease. Here we sought to investigate the cognitive and neural pathology interactions between the apoE4 domain interaction and rotenone exposure. We further tested the therapeutic potential of a neurogenic neurosteroid, allopregnanolone, in the restoration of cognitive function and brain neuronal circuits in these mice. In this study, the domain interaction in apoE4 is modeled via a point mutation (Thr-61 to Arg-61) from that introduces the domain interaction feature of human apoE4 into native mouse ApoE. The hippocampal dependent spatial and working memory, as assessed by radial arm water maze and novel arm discrimination, was impaired in Arg-61 mice when compared to C57BL/6J mice. The systematic-administration of rotenone caused the learning and memory impairment in C57BL/6J mice and further worsened the impairment in Arg61 mice. After the treatment of allopregnanolone, the short term and long term memory in Arg61 mice was improved. Allopregnanolone was also able to rescue the rotenone induced cognitive deficits in both C57BL/6J mice and Arg61 mice. We are in the process of characterizing cellular and molecular mechanisms that may explain these behavior findings. Our study demonstrated that ApoE4 domain interaction interacts with a neurotoxin, rotenone, and accelerate the cognitive impairment in AD. And in addition, allopregnanolone promotes the cognitive function and may serve as a therapeutic strategy for sporadic AD.

Title: Adult mesenchymal stem cells have a potential to lower cerebral Abeta amyloidosis in Alzheimer’s disease mouse model

Authors: *T. BOLMONT[1,2], A. LUKASHEV[2], T. LASSER[1];
[1]EPFL STI IMT LOB, Lausanne, Switzerland; [2]stemedica Int, Lausanne, Switzerland

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder pathologically characterized by extracellular senile plaques, primarily composed of polymerized amyloid-beta (Abeta) peptides. There is currently no cure for this devastating disease that represents one of today's major healthcare challenges due to its severe socio-economic burden. The huge potential offered by adult ischemic-tolerant mesenchymal stem cells (itMSC) for the treatment of various neurodegenerative disorders including AD is still not fully exploited. Safety phase I clinical trials with peripheral itMSC delivery have been successfully completed, however the impact of these cells on Abeta amyloid pathology have not been yet investigated in a pre-clinical study. To this end, we evaluated the impact of a repeated intravenous itMSC delivery on amyloid pathology in a mouse model of Alzheimer's disease. Ten weeks of itMSC treatment safely reduced cerebral Abeta plaques (~ - 30 %) in amyloid-depositing Alzheimeric mice. Microglial activation was quantified to evaluate neuroinflamation changes in transgenic brains following itMSC treatment. The beneficial effect on plaques was accompanied by a significant diminution of neuroinflammation markers without appearance of cerebral amyloid angiopathy (CAA) or microhemorrhages. An innovative imaging technology was developed to enable the three-dimensional visualization of individual Abeta plaques *in vivo* as well as quantitative blood flow imaging (Bolmont et al., 2012, Bouwens et al.,2013, 2014), giving an unprecedented opportunity for investigation at the microscopic scale of functional brain alterations related to amyloid deposition and clearance by itMSC in living Alzheimer mice.Our pre-clinical results indicate that adult itMSC can decrease Abeta amyloid pathology in a mouse model of Alzheimer's disease. As revealed in the current study, the combination of safety and efficacy to remove amyloid plaques offered by itMSC, together with successfully completed safety phase I clinical trials, may put itMSC as a perspective candidate for treating AD.

Abstract: Traumatic brain injury (TBI) is a major cause of disability in the military and civilian population, and for many years has been known to be a major risk factor for Alzheimer's disease (AD). Although the existence of this relationship is well recognized, and the overlap and distinction between pathological features of AD and TBI, have long been the subject of reporting and discussion, the precise nature of how TBI leads to or precipitates AD pathogenesis is currently not understood. To address this problem we are generating time-dependent molecular profiles of response to TBI and AD pathogenesis in mouse models, using proteomic and lipidomic analyses. We are using the well-validated PSAPP (PS1(M146L), APP(K670N,M671L) and hTau mouse models of AD that develop human amyloid and tau pathological features, and our well established model of single and repetitive mild TBI (mTBI) in C57BL/6 mice. Brain tissue and plasma from these animals are being collected at different ages (for AD models), or at different timepoints after single or repetitive mTBI. Liquid chromatography/mass spectrometry (LC-MS) and in source collision induced dissociation (SCID) approaches will be applied to develop molecular profiles of proteins and lipid species that are significantly differentially expressed as a consequence of AD or mTBI. We anticipate that the exploration of molecular profiles in brain and plasma samples from these animal models of mTBI and AD will enable us to identify cellular pathways that have pathogenic significance in human conditions. Moreover, we aim to further explore these identified pathways as potential targets for therapeutic intervention. Preparation of tissue and plasma samples and Omic analyses are currently ongoing and comparisons of TBI profiles at 24hrs and 3 months post-injury with profiles at 3 months of age in the AD models will be presented. This study is funded by a CDMRP award to FC (DoD/W81XWH-13-1-0253), and by the Roskamp Foundation.

Title: The galantamine prodrug, Memogain®, reverses deficits in hippocampal neurogenesis associated with the loss of basal forebrain cholinergic neurons

Authors: *J. M. VAN KAMPEN[1,2], D. G. KAY[1], A. MAELICKE[1];
[1]Neurodyn Inc., Charlottetown, PE, Canada; [2]Biomed. Sci., Univ. of Prince Edward Island, Charlottetown, PE, Canada

Abstract: Loss of basal forebrain cholinergic innervation of the hippocampus and severe neuronal loss within the hippocampal CA1 region are early hallmarks of Alzheimer's disease (AD), and are strongly correlated with cognitive status. This loss of cholinergic innervation is a key factor underlying alterations in hippocampal neurogenesis, which are also characteristic of AD. We have previously reported the effects of various cholinergic compounds on hippocampal neurogenesis indicating that acetylcholine serves as a potent neurogenic regulator. Memogain® (GLN 1062) is an inactive galantamine pro-drug with 15 fold higher brain availability than galantamine. It is designed to provide improved blood brain barrier penetration, greater potency, and fewer side effects than the cholinesterase inhibitors currently used for the treatment of Alzheimer's dementia. This would serve both to promote patient adherence and permit the use of higher doses. Galantamine is unique among the cholinesterase inhibitors in that it also has allosteric actions at α-7 nicotinic receptors, activation of which has been linked to both disease-modifying and cognitive enhancing effects, as well as effects on hippocampal cell proliferation. Here, we describe the neurogenic actions of Memogain® in a rodent model of cholinergic depletion. Infusion of the immunotoxin, 192IgG saporin (SAP), used to induce selective basal forebrain cholinergic cell loss reminiscent of that found in AD, resulted in a pronounced loss of basal forebrain cholinergic neurons and hippocampal ChAT fiber density. Consistent with earlier reports, SAP-lesioned animals had significantly fewer BrdU+ and PCNA+ cells in both the dentate gyrus and CA1 region of the hippocampus, when compared to sham-operated control animals. These animals also displayed significant impairments in spatial working memory, as assessed by a T-maze and the radial arm maze. By contrast, animals treated with Memogain® displayed a restoration of hippocampal cell proliferation, increased neuronal cell counts, normalized neuronal migration, and improvements in cognitive function. Thus, the beneficial effects of Memogain® may extend beyond acute cognitive enhancement, to include disease modification through support of hippocampal neurogenesis.

Title: Involvement of DNA polymerase beta in the regulation of neurogenesis in aging and Alzheimer’s disease

Authors: *M. M. MISIAK[1,2], P. SYKORA[1], D. CROTEAU[1], V. A. BOHR[1], M. P. MATTSON[2];
[1]Lab. of Mol. Gerontology, NIH/National Inst. On Aging, Baltimore, MD; [2]Lab. of Neurosciences, NIH/National Inst. on Aging, Baltimore, MD

Abstract: Alzheimer’s disease (AD) involves the progressive degeneration of neurons critical for learning and memory. In addition, findings from animal models and postmortem human brains suggest that neurogenesis in the hippocampus and olfactory bulb (OB) is impaired during aging and in AD. Olfactory deficits occur during normal aging, and a more profound olfactory deficit is an early symptom of AD. Because DNA base excision repair (BER) is reduced in aging and AD, we tested the hypothesis that inefficient BER due to reduced DNA polymerase-β (Polβ) levels can disrupt proliferation, differentiation and cellular metabolism in neural stem cells (NSC) in the adult brain. In the absence of Polβ, neurons in the brains of mice undergo massive perinatal apoptosis. Polβ levels in the brain decrease with normal aging, and in Down syndrome patients who invariably develop AD-like pathology, cognitive impairment and olfactory deficits. We noticed that Polβ-/- mouse embryos lack a discernible OB. To study the role of Polβ in neurogenesis during aging and in AD, Polβ+/- mice were crossed with 3xTgAD mice (an AD mouse model). We injected Polβ+/+, Polβ+/-, 3xTgAD and Polβ+/-/3xTgAD mice (cohorts of 6 and 14 month-old mice)with bromodeoxyuridine (BrdU) to monitor neurogenesis. The analysis demonstrates that Polβ+/- and 3xTgAD, have significantly decreased neuronogenesis in the hippocampus and in the OB, relative to wild type age-matched controls. The extent of reduced neurogenesis in the hippocampus was not substantially different between the Polβ+/-, 3xTgAD and the Polβ+/-/3xTgAD mice. The decline in BrdU-positive cells was correlated with an

increase in apoptosis in each strain. However, the Polβ+/-/3xTgAD mice showed the most substantial level of apoptosis suggesting that the DNA damage caused by lack of Polβ compounded by the stress of the amyloid and Tau accumulation in 3xTgAD mice converge on the apoptotic pathway. Consistent with the biochemical findings, the Polβ+/-/3xTgAD mice showed the most severe memory impairment in behavioral tests. Currently we are testing olfaction in the mice using multiple behavioral tests. We are also performing studies aimed at establishing the molecular mechanisms by which deficiency in a DNA repair enzyme adversely affects cellular energy metabolism and neurogenesis.

Title: Can the d-galactose administration by oral route in Wistar rats mimics the Alzheimer disease?

Authors: *J. BUDNI[1], R. PACHECO[1], S. DA SILVA[1], M. L. GARCEZ[1], F. MINA[1], J. DE MEDEIROS[1], S. M. FREITAS[1], D. V. VITTO[1], S. S. VALVASSORI[1], G. SCAINI[1], E. L. STRECK[1], J. QUEVEDO[1,2];
[1]Hlth. Sci. Unit, Univ. of Southern Santa Catarina (UNESC), Criciúma, Brazil; [2]Dept. of Psychiatry and Behavioral Sci., The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Background: Chronic systemic d-galactose administration using as a model of aging and Alzheimer disease in rodents, d-galactose is a reducing sugar at high levels, that can form advanced glycation endproducts, induce neurological impairments, mitochondrial dysfunctions and oxidative stress. The use of D-galactose administration by oral route is still controversial, if mimetic neurodegenerative disorders and brain aging or neuroprotective alternative, the

alterations d-galactose administration by oral route are still unknown, especially the changes in energy metabolism. **Objective:** The purpose of this study was to investigate the effects of on acquisition of short- and long-term memories through the inhibitory avoidance test and habituation to a novel environment, measure respiratory chain enzyme activities and levels of blood glucose in rats treated with d-galactose chronic administration by oral route. **Methods:** Wistar male adult rats received water or d-galactose (100 mg/kg) by oral gavage, once a day, during 8 weeks. Short-term and long-term memories were tested 1.5 and 24 h after training, respectively, in the inhibitory avoidance and 24 h after training in open field. Activity of mitochondrial respiratory chain complexes (I, II, III, and IV) was measured in prefrontal cortex and hippocampus and levels of blood glucose was measured the end of 1, 2, 4, 6 and 8 weeks after treatment. **Results:** Was observed cognitive impairment in open-field test and inhibitory avoidance tests in 4 weeks after initial treatment, in addition, rats showed cognitive impairment after 6 weeks of treatment with d-galactose observed by the decrease of the crossings in open field test. In biochemical analysis was observed increased activity of respiratory chain complexes I, II, II-III e IV in pre frontal cortex and hippocampus since the first week to the eighth week of treatment and only after the second week of treatment was observed increase in glucose concentration in animals treated with d-galactose. **Conclusion:** The administration of d-galactose by oral route caused cognitive impairment mainly 4 and 6 weeks of treatment, possibly this model mimics the mitochondrial abnormalities in early stages of Alzheimer disease. More studies should be conducted to elucidate the mechanisms by which d-galactose administrated via orally generates cognitive changes observed in this model.

Title: Neurotoxicity of alumina nanoparticles in transgenic mice bearing susceptible genes of Alzheimer's disease

Authors: *Q. ZHANG[1,2], B. ZHENG[1], R. KAUR[1], J. WANG[1];
[1]Pathology, Univ. of Mississippi Med. Ctr., Jackson, MS; [2]Dept. of Occup. Hlth., Sch. of Publ. Health, Shanxi Med. Univ., Taiyuan, Shanxi 030001, China

Abstract: Increasing exposure to environmental pollutants, such as nanoparticles (NPs) may be responsible for the prevalence of neurodegenerative diseases, including Alzheimer's disease (AD). NPs have by now habitually used in a vast range of industrial and medical applications, including hi-tech materials, plastics, paint, orthopaedic implants, paper derivatives, cosmetics and sun cream. Due to such a widespread use the toxicity of these NPs has been widely studied, proving the evidence for causing genotoxicity, cytotoxicity and oxidative damage. Among the NPs, the effects of alumina NPs on the central nervous having been received the attention. Aluminum (Al) is a vital etiopathogenic agent responsible for the incidence of neurodegenerative diseases. Many reports have demonstrated that nano-sized alumina particles have an enhanced capacity to produce reactive oxygen species and consequently have widespread toxic properties. Our previous work reported that the intranasal instillation of nano-sized alumina caused learning and memory impairment and brain inflammation in a size-dependent manner. In the present work, we are investigating the neurotoxicity of alumina nanoparticles in transgenic mice bearing familial and sporadic susceptible genes of Alzheimer's disease. We characterize the permeability of alumina-NPs in the nasal olfactory pathway and the hippocampal distribution after intranasal infusion, the cognitive performance and brain neuropathology in Tg and non-Tg mice. We concluded that alumina NPs could path through blood-brain barrier and deposit in the brain, and induce the decline of the learning and memory capacity of the in size-dependent and time-dependent manners. The present study may establish a path for studying the interaction of metal NPs toxicity with genetic mutations for AD progression.

Title: Why is not everybody getting Alzheimer's? Mammalian blood contains small molecules that prevent Aβ peptide aggregation

Authors: *A. V. KRIVOSHEIN[1], F. M. MUSTEATA[2];
[1]Dept. of Basic & Social Sci., [2]Dept. of Pharmaceut. Sci., Albany Col. of Pharm. & Hlth. Sci., Albany, NY

Abstract: How can we affect the equilibrium between monomeric and oligo/polymeric forms of Aβ peptides? Answering this question would hold a promise to novel therapeutics for Alzheimer's disease and other diseases involving intrinsically disordered proteins. It has been known for some time that both blood serum and cerebrospinal fluid (CSF) prevent and reverse aggregation of Aβ(1-40) and Aβ(1-42) peptides *in vitro*. Yet the chemical nature of substance(s) responsible for this amyloid-disaggregating effect remains unknown. To our surprise, we found that the disaggregating activity largely resides in the low-molecular-weight, protein-free fractions of human and mammalian blood serum and CSF, suggesting the existence of endogenous small molecules that inhibit aggregation of Aβ peptides. We report separation using a combination of activity-guided size exclusion chromatography and reversed-phase HPLC and structure elucidation using tandem mass spectrometry of some of these small molecules. We believe that these molecules can serve as therapeutic leads as well as biomarkers for early diagnosis of Alzheimer's disease. We also present preliminary data on structurally related amyloid-disaggregating small molecules found in plants of *Psychotria* genus. Some of these plants are used medicinally by the indigenous people in the Peruvian Amazon. Address correspondence to Arcadius V. Title: Bax-interacting factor 1 (Bif-1) expression is decreased in human Alzheimer's disease and modulates beta-amyloid related neuropathology in APP/PS1 mice

Authors: *D. B. WANG[1], Y. KINOSHITA[1], C. KINOSHITA[1], T. UO[2], B. L. SOPHER[3], G. A. GARDEN[3], Y. YANG[4], C. KEENE[4], T. BILOUSOVA[5], K. GYLYS[5], H.-G. WANG[6], R. S. MORRISON[1];

Abstract: Bax-interacting factor 1 (Bif-1) is a tumor-suppressor gene that promotes apoptosis and autophagy. Previously, we identified a novel neuroprotective function for Bif-1 related to expression of neuron-specific isoforms. Here, we report that protein and mRNA levels of neuron-specific Bif-1 isoforms are selectively decreased in the cerebral cortex of patients with late-stage (Braak VI) Alzheimer's disease (AD). Bif-1 protein in beta-amyloid (Abeta)-positive synapses was also decreased in AD patients, and there was a negative correlation between Abeta load and Bif-1 expression. Additionally, symptomatic AD mice expressing mutant amyloid precursor protein and presenilin 1 (APPswe/PS1dE9; Jankowsky et al., 2004) displayed lower levels of neuron-specific Bif-1 isoforms in both the cortex and hippocampus compared to wild-type controls and younger pre-symptomatic AD mice. To further evaluate the role of Bif-1 in AD pathology, we crossed Bif-1 knockout mice (Bif-1 KO; Takahashi et al., 2005) with AD mice. After 6 months, AD/Bif-1 KO mice showed a larger plaque burden, increased astrogliosis, and increased mortality compared to AD mice. AD/Bif-1 KO mice also displayed synaptic degeneration and cognitive impairment, which was not yet detected in AD mice at this early age, suggesting that loss of Bif-1 hastens disease onset. Although Bif-1 KO mice had no distinguishable phenotype at 6 months, they developed synaptic degeneration and cognitive and motor impairment by 12 months. Finally, overexpression of neuron-specific Bif-1 isoforms in mouse primary cortical neuron cultures protected against Abeta-induced apoptosis and mitochondrial dysfunction. Taken together, these results suggest that reduced expression of neuron-specific Bif-1 isoforms in human AD contributes to neuropathology and that Bif-1 may be a potential biomarker and/or drug target for AD.

Title: Activation of the brain's choroid plexus for monocyte trafficking to the CNS mitigates pathology in a mouse model of Alzheimer's disease

Authors: *N. ROSENZWEIG, K. BARUCH, A. KERTSER, G. KUNIS, A. DECZKOWSKA, A. SAREL, L. CAHALON, M. SCHWARTZ;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disorder and the leading cause of senile dementia worldwide; its pathophysiology is associated with unresolved chronic neuroinflammation. In this disease, blood-borne monocyte-derived macrophages (mo-MΦ) were shown to play an important role in mitigating the neuroinflammatory response, though their entry to the CNS appears to be insufficient, and the signals which regulate their trafficking are poorly understood. Our group recently pointed to the brain's choroid plexus (CP), which forms the blood-cerebrospinal fluid-barrier (BCSFB), as a selective gateway through which mo-MΦ are recruited to the CNS following acute injury. Here we show, in 5XFAD transgenic mouse model of AD (AD-Tg), that mo-MΦ trafficking to the CNS is suppressed due to CP dysregulation of IFN-γ signaling, needed for transepithelial migration of leukocytes across the CP. Pharmacological as well as genetic manipulations in AD-Tg mice, which led to increased levels of IFN-γ at the CP, resulted in epithelial upregulation of leukocyte trafficking determinants, which was followed by mo-MΦ recruitment via the CP-CSF migratory pathway to cerebral sites of amyloid-beta (Aβ) accumulation, plaque removal in the hippocampus and the cortex, and reversal of cognitive decline. Collectively, our results suggest that lacking mo-MΦ infiltration to the CNS, due to CP dysfunction, takes part in AD pathophysiology, and thus point to the BCSFB as a target amenable for immunomodulation as a potential therapy for AD. N.R. and K.B. contributed equally to this study.

Title: Age-dependent decline in aerobic glycolysis correlates with memory loss in a transgenic mouse model of Alzheimer's disease

Authors: *R. A. HARRIS[1], J. T. NEWINGTON[1], R. BARTHA[2], G. TAGLIALATELA[3], R. C. CUMMING[1];
[1]Biol., Univ. of Western Ontario, London, ON, Canada; [2]Robarts Res. Inst., London, ON, Canada; [3]The Univ. of Texas Med. Br., Galveston, TX

Abstract: The majority of glucose consumed by the adult brain is fully oxidized to carbon dioxide and water in the mitochondria of neurons to supply the large amounts of ATP required for synaptic transmission. However, a certain percentage of glucose in the brain is exclusively metabolized by glycolysis, even in the presence of oxygen, with the generation of lactate as a by-product. This process is known as aerobic glycolysis. Emerging evidence now suggests that aerobic glycolysis in the brain plays a critical role in generating biosynthetic metabolites during early CNS development and persists in certain regions of the adult brain to support synaptic plasticity, learning and memory. However, aerobic glycolysis steadily declines with age and virtually disappears in the elderly. Our lab has recently demonstrated that metabolic reprogramming toward aerobic glycolysis confers a survival advantage to nerve cells against the toxic effects of amyloid beta, a key pathogenic peptide in Alzheimer’s disease (AD). Neuronal cells with elevated aerobic glycolysis exhibited a marked reduction in mitochondrial-derived reactive oxygen species and a reduced propensity to undergo apoptosis. In this study, we demonstrate that a progressive decline in aerobic glycolysis occurs in the mouse brain with age, an event which correlates with a loss of spatial learning and memory. Proton magnetic resonance spectroscopy revealed an age-dependent decline in cortical lactate levels in wild-type mice. Western blot analysis of cortical extracts revealed a decline in key regulatory proteins of aerobic glycolysis in both control and, to a greater extent, transgenic AD mice at 12 months of age when compared to tissue from younger mice. The decline in aerobic glycolysis regulators correlated with the onset of memory loss in transgenic AD mice as measured by the Morris water maze. In addition, immunoblot analysis of post-mortem cortical tissue from non-demented individuals with AD neuropathology (NDAN) exhibited elevated markers for aerobic glycolysis as

compared to age-matched tissue from AD patients or control individuals. These data indicate that aerobic glycolysis in the brain declines normally with age, which may contribute to neurodegeneration and memory loss associated with aging and AD.

Title: Werner mice displays higher oxidative stress, tau phosphorylation and apoptotic/autophagic levels than wild type mice in hippocampus

Authors: G. DJIOKENG PAKA[1,2], M. PERROTTE[1,2], M. ARSENEAULT[1], M. LEBEL[3], *C. RAMASSAMY[1,2];
[1]INRS-Institut Armand-Frappier, LAVAL, QC, Canada; [2]INAF, Université Laval, QC, Canada; [3]Ctr. de Recherche sur le Cancer, Université Laval, QC, Canada

Abstract: Werner syndrome (WS) is an autosomal recessive disorder associated with mutations in a gene encoding for a RecQ-type DNA helicase. This enzyme is involved in different aspects of DNA repair, replication, and transcription. Clinically, WS is one of the most intriguing disorders characterized by an accelerated aging phenotype. Interestingly, Alzheimer's disease (AD)-associated neuropathology in the brains of individuals with WS has been reported with greater amyloid (Aß) load and plaque counts in the temporal lobe and an elevation of tau-immunoreactivity than normal cases. However, the association of mutations in the WS DNA helicase with CNS pathology and particularly AD-neuropathology remains to be elucidated. We generated a WrnΔhel/Δhel mouse model that lacks part of the DNA helicase domain of the WS gene homologue (WrnΔhel/Δhel). These mice recapitulate most of the WS phenotypes including premature visceral obesity, hypertriglyceridemia, insulin-resistant type 2 diabetes and

cardiovascular diseases, and increased genomic instability resulting in a 15%-17% decreased mean life span. Moreover, these mice also exhibit increased heart and liver tissue reactive oxygen species (ROS) and oxidative DNA damage. The objectives of this study were to compare the levels of oxidative markers/pathways and AD-neuropathology (Tau phosphorylation) on different regions of the brain from 12 months WrnΔhel/Δhel and age matched wild type C57Bl/6 animals. We have also analyzed the levels of apoptotic (caspase 3) and autophagic (eIF2, 46/48kDa) markers in order to point out one possible mechanism of cells death during this disorder. Our results showed that the basal levels of reactive oxygen species (ROS), as measured by DCFDA, were higher in hippocampus from WrnΔhel/Δhel than in control mice and similar in both groups in other brain structures. Glutathione and Nrf2 levels were also similar in both groups while levels of the antioxidant thioredoxine and of the protein carbonyls were lower in WrnΔhel/Δhel mice. Interestingly, p66Shc, the lifespan determinant and the primary source of ROS, and phosphorylated tau levels were higher in WrnΔhel/Δhel mice. Finally, we found an elevated level of EIF2 and caspase 3 in the hippocampus of mutant mice. These results are in accordance with previous studies demonstrating that WS patient fibroblasts displayed higher autophagy. To conclude, the WrnΔhel/Δhel mouse model displays some AD-related neuropathology and autophagy/apoptotic cell death and support the potential therapeutic use of mTORC1 inhibitors in the treatment of WS.

Title: A derivative of the neurochemical lanthionine ketimine affects autophagy by increasing beclin-1 protein expression in cell culture and in the 3xTg-AD mouse model of Alzheimer’s disease

Authors: *K. HENSLEY[1], K. VENKOVA[2], A. HRISTOV[2], P. ESLAMI[3], A. POTESHKINA[4], M. HARRIS-WHITE[5];
[1]Pathology, Univ. of Toledo Med. Ctr., Toledo, OH; [2]Pathology, Univ. of Toledo Hlth. Sci. Campus, Toledo, OH; [3]Neurosci., [4]Greater Los Angeles Veteran's Hosp., Los Angeles, CA; [5]Neurosci., Greater Los Angeles Veteran's Hosp. and UCLA, Los Angeles, CA

Abstract: Autophagy is a tightly-regulated cellular process for recycling proteins, macromolecular aggregates and damaged organelles. Autophagy is dysregulated in a number of conditions including Alzheimer's disease (AD), wherein the autophagy-regulating protein beclin-1 is significantly decreased. Genetic over-expression of beclin-1 reduces amyloid beta peptide (A-beta) burden in AD models, raising the possibility that beclin-1 regulation could be a novel route to AD treatment. The present study demonstrates that XN-001, a derivative of a natural brain sulfur amino acid metabolite that slows cognitive decline and reduces pathology in the 3xTg-AD mouse, can induce beclin-1 protein accumulation in brains of 3xTg-AD mice and also in human SH-SY5Y neuroblastoma cells. The beclin-1 increase is time and dose-dependent in cell culture and parallels alterations in other autophagy markers including LC3-II and p62/SQSTM1. Previous studies indicated that neurotrophic effects of XN-001 are mediated through the microtubule-associated protein, CRMP2 (DPYSL2), which collects in AD-associated neurofibrillary tangles. Beclin-1 from human brain lysates bound GST-rhCRMP2 and conversely, CRMP2 co-immunoprecipitated with beclin-1. Depleting cellular CRMP2 with shRNA caused a corresponding decrease in beclin-1, confirming a functional relationship between these two proteins. These findings further clarify the mechanism-of-action for XN-001; uncover a heretofore unappreciated relationship between beclin-1 and CRMP2; and suggest a novel role for brain sulfur amino acid metabolites in regulating neural autophagy pathways.

Title: Corticotropin-releasing factor receptor antagonism prevents onset of cognitive deficits and impacts amyloid pathology in an alzheimer's disease mouse model

Authors: *C. ZHANG[1], C.-C. KUO[2], S. H. MOGAHDAM[1], S. NUBER[1], L. MONTE[1], K. C. RICE[3], E. MASLIAH[1], R. A. RISSMAN[1];

Abstract: Alzheimer's disease (AD) is the most common form of dementia, characterized by progressive cognitive impairment and two neuropathological hallmarks: β-amyloid plaques (Aβ) and neurofibrillary tangles (NFT). Recent work has implicated environmental factors, prominently including stress, as promoting AD pathogenesis. Anatomical and biochemical study also supports an involvement of corticotropin-releasing factor (CRF) and its components involved in stress signaling system in AD. Data from our lab has demonstrated that chronic stress exposure can induce accumulation of tau phosphorylation (tau-P) aggregates in the rodent hippocampus, process dependent on signaling through the type 1 CRF receptor (CRFR1). Here, we demonstrate that CRFR1 antagonism can also impact production and accumulation of Aβ and prevent onset of cognitive impairment in an AD mouse model. To explore the impact of CRFR1 antagonist treatment on AD cognitive and neuropathological outcomes, we treated 30-day old Alzheimer's transgenic (PSAPP) mice and wild type (WT) littermates with daily administration of a small molecule CRFR1 antagonist (R121919). PSAPP female mice receiving R121919 had significantly better performance with less time and shorter distance spent in the spatial learning test using water maze, which demonstrates that the R121919 treatment significantly reduces both long-term and short-term memory deficits of Tg-female mice. Furthermore, the percentage of amyloid accumulation was significantly reduced in animals treated with R121919 regardless of gender and brain region. Therefore, we hypothesize that CRFR1 antagonism may present a viable option for preventative and/or disease-modifying therapy for AD.

Title: Use of the frailty index to compare the stages of aging in the 3x-Tg and 5xFAD mouse models of Alzheimer's disease

Authors: *R. E. BROWN[1], A. A. WONG[2], K. R. STOVER[2];
[1]Psychology & Neurosci., Dept. of Psychology and Neurosci., Halifax, NS, Canada; [2]Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: All mice show neural and behavioural changes as they age, but most murine aging data are based on the C57BL6 mouse, which has a long lifespan. The 3x-Tg and 5xFAD mouse models of AD, have much shorter lifespans than the C57BL6 mouse and within the 3x-Tg mice, males have shorter lifespans than females. All mice go through the same stages of age-related physical and cognitive changes, but at different chronological ages. In order to compare the stages of aging across different strains and sexes of mice, a measure is required which is independent of chronological age. The Frailty Index (FI) appears to meet this criterion (Parks, RJ, et al. 2012. J Gerontol A Biol Sci 67, 217-227; Whitehead, JC. et al. 2014, J Gerontol Biol Sci, in press). We used the FI to compare age-related changes in behaviour and physiology of male and female 3x-Tg and 5xFAD mouse models of AD and their wildtype controls. At 12 months of age, the 5xFAD mice showed a higher FI score than their WT controls, while the 3x-TG mice had a lower FI score than their WT controls. These FI scores correlated with measures of motor control, which decline more rapidly in 3x-Tg than in 5xFAD mice. We are determining whether the FI predicts differences in longevity of males and females in these two mouse models. The use of such a measure, which is independent of chronological age, will be important in the comparative studies of age-related neurodegenerative diseases in mice and in determining the appropriate age at which to initiate therapeutic procedures.

Title: Triptolide preserves cognitive function and reduces neuropathology in a mouse model of Alzheimer's disease

Authors: *S. CHENG, K. J. LEBLANC, L. LI;
Experimental/Clin Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease and a major form of dementia characterized clinically by progressive cognitive impairment. Pathological hallmarks of AD include deposits of aggregated amyloid-β protein (Aβ), neurofibrillary tangles (NFTs), and gliosis in the brain. Mounting evidence indicates an involvement of inflammation in the pathogenesis of AD and anti-inflammatory and immune-modulatory agents have emerged as potential therapeutics for AD. Triptolide, a major bioactive ingredient of a widely used herbal medicine, has been shown to possess multiple pharmacological functions, including potential neuroprotective effects pertinent to AD *in vitro*. However, the therapeutic potential of triptolide for AD *in vivo* has not been thoroughly evaluated. In the present study, we investigated the impact of peripherally administered triptolide on AD-related behavior and neuropathology in $APP_{swe}/PS1_{\Delta E9}$ (APP/PS1) mice, an established model of AD. Our results showed that two-month treatment with triptolide rescued cognitive function in APP/PS1 mice. Immunohistochemical analyses indicated that triptolide treatment led to a significant decrease in amyloid-β (Aβ) deposition and neuroinflammation in treated mice. In contrast to previous findings *in vitro*, biochemical analyses showed that triptolide treatment did not significantly affect the production pathway of Aβ *in vivo*. Intriguingly, further analyses revealed that triptolide treatment upregulated the level of insulin-degrading enzyme, a major Aβ-degrading enzyme in the brain, indicating that triptolide treatment reduced Aβ pathology by enhancing the clearance pathway of Aβ. Our findings demonstrate that triptolide treatment ameliorates key behavioral and neuropathological changes found in AD, suggesting that triptolide may serve as a potential therapeutic agent for AD.

Title: Increased synaptic sensitivity to Aβ-oligomer binding after traumatic brain injury in the rat

Authors: *W. FRANKLIN[1], M. PARSLEY[2], M.-A. MICCI[1], G. TAGLIALATELA[3]; [2]Anesthesiol., [3]Neurol., [1]UTMB At Galveston, Galveston, TX

Abstract: Compelling evidence indicates that traumatic brain injury (TBI) is a risk factor for later development of Alzheimer's disease (AD). However, the molecular mechanisms and changes that link the two conditions have not been yet established. Understanding such mechanism(s) is critical to develop effective interventions to reduce the incidence of AD in TBI subjects. Synaptic binding of amyloid beta (Aβ) oligomers (the most toxic form of Aβ) is an early dysfunctional event of the pathology of AD, driving initial cognitive decline through disruption of affected synapses. Notably, it has also been shown that there is a transient increase of Aβ levels after TBI in both humans and laboratory animals. Based on this evidence, we hypothesized that after TBI central synapses may remain vulnerable to the dysfunctional binding of Aβ oligomers, thus increasing the risk of triggering an Aβ-driven disruptive cascade later on in life. In the present work, we began testing this hypothesis by subjecting rats to traumatic brain injury using an established fluid percussion protocol. 3μL of preformed Aβ-oligomers at a concentration of 0.8μg/μL were then stereotaxically injected bilaterally into the CA1 and CA3 hippocampal areas, 2 or 7 days after TBI. The animals were then sacrificed 2 hrs after the Aβ injection and several brain areas (including the hippocampus) dissected and snap frozen for later isolation of synaptosomes. An ELISA was performed on isolated hippocampal synaptosomes to determine the presence of Aβ-oligomers comparing TBI versus sham animals. We found an increase in Aβ-oligomer in hippocampal synaptosomes from TBI rats as compared to sham injured animals. Increased Aβ was observed both ipsilaterally and contralaterally to the injury side, suggesting that the increased susceptibility of hippocampal synapses to Aβ binding is a global event and not limited to the immediate injury site. Overall, our results indicate that TBI causes synapses to become more vulnerable to Aβ binding. Although further ongoing studies are needed to better characterize this phenomenon, these initial results provide a novel insight into the molecular changes that may link TBI and increased risk of AD in humans.

Title: Age-dependent decrease of amyloid β toxicity in dentate gyrus granule cells of mice

Authors: *J. VON ENGELHARDT, M. MUELLER;
Synaptic Signalling and Neurodegeneration/A300, DKFZ & DZNE, Heidelberg, Germany

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease and is the most common form of dementia in the world. The disease involves formation of plaques and tangles, which are seen as hallmarks for AD. Plaques are insoluble protein aggregates composed of amyloid β (Aβ). Although Aβ plaques have been regarded to be critical in the neuropathology of AD, it was recently demonstrated that the appearance of soluble Aβ oligomers correlates better with the memory decline observed in AD patients. Although AD mostly affects elderly people of the age over 65, many investigations are done in cell culture or organotypic slices from newborn mice. Young neurons are known to be more vulnerable to stress and show different protein expression patterns (for example NMDA receptor subunit compositions) compared to adult neurons. Thus, we wondered whether there are differences in the Aβ toxicity in young and adult mice. To this end, we established a recombinant adeno-associated virus (rAAV) based mouse model, in which Aβ is specifically overexpressed in virus-infected neurons. To investigate age-dependent differences in Aβ toxicity we stereotactically injected rAAVs into the hippocampus of young and adult mice and analyzed infected cells several weeks post-infection. The frequency of miniature excitatory postsynaptic currents (mEPSC) frequencies was significantly reduced in infected dentate gyrus granule cells 9 weeks after injection of Aβ overexpressing rAAVs into the hippocampus of P7 mice, suggesting that Aβ reduces the number of functional synapses. However, overexpression of Aβ for 9-12 weeks did not affect mEPSC frequency or amplitude when rAAVs were injected into the hippocampus of P70 mice. Finally, overexpressing a mutated Aβ form (I716V), which leads to production of significantly more Aβ, induced a decreased mEPSC frequency in granule cells of P70 mice, indicating that higher Aβ-levels are required to induce toxicity in adult mice when compared to newborn mice.

Title: GPR84 deficiency reduces microgliosis and accelerates dendritic degeneration and cognitive decline in a mouse model of Alzheimer’s disease

Authors: L. VALLIÈRES, J. AUDOY-RÉMUS, A. DUMAS, M. FILALI, *S. LACROIX, S. RIVEST, M.-E. TREMBLAY;
Mol. Med., Univ. Laval, Quebec, QC, Canada

Abstract: Microglia surround the amyloid plaques that form in the brain of patients with Alzheimer’s disease (AD), but their role is controversial. These cells can express GPR84, an orphan receptor whose pathophysiological role is unknown. Here, we show that GPR84 is upregulated in microglia of APP/PS1 transgenic mice, a model of AD. Genetic deletion of GPR84 in these mice accelerated cognitive decline and reduced the number of microglia, especially near plaques. The lack of GPR84 did not affect the formation of the latter, but promoted dendritic degeneration. Furthermore, GPR84 did not seem to influence the progression of other diseases in which its expression has been reported, i.e., experimental autoimmune encephalomyelitis (EAE) and endotoxic shock, as the clinical signs of these diseases were comparable in mice expressing or not GPR84. We conclude that GPR84 plays a beneficial role in amyloid pathology by acting as a sensor for a yet unknown ligand that promotes the recruitment of microglia, a response affecting dendritic degeneration and required to prevent further cognitive decline.

Title: ACE-overexpressing macrophages exhibit a pro-healing phenotype in murine AD models

Authors: *A. RENTSENDORJ[1], J. SHEYN[2], D.-T. S. FUCHS[2], Y. KORONYO[2], E. Y. HYDEN[5], K. L. BLACK[2], S. FUCHS[6], D. B. TEPLOW[5], K. E. BERNSTEIN[3], M. KORONYO-HAMAOUI[4];

Abstract: Introduction: A key pathology of Alzheimer's disease (AD) is the accumulation of amyloid-β protein (Aβ). Angiotensin-converting enzyme (ACE) is known to degrade neurotoxic Aβ1-42 to less pathogenic alloforms. Our group and others have demonstrated a direct role for monocyte-derived macrophages (Mo/MΦ) in the clearance of fibrillar Aβ in transgenic murine models of AD. It has been recently reported that MΦ cell elongation by itself can promote polarization from the pro-inflammatory towards the "therapeutic" anti-inflammatory phenotype. To study the role of ACE on Mo/MΦ and ability to resist AD, we previously introduced targeted ACE overexpression in myelomonocytic cells (ACE10) to the double-transgenic APP/PS1 murine models (ADtg); these mice exhibited enhanced immune responses coupled with a remarkable prevention of AD-associated neuropathology and cognitive decline. Aims: To investigate the therapeutic potential of ACE10-Mo/MΦ *in vivo* and *in vitro* on AD-like progression. Methods: ACE10 vs. WT bone marrow-derived CD115+-Mo/MΦ were adoptively transferred to post-symptomatic ADtg mice, and then assessed for cognitive function and pathological outcomes. Further, primary cultures of ACE10 vs. WT Mo/MΦ were examined in response to fibrillar and non-fibrillar Aβ1-42 assemblies. Results: Our studies indicated that ACE10- Mo/MΦ have a significant 2.5-fold cell processes elongation relative to WT-Mo/MΦ *in vitro*, possibly entailing the macrophage-polarization towards a pro-healing and anti-inflammatory phenotype. While phagocytosis of fibrillar Aβ1-42 seems unchanged between ACE10- and WT-Mo/MΦ, our findings clearly indicated an accelerated rate of Aβ1-42 extracellular degradation by the ACE10-Mo/MΦ. Further, our data showed an enhanced cell

survival following exposure to toxic Aβ1-42. *In vivo* studies demonstrated that adoptive transfer of ACE10- vs. WT-Mo/MΦ CD115+-Mo/MΦ into symptomatic ADtg mice resulted in retained behavioral functions (Barnes maze test) and attenuation of neuropathology, especially in mice receiving the ACE10 Mo/MΦ. Blood-borne infiltrating ACE10-MΦ relative to WT-MΦ was increasingly present surrounding Aβ plaques and had a decreased TNF-α expression. Biochemical analysis of cerebral Aβ1-42 and Aβ1-40 levels in ACE10-ADtg mice further indicated greater enzymatic degradation of Aβ1-42. Conclusions: These studies provide both *in vivo* and *in vitro* evidences to support a potential therapeutic role for the ACE-overexpressing inflammatory cells in resisting Aβ-induced toxicity in AD murine models.

Title: *In vivo* effects of pyroglutamate-3 amyloid-beta seeding in APP/PS1ΔE9 mice

Authors: *H. CREHAN[1,2], H. CYNIS[1,2,3], J. L. FROST[1], K. LE[1], S. SCHILLING[3,4], H.-U. DEMUTH[3,4], C. A. LEMERE[1,2];

Abstract: Alzheimer's disease (AD) is neuropathologically characterized by neurofibrillary tangles composed of hyperphosphorylated tau and plaques composed of amyloid-β (Aβ). Pyroglutamate-3 Aβ (pGlu-3 Aβ) is an N-terminally truncated and pyroglutamate-modified Aβ species, which has been shown to be a major component of Aβ deposited in the plaques and blood vessels in AD and Down syndrome brain (Saido et al., 1995; Lemere et al., 1996). This pGlu-3 modified Aβ is formed following the cyclization of an exposed glutamate residue at the N-terminus by glutaminyl cyclase and has been shown to be highly neurotoxic with an increased

aggregation propensity (Russo et al., 2002; Schilling et al., 2006; Nussbaum et al., 2012). It is unclear as to whether pGlu-3 Aβ is initially present in the plaques and blood vessels or if it is modified at a later stage. We investigated whether pGlu-3 Aβ acts as a seed for Aβ aggregation and enhances Aβ deposition, neuroinflammation and neurodegeneration in APP/PS1ΔE9 transgenic mice. Female APP/PS1ΔE9 Tg mice (avg. 3.8 mo; C57BL/6J) received bilateral intrahippocampal stereotaxic injections of 2µl of brain extract (10% w/v protein) from aged mice overexpressing pGlu-3 Aβ peptides (APP-NLQ Tg) (n=7), brain extract from aged wildtype (WT) B6 mice (n=7) or PBS (n=7). Quantitative image analysis revealed a trend towards an increase in Aβx-42 immunoreactivity in hippocampus of NLQ extract-injected Tg mice compared with WT extract-injected Tg mice. No differences were observed in Thioflavin S fibrillar plaque load. Further analyses are underway to determine Aβ levels biochemically by ELISA, as well as neuroinflammatory and neurodegenerative changes using immunohistochemical markers of gliosis and synapses. We suggest that pGlu-3 Aβ may enhance AD-like pathogenesis in APP/PS1ΔE9 transgenic mice.

Title: Oral delivery of a small molecule TNFa inhibitor improves cognition and reduces AD pathology and neuroinflammation in the 3xTg AD mouse

Authors: *P. GABBITA[1], P. ESLAMI[3], M. JOHNSON[3], N. KOBRITZ[3], F. ZEMLAN[2], S. POTESHKINA[3], S. VARADARAJAN[4], J. TURMAN[4], M. HARRIS-WHITE[3];
[1]P2D Biosci., CINCINNATI, OH; [2]P2D Biosci., Cincinnati, OH; [3]VA-GLAHS, Los Angeles, CA; [4]Univ. of North Carolina-Wilmington, Wilmington, NC

Abstract: Neuroinflammation is widely accepted as one of the etiologic events in Alzheimer's Disease (AD). Increased production of the cytokine tumor necrosis factor-alpha (TNFa) has been proposed to contribute to the onset and progression of AD. Increased TNFa is found in the brains of patients with mild cognitive impairment (MCI) and may be important for the conversion of MCI to AD. However, TNFa is a multifunctional cytokine used by multiple cells types including hematopoietic and central nervous system glia and neurons. Although many studies suggest a negative impact of excess TNFa signaling on AD pathology, a number of studies demonstrate the neuroprotective benefits of TNFa. A recent study of long-term global inhibition of TNFa receptor signaling revealed enhanced AD pathology in the 3xTgAD mouse and that the absence of TNFa signaling resulted in CNS immune cells unresponsive to developing AD pathology. These findings highlight the importance of modulation, and not complete abolition, of TNFa signaling in the CNS. Orally bioavailable, small molecule TNFa inhibitors are an attractive approach to treating AD-related neuroinflammation. In the current study, we focus on the central role of TNFa modulation and resulting changes in neuroinflammation, amyloid pathology and cognitive function in the 3xTgAD mouse model. Pharmacokinetic studies show that oral administration of a small molecule TNFa inhibitor resulted in good systemic exposure in rodents. Six month old 3xTgAD mice were randomly allocated into treatment groups (Control diet, and three doses of the small molecule TNFa inhibitor formulated in the diet). The small molecule TNFa inhibitor delivered orally to 3xTgAD mice for 10 months significantly improved learning and memory function as assessed by Barnes maze. Small molecule TNFa inhibitor treatment also modulated brain cortical TNFα protein levels in 3xTg AD mice indicating that the compound engages and modulates the drug target, brain TNFa. AD pathology was assessed by amyloid (6E10 antibody) and phosphorylated tau (AT8 antibody) immunohistochemistry and revealed a reduction in both amyloid and phospho-tau. Long term oral treatment with the inhibitor had no apparent adverse effects. Taken together, these data strongly indicate that small molecule TNFa modulators are safe, orally bioavailable candidates for AD treatment. This work was supported by the Veterans Administration, Alzheimer's Drug Discovery Foundation and the National Institutes of Health.

Title: Spirulina maxima reduces the neurotoxicity and improves memory in rats with Aß25-35 in the hippocampus

Authors: *I. LIMON PEREZ DE LEON[1], L. ORTEGA[1], E. RÁMIREZ[1], I. MARTÍNEZ[2], L. PÉREZ-JIMÉNEZ[1];
[1]Pharmacy-, Benemerita Univ. Autonoma De Puebla FCQ Lab. Neurofarma, Puebla, Mexico;
[2]Lab. de Neuroquímica, Benemerita Univ. Autonoma De Puebla FCQ, Puebla, Mexico

Abstract: The Spirulina maxima (Sp max), cyanobacteria have a high protein content and its biochemical composition has a high content of vitamin E, phycocyanin, β-carotene, γ-linoleic acid, components that have been shown to increase antioxidant enzymes such as SOD , CAT and GPx and theirs properties as alkoxides scavenger radicals, hydroxyl and peroxyl. Because of this it is proposed that Spirulina maxima may be effective in the adjuvant treatment for neurodegenerative diseases such as Alzheimer's disease. The aim of this study was that the sub-chronic administration of Spirulina maxima reduces nitrosative stress, the damage in spatial memory and neurodegeneration in lesioned rats with peptide Aβ25-35 in the CA1 region of the hippocampus. The administration of Spirulina maxima by 50 days after injection of the Aβ25-35 peptide into hippocampal CA1 region improves learning and memory in rat . Also in these conditions the Spirulina maxima decreases levels of nitrites and protein nitration in injured rats with Aβ25-35 peptide in the CA1 region of the hippocampus . Finally we found that the maximum of Spirulina maxima decreased neurodegeneration lesioned rats in the Aβ25-35 peptide in the CA1 region of the hippocampus. These data suggested that the alls components of the Spirulina maxima help in the treatment of neurodegenerative diseases.

Title: Hypercholesterolemia aggravates Alzheimer's disease-related pathology in APP/PS1 mice

Authors: ***P. THÉRIAULT**, A. ELALI, S. RIVEST*;
Dept. of Mol. Medicine, Fac. of Med., Lab. of Neurosci. Res. Ctr. of CHUQ, Québec, QC, Canada

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by the accumulation and aggregation of the neurotoxic amyloid-β peptide (Aβ) within the brain parenchyma and vasculature. It was suggested that the dysfunction of the blood-brain barrier (BBB) accompanied by impaired immune responses contribute to AD pathogenesis. Age and hypercholesterolemia are two major risk factors associated to AD. Although suspected, their impact on BBB's characteristics and the immune responses remains elusive. This study aims to characterize the molecular and cellular mechanisms underlying the implication of these two risk factors in AD pathogenesis. For this purpose, 3 and 12 months old APP/PS1 transgenic mice were fed with a high-fat diet for 4 months. Afterwards, cognitive functions were assessed by T-water maze and new object recognition (NOR) neurobehavioral tests. Aβ deposits were quantified in the brain parenchyma by stereological analysis. Moreover, parenchymal and vascular Aβ deposition kinetics were visualized by two-photon intravial microscopy. Soluble Aβ levels were measured by ELISA in total brain homogenates and in isolated microvessels. Moreover, flow cytometry analyses were performed to investigate circulating monocyte responses. Finally, protein interaction (WB, IP, IF) and enzyme activity (zymographies) studies were used to assess BBB characteristics. Interestingly, our behavioral analyses revealed that the high-fat diet significantly worsens the cognitive functions of APP/PS1 mice. We also observed a significant increase in Aβ deposition in the cortex and hippocampus of animals fed with high-fat

diet, which correlated with the neurobehavioral data. Moreover, we observed that age increased the frequency of pro-inflammatory monocyte subset ($Ly6C^{high}$), which was exacerbated by the high-fat diet. Our results indicate that hypercholesterolemia accelerates AD-related pathology in APP/PS1 mice, by increasing the accumulation of soluble and insoluble Aβ in the brain, thus worsening the cognitive impairments of these mice. The mechanisms involved in these observations are presently under investigation. The increased oxidation of lipids in the circulation - as a direct consequence of age and the high-fat diet - triggers the activation of matrix metalloproteinases (MMPs) and promotes an exacerbated proinflammatory environment, both of which are involved in BBB destabilization and dysfunction. These orchestrated responses caused by age and hypercholesterolemia abolish the protective role of the BBB in detoxifying the brain, thus contributing in AD pathology.

Title: Restoration of lipoxin A_4 signaling reduces Alzheimer's disease-like pathology in the 3xTg-AD mouse model

Authors: *H. DUNN[1], R. R. AGER[2], D. BAGLIETTO-VARGAS[2], D. CHENG[2], M. KITAZAWA[3], D. H. CRIBBS[2], R. MEDEIROS[2];

Abstract: The initiation of an inflammatory response is critical to the survival of an organism. However, when inflammation fails to reach resolution, a chronic inflammatory state may occur, potentially leading to bystander tissue damage. Surmounting evidence suggest chronic inflammation contributes to the progression of Alzheimer's disease (AD), and identifying

mechanisms to resolve the pro-inflammatory environment stimulated by AD pathology remains an area of active investigation. Previously, we found that treatment with the pro-resolving mediator Aspirin-Triggered Lipoxin A_4 (ATL), improved cognition, reduced Aβ levels, and enhance microglia phagocytic activity, in Tg2576 transgenic AD mice. Here, we evaluated the effect of aging on brain lipoxin A_4 (LXA_4) levels using non-transgenic and 3xTg-AD mice. Additionally, we investigated the effect of ATL treatment on tau pathology in 3xTg-AD mice. We found that LXA_4 levels are reduced with age, and significantly more impacted in 3xTg-AD mice. Moreover, ATL (15 μg/kg) enhanced the cognitive performance of 3xTg-AD mice, reduced Aβ levels, as well as decreased the levels of phosphorylated-tau (p-tau). The decrease in p-tau was due in part to an inhibition of the tau kinases GSK-3β and p38 MAPK. In addition, microglial and astrocyte reactivity was inhibited by ATL treatment. Our results suggest that the inability to resolve the immune response to AD pathology is partially due to a reduction in LXA_4 levels. Furthermore, we demonstrate that activation of LXA_4 signaling could serve as a potential therapeutic to target AD related inflammation and cognitive dysfunction.

Title: Chronic LPS-induced inflammation and insulin signaling disruption in a diabetic model of Alzheimer’s Disease

Authors: *A. S. MURTISHAW[1], C. F. HEANEY[2], M. M. BOLTON[2], K. D. BELMONTE[2], P. M. HAGINS[2], M. A. LANGHARDT[2], J. W. KINNEY[2];

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by cognitive and behavioral impairments, in addition to pathological hallmarks that include amyloid plaques, neurofibrillary tangles, and neuronal loss. While the etiology of AD is largely unknown, the vast majority of AD cases are late onset and sporadic in origin (sAD), likely arising from interactions between genetic susceptibilities and external factors. Among the top risk factors associated with

sAD are Diabetes Mellitus (DM) and neuroinflammation. Specifically, disruptions to insulin signaling in patients with DM have been implicated as a leading mechanism for DM being an AD risk factor. While considerable research has been conducted to understand the role of neuroinflammation in transgenic models of AD, less progress has been made to understand the interaction of neuroinflammation in the non-transgenic diabetic model of AD. Utilizing streptozotocin (STZ) to disrupt insulin signaling in the brain, we have examined the effects of inflammation in this diabetic animal model of AD. Our lab previously demonstrated that an acute, one-time inflammatory response (LPS) in the STZ animals produced subtle improvements in spatial learning and reduced elevations of oligomeric beta-amyloid compared to the STZ alone group. This current investigation is directed at understanding the interactions of chronic inflammation and insulin signaling disruption, specifically, whether chronic immune activation exacerbates the STZ deficits. One week following STZ infusion, LPS was administered twice per week for 7 weeks, in order to chronically activate the immune system. Spatial learning and memory was examined in the Morris water maze and hippocampal tissue was analyzed for oligomeric beta-amyloid, phosphorylated tau, and other proteins relevant to AD. Our data indicate that both the STZ and STZ+LPS groups exhibited deficits in spatial learning consistent with AD animal models.

Title: Vascular amyloid and gliovascular dysfunction in a mouse model of Alzheimer’s disease

Authors: *I. KIMBROUGH[1], S. ROBEL[2], E. ROBERSON[2], H. SONTHEIMER[2];
[1]Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The brain is vitally dependent on blood flow alterations due to high energy demands during neuronal activity. This regulation is governed by astrocytes whose endfeet appose blood vessels and vasoregulate, thus acting as liaisons between neurons and the vasculature. Cerebral blood flow is reduced in Alzheimer's disease (AD), a devastating disease associated with the massive loss of neurons resulting in dementia and ultimately death. AD is characterized by amyloid plaque deposited throughout the brain and often lining blood vessels. In this study, we investigated the effects of this vascular amyloid on astrocyte-vascular coupling in a hAPP J20 mouse model of AD. Analysis of electron micrographs revealed morphological changes of the intimate vascular endfoot relationship in AD mice. Using immunohistochemistry, we detected strong astrogliosis as well as loss of endfeet or their polarity even at early stages of the disease. To investigate how these anatomical changes affected the blood-brain barrier (BBB), we injected vascular dyes of varied molecular weights retro-orbitally and performed *in vivo* two-photon imaging through a chronic cranial window, thus allowing us to observe and evaluate changes in blood-brain barrier (BBB) integrity over time. We found BBB breaches and leakage specifically where plaques were deposited. Finally, we induced calcium spikes both pharmacologically and via focal uncaging, allowing us to specifically activate the astrocytic component of the neurovascular unit (NVU) and explore changes in vascular regulation as a result of Aβ deposition in murine cerebral arteriole vessel walls. We found that AB deposition disconnected the functional control of astrocytic endfeet from the vasculature. In conclusion, through fixed tissue, acute slice, and *in vivo* analysis, we found anatomical disruption of astrocyte-vascular coupling that functionally translated to impaired vessel response in a mouse model of AD.

Title: Facilitation of GABAB receptor function modulates chronic inflammatory effects

Authors: M. A. LANGHARDT, A. S. MURTISHAW, C. F. HEANEY, M. M. BOLTON, K. C. D. BELMONTE, P. M. HAGINS, *J. W. KINNEY;
Univ. Nevada Las Vegas, LAS VEGAS, NV

Abstract: Chronic inflammation in the brain (neuroinflammation) has been implicated in numerous degenerative disorders, in particular Alzheimer's disease (AD). Substantial data indicate that persistently activated microglia contribute to AD pathology; including amyloid plaque deposition, the formation of neurofibrillary tangles, and behavioral deficits. The recent identification of greater risk for AD in individuals with the TREM2 mutation further supports a role for inflammatory processes contributing to AD. Numerous investigations have evaluated the effects of neuroinflammation utilizing chronic administration of Lipopolysaccharide (LPS), which is capable of mounting an immune response through the activation of Toll-like receptor 4 (TLR4). Additional investigations have evaluated mechanisms to ameliorate the inflammation, most frequently the use of NSAIDs. In the present study we capitalized on recent findings of an anti-inflammatory role associated with GABA signaling. Data indicating that astrocytes synthesize and release GABA to regulate immune responses and that microglia express GABAB receptors suggest a role for GABAB in mediating inflammation. A growing literature suggests that activation of GABAB on microglia serve to reduce the activation status and diminish the release of pro-inflammatory cytokines. In the below studies we investigated if administration of the GABAB receptor agonist baclofen would lessen both the immune response evoked by LPS, as well as behavioral deficits associated with chronic inflammation. Our data indicate that the administration of baclofen initially attenuated the pyrogenic effects of LPS, however, this effect was lost after the first 2 weeks of LPS administration. Our data further demonstrate that the administration of baclofen rescued spatial learning and memory deficits seen in animals chronically administered LPS alone. These data provide evidence that modulation of GABAB receptor function altered the immune response evoked by TLR4 activation. These data also suggest a potential role for GABAB in modulating the immune response in AD.

Title: Atherogenic diet-induced accelerated amyloid deposition in PDAPP Tg but not in APP-PS1 Tg mouse model of AD

Authors: *N. R. BHAT, K. SAMBAMURTI, M. KINDY, T. ZHU, S. MOHANTY; Neurosciences, Med. Univ. South Carolina, CHARLESTON, SC

Abstract: Dietary fat/cholesterol is known to induce amyloid deposition in different animal models of AD albeit to varying degrees. In this report, we compared two AβPP Tg mouse models of AD i.e., PDAPP (PDGFB-APPSwInd) and APP-PS1 (APPswe, PSEN1dE9) for amyloid accumulation in response to an atherogenic diet (Western diet, Research Diets). While 9 month-old PDAPP mice on a normal diet (ND) developed sparse amyloid plaques mostly confined to the hippocampus, those fed WD between 6 and 9 months showed increased amyloid in the hippocampus as well as in the cortical areas. The amyloid plaques were associated with clusters of activated microglia and astrocytes as revealed by immunohistochemistry. Increased accumulation of Aβ was confirmed by ELISA and Western blot analyses of the brain extracts. Western blot also showed the presence of increased PHF-1 reactive p-tau in WD-fed mice relative to ND-fed control PDAPP Tg mice. The above changes were accompanied by increased expression of VCAM1, P-Selectin, TNFα and iNOS, and reduced levels of phospho (Ser1177)-eNOS indicating adverse cerebrovascular and neuroinflammatory changes. Behaviorally, WD-fed PDAPP Tg mice performed worse on a water-version of T-maze relative to ND-fed controls. In contrast to the findings with the PDAPP Tg mice, the atherogenic diet failed to induce amyloid accumulation over basal (ND-fed) level and was overall less effective in the APP-PS1 Tg mice. The findings have implications for the correct choice of AD mouse models for the study of diet-induced β-amyloidosis.

Title: Beta-secretase 1 regulates the lipid profile of ca1 neurons in 3xtg-ad mouse model of Alzheimer’s disease

Authors: *J. G. VILLAMIL, A. BARRERA OCAMPO, D. PIEDRAHITA, J. CRUZ JIMENEZ, P. CARDONA GOMEZ;
Antioquia, Univ. De Antioquia- Neurosciences Lab., Medellin, Colombia

Abstract: Deposits of β-Amyloid peptides (βA) and hyperphosphorylated tau are histopathologic hallmarks of Alzheimer’s disease (AD). βA is product of the cleavage of the amyloid precursor protein by the enzyme β-secretase 1 (BACE1) through the amyloidogenic pathway, making BACE1 a therapeutic target against AD. Alterations in lipid metabolism are a risk factor for AD and the lipid composition of neural membranes seems to determine BACE1 activity by an unknown mechanism. The objective of this study is to determine the effect of RNA interference against BACE1 (shBACE-miR) on the lipid profile of hippocampal CA1 neurons in 3xTg-AD mice at 6 and 12 months of treatment. The results obtained by mass spectrometry show increased levels of DAG in AD mice compared with healthy animals ($p<0.05$). The treatment with shBACE-miR restores the basal levels of lyso-phosphatidylethanolamine ($p<0.05$) and ether-phosphatidylethanolamine ($p<0.05$) in 3xTg-AD mice treated for 6 and 12 months. Additionally, gas chromatography analysis evidences a tendency towards increase of stearic acid and diminution of polyunsaturated fatty acids like eicosatrienoic acid in AD mice compared to healthy animals, without changes by the shBACE1miR treatment. Our preliminary results suggest that silencing BACE1 induces changes in the composition of neural lipid profile that could favor the recovery of cellular homeostasis in the hippocampus of triple transgenic mice of AD.

Title: U1snRNP pathology identified by proteomics analysis of Alzheimer's disease links aberrant alternative splicing to elevated beta-amyloid levels

Authors: *P.-C. CHEN[1], B. BAI[1], C. M. HALES[2], Y. M. GOZAL[2], E. DAMMER[3], D. M. DUONG[2], H. D. REES[3], N. T. SEYFRIED[3], A. I. LEVEY[3], J. J. LAH[3], J. PENG[1]; [1]Structural Biol., St Jude Children Research's Hosp., Memphis, TN; [2]2Department of Neurology, Ctr. for Neurodegenerative Dis., [3]Dept. of Neurology, Ctr. for Neurodegenerative Dis., Emory Univ., Atlanta, TN

Abstract: Alzheimer's disease (AD), the most popular dementia, affects over 15 million people worldwide and it is expected to double in the next 20 years. However, there are currently no cures or treatments to slow down memory loss. Also clinical trials targeting on reducing amyloid-beta levels gains disappointing results. Therefore, it is urgent to find new targets for developing prevention or therapy for AD. With using large-scale proteomic analysis by liquid chromatography-mass spectrometry, we have identified accumulation of U1snRNP components in the detergent-insoluble proteome specifically in AD brain but not in Parkinson's or other degenerative diseases. In AD, these U1snRNP components, U1-70K and U1-A forms into cytoplasmic tangle-aggregates and eliminates from nuclear. As splicing happens in the nuclear, loss of nuclear U1snRNP indicates that loss-of function may play an important role in AD etiology. We found knockdown of U1-70K increases secreted amyloid-beta in both 293 and differentiated SH-SY5Y cells. Further, knockdown of U1-70K enhances exon skipping in *APP*, *BACE1*, *Presenilin-1, Presenilin-2*, in which the exon 5 skipping of *Presenilin-2* has been linked to sporadic AD. These data suggest aberrant splicing induced by loss of U1-70K may contribute to beta-amyloid elevation. We proposed elimination of nuclear U1snRNP in neurons may impair alternative splicing of genes and promotes the amyloid pathology and toxicity in AD.

Abstract: Cerebral amyloidosis is a common brain pathology associated with aging and age-related neurological diseases. Extracellular β-amyloid (Aβ) deposition in the parenchyma of the brain, especially in the form of neuritic or senile plaques, represents a hallmark lesion in Alzheimer's disease (AD). Amyloid deposition also occurs in the wall of blood vessels in the brain, referred to as cerebral amyloid angiopathy (CAA). CAA has been linked to vascular and overall cerebral dysfunctions during aging and in AD, while its pathogenic mechanism is poorly understood. Therefore, understanding its pathogenic mechanism may provide valuable information for developing effective therapeutic strategies for age-related dementia. Upregulation of the amyloidogenic enzyme β-secretase-1 (BACE1) has been shown to play a key role in Aβ overproduction and deposition in brain parenchyma. Here, we investigate a potential involvement of BACE1 in CAA by examination of postmortem human brains and human vascular cell models. Postmortem brains (n=27) from subjects aged 22-101 years were examined. BACE1 immunoreactivity (IR) was increased at local cerebral vasculature among 13 cases with extracellular plaques and/or CAA. Among the brains (n=14) lacking cerebral amyloidosis, vascular BACE1 IR was detectable at rare sites in some cases (n=4). BACE1 labeled vasculature appeared to be predominantly capillaries and arterioles. The BACE1 IR was localized mainly in the endothelium and partially coexisted with the vascular Aβ IR. Biochemical analysis confirmed the presence of BACE1 and other amyloidogenic proteins as well as their enzymatic activity in preparations of surgically removed peripheral human blood vessels, while primary cell culture indicated the expression of these proteins mainly in the endothelial cells. Notably, BACE1

protein expression and enzymatic activity as well as Aβ levels were elevated in cultured human umbilical endothelial cells in response to high cholesterol exposure. Together, these results suggest that Aβ overproduction by vascular cells may be involved in the development of CAA. Vascular Aβ overproduction may be mediated by BACE1 in response to circulatory/metabolic abnormalities including hypercholesterolemia.

Sch. of Medicine, The Univ. of Tokyo, Tokyo, Japan; [5]Dept. of Neuropathology and Neuroscience, Grad. Sch. of Pharmaceut. Sciences, The Univ. of Tokyo, Tokyo, Japan

Abstract: Alzheimer disease (AD) is a most common neurodegenerative disorder among dementia. AD is caused by aberrant accumulation and deposition of amyloid β peptide (Aβ), which is mainly secreted from neurons. Recently, pathophysiological roles of glial cells in AD have been highlighted, while it remains unclear how these non-neuronal cells are involved in the Aβ metabolism. To identify the Aβ-degrading enzyme derived from glial cells, we examined the degradation of Aβ in the cultured medium of human astrocytoma cell lines, U87 and CCF-STTG1. We found that these conditioned media from both cells showed the Aβ-degrading activity that was specifically inhibited by diisopropyl fluorophosphate, tosyl phenylalanyl chloromethyl ketone and zinc ion. These enzymatic characteristics suggested that kallikrein-related peptidase 7 (KLK7), which belongs to a member of tissue kallikrein-related peptidase family proteins, is involved in the Aβ degradation. Notably, low KLK7 level in CSF of AD

patients has been reported (Diamandis EP, et al. 2004). Supporting this notion, RNAi experiment revealed that KLK7 was required for the Aβ-degrading activity in the medium of CCF-STTG1 cells. Moreover, recombinant KLK7 protein was capable to degrade Aβ. Intriguingly, the conditioned media from rat primary astrocytes, but not neurons, showed the Aβ-degrading activity as well as KLK7 expression. These results suggest that KLK7 is a novel Aβ-degrading protease secreted from astrocytic cells.

Janssen Res. & Develop., Beerse, Belgium

Abstract: There is to date no efficacious treatment for patients suffering from Alzheimer's disease (AD), the most common form of dementia. With an increasingly ageing population worldwide, AD represents a huge burden to society. Genetic mutations promoting the proteolytic processing of the amyloid precursor protein (APP) by β- or γ-secretase (GS) are believed to be responsible for the rapid onset of the disease and their study has provided the genetic framework for the amyloid hypothesis. GS modulation has been proposed as a potential disease modifying anti-Alzheimer's approach. In contrast to γ-secretase inhibitors (GSIs), γ-secretase modulators (GSMs) cause a product shift from the longer amyloid isoforms to shorter, more soluble and less amyloidogenic isoforms, without inhibiting NOTCH proteolytic processing. Potent GSMs, from different chemicals classes, have been reported recently. Typically, these compounds are characterized by high lipophilicity and high molecular weight, properties that have been associated with low probability of success in clinical development. In this paper, we will discuss some aspects of the *in vitro* and *in vivo* pharmacological profiles of a new GS modulator, namely

JNJ-45261957, as well as early observations related to liver toxicity and tolerance studies conducted in rats and beagle dogs including single and repeated dose phases.

Title: BACE1 neuronal polarized sorting: Role of the clathrin adaptor protein GGA3

Authors: ***S. LOMOIO**, K. R. WALKER, G. TESCO;
NEUROSCIENCE, TUFTS UNIVERSITY SCHOOL OF MEDICINE, BOSTON, MA

Abstract: BACE1 localizes at the presynaptic terminal however the mechanisms of BACE1 axonal sorting remain unknown. Polarized delivery of membrane proteins is regulated by the interaction of signals present in their CTF-fragment with specific trafficking molecules. Sorting signals include the di-leucine motifs, [DE]XXXL[LI] or DXXLL, the tyrosine-based motifs, NPXY or YXXØ, and ubiquitin. The [DE]XXXL[LI] motif is recognized by the adaptor protein complexes AP-1, 2, 3 and 4, while GGA1, 2, and 3 bind to DXXLL via the VHS domain. The BACE1-CTF contains a specific di-leucine sorting signal (495DDISLL500) and an ubiquitination site at K501. GGA1, 2, and 3, a family of monomeric clathrin adaptors, have been shown to bind to the BACE1 496DISLL500 motif via their VHS domain and the phosphorylation of BACE1-S498 appears to increase their binding. Our previous studies have shown that BACE1 is degraded via the lysosomal pathway and that depletion of GGA3 results in increased BACE1 levels and activity owing to impaired lysosomal trafficking and degradation. Moreover we have demonstrated the role of GGA3 in the regulation of BACE1 *in vivo* by showing that BACE1 levels are increased in the brain of GGA3 null mice. We recently reported

that GGA3 regulates BACE1 degradation independently of the VHS/di-leucine motif interaction but requires binding to ubiquitin. More importantly we have previously shown that GGA3 levels are significantly decreased and inversely correlated with BACE1 levels in the post-mortem temporal cortex of AD patients. In spite of the compelling evidence showing that GGA3 regulates BACE1 trafficking, previous studies have been conducted in non-polarized cells. Moreover, while increasing evidence is accumulating for a role of the AP complexes in neuronal polarized sorting, the function of GGAs in neurons remains to be clarified. Interestingly, GGA3 is expressed highest in the brain and in neurons suggesting a specific role for GGA3 in neuronal function. In order to determine the polarized sorting of BACE1, mouse hippocampal neuronal cultures were transiently transfected with BACE1-GFP. After fixation neurons were imaged with a Leica confocal microscope and the polarity index (axon/dendrites ratio) was calculated using ImageJ. Our data indicate that BACE1 is present both in the axon and dendrites 1 day after transfection with a preference for dendritic targeting. We are currently investigating the extent to which GGA3 regulates axonal sorting of BACE1 using cultured hippocampal neurons from GGA3+/+ and GGA3-/- mice. We are studying the localization of GGA3 and BACE1 with axonal and dendritic markers and calculate polarity index for the proteins of interest.

Abstract: Accumulation of amyloid-β (Aβ) peptide in the brain is the first critical step in the pathogenesis of Alzheimer's disease (AD). Studies in humans suggest that Aβ clearance from the brain is frequently impaired in late-onset AD. Aβ accumulation leads to the formation of Aβ aggregates which disturb synaptic functions and lead to eventual neurodegeneration. Cell surface heparan sulfate proteoglycan (HSPG), abundantly expressed in neurons, have been implicated in several features in the pathogenesis of AD, including its co-localization with amyloid plaques and its modulatory role in Aβ aggregation. Previous studies have shown that heparin, which antagonizes HSPG, suppresses the interaction of Aβ to neurons and reduces Aβ neuronal toxicity. However, the mechanisms by which neuronal HSPG regulates brain Aβ clearance and related amyloid pathology *in vivo* remains unclear. Here, we show that HSPG negatively regulates Aβ clearance *in vivo*. Deletion of neuronal HSPG by conditionally disrupting the HS polymerizing enzyme Ext1 in postnatal neurons in adult amyloid model APP/PS1 mice significantly increased brain interstitial fluid (ISF) Aβ clearance when analyzed by *in vivo* microdialysis. A deficiency of neuronal HSPG also led to a dramatic reduction in the deposition of amyloid plaque, suggesting that Aβ binding to HSPG and related cellular uptake either inhibit or represent an inefficient pathway for Aβ clearance. Our findings have implications for AD pathogenesis and may provide insights into therapeutic intervention targeting Aβ-HSPG interaction.

Title: Pericyte loss influences Alzheimer-like neurodegeneration cascade in mice

Authors: *A. P. SAGARE[1], R. D. BELL[2], Z. ZHAO[1], Q. MA[1], E. A. WINKLER[2], A. RAMANATHAN[1], B. V. ZLOKOVIC[1];
[1]Dept. of Physiol. and Biophysics, USC, Los Angeles, CA; [2]Ctr. for Neurogenerative and Vascular Brain Disorders, Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Pericytes are vascular mural cells embedded within the basement membrane of blood microvessels. Pericytes are uniquely positioned within the neurovascular unit between endothelial cells of brain capillaries, astrocytes, and neurons. Recent studies have shown that pericytes regulate key neurovascular functions including blood-brain barrier formation and maintenance. Neurovascular dysfunction, microvascular reductions and pericyte degeneration and loss have been demonstrated in Alzheimer's disease (AD), a neurodegenerative disorder associated with abnormal elevation of amyloid β-peptide (Aβ), tau pathology and neuronal loss. Whether pericytes can influence the natural course of AD-like neurodegeneration and contribute to disease pathogenesis and accumulation of AD pathology remains, however, unknown. Utilizing mice which overexpress Aβ-precursor protein, we show that pericyte loss elevates brain Aβ40 and Aβ42 levels and accelerates amyloid angiopathy and cerebral β-amyloidosis by diminishing clearance of soluble Aβ40 and Aβ42 from brain interstitial fluid prior to Aβ deposition. We show that pericyte deficiency leads to the development of tau pathology and an early neuronal loss that is normally absent in Aβ-precursor protein transgenic mice resulting in cognitive decline. Our data suggest that pericyte loss influences and accelerates multiple steps of AD-like neurodegeneration pathogenic cascade in Aβ-precursor protein overexperssing mice. Therefore, pericytes may represent a novel therapeutic target to modify disease progression in AD.

Title: Roles of Nicastrin, Pen-2, and Aph-1 in gamma secretase catalyzed turnover of the C-terminal fragment of APP

Authors: *X. XU, C. HU, T. LI, L. ZENG, M.-Z. CUI;
Pathobiology, Univ. Tennessee, KNOXVILLE, TN

Abstract: Based on the "amyloid cascade hypothesis", the ratio of Aβ42 verses Aβ40 plays a key role in Alzheimer's disease (AD). The ratio of Aβ42/Aβ40 is controlled by gamma secretase, which cleaves APP (Aβ precursor protein) at C terminal and release Aβ in different length: Aβ38, Aβ40, Aβ42, Aβ43, Aβ46, Aβ49 and so on. Hence, dissecting the biological and biochemical nature of gamma secretase is important in understanding the mechanism of Aβ formation. Gamma secretase is a complex composed of four components: presenilins (PS1 or PS2), nicastrin (NCT), anterior pharynx-defective 1 (Aph-1), and presenilin enhancer 2 (pen-2). The roles of these components remain unclear. It is believed that all the four components are required for gamma secretse activity. Previous studies have suggested that PS functions as the catalytic subunit; NCT may serve as a receptor for the substrate; Aph-1 is assumed to stabilize the other three components; and pen-2 was reported to be essential for the endoproteolysis of PS. However, our recent study revealed that pen-2 is dispensable for the endoproteolysis of PS, but is required for gamma secretase activity. Our data also demonstrate that NCT is also required for gamma secretase activity. Interestingly, we found that APP is processed by gamma secretase activity in the absence of Aph-1, indicating that Aph-1 is not required for gamma secreatse activity. Furthermore, our data revealed that post-translational modification of PS1 has a strong effect on gamma secretase activity.

Title: FRET-based assays for the detection of amyloid degrading protease activity

Authors: *C.-Y. KO, M. ZHU, O. GURINOVICH, F. LI, R. ZHANG, J. ZHONG, V. RAKHMANOVA;
Anaspec, Inc. EGT Group, Fremont, CA

Abstract: Amyloid degrading proteases (AβDPs) have been identified as playing a role in β-amyloid (Aβ) cleavage. The accumulation of Aβ plaques, a hallmark of Alzheimer's disease (AD) patient brain, has been hypothesized to be due to the imbalance between AβDPs activity and Aβ production resulting in AD pathogenesis. In order to confirm the role(s) of AβDPs in neuronal degeneration diseases, reliable assays for AβDPs activity detection have to be developed. We have designed several assays to detect AβDP targets using fluorescence resonance energy transfer (FRET) based peptide substrates. Substrate sequence is derived from the cleavage site of each AβDP target. The peptide substrate is coupled with an optimized fluorescent donor (HiLyte™ Fluor 488 or 5-FAM) and a quenching acceptor (QXL® 520). Upon cleavage by active AβDP, the fluorescent donor is separated from the quencher and resulted in an increased fluorescence signal. The long-wavelength fluorescence signal has minimal interference from autofluorescence derived from biological samples and testing compounds. Moreover, the perfect overlap of absorption and emission spectra of our proprietary FRET pairs allows for a greater level of sensitivity detection. Utilizing FRET technology, the assay offers a homogeneous format which can be easily adapted for high-throughput screening (HTS) for drug discovery. Several AβDPs, such as β-secretases, neprilysin, ADAMs, IDE, MMPs, and cathepsins have been proven to play roles in the regulation of Aβ clearance in AD. Using different FRET pairs and novel sequence design, assays have been developed for monitoring enzyme activity of β-secretases, neprilysin, ADAM 10, TACE (ADAM17), MMP-2, MMP-9, cathepsins B and D. The origin of peptide substrate sequence ensures that the assays can be used for either specific β-amyloid degradation detection or general enzyme activity screening. Furthermore, long wavelength, fluorescent readouts yield sensitivity in the sub-nanogram range. In order to increase specificity of AβDPs activity detection in biological samples, our future goal will aim at combining FRET technology and specific antibody to develop immunocapture-based fluorometric assay.

Title: Curcumin prevent alzheimer's pathology through a new mechanism for the inhibition of aβ oligomer formation

Authors: Y.-Q. YANG[1], Y.-L. ZHANG[1], S.-L. LI[1], M.-M. KANG[1], Z.-B. LIANG[1], X.-Q. HU[2], *W.-J. GAO[3], F. LI[1];

Abstract: In the last decade of studies, soluble oligomeric forms of amyloid-β (Aβ) were believed to play a larger role in the pathogenesis of Alzheimer's disease (AD) than deposited β-amyloid. However, there is still a lack of direct evidence, and its mechanism remains largely unknown. In this study, we first found a new type of senile plaques composed of soluble non-fibrillar Aβ oligomers on the posthumous brain specimens of the patients with Alzheimer's disease. We refer to as the Aβ oligomer plaques. They were distributed among the classical senile plaques comprised of insoluble fibrillar β-amyloid in the cerebral cortex and hippocampus. To some extent, the Aβ oligomer plaques were only part of classical senile plaques, but sometimes they could make senile plaques in whole by themselves, suggesting the possibility that the Aβ oligomer plaques were a critical transition state of senile plaques. We speculated that, by soluble nature of oligomers, some therapeutic agents targeting the oligomers might make the Aβ oligomer plaques dissolution. In this study, we also observed that the anti-Aβ oligomer humanized antibody had a high affinity for the Aβ oligomer plaques, but the anti-Aβ antibody that specifically binds only to the fibrillar β-amyloid could not recognize them. Curcumin, a phenolic compound extracted from the rhizome of the herb curcuma longa, could label the Aβ oligomer plaques on brain sections of AD patients and stain the same structures as antibody against Aβ oligomer. *In vitro*, we found that curcumin could inhibit the Aβ aggregation pathway from Aβ monomers to oligomers and from oligomers to Aβ deposition. We further confirmed that the effects of curcumin on Aβ aggregation were associated with its blocking a conversion of α-helical conformation of β-amynoid into the β-stranded conformation at the early step. It is

generally known that the conformational conversion can result in the exposure of the hydrophobic surface of β-amynoid which is conducive to Aβ aggregation. Our study might offer insights in better improving our understanding of oligomeric Aβ-induced toxicity. Based on the pleiotropic activity of curcumin, we might make curcumin potentially useful for treatment of Alzheimer's disease by targeting the soluble Aβ oligomers.

Title: Role of NMDA in amyloid-beta generation

Authors: ***J. HETTINGER**[1,2,3], J. R. CIRRITO[1,2,3];
[1]Neurol., Washington Univ., Saint Louis, MO; [2]Knight Alzheimer's Dis. Res. Ctr., Saint Louis, MO; [3]Hope Ctr. for Neurolog. Disorders, Saint Louis, MO

Abstract: Extracellular accumulation of the amyloid-beta (Abeta) peptide as oligomers and plaques is thought to be a key event in Alzheimer's disease (AD) pathogenesis. Amyloid-beta aggregation is concentration-dependent, with higher concentrations of Abeta much more likely to form these toxic multimers. Mechanisms that reduce Abeta production and extracellular levels are therefore promising targets for influencing disease pathology. Previously, our lab found that administration of *N*-methyl-D-aspartic acid (NMDA) directly to the brain reduced Abeta levels in the interstitial fluid (ISF) of wild-type mice and the APP/PS1 mouse model of AD. We have shown that this NMDA-mediated suppression requires the phosphorylation and activation of extracellular-regulated kinase (ERK). ERK signaling then reduces Abeta production, apparently

through increased α-secretase enzymatic activity. ERK can be activated through a wide selection of receptors and signaling molecules; however, its selectivity for downstream effects is largely dependent on the cellular context in which it is activated. In order to understand the downstream effects of NMDA receptors on Abeta production, we must first determine the pathway(s) through which NMDA receptors signal to ERK. In order to define this pathway, we have inhibited key signaling molecules and measured the effect on NMDA receptor-mediated Abeta generation using a combination of *in vivo* microdialysis in the hippocampus of young PS1/APP mice as well as *in vitro* primary hippocampal neuronal culture. By detailing the components necessary for NMDA receptors to decrease brain Abeta levels, we hope to identify potential selective targets for the regulation of Abeta production.

Title: Human ES cell-derived neurons as a preclinical model system for testing gamma-secretase inhibitors and modulators

Authors: *D. KARLSSON, H. MURREY, D. JOHNSON, I. SINGEC;
Pfizer Inc, Cambridge, MA

Abstract: Alzheimer's disease (AD) is the most common form of dementia, accounting for an estimated 70 percent of cases. γ-Secretase (GS) is an intramembrane aspartyl-protease that cleaves amyloid precursor protein (APP) to generate Aβ species, including the neurotoxic Aβ-42. Aβ-42 is a component of β-amyloid plaques, which are histopathological hallmarks of AD. γ-Secretase modulators (GSMs) are potentially important treatment options for AD, since they decrease the production of Aβ-42 without affecting the processing of other critical γ-secretase substrates. Human neurons, for instance derived from human ES cells, hold great promise for streamlined testing of known and new drugs under defined conditions. In fact, "humanizing" the drug discovery process in early stages, could pave the way for more rapid, accurate, and economic strategies. As part of Pfizer's Humanizing Drug Discovery initiative, we studied functional human neurons (H9 line), and used clickable GSM and GSI photoaffinity probes to assess the functionality of GS. In addition, we developed γ-Secretase inhibitor-photoaffinity

probes for fluorescent imaging applications to monitor the subcellular localization of these compounds in live cells. We found that human neurons expressed functional GS and produced detectable levels of Aβ peptides. Generation of these peptides was inhibited by known GSIs, with IC_{50} values comparable to other live-cell assays. Lastly, we observed discrete subcellular localizations of GSIs in live human neurons. Together, these studies suggest that functional human neurons contain active GS thereby representing an invaluable preclinical model system for assessing compound activity and providing new mechanistic insights into molecular targets and drug response.

Title: Role of deubiquitinating enzyme ubiquitin specific peptidase 8 (USP8) in β-Site amyloid precursor protein cleaving enzyme (BACE1) degradation

Authors: *E. F. YEATES, G. TESCO;
Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Alzheimer's disease (AD) is a progressive neurological disorder that affects 1 in 9 people over age 65 in the United States. Amyloid beta (Aβ) is the chief component of the amyloid plaques characteristic of AD. β-Site amyloid precursor protein cleaving enzyme (BACE1) is the rate-limiting enzyme in the formation of Aβ from amyloid precursor protein (APP). Increases in BACE1 protein levels have been seen in post mortem samples from AD patients. We have previously shown that BACE1 is ubiquitinated on lysine 501 and is degraded in lysosomes. However, the ubiquitin ligases and deubiquinating enzymes that regulate BACE1 ubiquitination, remain to be identified. As BACE1 is degraded in the endosomal-lysosomal system, we hypothesize that ubiquitin specific peptidase 8 (USP8), an endosomal-associated

deubiquitinating enzyme, regulates the degradation of BACE1, by deubiquinating it. In particular, decreasing levels of USP8 are expected to increase BACE1 degradation, decrease BACE1-mediated APP processing and ultimately decrease amyloid beta formation. The goals of the study were to determine whether knockdown of USP8 *in vitro* increased BACE1 degradation and resulted in decreased BACE1-mediated APP processing. We used an H4 neuroglioma cell line overexpressing BACE1-GFP to determine the effects of USP8 on BACE-GFP *in vitro*. In overexpression experiments, cells were transfected either with a HA-tagged USP8 plasmid or vector. In siRNA-mediated silencing experiments, cells were transfected with either USP8 siRNA or non targeting siRNA. Total cell lysates were examined for expression of BACE-GFP by Western blotting. Preliminary evidence shows that while an overexpression of USP8 does not result in a change in BACE-GFP levels compared to empty vector, knockdown of USP8 results in decreased BACE1-GPF protein levels. Furthermore, knockdown of USP8 results in increased full length APP and decreased APP C-terminal fragment (CTF) levels, suggesting a decrease in BACE1-mediated APP processing. Conditioned media samples from siRNA treated cells were analyzed for secreted Aβ40 content using an Aβ40 ELISA. USP8 knockdown did not alter secreted Aβ40 levels in conditioned media. Future experiments will determine whether USP8 knockdown decreased APP CTFs levels independent of BACE1-mediated processing, by increasing CTF degradation. Furthermore, future experiments will determine whether USP8 knockdown affects the levels of the alpha and gamma secretases involved in APP processing. The results of our studies will aid our understanding of the regulation and degradation of BACE1, an important enzyme in the formation of Aβ.

Title: APP metabolism is modulated by cholesterol in cultured astrocytes

Authors: *M. E. AVILA-MUÑOZ, C. ARIAS;
Medicina Genómica y Toxicología Ambiental, Inst. de Investigaciones Biomédicas, UNAM, Mexico, Mexico

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by extracellular deposits of amyloid β protein (Aβ) derived from the amyloid precursor protein (APP) through the amyloidogenic pathway. Studies in neurons have found that the APP cleavage enzymes, β- and γ- secretases, reside in cholesterol- and sphingolipid-rich detergent-resistant lipid raft microdomains. Cholesterol has long been associated with AD pathogenesis and different studies have found a positive correlation between the level of circulating cholesterol and Aβ load in the AD's brain. Although the majority of studies on APP processing have been performed in neurons, recent studies suggest that astrocytes can be an important cellular source of Aβ. However, it is not completely understood the mechanisms involved in APP processing in astrocytes. The aim of this work was analyze the relationships between cholesterol content and expression of APP and Aβ production in astrocytes. Primary cultured astrocytes were used trough the study and were incubated with cholesterol at different doses to analyze the expression of GFAP, APP and β-secretase. At present we have found that cholesterol induces the activation of astrocytes and the increase of APP and BACE-1 proteins. Also, cholesterol promotes the association of APP with BACE-1 and the production of C-99 fragment derived from the APP cleavage by this enzyme. Concomitant with these effects the non-amyloidogenic pathway-related fragment, sAPPα was found decreased. These results confirm that cholesterol contents may have an impact in the APP metabolism in astrocytes and may be a risk factor for amyloid production by these cells.

Title: FLICE-inhibitory protein(c-Flip) is a novel substrate of gamma-secretase

Authors: *L. ZENG, C. HU, T. LI, F. ZHANG, M.-Z. CUI, X. XU;
Pathobiology, The Univ. of Tennessee, Knoxville, TN

Abstract: Mutations in the presenilin 1 (PS1) gene are responsible for the majority of familial form of Alzheimer disease. Studies suggest that PS1 functions as the catalytic subunit of the γ-secretase complex, which is a key enzyme involved in β-amyloid peptide (Aβ) formation, a hallmark of Alzheimer's disease (AD). In addition to Aβ formation, PS1 has also been implicated in apoptosis. However, the mechanism by which PS1 is involved in apoptosis remains elusive. In this study, we investigated the effect of PS1 on the turnover of cellular FLICE-inhibitory protein (c-FLIP). We found that overexpression of PS1 induced apoptosis in certain types of cells and the induction of apoptosis is associated with the cleavage of c-FLIP. Our data further demonstrated that PS1-induced cleavage of c-FLICE was inhibited by γ-secretase inhibitors, but not by caspase inhibitor, indicating that cleavage of c-FLIP is catalyzed by γ-secretase. Moreover, our data also demonstrated that addition of γ-secretase inhibitors also blocked PS1-induced apoptosis. These data suggest that c-FLIP is involved in PS1-induced apoptosis. To further elucidate the pathway, we examine the roles of some key caspase and mitochondrial apoptotic factors in PS1-induced apoptosis. To this end, our data revealed that knockdown of caspase-8, FADD, bid, and Bax, or overexpression of Bcl-2 strongly blocked PS1-induced apoptosis, while knockdown of Bak had no effect on PS1-induced apoptosis. Knockdown of caspase-9 and SMAC at the same time also significantly inhibited PS1-induced apoptosis. Taken together, our data suggest that PS1 induces a FLIP-mediated mitochondria dependent apoptosis. In addition, our study also revealed that c-FLIP is a novel substrate of γ-secretase.

Title: EphrinB2 processing by γ-secretase regulates migration of microglia

Authors: ***N. KEMMERLING**[1], P. WUNDERLICH[1], N. HERSCH[2], B. HOFFMANN[2], K. GLEBOV[1], B. D. STROOPER[3], H. NEUMANN[4], J. WALTER[1];
[1]Uniklinik Bonn, Bonn, Germany; [2]Res. Ctr. Jülich GmbH, Jülich, Germany; [3]KULeuven and Flanders Interuniversitary Inst. for Biotech. (VIB), Leuven, Germany; [4]Inst. of Reconstructive Neurobio., Bonn, Germany

Abstract: *Introduction*: Presenilin mutations are a major cause of early onset familial Alzheimers disease (FAD) cases. Presenilin proteins are critical components of the γ-secretase complex that cleaves many type I transmembrane proteins, including EphrinB2. Microglia, which are important immune cells in the central nervous system (CNS), also play a crucial role in the clearance of the Alzheimer-associated amyloid β peptide. The sensing of amyloid β deposits or other cellular debris and pathogens induces migration of microglia to allow efficient phagocytosis. Here, we investigated the functional role of γ-secretase dependent cleavage of EphrinB2 in microglial migration. *Materials and Methods*: Mouse embryonic stem cell derived microglia (ESdM) from wild-type (WT) and presenilin double knock (PSdKO) mice were investigated regarding their migrational behaviour. In addition, podosome morphology and characteristic signaling proteins related to the migrational processes were analyzed by cell biological and biochemical methods. *Results*: ESdM from PSdKO mice showed significantly impaired migration as compared to ESdM from WT mice. Interestingly, the migrational deficit could be rescued by expression of the EphrinB2 intracellular domain. Furthermore, cleavage of EphrinB2 by γ-secretase was also involved in the phosphorylation of key proteins in the formation of podosomes. *Conclusions*: γ-Secretase dependent cleavage of EphrinB2 is involved in the regulation of microglial migration and thus, might also affect the clearance of amyloid β in Alzheimer's disease**.**

Title: Bioorthogonal γ-secretase inhibitor (GSI) photoaffinity probes enable determination of target-engagement and compound localization in live cells and primary rat neurons

Authors: *H. E. MURREY[1], D. S. JOHNSON[2];
[2]WWMC and Chem. Biol., [1]Pfizer, Cambridge, MA

Abstract: γ-Secretase (GS) is an intramembrane aspartyl protease, comprised of at least four protein subunits. This complex cleaves the amyloid precursor protein to generate Aβ species, including the neurotoxic Aβ-42. Aβ-42 is a component of β-amyloid plaques, and is believed to play a causative role in Alzheimer's disease (AD) progression. γ-Secretase inhibitors (GSIs) have emerged as early potential treatments for AD. However, these compounds have often failed in clinical trials due to negative effects, likely due to cleavage inhibition of other GS substrates. We have developed a suite of bioorthogonal GSI photoaffinity probes based on the structure of BMS-708,163, an allosteric sulfonamide GSI which binds to the N-terminal fragment of presenilin (PS1-NTF). We evaluated these small-molecule probes in HeLa membranes, live HeLa cells, and primary neuronal cultures to interrogate the compound mechanism-of-action. Probes were synthesized with a benzophenone for photocrosslinking the compound to target proteins and a bioorthogonal handle for reaction with cognate bioorthogonal reporter molecules. We evaluated different bioorthogonal chemistries, including the inverse-electron demand Diels-Alder ligation and the strain promoted azide-alkyne cycloaddition chemistry, and compared these live cell labeling approaches to traditional Cu-catalyzed click chemistry. Initially, we labeled HeLa membranes to validate each bioorthogonal probe. We observed selective labeling of PS1-NTF with bioorthogonal probes in HeLa membranes, whereas a direct-fluorophore linked probe had a high-degree of non-specific labeling, demonstrating the utility of installing a smaller, bioorthogonal handle. We next investigated labeling of presenilin in live cells. In addition, we competed off binding of the probes with the parent compound to determine specificity. We were able to demonstrate specific labeling of PS1-NTF in live HeLa cells and neurons, with different kinetics depending on the bioorthogonal reactive group. Furthermore, we were able to determine the target engagement of an alkyne-modified probe in live, primary cortical neurons with an EC_{50} of ~10 nM. These compounds were then used for live cell imaging, to interrogate their distribution in different subcellular compartments. We identify a punctate distribution of BMS-708,163 photoaffinity probes in live cells, with significant localization to lysosomes and endosomes. These studies validate bioorthogonal probes for the investigation of γ-secretase inhibition in live cells, and provide a method that can be applied to characterize novel GSIs and GSMs developed to treat AD.

Title: A role of Alzheimer's disease associated γ-secretase activity in lipid metabolism and lipid droplet formation

Authors: *E. GUTIERREZ[1], D. LÜTJOHANN[2], L. KÜRSCHNER[3], C. THIELE[3], J. WALTER[1];
[1]Neurol., Bonn Univ. Clin., Bonn, Germany; [2]Inst. for Clin. Chem. and Clin. Pharmacol., Bonn university clinic, Bonn, Germany; [3]Life and Med. Sci. (LIMES) institute, Membrane Biol. & Biochem. Unit, Univ. of Bonn, Bonn, Germany

Abstract: ***Objectives:*** Mutations in genes encoding for Presenilins (PS) and the amyloid precursor protein (APP) are the main cause for most cases of early-onset Alzheimer's disease (EOAD). PS are the catalytically active components of the γ-secretase complex (γ-sec), which is responsible for the cleavage of C-terminal fragments (CTF) of APP, leading to the formation of Aβ. Aß is a major component of extracellular plaques found in brains of Alzheimer disease (AD) patients. While the involvement of both PS and APP in AD is well recognized, as is their role in the cellular production of Aβ, the mechanisms linking these proteins to the disease are not comprehensively understood. It has been shown that PS proteins are also involved in cholesterol metabolism. The purpose of this study is to further elucidate the role of PS on sterol, triglyceride and lipid droplet (LD) metabolism, as well as the contribution of the accumulation of the APP CTF C99 to these processes. ***Methods:*** To study the effects of PS activity we used pharmacological inhibition of γ-sec and knock-out cell models lacking PS expression. LD content was analyzed by fluorescence microscopy using the dye LD540. Sterol levels and esterification ratios where analyzed by gas-liquid chromatoraphy-mass spectrometry (GLC-MS) and the Amplex red cholesterol assay. The interaction between C99 and cholesterol was studied by fluorescence microscopy on cell models overexpressing a C99-GFP fusion protein, together with a cholesterol staining with Filipin. ***Results:*** Genetic deletion of PS or pharmacological inhibition of γ-sec activity lead to significantly increased amounts of lipid droplets and triglycerides, together with significantly higher levels of the cholesterol precursors lathosterol

and desmosterol, and significantly lower sterol esterification ratios. Moreover, following pharmacological inhibition of γ-sec, overexpressed APP C99-GFP was observed to accumulate in cholesterol-positive intracellular membrane structures, and an increased expression and accumulation of C99-GFP was shown to correlate with an increased number of cellular LDs. ***Conclusions:*** Our findings support an important role of PS and γ-sec in lipid metabolism. We identified alterations relevant to cellular sterol and lipid homeostasis upon loss of PS activity. Furthermore, the observed association of C99-GFP with cholesterol in cell-based assays, together with the correlation between C99-GFP accumulation and increased LD formation, indicates that this γ-sec substrate represents a potential link between PS activity and lipid metabolism.

Title: PS1/γ-secretase promotes EphB4-induced angiogenic complexes and angiogenesis via ephrinB2 processing

Authors: *A. GEORGAKOPOULOS[1], N. WARREN[2], G. VOLOUDAKIS[3], N. K. ROBAKIS[3];
[2]Psychiatry, [1]Mount Sinai Sch. Med., NEW YORK, NY; [3]Psychiatry, Mount Sinai Sch. of Med., New York, NY

Abstract: Evidence in the last decade implicates cerebral microvasculature abnormalities in the genesis of Alzheimer's disease (AD) neuropathology by mechanisms that remain unknown. EphB4/ephrinB2 system is an important regulator of the vascular system in both development

and adulthood. Binding of EphB4 receptor to its transmembrane ligand ephrinB2 on the surface of endothelial cells of blood vessels stimulates angiogenesis, which is the generation of new blood vessels from pre-existing vasculature and transgenic mouse experiments indicate that the intracellular (cytoplasmic) domain of ephrinB2 is necessary for this function. We found that Presenilin1 (PS1), a component of the γ-secretase proteolytic complex which plays a central role in familial AD (FAD), interacts with ephrinB2/EphB4 system and regulates its vascular functions. More specifically we found that EphB4 stimulates processing of ephrinB2 in a PS1/γ-secretase-dependent manner producing cytosolic peptide ephrinB2/CTF2, which corresponds to ephrinB2 cytoplasmic domain, and that EphB4-induced sprouting of endothelial cells depends on γ-secretase activity. When peptide ephrinB2/CTF2 is overexpressed in endothelial cells it stimulates their sprouting and tube formation and mutations that inhibit its phosphorylation at conserved tyrosine residues or removal of its PDZ-binding domain hinder its angiogenic activity. Recent literature shows that a crucial step in angiogenic factor-induced angiogenesis is formation of complexes between Raf-1/Rok-α kinases and Vascular Endothelial cadherin (VE-cadherin), a process regulated by small G protein Rap1. We observed that treatment of endothelial cell cultures with EphB4 increases these angiogenic complexes in a γ-secretase-dependent manner and that overexpression of ephrinB2/CTF2 also promotes the formation of these complexes. In addition, both EphB4- and ephrinB2/CTF2-induced cell sprouting require Rap1 activity. Together the above observations raise the possibility that PS1/γ-secretase affects the EphB4/ephrinB2-induced angiogenesis by regulating proteolytic processing of ephrinB2 and angiogenic complex formation. Our data raise the possibility that PS1 FAD mutations, which inhibit γ-secretase function, may decrease the production of ephrinB2/CTF2 in endothelial cells and consequently inhibit angiogenesis. This provides a potential pathogenic mechanism for the impaired angiogenesis observed in AD brains.

Abstract: Members of tyrosine kinase growth factor receptors are regulated by presenilin1 (PS1), a protein important to Alzheimer disease (AD) as PS1 mutants are linked to familial AD (FAD). Previously, we showed that PS1 is needed for the neuroprotective activities of neurotrophin factor BDNF, a ligand for receptor tyrosine kinase TrkB. Ligands of tyrosine kinase Epidermal Growth Factor Receptor (EGFR) protect neurons from toxic insults such as excitotoxicity and ischemia. Here we report that neurons lacking PS1 show decreased ligand-induced (EGF & HB-EGF) Akt activation and reduced neuroprotection against excitotoxicity. Consistent with neuronal survival outcomes, PS1 null primary neuronal cultures contain dramatically reduced levels of this receptor, a state which can be reversed by the reintroduction of PS1. These observations are inconsistent with literature reports that PS1 negatively regulates EGFR. Acute downregulation of PS1 using siRNA decreases the expression of neuronal EGFR and brains from PS1 null mice have reduced levels of EGFR relative to WT brains. Additional experiments indicate that decreased EGFR in PS1 null neurons is due to decreased EGFR mRNA, a change independent of γ-secretase activity. Neurons that lack Presenilin 2 (PS2) exhibit normal EGFR expression levels and ligand-induced neuroprotection against excitotoxicity. Interestingly, neither primary fibroblasts nor glia cells from PS1 null mice contain increased levels of EGFR. In addition, EGFR protein levels showed no correlation with PS1 expression levels when we compared different immortalized fibroblast clones from WT, PS1 hemizygous and PS1 null mice. Together, our data suggests that in contrast to reports obtained in immortalized cells, PS1 positively regulates the expression of neuronal EGFR and the neuroprotective effects of its ligands. Furthermore, immortalized fibroblasts may not be reliable indicators for the effects of PS1 on the EGFR of primary cells and brain tissue.

Title: The anti-diabetic drug metformin reduces BACE protein level by interfering with the MID1-PP2A-mRNP

Authors: *S. KRAUSS, M. HETTICH, F. MATTHES, D. RYAN, N. GRIESCHE, S. SCHRÖDER, S. DORN, D. EHNINGER;
DZNE / German Ctr. of Neurodegenerative Dis., Bonn, Germany

Abstract: Alzheimer's disease (AD), the most common form of dementia in the elderly, is characterized by two neuropathological hallmarks: senile plaques, which are composed of Aβ peptides, and neurofibrillary tangles, which are composed of hyperphosphorylated tau protein. Diabetic patients with dysregulated insulin signalling have an increased risk of developing AD and in several animal models of diabetes show increased levels of expression of Aβ and hyperphosphorylated tau. As we have shown recently, the anti-diabetic drug metformin is capable of dephosphorylating tau at AD-relevant phospho-sites. Here, we investigated the effect of metformin on the main amyloidogenic enzyme BACE1 and thus on the production of Aβ peptides, the second pathological hallmark of AD in cultures of primary neurons, a human cell line model of AD and *in vivo* in mice. We show that treatment with metformin decreases BACE1 protein expression by interfering with an mRNA-protein complex that contains the ubiquitin ligase MID1, thereby reducing BACE1 activity. Together with our previous findings these results indicate that metformin may target both pathological hallmarks of AD and may be of therapeutic value for treating and/or preventing AD.

Title: Snapin-mediated bace1 retrograde transport is essential for its degradation in lysosomes and regulation of app processing in neurons

Authors: *Q. CAI, X. YE;
Cell Biol. and Neurosci., Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: β site amyloid precursor protein (APP)-cleaving enzyme 1 (BACE1) is the major β secretase for generating β-amyloid (Aβ) peptides. The acidic environment of endosomes is optimal for β secretase activity. However, the mechanisms regulating BACE1 traffic from endosomes to lysosomes for degradation are largely unknown. Here, using snapin-deficient mice combined with gene rescue experiments, we reveal that Snapin, as a dynein motor adaptor for late endosomes, mediates BACE1 retrograde transport. hAPP mutant live neurons and mouse brains exhibited BACE1 accumulation within the altered late endocytic organelles and defective lysosomal targeting due to reduced Snapin-dynein coupling. Deleting snapin or disrupting Snapin-dynein coupling reduces BACE1 transport to lysosomes for degradation, thus enhancing APP processing. Overexpressing Snapin in hAPP neurons reduces β site cleavage of APP by enhancing BACE1 turnover. Altogether, our study provides mechanistic insights into the complex regulation of BACE1 level and activity and turnover through retrograde transport, thus controlling Aβ generation in neurons.

Title: N-terminally truncated beta-amyloid peptides are generated by alternative beta-secretase cleavage

Authors: *H. CYNIS[1], D. SCHLENZIG[1], U. ZEITSCHEL[2], M. HARTLAGE-RUEBSAMEN[2], S. ROSSNER[2], S. SCHILLING[1], H.-U. DEMUTH[1];

Abstract: The accumulation of beta-amyloid (Abeta) peptides is causal for the development of Alzheimer's disease (AD). Abeta is liberated by sequential cleavage of beta- and gamma-secretase and BACE I was identified as major beta-secretase mediating the N-terminal step of Abeta generation. N-terminally truncated and pyroglutamate-modified (pGlu-3) Abeta peptides are an emerging species in AD research showing an exceptionally high aggregation propensity and toxicity. Since catalysis by BACE I preferentially produces full-length Abeta peptides, the mechanism of generating N-terminally truncated Abeta peptides could lead to novel drug targets for AD treatment. Consequently, we studied pathways leading to the generation of such truncated Abeta peptides. We applied vectors containing APP (wt) or the KM595/596NL "Swedish" mutation (APP (sw)) in different cellular models including transient overexpression in different permanent cell lines and in fibroblasts generated from BACE I/II knockout mice. Abeta formation was also studied in primary neurons from APP (wt) and APP (sw)-overexpressing mouse lines. The different Abeta species were dissected by highly specific ELISAs discriminating between N-terminal Abeta variants. Results were verified by siRNA and Western Blot experiments as well as co-expression of APP (wt) with putative alternative beta-secretases. Major outcome of the study is that a significant amount of Abeta is generated by BACE I-independent cleavage in the cellular models, including primary neurons. A monitoring mutation in APP (E599Q) revealed that especially pGlu-3 Abeta is liberated by a BACE I-independent mechanism. Furthermore, classical BACE I inhibition is not sufficient to block the generation of pGlu-3 Abeta peptides. The results have implications for further drug development strategies aiming at reduction of pGlu-modified Abeta species.

Title: Aβ-induced BACE1 elevation in primary neurons and in 5XFAD mouse model of Alzheimer's disease is not dependent on eIF2α phosphorylation

Authors: *K. R. SADLEIR[1], W. A. EIMER[2], R. J. KAUFMAN[3], P. OSTEN[4], R. VASSAR[1]; [1]Cell and Mol. Biol., Northwestern Univ., CHICAGO, IL; [2]Dept. of Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [3]Sanford Burnham Med. Res. Inst., La Jolla, CA; [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The β-Secretase, β-site APP Cleaving Enzyme1 (BACE1) is the enzyme that initiates production of the β-amyloid (Aβ) peptide involved in Alzheimer's disease (AD). Reduction of BACE1 levels inhibits Aβ generation and amyloid plaque formation. Modest overexpression of BACE1 in transgenic mice increases amyloid, demonstrating that Aβ production and amyloid pathology can be modulated by BACE1 levels. BACE1 protein and activity are elevated in the brains of AD patients and mouse models of AD, accumulating specifically in dystrophic neurites around plaques, suggesting that Aβ itself causes increased BACE1. Blocking this increase in BACE1 could be therapeutically useful in slowing or preventing AD without affecting baseline levels of BACE1, which has other substrates, but first we must understand what causes the BACE1 accumulation around plaques. Previous work indicated the increased phosphorylation of the eukaryotic initiation factor subunit alpha (eIF2α) led to increased translation of BACE1 and increased Aβ generation during energy deprivation. BACE1 and eIF2α phosphorylation were elevated and correlated in brains of AD patients, and in the 5XFAD mouse model of AD. We hypothesized that increased eIF2α phosphorylation led to the Aβ-induced BACE1 increase we observe in cultured neurons and in dystrophic neurites near plaques. To test this hypothesis, we used three complementary approaches 1) dephosphorylation of eIF2α by transduction of adeno-associated virus expressing a constitutively active form of GADD34, a subunit of protein phosphatase 1c 2) a non-phosphorylatable allele, S51A, of eIF2α and 3) a BACE1-YFP transgene lacking the 5'UTR required for regulation by eIF2α. Although the constitutive active GADD34 reduced eIF2α phosphorylation by 90% in primary neurons and the brains of 5XFAD mice, there was no decrease in Aβ-induced BACE1 elevation, or BACE1 accumulation around plaques. Similarly, neurons homozygous for eIF2α S51A allele had no eIF2α phosphorylation but still showed robust BACE1 elevation upon Aβ42 exposure. 5XFAD mice heterozygous for S51A had 40% less eIF2α phosphorylation and a robust BACE1 increase. Finally we observed 125% increase in BACE1-YFP lacking the 5'UTR in 5XFAD mice compared to controls, and the BACE1-YFP protein accumulated around plaques in the same manner as endogenous BACE1. We conclude that the amyloid-associated increase in BACE1 level is not caused by translational de-repression via eIF2α phosphorylation, but appears to involve a post-translational

mechanism. These definitive genetic results resolve confusion over the role of eIF2α phosphorylation in Aβ-dependent BACE1 elevation reported in other studies.

Title: Par3 limits APP and BACE1 convergence by directing their trafficking to two distinct pathways

Authors: M. SUN, *H. ZHANG;
Neurosci. and Cell Biol., Robert Wood Johnson Med. School, Rutgers Univ., Piscataway, NJ

Abstract: Alzheimer's disease (AD) is the most common form of neurodegenerative diseases affecting the elderly. It is characterized by extracellular plaques made up of β-amyloid peptides (Aβ), which is derived from the transmembrane protein APP through cleavage by β- and γ-secretases. Previous studies suggest the intracellular trafficking properties of APP and its secretases determine how APP is processed, with amyloidogenic processing occurring mostly in endocytic compartments and non-amyloidogenic processing occurring on the cell surface. However, how the trafficking properties of APP and its secretases are regulated is still not well understood. The Par polarity complex is emerging as a key regulator of vesicle trafficking. This complex consists of Par3, Par6 and atypical PKC (aPKC), which are conserved proteins that regulate cell polarization from worms to mammals. Increasing evidence suggests that the Par complex promotes polarity establishment in part by regulating the asymmetric trafficking of cellular components. Here we show that loss of the polarity protein Par3 is associated with Alzheimer's disease pathogenesis. Knockdown of Par3 promotes amyloidogenic APP processing and increases Aβ generation, while overexpression of Par3 promotes non-amyloidogenic APP processing. We further show that Par3 regulates APP trafficking by promoting its targeting to the recycling pathway, while knockdown of Par3 leads to lysosomal targeting of APP. Unexpectedly, we found that Par3 regulates the retrograde trafficking of the β-secretase BACE1.

However, loss of Par3 does not seem to cause a global disruption of vesicular trafficking. Rather, Par3 regulates APP and BACE1 trafficking through two distinct mechanisms. Taken together, our studies reveal a novel role for Par3 in AD pathogenesis through a two-pronged mechanism that involves regulation of APP and BACE1 trafficking.

Abstract: The β-site amyloid precursor protein (APP)-cleaving enzyme 1 (BACE1) is the rate-limiting enzyme mediating the first proteolytic step leading to production and deposition of amyloid-β peptide (Aβ). BACE1 is a major drug target for the treatment of Alzheimer's disease (AD) and clinical development of BACE1 inhibitors is currently being intensely pursued. While

genetic and pathological evidence support the critical role for BACE1 in pathophysiology of AD, the mechanisms regulating the cellular activity of BACE1 require further study to facilitate therapeutic development. To this end, we employed a chemical genetics approach to identify chemical probes targeting novel pathways which effect BACE1 cleavage of APP and subsequent Aβ production. We developed a cell-based assay that directly monitors BACE1-mediated cleavage of APP in intact **neuronally-derived SH-SY5Y cells** based on antibody-mediated capture of the BACE1-derived secreted APP ectodomain (sAPPβ) fused to a secreted alkaline phosphatase (SEAP) reporter. By screening small molecule libraries using this cell-based system, we identified compounds that can inhibit sAPPβ secretion through mechanisms independent of direct enzymatic inhibition of BACE1. One hit compound was a tetrahydropyrrole derivative of GBR12909, a dopamine reuptake inhibitor harboring a piperazine ring. Subsequently, analogs of GBR12909 were synthesized (C-series compounds, C2) for enhanced potency. C2 treatment led to reduced Aβ levels in primary neurons as well as in brain of a mouse model of AD. Based on homology with GBR compounds, candidate cellular targets for the Aβ-lowering activity of C2 are classical and atypical monoamine transporters. Pharmacological characterization using antagonists against monoamine transporters revealed a putative cellular target for C2 as one of the atypical monoamine transporters, plasma membrane monoamine transporter (PMAT). We found that both pharmacological inhibition and genetic suppression of PMAT expression reduced secretion of sAPPβ and Aβ in neurons. Current work is in progress to further validate PMAT as a novel cellular target in AD.

Abstract: Recent GWAS studies revealed that variants at BIN1 locus are associated with the onset of Alzheimer disease that is characterized by massive deposition of amyloid-β proteins (Aβ). Bin1 is a membrane trafficking-related adapter protein that contain N-terminal BAR and C-terminal SH3 domains. BAR domains recognize specific phospholipids and sculpt membranes to generate protrusions or invaginations. However, little is known how Bin1 as well as membrane dynamics contribute to the pathogenesis of the Alzheimer disease. To understand this issue, we examined the Bin1 function on the levels of secreted Aβ as well as the trafficking of secretases. Ablation of Bin1 expression in mouse primary neurons and non-neuronal cells resulted in the increased production of Aβ and sAPPβ. In addition, protein level of BACE1, which corresponds to the β-secretase, was increased without affecting its mRNA levels. Imaging analysis revealed that trafficking of BACE1 protein from early endosomes to late endosome/lysosome was impaired by loss-of-Bin1 function, suggesting that Bin1 promotes BACE1 degradation by lysosomal targeting. In addition to Bin1, we identified that the other BAR domain proteins as well as phospholipid enzymes impacted on the BACE1 activity and secreted Aβ levels. These data suggest that Aβ production is modulated by the endosomal trafficking of BACE1, which is regulated by BAR domain proteins and specific phospholipids.

Title: A highly novel role for the clathrin adaptor protein gga3 in anxiety and depression circuitry in the mouse brain

Authors: *K. R. WALKER[1], T. DEEB[2], J. L. ROYAL[1], S. LOMOIO[1], M. E. TOLMAN[3], S. J. MOSS[2], G. TESCO[1];
[1]Neurosci., Alzheimer's Dis. Res. Laboratory, Tufts Univ. Sch. of Med., Boston, MA; [2]Tufts-AstraZeneca Lab. for Translational Res., Boston, MA; [3]Neurosci., Sackler Sch. Tufts Univ. Sch. of Med., Boston, MA

Abstract: Golgi-localized, gamma adaptin ear-containing, ARF binding proteins (GGA's) are a family of monomeric clathrin adaptors which facilitate the trafficking of membrane bound proteins at the TGN and endosomes via clathrin coated vesicles. The neuronal family member, GGA3, plays a key role in trafficking β-secretase (BACE1) from early endosomes to lysosomes for degradation. Additionally, we have demonstrated that caspase-mediated depletion of GGA3 plays an important role in mediating BACE1 elevation and Aβ production following acute brain injury. We have generated GGA3null mice that are healthy, viable and fertile and which demonstrate BACE1 elevations of approximately 30% in the brain. To further understand the effect of GGA3 depletion in the mouse brain we performed extensive behavioral phenotyping of 8-10wk old GGA3null mice and their wild-type littermates. GGA3null mice displayed novelty-induced hyperactivity and increased exploratory behavior as evidenced by their increased exploration of an open field arena ($p<0.0001$); increased arm entries in y-maze ($p=0.0044$) and increased visits to objects in the novel object recognition task ($p=0.0020$). Additionally, GGA3null mice displayed a robust anxiolytic phenotype compared to their WT littermates in three different anxiety paradigms (Open Field Testing, Elevated Plus Maze and Light/Dark transition). GGA3null mice spent significantly more time exploring the center of the open field arena ($p= 0.0321$). While in the elevated plus maze GGA3null mice showed a robust preference for the open arm of the maze (entries: $p=0.0017$) and spent significantly more time in the open arm ($p=0.0002$). Additionally, GGA3null mice showed a preference for the light chamber entering it more often ($p=0.0029$) and spending more time in the light chamber ($p=0.0473$) than their WT littermates in the light/dark transition test. In addition to their robust anxiolytic phenotype GGA3 null mice also displayed a robust anti-depressive like phenotype when tested by the Porsolt swim test (Immobility time: $p<0.0001$). In keeping with robust anxiolytic, anti-depressive phenotype and increased motivational behaviors, GGA3null mice demonstrate elevated dopamine levels in the hippocampus. The effect of GGA3 depletion is specific for emotional and motivational behavior as no differences were observed in spatial working memory, recognition memory, spatial reference memory or fear associated memory between GGA3null and WT mice. Further work is ongoing to clarify the specific circuitry by which GGA3 depletion mediates the observed novelty induced hyperactivity, robust exploratory, anxiolytic and anti-depressive behaviors witnessed.

Title: S-Nitrosylation of insulin degrading enzyme in Alzheimer's disease

Authors: *M. W. AKHTAR, S. SANZ-BLASCO, N. DOLATABADI, K. CHON, J. PARKER, R. AMBASUDHAN, W. SOUSSOU, S. R. MCKERCHER, T. NAKAMURA, S. A. LIPTON; Sanford-Burnham Ctr. for Neurosci. and Aging Res., Sanford-Burnham Med. Res. Inst., La Jolla, CA

Abstract: Alzheimer's disease (AD) is the most common form of dementia in the elderly. Cognitive dysfunction in AD is best correlated with synaptic injury, especially in the hippocampus and neocortex. AD is characterized by the presence of extracellular amyloid plaques rich in amyloid-beta (Aβ) peptides and intracellular neurofibrillary tangles of hyperphosphorylated Tau protein. Work over the last decade suggests that in most cases oligomeric Aβ is the toxic species to neurons rather than the plaques themselves. During AD onset, Aβ levels increase, apparently due to excessive production as well as decreased catabolism. Insulin degrading enzyme (IDE), a zinc-metalloproteinase, is one of the enzymes that degrades Aβ and plays an important role in maintaining the level of Aβ in the brain. Here we report that IDE can be S-nitrosylated upon exposure to the nitric oxide (NO) donor S-nitrosocysteine (SNOC) in cortical neuronal cultures, which leads to inhibition of its Aβ-degrading activity. Moreover, we found that exposure of rat cortical cultures or hippocampal slices to oligomeric Aβ, known to cause nitrosative stress via increased NO production, leads to an increase in S-nitrosylation of IDE (forming SNO-IDE). Furthermore, we observed an increase

in SNO-IDE in human AD postmortem brains compared to age-matched controls. Taken together, our results suggest that S-nitrosylation of IDE compromises its activity in AD brain.

Title: Single molecule tracking of tau reveals fast kiss-and-hop interaction with axonal microtubules in living neurons

Authors: D. JANNING, M. IGAEV, F. SÜNDERMANN, J. BRÜHMANN, O. BEUTEL, J. J. HEINISCH, L. BAKOTA, J. PIEHLER, W. JUNGE, *R. BRANDT;
Univ. of Osnabrueck, Osnabrueck, Germany

Abstract: The neuronal microtubule-associated phosphoprotein tau regulates microtubule (MT) dynamics and is involved in neurodegenerative diseases collectively called tauopathies. It is believed that tau molecules exhibit long lived interactions with axonal MTs thereby stabilizing them. It is thought that the detachment and attachment of tau are regulated by phosphorylation/dephosphorylation cycles, and that increased phosphorylation during disease leads to the detachment of tau from MTs causing their breakdown. Here we address the apparent paradox that tau regulates microtubule dynamics but does not interfere with microtubule-dependent axonal transport. By fast single molecule tracking (SMT) of HaloTag® tagged tau in living neurons we found that tau dwells on one microtubule for an unexpectedly short time of

~40 ms before it hops to the next one. The dwell time is 100-fold shorter than previously reported. We observed that even a tau construct mimicking disease-like hyperphosphorylation, pseudohyperphosphorylated (PHP) tau (Tackenberg C, and Brandt R (2009) J. Neurosci. 29 :14439-14450), still interacted with MTs although with a moderately reduced dwell time. Step-size distribution analysis revealed characteristic jump sizes that correlate well with the MT arrangement in neurites of living cells. Furthermore, we employed FDAP measurements to show that, despite tau´s rapid dynamics, it regulates the tubulin-MT balance in neurites of living cells. The rapid kiss-and-hop interaction between tau and MT-filaments explains why tau, although binding to MTs, does not interfere with the axonal transport. In addition, the data indicate that tau's dwell time on MTs is still sufficiently long to influence the life time of a tubulin subunit in a GTP cap.

Title: Effects of Metformin on tau pathology in the P301S tau transgenic mouse

Authors: E. BARINI, O. ANTICO, *L. GASPARINI;
Dept. of Neurosci. and Brain Technologies, Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: The accumulation of intracellular inclusions made of microtubule-associated tau protein is a defining pathological hallmark of Alzheimer disease (AD). The progression of tau pathology in the AD brain correlates with cognitive impairment and appears to be influenced by several risk factors, including brain insulin resistance and the use of antidiabetic drugs such as metformin. Indeed, there is evidence that metformin enhances protein phosphatase 2A (PP2A) activity and dephosphorylates tau in cultured mouse primary cortical neurons, suggesting a potential effect on tau pathology progression. This prompted us to investigate the potential use of metformin as a therapy for tauopathy in the P301S tau transgenic (P301S-tau) transgenic mouse model that develops widespread cerebral tau inclusions, progressive motor impairment and severe paraparesis at 5 months of age. Metformin was administered in the drinking water

(2mg/ml) to P301S-tau transgenic and C57BL6/J wild type (WT) mice starting from 4 weeks of age for 4 months and weight, glycemia, food and water intake were monitored weekly. Chronic administration of metformin does not alter weight, glycemia, water and food intake in both WT and P301S-tau mice. At the tail suspension test, the hindlimb extension reflex is impaired in P301S-tau, but not WT, mice and significantly worsens when transgenic mice are treated with metformin. Cerebral tau phosphorylation and tau inclusions were evaluated by biochemical and immunohistochemical analyses. Initial findings indicate that, in P301S-tau mice, chronic treatment with metformin significantly increases the number of β-sheet filamentous tau inclusions in the hippocampus. We hypothesize that metformin directly acts on mutant tau aggregation. In fact, in *in vitro* aggregation assays, metformin promotes the aggregation of recombinant human tau bearing the P301S mutation. We also found that, in P301S-tau mice, chronic treatment with metformin increases the levels of phosphorylated tau in the brainstem and affects the expression levels of PP2A, possibly contributing to tau phosphorylation state. These results indicate that chronic use metformin may favor the development of tau pathology and suggest that metformin should be used with caution in elderly patients with dementia.

Title: Mitigation of tau pathology with CD40 receptor deficiency in a mouse model of neurodegeneration

Authors: *M. TWEED[1,2,3], Z. ZAKIROVA[1,2,3], D. PARIS[1,2,3], F. CRAWFORD[1,2,3], M. MULLAN[1], G. AIT-GHEZALA[1,2,3];
[1]Roskamp Inst., Sarasota, FL; [2]The Open Univ., Milton Keynes, United Kingdom; [3]James A. Haley Veterans' Hosp., Tampa, FL

Abstract: Alzheimer’s disease (AD) is characterized by three main pathologies: ß-amyloid (Aß) deposition, tauopathy and chronic inflammation. There appears to be an important feed-forward mechanism of the inflammatory mediators on the pathology of AD, even though the primary

trigger for the inflammatory events is assumed to be accumulation of Aβ peptides or the downstream consequences thereof. The tauopathy of AD presents itself as accumulations of fibrillar microtubule associated protein tau (MAPT) that forms within neurons. The consequent neurofibrillary degeneration closely correlates with loss of cognition. The CD40-CD40L dyad is activated upon pro-inflammatory stimulation, which further enhances the inflammatory response, and we have demonstrated a significant constitutive CNS role of CD40-CD40L interaction in AD pathogenesis. For instance, in a transgenic mouse model of AD, we have shown that CD40/CD40L interaction is required to observe the full gamut of pathology. Furthermore, we have shown that CD40L or CD40 deficiency reduces Aß deposition and dystrophic neurites in Tg2576 mouse brain, as well as, cdk5 expression resulting in decreased tau phosphorylation. Overall, these data suggest that CD40-CD40L interaction has an effect on tau phosphorylation, however, we have never investigated the effect of CD40 receptor deficiency on tau pathology in a pure model of tauopathy. In our current study to investigate the effect of CD40R deficiency on tau pathology in a mouse model of tauopathy, we have crossed homozygous CD40R knockout mice with the PS19 transgenic mouse model that expresses the P301S FTD-associated mutation. The PS19 model exhibits robust tau pathology and develops neurodegeneration leading to motor neuron dysfunction and loss of locomotor coordination starting at 4 months of age. Motor function behavioral data from aged (10 month old) CD40 receptor deficient X P301S mutant tau expressing animals show improvement. Preliminary histological data demonstrates a decrease of AT8 positive tau after genetic reduction of CD40 receptor expression in the crossed animals. Ongoing pathological and biochemical analysis will be conducted to further clarify the effects of CD40 receptor deficiency on the mitigation of tau pathology in-vivo. Furthermore, a correlation in changes in the inflammatory markers to changes in tau pathology will be presented. This work demonstrates a link between the neuroinflammation associated with AD and the progression of tauopathies.

Title: Increased retinal tau is neurotoxic in experimental glaucoma

Authors: ***M. CHIASSEU**, L. DESTROISMAISONS, C. VANDE VELDE, N. LECLERC, A. DI POLO;
CR-CHUM/University of Montreal, Montreal, QC, Canada

Abstract: Increased retinal tau is neurotoxic in experimental glaucoma Marius Chiasseu, Laurie Destroismaisons, Christine Vande Velde, Nicole Leclerc & Adriana Di Polo Retinal ganglion cell (RGC) death is the primary cause of vision loss in most optic neuropathies, including glaucoma. There is a high occurrence of glaucoma amongst Alzheimer's disease (AD) patients. Indeed, preferential loss of large diameter RGCs has been documented and may account for the impaired contrast sensitivity and motion perception experienced by individuals with AD. Moreover, AD and glaucoma share a number of pathological and clinical features such as the presence of amyloid beta plaques and tau aggregates. In this study, we examined changes in retinal tau expression and the effect of tau on RGC survival using an experimental rat glaucoma model. Ocular hypertension (OHT) was induced in rats by injection of hypertonic saline solution into an episcleral vein. Retinal tau protein expression and phosphorylation were assessed by western blot analysis using a panel of antibodies against phospho-specific tau epitopes as well as total tau. The cellular localization of tau was investigated by retinal and optic nerve immunohistochemistry using cell-specific markers. Our data demonstrate that ocular hypertension leads to rapid accumulation of retinal tau characterized by a complex phosphorylation profile. Both hyperphosphorylated and hypophosphorylated forms of tau were detected in glaucomatous retinas compared to intact controls. We show that tau accumulates within RGCs, primarily in their somato-dendritic compartment, soon after induction of ocular hypertension. Importantly, tau knockdown using short interfering RNA (siRNA) led to substantial protection of RGC soma and axons from glaucomatous damage compared to retinas treated with a control siRNA. We conclude that ocular hypertension glaucoma displays features of a tauopathy including compartmental redistribution of tau, altered phosphorylation profile and neurotoxicity.

Title: p62/SQSTM1 mediates tau protein degradation through proteasome system

Authors: J. IM, *S. PARK, Y.-J. KIM;
Neurol., Soonchunhyang Univ. Bucheon Hosp., Bucheon, Gyeonggi-Do, Korea, Republic of

Abstract: The accumulations of abnormal tau proteins, hyperphosphorylated, insoluble and filamentous tau proteins, lead to various neurodegenerative diseases including Alzheimer's disease. Therefore, enhancing tau degradation and decreasing its aggregation are hot research subjects for development of efficient treatments. Previously, we identified the diminished p62/SQSTM1 expression was linked to high accumulations of abnormal tau proteins in the cortex of type 2 diabetic obese rats, which suggest the critical role of p62/SQSTM1 in clearing tau proteins. To determine the molecular mechanisms of p62/SQSTM1 mediated tau degradation we started this study. We cotransfected various p62/SQSTM1 constructs with human tau constructs to cultured cell lines or primary neurons. The expression of tau proteins, both total and phosphorylated form (Thr212, Thr231, and Ser199) were decreased in dose-dependent manner with p62/SQSTM1. Also we treated cotransfected cells the proteasome inhibitor MG132, or the lysosome inhibitor leupeptin, or the autophagy inhibitor 3-Methyladenine (3-MA) to understand the clearance mechanism. p62/SQSTM1 mediated tau degradation was inhibited by treatment of MG132, but not by leupeptin or 3-MA. To know the molecular mechanism of p62/SQSTM1 mediated tau clearance various mutation constructs of p62/SQSTM1 were developed. The direct interaction between p62/SQSTM1 and Tau proteins were identified at specified domains. Our results suggest that p62/SQSTM1 regulates the degradation of tau proteins through proteasome pathway through physical interaction between two molecules at specific region.

Title: Acetylcholine release in the brains of tau-transgenic mice

Authors: *C. STEIN[1], J. KLEIN[1,2], M. HOLZER[2];
[1]Pharmacol., Goethe Univ., Frankfurt Am Main, Germany; [2]Paul Flechsig Inst. of Brain Res., Univ. of Leipzig, Leipzig, Germany

Abstract: "Tauopathies" refer to a group of neurodegenerative diseases such as Alzheimer's disease (AD) or frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17) which show inclusions comprised of microtubule- associated protein tau (also known as MAPT) in the brain. The occurrence and density of fibrillar tau inclusions are related to cognitive decline explaining the current interest in murine transgenic tau-models. In the present study, we applied the microdialysis technique to monitor energy metabolism and central cholinergic function in 4 and 10 month old tau-transgenic P301L and control mice. On day 1 after probe implantation, we collected basal samples and samples during behavioral stimulation in a novel environment ("open field") for 90 minutes. High performance liquid chromatography was used to measure acetylcholine (ACh) and choline. Basal levels of ACh in 4 month old control mice were 37.8 ± 3.3 fmol/5µl S.D. (N=10). Tau mice of the same age had significantly higher basal ACh concentrations in hippocampal samples (68.5 ± 12.8 fmol/5µl; N=10) ($p<0.05$). Time courses of ACh release revealed an increase to 99.1 ± 4.0 fmol/5µl in control mice (262% of basal values) and to 185 ± 15.8 fmol/5µl (270%) in tau-transgenic mice during "open field" exposure. On day 2, microdialysis probes were perfused with aCSF containing 1µM of scopolamine to stimulate acetylcholine release pharmacologically. ACh release increased to 145 ± 9.9 fmol/5µl (384% of basal values) in control mice and 345 ± 34.4 fmol/5µl (504%) in tau-transgenic mice during scopolamine stimulation. Aged, 10 months old control mice had basal ACh levels of 123 ± 11.8 fmol/5µl (N=9) which were significantly higher than the values measured in young controls. ACh levels increased to 321.2 ± 12.8 fmol/µl (261% of basal level) during behavioral stimulation on day 1. In aged P301L mice, time courses of ACh release were very similar to those measured in young P301L mice (data not shown). After sacrifice on day 3, mouse brains were used to measure acetylcholinesterase (AChE) activity which was identical in all groups. In conclusion, our data demonstrate that young tau-transgenic mice had higher ACh levels than control mice whereas ACh levels increased with age in control mice. Both groups of mice responded with a large ACh release to behavioral and pharmacologic stimulation. The reasons for this surprising finding are presently under investigation.

Title: Heparan sulfate sulfotransferases and pathologic phosphorylation of tau in Alzheimer's disease-related tau pathology

Authors: J. E. SEPULVEDA DIAZ[1], M. O. OUIDJA[2], S. CHANTEPIE[2], M. B. HUYNH[2], S. B. SOCIAS[1], J. VILLARES[3], *R. RAISMAN-VOZARI[1], D. PAPY-GARCIA[2]; [1]INSERM U1127/CNRS UMR 7225, Paris, France; [2]Lab. Croissance, Réparation et Régénération Tissulaires (CRRET), Univ. Paris Est-Créteil, Créteil, France; [3]Aging and Neurodegenerative Dis. Brain Bank Investigation Lab., Univ. Federal de São Paulo, São Paulo, Brazil

Abstract: The accumulation of abnormally phosphorylated tau is a central event in Alzheimer's disease. Although *in vivo* the critical pathologic phosphorylation of tau is assumed to be mediated by the same kinases that phosphorylate tau in normal brain, *in vitro*, these kinases abnormally phosphorylate tau at disease-specific sites only if the enzymatic reaction takes place in the presence of certain polyanions such as heparin, a highly sulfated analogue of the complex heparan sulfates family of glycosaminoglycans. Currently, it is unknown whether this complex family of molecules, which structural and functional diversity in brain results from the action of several heparan sulfate sulfotransferases, is involved in the cellular mechanism leading to tau pathology. Recently, we have observed that specific heparan sulfate sulfotransferases are increased in Alzheimer's disease brain and that the products of these enzymes are critically involved in the biochemical and cellular mechanisms leading to the pathologic phosphorylation of tau. Inhibiting the expression of one of these enzymes strongly attenuates the pathologic phosphorylation of tau induced in cells by oxidative stress or by expression of hTauP301L, indicating an essential role of specific heparan sulfates domains in the mechanism leading to the abnormal phosphorylation of tau at Alzheimer's disease characteristic sites. We propose a novel hypothesis for the better comprehension of the pathophysiological mechanisms leading to Alzheimer's disease related tauopathy, with groundbreaking therapeutic outcomes.

Title: Regulation of Alzheimer's Disease tau pathology by membrane bound and soluble fractalkine

Authors: *S. M. BEMILLER[1], C. MILLER[2], G. WILSON[4], G. XU[3], S. CRISH[4], B. T. LAMB[2];
[1]Cleveland Clin. Lerner Res. Inst., Ashland, OH; [2]Neurosciences, [3]Cleveland Clin., Cleveland, OH; [4]Pharmaceut. Sci., NEOMED, Rootstown, OH

Abstract: Hyperphosphorylation and aggregation of microtubule associated protein tau (MAPT) within neurons is an invariant feature of multiple neurodegenerative diseases collectively termed tauopathies. While recent evidence suggests that alterations in innate immune pathways within the brain directly influence the development of MAPT pathology, the exact mechanisms linking inflammatory pathways to intracellular MAPT pathology remains to be determined. One key innate immune pathway within the brain involves signaling between the neuronally-derived chemokine, CX3CL1 and the cognate microglial receptor, CX3CR1. Notably, CX3CL1 exists both as a membrane bound glycoprotein, as well as a soluble form generated by cleavage with the ADAM10/17 metalloproteases. Previous studies from the Lamb laboratory demonstrated that chemical (lipopolysaccharide/LPS) or genetic (deletion of CX3CR1) alterations in innate immunity accelerated MAPT pathology and impairment of working memory in a mouse model of tauopathy (hTau) at six months of age. Additional studies suggested that the mechanism linking micr5oglia to intraneuronal MAPT pathology occurred via the neuronal interleukin-1 receptor (IL1R) and p38 mitogen activated protein kinase (p38 MAPK) pathway. The current study examined the role of both the membrane bound as well as the soluble isoforms of CX3CL1 signaling in the development of MAPT pathology in the hTau model. Through both a CX3CL1 deficient mouse and a mouse expressing only soluble CX3CL1 (sCX3CL1), we demonstrated that; 1) CX3CL1 deficiency phenocopied the effects of CX3CR1 deficiency in promoting both microglial activation and MAPT pathology and 2) sCX3CL1 was capable of rescuing the effects on both microglial activation and MAPT pathology. Taken together these findings suggest that sCX3CL1 both ameliorates MAPT pathology and modulates microglial activation states in a mouse model of tauopathy.

Title: Phosphorylation of Tau at S422 is related to autophagic vesicle accumulation in patients with corticobasal degeneration

Authors: *A. PIRAS[1], L. COLLIN[2], F. GRUENINGER[2], C. GRAFF[1,3], A. RÖNNBÄCK[1]; [1]NVS, Ctr. for Alzheimer Research, Div. for Neurogeriatrics, Karolinska Institutet, Huddinge, Sweden; [2]F. Hoffmann-La Roche AG, NORD DTA, Pharmaceut. Res. and Early Develop., Basel, Switzerland; [3]Dept Geriatric Medicine, Genet. Unit, Karolinska Univ. Hosp., Stockholm, Sweden

Abstract: Accumulation of misfolded proteins within neurons and glia cells is a common feature of many neurodegenerative diseases. Abnormal aggregation and accumulation of the microtubule-associated protein tau underlies the neuropathology of tauopathies, such as corticobasal degeneration (CBD). It has been proposed that hyperphosphorylation of tau causes conformational changes in tau leading to an increased aggregation propensity, as well as a reducing its affinity for microtubules. Phosphorylation at the serine 422 (pS422) epitope occurs only in pathological forms of tau, and pS422 tau has been found in neurofibrillary tangles, neuropil threads and dystrophic neurites in Alzheimer's Disease (AD), as well as in Pick bodies in Pick's disease and tufted astrocytes in progressive supranuclear palsy (PSP). One mechanism that could contribute to the accumulation of aggregated proteins in the brain is dysfunction of macroautophagy (herein referred to as autophagy), a major lysosomal degradative pathway for cytoplasmic material in eukaryotic cells. Here, we hypothesized that phosphotau aggregates interfere with autophagic flux creating a vicious circle in which not only tau clearance is further impaired but also the turnover of other autophagy substrates, with toxic consequences for the cell. To explore this possibility, we analysed autophagy markers by immunohistochemistry in human post-mortem brain samples (frontal cortex) from neuropathologically confirmed CBD patients compared to control individuals (n=3/group). Interestingly, CBD patients displayed an increase in autophagic markers, such as LC3 and p62. Moreover, we assessed abnormalities in the autophagy system using *in situ* proximity ligation assay (PLA), a new technique to detect and quantify protein interactions, to study co-localization of phosphotau with autophagy vesicles (LC3). We observed clear colocalization between LC3 and phosphotau in brain tissues from

CBD patients but not in healthy controls. The increased levels of autophagic markers and co-localization between LC3 and phosphotau in human tissues from CBD patients suggested an accumulation of autophagosomes unable to degrade phosphotau, including pS422. Taken together, our results indicate a strong relationship between tau phosphorylation and autophagy vesicle accumulation in human tissues from CBD patients.

Title: An important role for microglia in the phagocytosis and clearance of various soluble and insoluble tau species in Alzheimer’s disease

Authors: *W. LUO, W. LIU, X. HU, M. HANNA, A. CARAVACA, S. M. PAUL;
Brain and Mind Res. Institute, Helen and Robert Appel Alzheimer's disease re, Weill Cornell Med. Col., New York, NY

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by amyloid plaques and neurofibrillary tangles (NFTs). NFTs are composed of aggregated and phosphorylated forms of the microtubule-binding protein tau. Recent studies suggest that tau is “released” from neurons where it can “spread” from cell-to-cell and contribute to tau pathology in both AD and frontal temporal dementia (FTD). The exact mechanisms involved in tau metabolism and clearance in brain are still poorly understood. However, recent genome-wide association studies (GWAS) have identified several genes encoding proteins that regulate innate immunity as being strong genetic risk factors for late-onset AD (LOAD), suggesting an important role for innate immunity in AD pathogenesis. Microglia, the major component of the innate immune system in brain, play key roles in mediating the central nervous system (CNS) response to tissue injury and the clearance of cell debris. Numerous studies have shown that microglia contribute to brain Aβ/amyloid clearance. However, to our knowledge it is not known whether microglia play a similar role in the clearance of tau. To test this hypothesis, we initially

cultured primary postnatal murine microglia with sarkosyl-insoluble tau (SI-tau) isolated from AD brain. We now report that microglia from wild-type mice rapidly phagocytose/internalize and efficiently degrade SI-tau in a time-dependent manner. Confocal microscopy of AT8-positive tau aggregates revealed time-dependent phagocytosis of p-tau by microglia. Using an *ex vivo* assay, in which microglia are cultured with NFT-bearing frozen brain sections from either homozygous P301S mutant mice or from AD brain, we further demonstrated that microglia can rapidly degrade brain-derived soluble tau species (both p-tau and full length tau in the media) and eliminate NFTs (insoluble tau) from the brain sections themselves. Pre-treatment of microglia with the toll-like receptor (TLR) agonist LPS increased phagocytosis and degradation of both soluble and insoluble tau. These data identify an important role for microglia in the phagocytosis and degradation of various species of tau, including full length tau and various phosphorylated soluble and insoluble tau species. Our data suggest that impaired or senescent microglia-mediated tau "clearance" may contribute to the pathogenesis of AD and related tauopathies. Targeting microglia-mediated Aβ and tau clearance with drugs that increase clearance of both tau and Aβ may represent a novel therapeutic strategy for preventing (or reversing) both neuropathological hallmarks of AD.

Title: Development of novel GSK3β inhibitory peptide targeting tau hyperphosphorylation

Authors: ***H. CHUN**, E. LEE, Y. LEE, S. JI, J. KIM, K. LEE, J. LEE;
Pharm., Pusan Natl. Univ., Busan, Korea, Republic of

Abstract: Tau hyperphosphorylation and accumulation in neurofibrillary tangles are closely associated with cognitive deficits in Alzheimer's disease (AD). Abnormal overexpression of

GSK3β has been implicated in tau hyperphosphorylation, thus many GSK3β inhibitors have been developed as drug candidates for AD. However, the potent GSK3β inhibitors are prone to show side effects because they can interfere with basal GSK3β function. We have recently reported that the PPPSPxS motifs in the Wnt coreceptor LRP6 are able to directly inhibit GSK3β when phosphorylated, an thus a novel GSK3β inhibitory peptide (GIP) that can be activated by Akt, was generated by combining the PPPSPxS motif and an Akt target sequence. GIP effectively blocked GSK3β-induced tau phosphorylation in hippocampal homogenate. In addition, the GIP fused with a cell permeable sequence attenuated Aβ-induced tau phosphorylation and cell death in human neuroblastoma cells. Furthermore, the designed GIP significantly reduced tau phosphorylation in the hippocampus of 3xTg-AD mice without affecting levels of Aβ plaques. In conclusion, the current findings provide a novel concept for the drug development targeting tau hyperphosphorylation in AD.

Title: Two stable SHSY-5Y cell lines over-expressing full length and truncated tau441 as screening tools for tauopathies

Authors: R. WRONSKI, N. TAUB, V. SCHIFFER, C. SCHWEINZER, *B. HUTTER-PAIER; QPS-Austria Gmbh, Grambach, Austria

Abstract: Background Tau proteins belong to the family of microtubule-associated proteins and play an important role in stabilizing the neuronal microtubules network. They are the major constituents of intraneuronal and glial fibrillar lesions described in Alzheimer's disease and numerous neurodegenerative disorders referred to as 'tauopathies', including progressive supranuclear palsy, corticobasal degeneration, argyrophilic grain disease, as well as the inherited frontotemporal dementia and parkinsonism linked to chromosome 17. Molecular analysis revealed that hyperphosphorylation might be the important event leading to Tau aggregation resulting in neurodegeneration and dementia. Development of new compounds capable of preventing tau hyperphosphorylation is an increasingly hot topic. Thus, reliable models are

needed that reflect tau hyperphosphorylation in human diseases. Methods For this purpose, we generated two stably transfected SHSY-5Y cell lines either over-expressing the longest human tau441 isoform comprising two disease related mutations (SH-SY5Y-TMHT441) or a truncated version of tau441 (SHSY-5Y-tTMHT441). Results Comparison of tau expression and phosphorylation levels in SHSY-5Y versus SHSY-5Y over-expressing cells confirmed relevance to human diseases. The phosphorylation pattern of tau can be reliably modulated by distinct kinase inhibitors targeting CDK, JNK or GSK3beta. Effects on tau phosphorylation (residues Thr231, Thr181, and Ser202) were determined by immunosorbent assays (Mesoscale Discovery). Conclusion These protein kinases are known to be involved in tau phosphorylation and are therefore reliable indicators for the suitability of these two cell lines as *in vitro* models for tauopathies.

Title: The anti-tau monoclonal antibody MC1 promotes microglia-mediated phagocytosis and degradation of pathological tau

Authors: *W. LIU[1], W. LUO[1], X. HU[1], N. POLTORATSKAIA[1], M. HANNA[1], A. CARAVACA[1], P. DAVIES[2,3], S. PAUL[1];
[1]Brain and Mind Res. Institute, Helen & Robert Appel Alzheimer's Dis. Inst., Weill Cornell Med. Coll, NEW YORK, NY; [2]Dept. of Pathology, Albert Einstein Col. of Med., New York, NY; [3]Litwin-Zucker Ctr. for Res. in Alzheimer's Dis., Feinstein Inst. for Med. Res., New York, NY

Abstract: Progressive tau pathology in brain correlates well with the age-dependent decline of cognitive function in patients with Alzheimer's disease (AD). Accumulated evidence suggests that the inter-synaptic spread and transmission of tau within and between vulnerable brain regions contributes to the progressive neurodegeneration that characterizes AD and related

tauopathies. Therefore, treatments that might reduce tau mis-folding, aggregation or spread may prevent or slow the progression of tau-dependent neurodegeneration. Recently, anti-tau immunotherapy has been shown to reduce tau pathology in various tauopathy mouse models. For example, passive immunization with the anti-tau antibody MC1 (a high affinity anti-tau antibody directed at a pathological conformational tau epitope), has been shown to significantly reduce tau pathology in several mouse tauopathy models (see Chai et al., 2011; d'Abramo et al., 2013). It has been hypothesized that these anti-tau antibodies reduce tau pathology by binding to extracellular tau and by blocking the spread and (or) seeding/aggregation of tau throughout the brain. However, it is also possible that anti-tau antibodies may promote phagocytosis of tau by microglia and clear extracellular tau via a Fc receptor-mediated microglial mechanism as has been shown previously for certain anti-Aβ antibodies which prevent the deposition and formation of brain Aβ/amyloid plaques (Bard et al., 2000). To test this possibility, we have established sensitive *in vitro* and *ex vivo* methods using sarkosyl-insoluble brain extracts and tissue sections from P301S mice and AD brain which contain abundant paired helical filaments (PHF-tau) to measure the phagocytosis and degradation of pathologic tau by primary mouse microglia. We have found that tau is rapidly degraded by mouse microglia (see companion abstract W. Luo et al) using these *in vitro* and *ex vivo* methods and several sensitive p-tau/tau ELISAs. We now report that the anti-tau monoclonal antibody MC1, but not an IgG control antibody, promotes microglia-mediated phagocytosis and degradation of various soluble and insoluble p-tau species. MC1 enhances microglia-mediated degradation of soluble and insoluble tau in a time-dependent manner. Our data suggest microglial-mediated phagocytosis may in part underlie the reduced tau pathology observed following passive immunization of tauopathy mice with certain anti-tau antibodies. We are currently testing this hypothesis *in vivo*, and also studying a variety of other anti-tau antibodies to determine whether they augment microglia-mediated tau phagocytosis and clearance.

Dis., San Francisco, CA; [5]Dept. of Neurol., [6]Memory and Aging Ctr., Univ. of California, San Francisco, San Francisco, CA

Abstract: Alzheimer's disease (AD) is a common neurodegenerative disorder characterized by a progressive decline in memory along with other cognitive abilities. The pathological hallmarks of AD include elevated levels of amyloid beta peptide and abnormal tau pathology, such as hyperphosphorylation of tau, a major microtubule-associated protein in neurons. The current study tested the hypothesis that systemic administration of a microtubule-stabilizing agent reduces pathological aggregation and phosphorylation of tau and leads to cognitive improvements in a mouse model of AD and related tauopathies. Microtubule-stabilizing taxanes, including paclitaxel, have been identified as possible therapeutic agents for these indications; however, paclitaxel has poor blood-brain barrier permeability and is thus unsuitable for treatment of CNS disease. TPI 287, a novel and clinically safe taxoid, is a microtubule-stabilizing agent that readily crosses the blood-brain barrier. In a pilot proof of concept study, TPI 287 was administered intravenously, every 4 days, at 1 mg/kg or 3 mg/kg to PS19 transgenic mice overexpressing mutant human tau. Following this dosing period, behavioral tests were conducted to assess general activity, as well as contextual learning and memory. Treatment with TPI 287 improved exploratory and anxiety-like behaviors in PS19 mice. Moreover, terminal biochemical assessment of PS19 brain samples showed that TPI 287 reduced levels of hyperphosphorylated tau. We are currently confirming these preliminary findings in a follow-on study. These results suggest that modulation of tau phosphorylation and microtubule-stabilization may hold unexplored therapeutic potential with a novel mechanism of action.

Abstract: Clinical research suggests that stress exposure can dramatically increase risk for Alzheimer's disease (AD). Although the links between stress and AD remain unsettled, data from our group and others have established that stress exposure in rodents may confer susceptibility to AD pathology by inducing tau phosphorylation (tau-P) in the hippocampus. Previous data from our lab directly implicate stress and the CRF system in neuronal vulnerability, and demonstrate that repeated stress exposure elicits cumulative effects on tau-P and its sequestration in an insoluble and potentially pathogenic form. Here, we also reported that hippocampal tau-P elicited by emotional stress was not regulated by the stress-induced rise in glucocorticoids but was dependent on corticotropin-releasing factor receptor type 1 (CRFR1). CRF over-expressing (CRF-OE) mice have marked hippocampal atrophy, learning and memory deficits by 9 months of age, and are characterized by chronically high levels of glucocorticoids. We examined how this sustained exposure to CRF and stress steroids might impact tau-P and kinase activity in the presence or absence of CRFR antagonist in the months immediately preceding cognitive impairment. In the hippocampus, CRF-OE mice had significantly elevated tau-P compared to WT mice at the AT8 (S202/T204), PHF-1 (S396/404), S262 and S422 sites.

Pretreatment with CRFR-antagonist blocked phosphorylation at the AT8 (S202/T204) and PHF-1 (S396/404) sites, but not at the S262 and S422. Although the reduction of several kinases was observed, only concomitant regulation of c-Jun N Terminal Kinase (JNK) was found with CRFR antagonist treatment. Examination of extracts from CRF-OE mice at the ultrastructural level revealed negatively stained round/globular aggregates that were positively labeled by PHF-1. These data suggest critical roles for CRF and CRFRs in tau-P and aggregation and may have implications for cognitive decline in AD.

Title: New composite neuronal tau inclusions in two siblings with a tau mutation-associated disease

Authors: *M. BRESJANAC[1], A. FABJAN[2], J. MRAZ[3], D. GLAVAč[3], J. MAGDIč[4], A. ZUPAN[3], M. DROLEC NOVAK[1], M. POPOVIć[3];

Abstract: We present novel composite neuronal tau inclusions (CNTI) found in two siblings with a P364S tau mutation-associated tauopathy. Both sisters presented with mild cognitive decline, depression, symmetric bradykinesia, rigidity, slow and forward-bent gait. Signs of motor neuron disease were found in one sister. Bidirectional sequencing of the tau gene revealed heterozygous mutation P364S in both sisters. The patients died due to respiratory insufficiency within 2 years of initial presentation. Formalin-fixed brains and spinal cords were examined and histopathological analysis was done with selected histochemical and immunolabeling of paraffin-embedded tissue sections. Neurodegenerative changes consistent with a tauopathy were found in all regions examined. Extensive neuronal loss and reactive gliosis were found in the nucleus

basalis of Meynert, substantia nigra, locus coeruleus, transentorhinal and motor cortex, and in the anterior horn of the spinal cord. Sparse glial coiled bodies were found. Neuronal tau inclusions were globose neurofibrillary tangles (gNFT; predominant), ghost gNFT (frequent) and flame-shaped NFT (fNFT) found mostly in the pyramidal cells of CAI and CAII, the subiculum, and the transentorhinal cortex. Some granular neurons displayed Pick body (PiB)-like inclusions. A new and unique neuropathological finding in both brains were neuronal tau inclusions composed of two distinct parts. In H&E they have a pale eosinophilic core and a basophilic peripheral halo. Gallyas silver impregnation preferentially labeled the CNTI halo. AT8 immunolabeling was more pronounced at the periphery, but also labeled the core. Immunohistochemistry to 3R isoform labeled the whole CNTI, while the 4R tau epitope was found only at the periphery. Regional distribution of CNTI was similar in both brains: frequent in subiculum, subthalamic nucleus, thalamus, motor cortex, and nigra, rare in frontobasal, insular, and cingular cortex, and absent from dentate nucleus, cranial nerves nuclei, visual cortex and basal ganglia. Our cases of P364S tau mutation-associated tauopathy displayed a new type of tau neuronal inclusion composed of two distinct parts, with the periphery and core displaying characteristics of gNFT and PiB, respectively.

Title: Fibroblast aggregation rate converges with validated peripheral biomarkers for alzheimer's disease

Authors: *F. V. CHIRILA, T. K. KHAN, D. L. ALKON;
Blanchette Rockefeller Neurosciences Inst., MORGANTOWN, WV

Abstract: The inaccuracy of the diagnosis for Alzheimer's disease (AD) has made the therapeutic intervention difficult, particularly early enough to prevent significant neurodegeneration and cognitive dysfunction. Here, we describe a novel, highly accurate peripheral diagnostic for AD patients based on quantitatively measured aggregation rate of human skin fibroblasts. The elevated aggregation rate with increasing cell density in AD cases is

the basis of this new bio-marker. The new biomarker, was successfully cross-validated, with two more mature assays, AD-Index, based on the imbalances of ERK1/2, and Morphology, based on network dynamics, and showed 92% overlap. A significant number of cases tested with this new bio-marker were freshly obtained, 29, and 82% of the cases are hyper-validated cases i. e. autopsy and/or genetically confirmed AD or non-Alzheimer's Demented patients(Non-ADD) and non demented age-matched controls(AC). Furthermore we show that by using a simple majority rule, i. e. two out of the three assays have the same outcome, we significantly increase the agreement with clinical AD diagnosis (100%). Based on the high accuracy of this strategy, the bio-marker profile appears to identify accurately the AD patients for therapeutic intervention.

Abstract: BACKGROUND: A critical unmet need for FTLD research, especially therapeutic trials, is the development of biomarkers to distinguish FTLD-tau from FTLD-TDP and other non-tau FTLD pathologies. METHODS: We are using [18F] T807, a novel PET ligand, to scan a series of patients with FTLD, to date including one MAPT P301L mutation carrier with moderate severity FTD dementia, an asymptomatic carrier of the same mutation, six patients with sporadic mild primary progressive aphasia, and three patients with progressive supranuclear palsy. We analyzed SUVR (cerebellum reference) data to localize and quantify [18F] T807

signal. We also co-registered analyzed [18F] T807 images to MRI images for visualization and calculation of % atrophy relative to controls. RESULTS: [18F] T807 signal was elevated in frontal, insular, and anterior temporal cortex in the MAPT carrier with dementia, and colocalized with atrophy. In non-fluent aphasic patients, [18F] T807 signal was highest in inferior frontal and middle temporal gyri and temporal pole with marked asymmetry, most prominent in the dominant hemisphere, and localized remarkably well with atrophy. The asymptomatic carrier had mildly elevated signal in frontal, insular, and anterior temporal cortex as well as white matter. PSP patients showed elevated brainstem, basal ganglia, thalamic/subthalamic, cerebellar, and frontal signal. CONCLUSIONS: T807 is a promising new PET ligand for imaging tau pathology *in vivo* in patients with FTLD.

Title: Cortical regions are associated with risk of clinical symptom onset during preclinical Alzheimer’s disease

Authors: C. PETTIGREW[1], *A. SOLDAN[3], Y. LU[7], M.-C. WANG[7], T. BROWN[4], O. SELNES[1], S. MORI[2], L. YOUNES[5], T. RATNANATHER[6], M. I. MILLER[6], M. ALBERT[1]; [1]Neurol., [2]Radiology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Neurol., [4]Ctr. for Imaging Sci., [5]Applied Mathematics and Statistics, [6]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [7]Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Abstract: The pathological processes underlying Alzheimer’s disease (AD) are thought to begin during the preclinical phase, prior to the onset of clinical symptoms. Previous work suggests that thinning in specific cortical regions (known as the ‘cortical signature of AD’) is associated with increased risk of developing dementia. However, less is known about whether these regions are

also sensitive to the transition from normal cognition to Mild Cognitive Impairment (MCI), an earlier disease time point. This study examined the relationship of the AD signature regions of interest (ROIs) during preclinical AD, in order to determine whether these regions were associated with time to onset of clinical symptoms, an even earlier time point than the diagnosis of MCI. The present analyses included 212 individuals from the BIOCARD study who were cognitively normal and primarily middle aged at baseline. Participants have been prospectively followed for up to 18 years (M = 9 years) with annual clinical and cognitive assessments; to date, 50 of these participants have developed MCI or AD dementia. Baseline MRI measures of regional cortical thickness were obtained, using FreeSurfer, for the 9 'AD signature' ROIs, including two frontal regions, 3 parietal regions, and 4 temporal regions. Cox regression models (covarying baseline age and education) were used to determine whether the individual cortical ROIs, as well as the average thickness of these regions, were associated with time to onset of clinical symptoms. The mean time from baseline to the onset of clinical symptoms in this sample was 6.6 years. The average thickness of the regions was associated with time to onset of clinical symptoms (hazard ratio (HR) = 0.72, $p = .05$). However, the ROIs taken individually were not significant in these models. Follow-up analyses indicated that lower baseline cortical thickness of each ROI, as well as the combination of ROIs, was associated with increased risk of progression to clinical symptoms within 7 years after baseline (all HRs < 0.59, all $p < .05$). In contrast, these ROIs were not associated with risk of progression to clinical symptoms among individuals who progressed more than 7 years from baseline, suggesting that cortical thinning occurs more proximal to symptom onset. These results suggest that cortical thinning is detectable in cognitively normal individuals several years prior to clinical symptom onset, and that this atrophy is associated with time to onset of clinical symptoms that are a harbinger of a diagnosis of MCI. Ongoing analyses are examining the relationship between these MRI measures and other assessments in the same individuals (e.g., CSF).

Abstract: Soluble amyloid-β protein (Aβ) oligomers have been recognized to be early and key intermediates in Alzheimer's disease-related synaptic dysfunction. In this study, using *in vitro* electrophysiology, we investigated interactions of the acidic oligosaccharide sugar chain (AOSC), a marine-derived acidic oligosaccharide, with oligomeric Aβ. We found that the inhibition of long-term potentiation (LTP) induced by Aβ oligomers can be dose dependently reversed by the application of AOSC, whereas AOSC alone did not alter normal LTP induction. Interestingly, treatment with Aβ monomers with or without AOSC did not affect LTP induction. Additionally, when fresh-made Aβ was co-incubated with AOSC before *in vitro* testing, there was no impairment of LTP induction. The results from Western blots demonstrated that AOSC prevent the aggregation of Aβ oligomers. These findings indicate that AOSC may reverse Aβ oligomer-mediated cytotoxicity by directly disrupting the amyloid oligomer aggregation, and this action is concentration dependent. Thus, we propose that AOSC might be a potential therapeutic drug for Alzheimer's disease due to its protection against oligomeric Aβ-induced dysfunction of synaptic plasticity.

Title: Dual use of 11C-deuterium-L-deprenyl tracer in positron emission tomography (PET) imaging of Alzheimer's disease

Authors: *E. RODRIGUEZ-VIEITEZ[1], K. BUTINA[1], S. F. CARTER[1], M. SCHÖLL[1], K. FARID[1], A. WALL[2], A. NORDBERG[1,3];
[1]Neurobiology, Care Sci. and Society, Karolinska Inst., Stockholm, Sweden; [2]Dept. of Radiology, Oncology and Radiation Sci., Uppsala Univ., Uppsala, Sweden; [3]Dept. of Geriatric Med., Karolinska Univ. Hosp. Huddinge, Stockholm, Sweden

Abstract: Background: Alzheimer's disease (AD) is the most common dementia disorder. The accumulation of amyloid plaques in AD brain has been hypothesized to play a causative role in AD. However, there is increasing evidence that additional mechanisms including neuroinflammatory and neurovascular changes may precede plaque deposition and contribute to disease development. Reactive astrocytes have been investigated in patients using the PET tracer ^{11}C-deuterium-L-deprenyl (^{11}C-DED) [1], where the presence of deuterium serves to reduce the influence of cerebral blood flow (CBF) on tracer binding, compared to a previously investigated ^{11}C-L-deprenyl compound [2]. In this study, ^{11}C-DED was applied together with ^{11}C-Pittsburgh compound B (^{11}C-PIB) and ^{18}F-FDG in a multitracer PET study in the same group of patients. The aim of this study was to further investigate the kinetic properties of ^{11}C-DED and its potential dual use to measure brain astrocytosis and cerebral blood flow (CBF). **Methods:** ^{11}C-DED, ^{11}C-PIB and ^{18}F-FDG PET scans were performed in 25 patients including sporadic AD (n=8) and mild cognitive impairment (MCI) (n=17). Healthy controls (n=14) underwent ^{11}C-DED PET imaging. PET quantification was performed in 12 bilateral regions of interest (ROIs). ^{11}C-PIB and ^{18}F-FDG uptake was quantified as target-to-pons Standardized Uptake Value ratios (SUVr). ^{11}C-DED was modeled using: (1) a modified reference Patlak model; (2) a Simplified Reference Tissue Model (SRTM) using PMOD v3.3 software with the cerebellum gray matter as a reference region. CBF was estimated by: (1) the 1-4 minute early frames of ^{11}C-DED with reference to the cerebellum (eDED); (2) the R_1 parameter (ratio of tracer delivery to a ROI with

respect to the cerebellum) obtained from the SRTM. **Results**: ^{11}C-DED binding estimated by the reference Patlak (DEDslope) and SRTM (binding potentials, BPnd) models were highly correlated in every ROI (Pearson's $r = 0.80 - 0.92$, $p < 0.001$), providing evidence that ^{11}C-DED is a reversible tracer, not strongly dependent on CBF. The eDED values were highly correlated to R_1 values in every ROI (Pearson's $r > 0.90$, $p < 0.001$), and both also strongly correlated with ^{18}F-FDG uptake. Therefore eDED and R_1 were considered measures of CBF. Neither DEDslope nor BPnd were correlated to eDED or R_1. **Conclusions**: The ^{11}C-DED tracer provided dual physiological (CBF) and pathological (astrocytosis) information from a single PET scan, and may contribute to the understanding of the time course and regional pathological brain changes at different stages in AD. Title: White matter integrity is associated with CSF markers of AD in normal adults

Authors: *B. T. GOLD, Z. ZHU, C. BROWN, F. SCHMITT, C. SMITH;
Univ. of Kentucky, Lexington, KY

Abstract: We explored whether white matter (WM) integrity in cognitively normal (CN) older adults is associated with cerebrospinal fluid (CSF) markers of Alzheimer's disease (AD) pathology. Twenty CN older adults underwent lumbar puncture and magnetic resonance imaging within a few days of each other. Analysis of diffusion tensor imaging data involved *a priori* region of interest (ROI) and voxelwise approaches. The ROI results revealed a positive correlation between CSF measures of amyloid-beta ($A\beta_{42}$ and $A\beta_{42}$/p-Tau_{181}) and WM integrity

in the fornix, a relationship which persisted after controlling for hippocampal volume and fornix volume. Lower WM integrity in the same portion of the fornix was also associated with reduced performance on the Digit Symbol test. Subsequent exploratory voxelwise analyses indicated a positive correlation between CSF $A\beta_{42}$/p-Tau_{181} and WM integrity in bilateral portions of the fornix, superior longitudinal fasciculus, inferior fronto-occipital fasciculus, and in the corpus callosum and left inferior longitudinal fasciculus. Our results link lower WM microstructural integrity in CN older adults with CSF biomarkers of AD and suggest that this association in the fornix may be independent of volumetric measures.

Title: Mixed pathology in Alzheimer could be explained by the presence of hybrid oligomers

Authors: *M. J. GUERRERO[1], D. L. CASTILLO-CARRANZA[2], A. PAULUCCI-HOLTHAUZEN[3], U. SENGUPTA[2], C. LASAGNA-REEVES[2], R. KAYED[2];

Abstract: Introduction Alzheimer's disease (AD) is characterized by the formation of insoluble, fibrillar deposits of amyloid ß (Aß) peptide and tau protein. Recent studies in humans and in an APP mouse model demonstrate the abundance of mixed pathology proteinopathies. These results highlight the importance of pathogenic protein interactions on disease progression and possibly the disease phenotype, as well as the overlap between different neurodegenerative diseases. TDP-43, a protein highly related to Amyotrophic lateral sclerosis, has been observed to be aggregated in around 75% of brains from AD patients. Here, we show the presence of hybrid oligomers composed of TDP-43 and other amyloidogenic proteins, such as Aβ, α-synuclein, and

Prion protein in human AD brain samples, but not in age-matched controls. Methods We used a novel anti-oligomer monoclonal antibody (F11G3), anti-TDP-43 antibodies, 6E10 for Aß, 4D6 for α-synuclein, and 6D11 for PrP. We performed immunohistochemical and analyses of brain tissue from moderate to severe human AD cases, non-demented elderly controls and Tg2576 mice. Results We found hybrid oligomers composed of TDP-43 and either Aβ, PrP, or α-syn in human AD brain samples. However, the presence of hybrid oligomers in the Tg2576 AD mouse model was much lower than in human samples. Conclusions Detection of hybrid oligomers of TDP-43 and Aβ in AD human and mouse brain samples suggest that Aβ oligomers interact and seed TDP-43 aggregation which may contribute to the pathogenesis in AD. *In vitro* assay showed that TDP-43, PrP, or α-syn proteins acquire Aβ oligomer conformation.

Abstract: Synaptic loss and dysfunction are associated with cognitive decline in the early stages of Alzheimer’s disease. Thus, rescuing synaptic deficits is a promising therapeutic strategy for the disease. We recently found that the receptor tyrosine kinase, EphA4, is aberrantly activated in the hippocampus of the APP/PS1 mouse model of Alzheimer’s disease and that inhibition of

EphA4 signaling alleviates synaptic dysfunctions. Using a traditional Chinese medicine database, we performed a virtual screen to identify small molecule EphA4 inhibitors that target the ligand-binding pocket of EphA4. The small molecules identified blocked both the interaction of EphA4 with its ligand, ephrin-A, as well as ephrin-A-induced tyrosine phosphorylation and growth cone collapse in cultured neurons. Furthermore, these EphA4 inhibitors attenuated the impaired synaptic plasticity induced by oligomeric Aβ, which is believed to be the major agent that contributes to the synaptotoxicity in Alzheimer's disease. Administration of these EphA4 inhibitors *in vivo* rescued synaptic impairment and Alzheimer's pathology in the APP/PS1 mouse model. Work is in progress to conduct preclinical studies for these small molecules.

Abstract: Impairment of hippocampal synaptic plasticity is associated with learning and memory deficit in Alzheimer's disease. It is therefore important to understand the molecular mechanisms underlying synaptic dysfunctions. We found that activity of a receptor tyrosine kinase EphA4 was increased in hippocampal synaptic fractions of APP/PS1 Alzheimer's disease mouse model at 3 months, an early stage when the deposition of amyloid plaques s is observed.

Furthermore, deletion of postsynaptic EphA4 was able to alleviate the suppression of hippocampal long-term potentiation in the Schaffer collateral-CA1 pathway of APP/PS1 mice. Thus, our findings suggest that EphA4 is a potential target for disease-modifying strategies for Alzheimer's disease. Using docking analysis, we identified various small molecule inhibitors for EphA4, which were able to inhibit the binding between EphA4 and its endogenous ligands in cultured neurons. Further analysis showed that oral administration of an EphA4 inhibitor blocked the EphA4 signaling in APP/PS1 mice, and rescued the impaired synaptic plasticity observed in those mice. Taken together, blockade of the EphA4-ligand interaction is a promising approach to developing effective treatments for Alzheimer's disease.

Title: Histone modifications and Egr1 expression in response to prenatal Arsenic exposure and High Fat Diet

Authors: K. N. NAM[1], A. N. MOUNIER[1], D. GEORGIEV[1], N. F. FITZ[1], A. A. CRONICAN[1], R. KOLDAMOVA[1], *I. M. LEFTEROV[2];

Abstract: Alzheimer's disease is a complex quantitative variation in disease susceptibility, controlled by multiple genes and environmental factors, as well as gene-gene and gene-environment interactions. Environmental risk factors, such as dietary patterns, exposure to environmental toxicants, intellectual and physical activity, as well as cardiovascular disease and Type 2 Diabetes, have the highest level of AD association. However, the molecular mechanisms underlying the increased susceptibility to, earlier development or aggravated course of the disease remain poorly understood. Possible molecular links between certain environmental exposures/factors and AD could be changes in regulatory and metabolic pathways due to dysregulation in transcription factor binding, or epigenetic changes known to influence synaptic transmission, memory and cognitive performance. Previously we have demonstrated that Early growth response 1 (EGR1) transcription factor regulates the constitutive expression of genes involved in vesicular transport and synaptic transmission that may be critical for memory and cognition, as well as, for the development and progression of AD. In a preliminary study we have been able to reveal changes in H3K9 acetylation profile in the proximal promoter of mouse Egr1 in response to prenatal arsenic exposure and normal diet. We also found a significantly decreased levels of Egr1 mRNAs in brains of WT offspring following in-utero exposure, as well as in 2 month old mice exposed to human relevant 100 μg/L arsenic in drinking water. The goal of this study is to identify and correlate changes in Egr1 binding to histone modifications and gene expression levels in young AD mice in response to arsenic treatment. The results and comparisons with EGR1 biding in APP mice without any treatment or exposure, will answer the question if EGR1 mediated transcriptional control is linked to histone modifications or is an independent mechanism for inducing phenotypic changes in AD mice in response to As.

Title: Effects of streptozotocin-induced diabetes on synaptic proteins and tau phosphorylation in mice expressing P301L human tau

Authors: *C. C. RUDY, H. C. HUNSBERGER, D. S. WEITZNER, M. N. REED;
Psychology, West Virginia Univ., Morgantown, WV

Abstract: The cause of sporadic Alzheimer's disease (AD) is largely believed to multifactorial, and it has been suggested that diabetes may be an important risk factor for AD. Recent work suggests diabetes-induced insulin dysfunction can induce memory deficits via its effects on glutamatergic signaling and synaptic plasticity. Though much initial work focused on the synaptic effects of beta-amyloid, emerging evidence suggests tau plays a critical role in the synaptic degeneration observed in AD. Thus, the synapse may be a point of convergence for diabetes and AD. To induce impairments in cerebral glucose utilization and energy metabolism that are assumed to play a prominent role in the pathogenesis of AD, we injected mice with low doses (50 mg/kg, i.p.) of streptozotocin (STZ) over 5 consecutive days, a protocol reported to reduce the mortality rates associated with high doses of STZ. To determine the effects of diabetes in mice with existing tau pathology, mice expressing mutant P301L human tau (tauP301L), which results in age-dependent memory deficits, neuron loss, and tangle formation, were used. We also examined the effects of STZ on mice expressing wild-type human tau (tauWT). These mice do not exhibit memory deficits or tau pathology, but by comparing the effects of STZ in tauWT to transgene negative littermates, we were able to determine whether human tau is more susceptible to the effects of diabetes than mouse tau. To determine whether diabetes increases hyperphosphorylation of tau, leading to tau accumulation in dendritic spines, tau levels and tau phosphorylation status in the hippocampal postsynaptic density (PSD) were examined. Alterations in pre- and post-synaptic proteins, such as synaptophysin, PSD95, and ionotropic glutamatergic receptors, were also examined. STZ resulted in blood glucose levels greater than 300 mg/dL, indicating hyperglycemia. We anticipate diabetes, resulting from STZ, will exacerbate tau pathology and synaptic alterations observed in tauP301L mice. We anticipate STZ will induce tau pathology and synaptic alterations in mice expressing tauWT mice above and beyond that observed in transgene negative controls. Though tauP301L mice are commonly used to model the tau pathology observed in AD, there are no known mutations in tau linked to AD. Because there are no known tau mutations resulting in AD, identifying mechanisms that alter wild-type human tau functioning is essential to understanding the etiology of sporadic AD. To date, however, there are no studies investigating the effects of diabetes in transgenic mice expressing wild-type human tau.

Title: Altered genomic mosaicism with increased DNA content and CNVs in single sporadic Alzheimer's disease neurons

Authors: *G. E. KAESER, B. SIDDOWAY, D. M. BUSHMAN, J. CHUN;
The Scripps Res. Inst., La Jolla, CA

Abstract: Somatic genomic mosaicism in the CNS is characterized by aneuploidy, neuron-specific DNA content variations (DCV), copy number variations (CNVs), and other forms of mosaically altered genomic DNA. The function(s) of these genomic changes is currently unknown. However, the identification of regional DCV as a feature of the normal human brain suggested that alterations in genomic mosaicism might play a role in brain disorders. Here we report genomic mosaicism in Alzheimer's disease (AD) characterized by increases in DNA content and amyloid precursor protein (*APP*) CNVs. Five independent methodologies were used to identify and characterize genomic mosaicism: DNA content analysis by flow cytometry, small population qPCR, dual point-paint fluorescence *in situ* hybridization (FISH), single cell qPCR, and single gene-targeted FISH. Flow cytometric analysis revealed DNA content increases in AD cortical nuclei over lymphocytes and age matched non-diseased cortical controls. Gene dosage of *APP* has been well documented in familial AD and Down syndrome yet has remained genetically unlinked to sporadic AD. By small population qPCR, half of AD samples showed mosaic increases in *APP*, reaching up to 6 copies. To assess whether these relative increases were due to trisomy 21, FISH combined with liberal counting criteria was used, which nevertheless showed no change between AD and non-diseased samples. Single cell techniques for detecting mosaic CNVs in neurons were implemented using the Biomark HD (Fluidigm) microfluidic platform, which detected increases in ~50% of AD cortical nuclei (~10% of non-diseased), ranging up to 12 copies. To visualize these CNVs directly without preamplification, we designed *APP*-specific FISH probes. Combined with super resolution microscopy, amplified loci were detected in ~50% of AD cortical nuclei and were observed as predominantly single loci of variable fluorescence intensity. Together, these data support a function for somatic changes in neuronal genomes, and

implicate genomic mosaicism in sporadic AD, with additional relevance to normal brain function.

Abstract: Synaptic loss is the structural basis for memory impairment in Alzheimer's disease (AD). While the underlying pathological mechanism remains elusive, it is known that misfolded proteins accumulate as β-amyloid (Aβ) plaques and hyperphosphorylated Tau tangles decades before the onset of clinical disease. The loss of Pin1 facilitates the formation of these misfolded proteins in AD. Pin1 protein controls cell-cycle progression and determines the fate of proteins by the ubiquitin proteasome system. The activity of the ubiquitin proteasome system directly affects the functional and structural plasticity of the synapse. We localized Pin1 to dendritic rafts and the PSD and found the pathological distribution of Pin1 within the synapses of AD brains. The loss of Pin1 activity may alter the ubiquitin-regulated modification of PSD proteins and decrease levels of Shank protein, resulting in aberrant synaptic structure. The loss of Pin1 activity may also render neurons more susceptible to the toxicity of oligomers of Aβ and to excitation, thereby inhibiting NMDA receptor-mediated synaptic generation and exacerbating NMDA receptor-mediated synaptic degeneration. These findings provide a common pathological role of Pin1 in the development of the three pathological hallmarks of AD (Aβ plaques, Tau

tangles, and synaptic loss) and suggest that Pin1 may serve as a common target to protect synaptic function and to prevent the formation of misfolded proteins in preclinical AD.

Title: The role of the extracellular domain in the regulation of transmitter release by beta amyloid, nitric oxide and cyclic guanosine monophosphate

Authors: A. K. DEGRUTTOLA[1], *D. GRAY[2];
[1]Biol., [2]Simmons Col., BOSTON, MA

Abstract: Alzheimer's disease (AD), the most common neurodegenerative disorder, is strongly associated with insoluble deposits of beta amyloid (Ab) peptide in plaques within the brain. Recent work has suggested a non-pathological role of Ab as a regulator of presynaptic release of the neurotransmitter acetylcholine (ACh). In this cascade pathway which was discovered in cholinergic synapses in a chick embryo choroid layer of the eye, soluble oligomers of Ab cause the synthesis of nitric oxide (NO) which binds and activates guanyl cyclase, cyclic-guanosine monophosphate (cGMP) levels rise, protein kinase G (PKG) activates and phosphorylates exocytotic proteins, which inhibit evoked transmitter release. However the literature is split whether Ab and NO act in a neuro-protective or neuro-destructive fashion. One explanation for these discrepancies may be due to opposing actions of intracellular versus extracellular cGMP, as shown by previous research in transformed cells. Potassium-evoked radiolabeled ACh release was measured from presynaptic membrane terminals in the 14 day choroid tissues after overnight incubation with and without Ab or other pharmaceutical compounds. Here we report that membrane impermeable cGMP acts differently than membrane permeable cGMP forms (8-Bromo-cGMP) on potassium-evoked ACh release in choroid nerve terminals. Whereas 8-Bromo-

cGMP is able to mimic the inhibition of ACh release, the membrane impermeable form is not, thus suggesting that intracellular cGMP is required for the Ab-induced inhibition of evoked ACh release. However saturation of the choroid prep with soluble hemoglobin (100 uM), which strongly binds extracellular NO, reverses the Ab effect on ACh release. This suggests that NO transiently travels through the extracellular domain before interacting with intracellular cGMP during the Ab-induced pathway.

Abstract: The increase progressive in neurodegenerative diseases (ND) prevalence in relation with the age has increased in recent years in the world population. Advances in molecular genetics have opened high development for study of neurodegenerative diseases. The aim of this research is to identify and know the gene expression and demographics data of Alzheimer's (AD), Parkinson's (PD), Multiple Sclerosis (MS) and Huntington (HD) in Ecuadorian population. Our results demonstrate significant increases in APP and HLA -DRB1 gene expression and reduction of LRRK2 gene. On the other hand we identified the IT15 gene expansion and the genetic pedigree was performed obtaining presence of autosomal dominant inheritance of Huntington's disease. When we study the relation of the (ND) with age we found that most of patients with AD, PD, MS and HD were in the age group of 71-80, 60-70, 51-60 and

41-50 years respectively. By relating the BMI with gene expression was observed the majority patients with AD were obese patients; the rest of neuropathology's present low weight. The personal medical history (PMH) in HD is present in most individuals, the other pathologies show different PMH, where the lack of PMH presence is shown in most individuals analyzed. Finally research the gender distribution, and we found the increased presence of female gender in Alzheimer's and Huntington and more individuals of male gender in Parkinson's and Multiple Sclerosis. We can conclude that has been showed the gene expression and demographic data of neurodegenerative diseases studied in this investigation in Ecuadorian population, and has been obtained similar conditions and data showed in others researcher around the world. Keywords: Neurodegenerative diseases, APP, IT15, HLA -DRB1, LRRK2, RT- PCR, pedigree.

Title: Gene-based rare allele analysis identified a risk gene of Alzheimer's disease

Authors: *J. KIM;
Dept. of Neurology, Ilsan Hospital, Natl. Hlth. Insurance Corp., Koyang-Shi, Korea, Republic of

Abstract: Objective: Alzheimer's disease (AD) has a strong propensity to run in families. In various complex diseases, gene studies have targeted rare alleles for unsolved heritability. Our study aims to elucidate unknown risk genes for AD by targeting rare alleles. **Methods:** We used data from five publicly available genetic studies from the ADNI and the dbGaP. The genotype information of rare alleles was imputed using 1000 genomes. We performed gene-based analysis of rare alleles (MAF $\leq$ 3%). **Results**: *ZNF628* showed a genome-wide significant association with AD. *APOE* and *TREM2* were also significantly associated with AD, although not at genome-wide significance levels. Other genes identified by targeting common alleles could not

be replicated in our study. **Conclusions:** We identified that rare variants in *ZNF628* are associated with AD. Furthermore, the significant associations of *APOE* and *TREM2* with AD imply that further deep sequencing of these genes is required in AD heritability studies.

Title: Identification of differentially hydroxymethylated loci in Alzheimer's disease

Authors: *A. I. BERNSTEIN, C. STREET, L. LI, M. GEARING, A. I. LEVEY, P. JIN; Emory Univ., Atlanta, GA

Abstract: Alzheimer's disease (AD) is a chronic neurodegenerative disorder characterized by progressive deterioration of cognitive function. Many lines of evidence suggest a role for epigenetic regulation, in particular cytosine modifications (5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC)), in AD. Methylation of cytosine in genomic DNA is carried out by DNA methyltransferases. 5hmC, highly enriched in the nervous system, is generated from 5mC by Tet proteins. 5hmC displays temporal and spatial changes during neurodevelopment and aging. To determine the role of 5mC and 5hmC in AD, we carried out genome-wide analyses of 5mC and 5hmC of using the DNA isolated from prefrontal cortex of post-mortem AD and age-matched control brains. We also performed RNA-Seq to correlate changes in methylation status with transcriptional changes. Our analyses showed a change in the distribution of 5hmC across the genome, with 6,989 differentially hydroxymethylated loci (DhMLs) gained in AD and 15,201 DhMLs lost in AD. Annotation revealed that 30% of these DhMLs are located in intergenic regions and 70% are located within genes (intragenic). Correlation of these genes with RNA-Seq results revealed 230 genes showing significant differences between AD and age-matched controls. Three of these genes show confirmed differential splicing between the 2 conditions (ITSN2, CACNA1D, and NCOR2), while 160 genes show differential isoform expression. Gene ontology analysis of these 230 genes showed enrichment for genes located at the plasma membrane, genes involved in calcium ion transport and voltage-gated calcium

channel activity, and genes associated with clathrin-coated endocytic vesicles, suggesting a disruption of proper synaptic vesicle cycling during neurotransmission in AD. Together, these data suggest that 5hmC plays an important role in modulating gene expression in AD pathogenesis.

Abstract: Transcriptome array analysis has been used to study genome-wide protein expression and its regulation by non-coding RNA. Although the functions of non-coding RNAs have been studied in many diseases, little is known about the relationships between miRNA and mRNA expression in Alzheimer's disease (AD) at early- or late-symptomatic stages. Sequence-based

target prediction algorithms and anti-correlation profiles have been applied to predict miRNA targets using omics data, but this approach often leads to false positive predictions. Here, we applied the joint profiling analysis of mRNA and miRNA expression levels to Tg6799 AD model mice at 4 and 8 months of age using a network topology-based method. We constructed gene regulatory networks and used the PageRank algorithm to predict significant interactions between miRNA and mRNA. In total, 8 cluster modules were predicted by transcriptome data for co-expression networks of AD pathology. AD networks were constructed by integrating mRNA and miRNA profiles. In total, 54 miRNAs were identified as being differentially expressed in AD. AD networks were constructed by integrating mRNA and miRNA profiles. Among those, 50 significant miRNA-mRNA interactions were predicted by integrating sequence target prediction, expression analysis, and the PageRank algorithm. We identified a set of miRNA-mRNA interactions that were changed in the hippocampus of Tg6799 mice at both early- and late-symptomatic stages compared to littermate controls. Our results demonstrate AD-specific changes in the miRNA regulatory system as well as a relationship between the levels of miRNAs and those of their targets in the hippocampus of Tg6799 mice. These data suggest the potential functions of various miRNAs and their target genes in the molecular pathology of AD.

Title: Abnormalities in synaptic responses within dendritic spines associates with suppressed network-level CA1 plasticity in presymptomatic Alzheimer’s disease mice

Authors: S. CHAKROBORTY[1], *E. S. HILL[2], W. N. FROST[2], G. E. STUTZMANN[1]; [1]Neurosci., [2]Cell Biol. and Anat., Rosalind Franklin Univ., North Chicago, IL

Abstract: Several neurological disorders with cognitive deficits such as Alzheimer’s disease (AD) have altered hippocampal synaptic plasticity. However, the progression by which cellular synaptic function becomes impaired and manifests itself within the broader hippocampal

networks that encode memory are still unidentified and are the focus of this study. To accomplish this, we examined synaptic plasticity mechanisms at the single spine and neuron level using video-rate 2-photon calcium imaging and patch clamp electrophysiology, in parallel with observations of synaptic plasticity over the broader Schaffer collateral - CA1 hippocampal network using a fast voltage-sensitive absorbance dye and 128x128 CMOS camera sampled at 1250 Hz. Acute hippocampal brain slice preparations from 2-3 month old 3xTg-AD and control mice were used. The goal was to compare the magnitude of synaptic plasticity and calcium signals evoked in individual CA1 neurons and spines by Schaffer collateral stimulation, with synaptic plasticity responses throughout all regions of CA1. At the single neuron level, we found that calcium responses evoked by an LTP-inducing stimulus were 3-fold greater in dendrites and spines from 3xTg-AD mice compared to NonTg animals. In parallel, there was an increase in the frequency of spontaneous vesicle release in 3xTg-AD mice, and markedly reduced post-tetanic potentiation (PTP), a short-term form of calcium-dependent plasticity. Short-term potentiation (STP), a form of plasticity that likely sets the threshold for LTP, was also greatly reduced in 3xTg-AD CA1 neurons. Field potential recordings of PTP and STP from the CA1stratum radiatum subfield mirrored these findings. To map these observations from single neurons onto a larger network, we used VSD imaging to measure PTP and STP plasticity evoked by the same LTP-inducing stimulus throughout the CA1 subfield. We found a similar deficit of STP and PTP plasticity in 3xTg-AD animals vs controls in all CA1 subfields, including the stratum radiatum, stratum oriens, stratum lucidem, and stratum moleculare. The findings suggest that the increased synaptic calcium responses and reduced short term plasticity at the single cell level are reflected as synaptic plasticity deficits throughout CA1 before memory impairments emerge in AD mice.

Title: A-beta oligomers induced actin cytoskeleton abnormalities and reduced synaptic plasticity in dendritic spines of cortical neurons

Authors: M. DOLLMEYER, T. J. RUSH, M. FRANDEMICHE, M. ROLLAND, E. BOREL, K. PERNET-GALLAY, F. LANTÉ, *A. BUISSON;
Batiment Safra, Gin-U836-Université J. Fourier Grenoble 1, La Tronche, France

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease characterized by cognitive deficits and memory loss due to synaptic damage. The amyloid beta peptide, deposition of which is a histo-pathological hallmark of AD, is known to be neuro- and synaptotoxic in its several forms. Soluble, low-molecular weight oligomers of amyloid beta (Aβo) are of specific interest, as they are known to occur prior to fibril formation and subsequent plaque deposition. Accumulating evidence suggests a causal role for Aβo in disease. The synaptotoxic mechanisms of Aβo are still unclear. This study aims to investigate how Aβo triggers spine dysfunction. Here we have used primary cortical neurons cultured from mouse to study the effects of Aβo on several synaptic features related to plasticity. Using video and confocal microscopy of live neurons, we exposed our culture neurons to chemical long-term potentiation (cLTP) protocol. For this purpose, we used a GABA-A receptor antagonist (bicuculine, Bic, 50 μM), and a K+-channel blocker (+4-amino pyridine, 4AP, 2.5 mM). We observed that spine volume is increased by our cLTP protocol. Pre-incubation with Aβo (at 100 nM for 15 min) reduced both the amount of intracellular free calcium and spine enlargement provoked by cLTP. The reduced calcium levels were observed both in the neuronal soma and within individual dendritic spines (using GCaMP-6 fast, a genetically encoded calcium indicator). Western blot analysis of samples subjected to a fractionation protocol to isolate post-synaptic density- (PSD) enriched and Non-PSD-enriched synaptic membrane compartments allowed several observations: exposure to Aβo disrupted two important plasticity related and stimulation-induced responses of dendritic spines: increase in the AMPA-receptor GluA1 subunit at the PSD and ERK pathway activation. Next, we performed live imaging confocal microscopy with a filamentous actin (F-actin) marker (LifeAct) to observe actin cytoskeleton in spines. We showed that short period of Aβo exposure (at 100nM) did not induce any spine loss. However, we observed an increase in spine size, characterized by the presence of F-actin enriched membrane protrusions at the spine apex. These morphological abnormalities occurred in a subset of spines characterized as mushroom spines. Understanding the mechanism(s) by which Aβo affects actin cytoskeleton and its related effectors at the spine levels would be useful to developing therapies targeting synaptic plasticity deficits in AD. Title: Locus coeruleus projection system cellular and molecular dysfunction in amnestic mild cognitive impairment

Authors: *S. E. COUNTS[1,2], S. D. GINSBERG[3,4,5], E. J. MUFSON[6];
[1]Transl Sci. and Mol Med., [2]Family Med., Michigan State Univ., Grand Rapids, MI; [3]Ctr. for Dementia Res., Nathan Kline Inst., Orangeburg, NY; [4]Psychiatry, [5]Physiol. and Neurosci., NYU Langone Sch. of Med., New York, NY; [6]Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL

Abstract: A major feature of Alzheimer's disease (AD) is the loss of noradrenergic locus coeruleus (LC) projection neurons that mediate attention, memory, and arousal. However, the extent to which the LC projection system degenerates during the initial stages of AD remains unclear. To address this question, we performed tyrosine hydroxylase (TH) immunohistochemistry and unbiased stereology of LC neurons in tissue harvested postmortem from subjects who died with a clinical diagnosis of no cognitive impairment (NCI), amnestic mild cognitive impairment (aMCI, a prodromal AD stage), or mild AD (n = 5-6/group). Stereologic estimates of total LC neuron number revealed a 30-35% decrease in aMCI vs. NCI ($p < 0.01$) and a 45% loss of cells in mild AD compared to NCI ($p < 0.01$). Furthermore, LC fiber density was selectively reduced in the hippocampus compared to the neocortex of aMCI subjects, suggesting that coeruleo-hippocampal pathway degeneration marks the transition from normal cognition to prodromal disease. To examine the molecular pathogenic processes underlying noradrenergic neurodegeneration in aMCI, we combined laser capture microdissection with custom microarray technology to quantify gene expression patterns in individual TH-immunopositive neurons accessed from LC tissue samples. These studies revealed significant reductions in select functional classes of mRNAs regulating mitochondrial metabolism (e.g., cytochrome c1, cytochrome oxidase subunit 5a, $p < 0.01$), redox homeostasis (e.g., superoxide dismutase 2, glutathione peroxidase 1, $p < 0.01$) and cytoskeletal plasticity (e.g., microtubule associated binding protein 1a, utrophin, $p < 0.01$) in both aMCI and AD subjects compared to NCI. Taken together, these observations show that noradrenergic LC projection system

degeneration is a prominent feature of aMCI and provides a rational basis for targeting LC neuroprotection as a disease modifying strategy.

Title: Late onset Alzheimer's disease risk variants and duration of cognitive impairment show association with end-stage plaque load in the hippocampus

Authors: A. J. RAJIC[1], M. T. WOJNOWICZ[2], T. T. LEE[4], M. B. DICK[1], A. L. PIERCE[3], *W. W. POON[1];

Abstract: Unlike Familial Alzheimer Disease (FAD), which is caused by single dominantly inherited mutations, late onset Alzheimer Disease (LOAD) is influenced by multiple genetic loci and environmental risk factors. LOAD is also characterized by greater variation in quantitative endophenotypes compared to FAD, including age of onset, rate of cognitive decline and end-stage pathology. Recent studies have attempted to elucidate the effect of single nucleotide polymorphisms (SNPs) identified by GWAS on various quantitative endophenotypes in LOAD populations. In particular, pathway analyses have been employed to identify combinatorial effects of physiologically related risk loci on these endophenotypes. Here, we tested the hypothesis that risk SNPs located within genes encoding proteins involved in APP endocytosis(PICALM, CD2AP, BIN1) and subsequent Aβ metabolism(APOE) within the CNS affect the rate of plaque deposition in AD patients. We developed a genetic risk score based on the number of risk alleles within the endocytic pathway. Our preliminary results demonstrate that the genetic risk score combined with duration of cognitive decline correlate with end-stage

hippocampal plaque burden. These results suggest that the endocytic pathway interacts with APOE to increase the rate of plaque formation in LOAD.

Title: Amyloid beta co-localizes with dopamine beta hydroxylase in axon terminals of the rat frontal cortex

Authors: ***J. ROSS**[1], B. A. S. REYES[1], A. SAUNDERS[2], E. J. VAN BOCKSTAELE[1]; [1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Biol., Drexel Univ. Col. of Arts and Sci., Philadelphia, PA

Abstract: Alzheimer's disease (AD) currently affects 5.2 million Americans and has no effective therapeutic treatment. Characterized by a progressive loss of neuronal function marked by an accumulation of amyloid beta (Aβ) peptides that aggregate to form Aβ plaques, and hyper-phosphorylated tau proteins that form neurofibrillary tangles, the mechanisms by which these features ultimately lead to neuronal death are not understood. One of the earliest sites to be affected in AD is the locus coeruleus (Zarrow et al., 2003, Arch Neurol 60:337-341), the primary site of synthesis for the neurotransmitter norepinephrine (NE) that sends projections to almost all levels of the neuraxis. While it is known that NE is produced from dopamine by the enzyme dopamine-β-hydroxylase (DBH), the precise details regarding its interaction with cellular machinery involved in Aβ processing has yet to be described. Dysregulation of NE results in complex and poorly understood interactions involving neuroinflammation that hinders Aβ degradation, therefore promoting plaque formation (Chalermpalanupap et al., 2013, Alzheimer's Research & Therapy, 5:21). *In vitro* studies utilizing neuron-like chromaffin cells demonstrate

the co-localization of Aβ with catecholamine neurotransmitters in dense core secretory vesicles (DCSV) required for synaptic transmission (Toneff et al., 2013, Peptides, 46:126-35). However, interactions between Aβ and NE have not been elucidated *in vivo*. In the present study, we examined the cellular substrates for interactions between Aβ and DBH, a marker of noradrenergic axon terminals in the rat frontal cortex (FC) using light, immunofluorescence and electron microscopy. Light microscopic analysis indicated that Aβ-immunoreactive processes are present in the FC as previously described in the mouse. Confocal immunofluorescence microscopy revealed that Aβ-immunoreactive processes are co-localized with DBH fibers and processes. Using high resolution immunoelectron microscopy Aβ is localized in both somatodendritic processes and axon terminals. When localized in axon terminals, Aβ is evident in dense core vesicles of DBH-containing axon terminals. Semi-quantitative preliminary analysis revealed that 21% of DBH-containing axon terminals (31/154) also exhibited Aβ-immunogold silver particles that are predominantly associated with dense core vesicles. These results suggest an anatomical basis for the regulated co-secretion of Aβ with NE from dense core vesicles. An on-going study aims to investigate the cellular substrate of interactions between Aβ and a noradrenergic marker in an AD transgenic mouse model.

Topic: C.05. Aging

Title: Age-related changes of the axon initial segment and subcellular localization of tau protein in the rat brain

Authors: *A. KNEYNSBERG, T. GRABINSKI, N. M. KANAAN;
Neurosci. Program, Michigan State Univ., Grand Rapids, MI

Abstract: Aging is the primary risk factor for numerous neurodegenerative diseases, including Alzheimer's disease (AD). Yet, little is known of the specific aging-related contributions that directly lead to neuron dysfunction and death in AD. AD is characterized by the pathological accumulation of the microtubule-associated protein tau and a substantial body of evidence supports the hypothesis that tau plays an important role in disease pathogenesis. The progressive

accumulation of tau pathology occurs in the brain regions responsible for cognitive functions (e.g. the hippocampus) that are compromised in AD and correlates well with progressive cognitive decline. In healthy neurons, tau is enriched in the axonal compartment, where it can stabilize microtubules and play a role in regulating axonal transport. The preferential localization of tau in axons is mediated, at least in part, by aspects of the axon initial segment (AIS), acting as a retrograde barrier. The redistribution of tau from the axonal compartment to the somatodendritic compartment is thought to be an important event in tau-mediated toxicity because tau can no longer perform its axonal functions and may actively cause problems in the soma and dendrites. Thus, disruption in the stability of the barrier properties of the AIS may allow tau to diffuse freely back into the somatodendritic compartment and potentially lead to neurotoxicity. We will examine the effects of aging on AIS integrity and tau protein localization to better understand aging-related changes in aspects of tau biology that may facilitate neuronal dysfunction. Using a combination of immunohistochemical and immunoblotting approaches we will analyze AIS proteins/structure and tau protein localization in the aging rat brain. Specifically, changes in the AIS and the distribution of tau will be analyzed in hippocampal neurons of young, middle-, and old-age (4, 14, and 24 months) Fischer 344 rats. AISs (i.e. Ankyrin G positive) will be quantified using stereological methods, while the localization of tau in the somata of neurons will be measured using confocal microscopy and Licor image analysis. Changes in the overall level of AIS and tau proteins will be measured using immunoblotting techniques. Collectively, these studies may identify whether aging is characterized by changes in the AIS or associated with a redistribution of tau from the axon to the somatodendritic compartment.

Abstract: Animal models are an essential asset for basic pathophysiological research as well as validation of therapeutic strategies of human diseases. The absence of adequate *in vivo* experimental models has severe repercussions for therapeutic intervention success. Despite unprecedented progress in animal modelling, no mammalian model recapitulates the required age-dependent phenotypes associated with Parkinson's disease (PD). We selected an elegant series of models of ascending complexity, i.e. two different mouse strains (C57Bl/6J and senescence-accelerated mouse (SAMP8), as a model of aging), adult rats and marmoset monkeys (Callithrix jacchus) at various ages. Each model received a stereotactic injection in the substantia nigra pars compacta (SNpc) of high-titer (10E10 vg/g of body weight) bolus of adeno-associated virus (AAV) serotype 9 carrying mutant human α-synuclein (A53T) under the neuron specific synapsin promoter including a WPRE enhancer element. Sixteen weeks after injection, we systemically investigated all species specifics and age-dependent differential susceptibility of dopamine neurons regarding the extent and pattern of neuronal loss. We also assessed α-synuclein spreading, pathological state (i.e. S129 phosphorylation) and occurrence of intracellular inclusion formation. According to the species used, we observed differences in the PD-related neurodegeneration progression over time associated with α-synuclein pathology and spreading in many brain areas.

Title: Increased vesicular monoamine transporter 2 (VMAT2) expression opposes dopaminergic neurotoxicity in the nigrostriatal pathway

Authors: *K. M. LOHR[1], M. WANG[2], A. SALAHPOUR[3], T. S. GUILLOT[2], G. W. MILLER[2]; [1]Envrn. Hlth., [2]Emory Univ., Atlanta, GA; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: The vesicular monoamine transporter 2 (VMAT2; Slc18a2) is responsible for packaging the monoamines into vesicles for subsequent release and neurotransmission. We have previously shown that BAC-transgenic VMAT2-overexpressing mice (VMAT2-HI) have an increased vesicular capacity for dopamine and increased synaptic dopamine release. In addition to its importance in transmitter packaging, VMAT2 is also critical for sequestering both exogenous and endogenous toxicants away from their sites of action inside the neuron. Recent human data have even suggested that enhanced VMAT2 level may confer a reduced risk of Parkinson's disease. To examine the neuroprotective effects of increased VMAT2, we treated VMAT2-HI mice with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an established parkinsonism-inducing toxicant model. Following a 2 x 15 mg/kg MPTP dose, VMAT2-HI mice show only a 15% loss of tyrosine hydroxylase (TH) and a 55% loss of the dopamine transporter (DAT) in the striatum, compared to wildtype losses of 43% and 66%, respectively. VMAT2-HI mice also show only a 36% loss of TH+ neurons in the substantia nigra pars compacta compared to the 53% cell loss seen in wildtype littermates after a 5 x 20 mg/kg MPTP dosing regimen. Additionally, we show that elevated VMAT2 is protective against striatal terminal damage following methamphetamine treatment, another classic dopaminergic toxicant. VMAT2-HI mice show a 17.9% DAT loss, compared to the 59% DAT loss seen in wildtype littermates after a 4 x 10 mg/kg dose of methamphetamine. These data suggest that elevated VMAT2 levels may be advantageous in disease states characterized by vulnerable dopamine neurons, such as Parkinson's disease. Thus, in a hypo-dopaminergic disease state, increasing vesicle function would provide two therapeutic benefits: restoration of dopaminergic signaling and protection against further damage from neurotoxic species in the cytosol. Title: Preservation of serotonin neurons in mice with reduced vesicular monoamine storage

Authors: *S. ALTER[1], T. N. TAYLOR[3], T. S. GUILLOT[2], G. W. MILLER[2];
[1]Envrn. Hlth., [2]Emory Univ., Atlanta, GA; [3]Univ. of Minnesota, Minneapolis, MN

Abstract: Basic and clinical research indicate that synaptic vesicle function is compromised in Parkinson's disease, while insufficient vesicular transport of catecholamines has been demonstrated to be neurotoxic. We have previously reported that mice with drastically reduced expression of the vesicular monoamine transporter 2 (VMAT2 LO) undergo progressive catecholaminergic degeneration in the substantia nigra [J. Neurosci 27, 8138 (2007)] and locus ceruleus [Neuropharmacology 76A, 97 (2014)], and exhibit motor and nonmotor symptoms of Parkinson's disease [J. Neurosci 29, 8103 (2009)]. In the present work, we examined the effects of VMAT2 deficiency on the serotonin system. We assessed the integrity of the serotonin system with immunohistochemistry and radioligand binding, and examined behaviors associated with serotonergic signaling. Notably, no differences were observed in the number of TPH2+ neurons within the dorsal raphe in young (3 months) and aged (24 months) mice. Serotonergic innervation in the forebrain was also spared, as determined by SERT immunoreactivity and paroxetine binding. VMAT2 LO mice exhibited depressive-like behaviors (increased immobility in forced swim and tail suspension tests) that were responsive to fluoxetine. Additionally, VMAT2 LO mice have alterations in 5HT receptor-mediated physiology and behavior. VMAT2 LO mice exhibited an abolished hypothermic response to the 5HT1a agonist 8-OH-DPAT, suggesting reduced autoreceptor sensitivity; in contrast VMAT2 LO mice had a ~65% increase in head twitch response following treatment with the 5HT2 receptor agonist DOI, indicating increased post-synaptic receptor sensitivity. PD consistently features degeneration of the dopaminergic and noradrenergic systems, but the serotonergic innervation is often spared, and has been postulated to compensate for the catecholaminergic loss. Collectively, these findings in VMAT2 LO mice demonstrate that loss of vesicular monoamine transport is not toxic to the integrity of serotonin system (despite neurochemical loss), but may contribute to aberrant signaling in PD in which vesicular function is compromised. Abstract: Alpha-synuclein (α-SYN) is considered a key player in Parkinson's disease (PD). Alpha-SYN aggregates under pathological conditions into soluble oligomers and protofibrils and finally insoluble β-sheet-rich fibrils. Although the exact relationship between α-SYN aggregation and pathogenesis remains elusive, inhibition of α-SYN oligomerization is explored as a potential therapeutic strategy. We developed a bioluminescent protein-protein complementation assay based on split firefly luciferase (fLuc) and viral vector technology to obtain stable expression to quantify α-SYN oligomerization. Both in different human immortalized cell lines (i.e. HEK293T, HeLa, SH-SY5Y) and non-invasively in the mouse brain, we demonstrated that expression of a combination of two complementary split-fLuc α-SYN fusions resulted in a significantly higher bioluminescent signal than either split-fLuc α-SYN fragment alone or in combination with a non-related partner. Injection of the split-fLuc α-SYN viral vectors in the mouse substantia nigra (SN) led to extensive dopaminergic degeneration, reminiscent of what is observed in our in-house developed PD animal models based on viral vector-mediated overexpression of α-SYN in the SN. In addition, we could demonstrate that the bimolecular interaction reflected by the successful luciferase complementation results from pre-aggregate oligomeric α-SYN species. Moreover, we detected an inhibitory effect of the small molecule FK506 on the oligomerization process both in cell culture and in the mouse brain, underscoring the potential of our models to evaluate small molecules. Subsequently, we optimized and upscaled the cell-based split-fLuc α-SYN oligomerization assay towards a high throughput screening assay ($Z' > 0.5$). Together, these data indicate that α-SYN split-fLuc viral vectors can

be applied to discover small molecule compounds inhibiting α-SYN oligomerization in cell lines and to non-invasively monitor α-SYN oligomerization in live animals.

Abstract: Alpha-synuclein (α-SYN) is a key protein implicated in the pathogenesis of Parkinson's disease (PD). Testing of new therapeutic strategies targeting α-synucleinopathy is currently hampered by the lack of robust and reproducible α-SYN-based animal models that display the hallmark features of PD, especially progressive dopaminergic neurodegeneration over time. We developed and optimized a rat and mouse PD model based on viral vector-mediated overexpression of α-SYN. An adeno-associated viral (rAAV) serotype 2/7 vector encoding A53T mutant or wild-type α-SYN was stereotactically injected into the substantia nigra

(SN) of rats or mice and the effects were determined by histology, non-invasive imaging and behavioral analysis. We noted a significant and dose-dependent α-synucleinopathy over time upon nigral rAAV2/7-mediated α-SYN overexpression. A strong, progressive and dose-dependent loss of approximately 80% of the dopaminergic neurons in the SN was observed at 4 to 8 weeks post-injection in rat and mouse, respectively. This effect correlated with a reduction in tyrosine hydroxylase immunoreactivity in the striatum. In rats, monitoring of dopamine transporter binding with micro-PET scan revealed the most extensive dopaminergic degeneration between day 7 and day 21 post-injection. Moreover, behavioral analysis revealed significant motor impairments in both rats and mice. In addition, we detected the presence of α-SYN-positive aggregates in the remaining surviving neurons. In conclusion, we have developed robust and reproducible rodent models for α-synucleinopathy allowing rapid and thorough evaluation of new therapeutic strategies *in vivo*.

Abstract: Patients with Parkinson’s disease (PD) patients experience progressive motor impairments, including severe gait deficits. The past 2 decades have seen unprecedented

preclinical and clinical efforts to identify and validate novel antiparkinsonian therapies. Non-human primate (NHP) models of PD played a pivotal role for the safe and efficacious translation of therapeutic interventions developed in rodents to viable clinical applications for humans. Notably, MPTP-treated NHPs remain the gold standard for modelling motor and non-motor symptoms of PD and providing preclinical validation of potential therapies. However, the lack of consensus on a methodology and the almost exclusive reliance on clinical scores of PD have often hindered successful translation of interventions to clinical settings. Consequently there is a critical need to develop translational methodologies to enable robust and reliable evaluation of therapies across species. Here, we leveraged a newly established multimodal analysis platform to characterize alteration of kinematic and muscle activity during unconstrained locomotion in MPTP-treated NHPs. The connection-free platform allowed us to monitor muscle synergies and kinematics while the subjects walked on a treadmill, along a corridor, and across horizontal ladders of varying complexities. Using principal component analysis (PCA) applied on a large number of parameters, we could objectively quantify and rank task-specific deficits of gait patterns across a wide range of PD severities. This analysis also uncovered kinematic parameters that were specifically improved after the administration of L-Dopa, and others that remain resistant to dopamine replacement therapy. To assess the translational value of the developed analyses, we recorded Parkinsonian patients and rats with alpha-synuclein-mediated nigrostriatal degeneration under the same conditions as NHPs. We found striking similarities in the pattern of gait deficits across species, and on the therapeutic effects mediated by L-Dopa. The developed methodologies establish a highly-sensitive analytic framework to evaluate safety and efficacy of therapeutic interventions to alleviate locomotor deficits in animal models of PD and in Parkinsonian patients.

Abstract: Electrical neuromodulation of cervical segments increased spontaneous locomotor activity in rodent models of Parkinson's disease. However, the therapeutic effects of this paradigm have been highly variable in human patients. The use of large electrodes in animal models versus small electrodes in humans triggered a debate on the importance of electrode dimensions, electrode location, and spatial distribution of the generated voltage fields to mediate therapeutic effects. To evaluate the importance of these parameters, we leveraged a newly developed multi-electrode array that enables generation of localized or distributed voltage fields in the same neural interface. Rats were injected with AAV9 α-synuclein in the substantia nigra to induce nigrostriatal neurodegeneration. Detailed kinematic analysis during basic and skilled locomotion uncovered significant gait deficits and reduced locomotor activity that emerged around 2 months post-injection. After the occurrence of parkinsonian symptoms, we tested the therapeutic impact of electrical neuromodulation delivered through single electrodes or combinations of electrodes distributed along lumbosacral segments. We used a computational model to identify the electrical fields generated by each electrode configuration. We found that significant improvement of locomotor performance required fine-tuning of neuromodulation parameters through multiple electrodes distributed along lumbar and sacral segments. These results highlight the critical importance of mechanistic models to develop effective neuromodulation therapies that alleviate locomotor deficits after neuromotor disorders.

Title: Dopamine neuron produced Sonic Hedgehog (Shh) is a critical modulator of Acetylcholine neurons and important for reinforcement learning

Authors: *A. W. STUCKY[1], A. KOTTMANN[1,2];
[1]Physiology, Pharmacol. and Neurosci., Sophie Davis Sch. of Biomed. Education, CUNY, New York, NY; [2]Dept. of Pathology and Cell Biol., Columbia Univ., New York, NY

Abstract: Parkinson's Disease (PD) is recognized as a multi-systems, progressive neurodegenerative disorder with motor - and non motor - manifestations including difficulties in the expression of automatic, habitual components of motor behaviors and an increase in the display of volitional and goal directed behaviors. PD is characterized by a progressive dopaminergic and cholinergic dysfunction that spreads anteriorly and eventually involves the basal ganglia, the basal forebrain and the cortex. We find that all mesencephalic dopamine (DA) neurons express the secreted cell signaling factor sonic hedgehog (Shh) throughout life, and that DA neurons produced Shh is critical for the long term survival of cholinergic (ACh) neurons throughout the forebrain and fast spiking (FS), parvalbumin+, interneurons in the striatum [1]. We revealed that acute Shh regulates the efficacy of muscarinic autoreceptor signaling in a dose dependent manner leading to a modulation of the levels of extracellular acetylcholine. We further find that DA produced Shh regulates dendritic arborization of ACh neurons and the location and size of glutamatergic boutons on the soma of ACh neurons in the striatum, which likely impacts cortico-striatal neuro-transmission. Importantly, Shh signaling is graded across functionally distinct domains in the striatum, with the greatest impact in the dorsal lateral striatum, an area crucial for reinforcement learning and motor habit formation. Consistent with this finding we reveal that animals without Shh expression in mature DA neurons manifest hypercholinergic sensitivity, habituation deficits and impaired reinforcement learning before developing motor signs. Our data indicate that altered Shh expression in DA neurons of PD patients could contribute to the manifestation of cognitive dysfunction in PD. We will present recent data on the dynamic regulation of Shh expression in adult DA neurons and on the involvement of Shh signaling from DA neurons in the devaluation of reward and in motor habit formation.

Title: Impulsivity in GDNF heterozygous mice receiving chronic unpredictable stress

Authors: *B. Z. YANG, M. BUHUSI, C. V. BUHUSI;
Psychology, Utah State Univ., Logan, UT

Abstract: Administration of dopamine (DA) agonists is a common therapy used to help people suffering from Parkinson's disease (PD). However, DA agonists have been found to be a double-edged sword: they alleviate the motor symptoms of PD, but increase the levels of impulsivity in these patients. Partial glial cell line-derived neurotropic factor deficient (GDNF+/-) mice have been found to have a marked reduction in striatal DA levels, hinting at a dysfunctional substantia nigra DA neurons, as well as an accelerated age-related deterioration of motor functions. These neuroanatomical and behavioral symptoms match those observed in patients suffering from PD, supporting the GDNF+/- mice model as a mouse model of PD. At the same time, chronic unpredictable stress has been found to aggravate the onset of experimentally induced PD in rats, suggesting the possibility of a double hit model for the onset of PD. Therefore, in our study we evaluated impulsivity in GDNF+/- mice and wildtype littermates(WT) via a temporal discounting paradigm before and after chronic unpredictable stress. In our paradigm, mice chose between a smaller-sooner (SS) option, and a larger-later (LL) option delivered at varying delays of 0s, 4s, 16s, and 64s for 7 days. Afterwards, mice were subjected to 18 days of daily unpredictable chronic stress. The type of stressor and the time of stress activity was pseudo-randomized throughout the course of the 18 days. Finally, mice were tested again with the same temporal discounting paradigm. Results indicate that prior to stress, GDNF+/- mice were reliably less impulsive than their WT counterparts, possibly due to lower levels of DA. Post-stress, GDNF+/- mice showed a reliable increase in impulsivity while WT mice exhibited a less steep (not reliable) increase in impulsivity. Post-stress, the levels of impulsivity in GDNF+/- mice were not reliably different from those of WT mice, suggesting that GDNF+/- mice may be more susceptible to stress than WT mice. Taken together, our findings support the GDNF+/- mice as a dual-hit mouse model of PD.

Title: Aggregated α synuclein intoxication of primary dopaminergic neurons as an *in vitro* model of Parkinson disease

Authors: D. BUTTIGIEG, E. GRAS LAVIGNE, M. OUAMER, R. STEINSCHNEIDER, *B. DOROTHEE;
Neuron Experts, Marseille, France

Abstract: Parkinson's disease (PD) is the second most common age-related neurodegenerative disorder leading to severe motor symptoms. Major pathological features of PD are the loss of dopaminergic neurons in the substantia nigra (SN) and the presence of intraneuronal proteinacious cytoplasmic inclusions (termed Lewy bodies, LB) majority composed by alpha-synuclein (a-syn), a pre-synaptic protein implicated in dopamine trafficking but also in neuronal protection. A large body of evidence suggests that aggregation of a-syn plays a crucial role in the pathogenesis because of its neurotoxic activity and its ability to trigger inflammatory process. To study the mechanisms by which aggregated a-syn acts, we developed a relevant *in vitro* cellular model where dopaminergic neurons are reproductively intoxicated by a-syn. For this, we first assessed a-syn toxicity on dopaminergic neuron survival according to its form (linear or prefibrillar) and preparation. After having confirmed the predominantly toxic effect of a-syn prefibrillar oligomers, its assumed most toxic form; we develop a new method to produce a-syn oligomers in a more predictable manner. We investigated its toxicity according to its concentration and time of incubation. Finally, we validated our cellular model by using several reference compounds and demonstrated protective and restorative effects of two neurotrophic factors belonging to the Glial Cell Line-Derived Neurotrophic Factors (GDNF) Family of Ligands (GFLs). This improved and reproducible cellular model displays a prerequisite to further experiments on a-syn involvement in Parkinson disease and drug discovery through *in vitro* high content screening.

Abstract: α-Synuclein has long been recognized as a key player and a potential therapeutic target for Parkinson's disease, as well as other synucleinopathies. Supporting this, mutations/multiplication in the gene encoding α-synuclein increases the risk for developing PD. Several observations underline the pathophysiological role of α-synuclein, including its presence in cellular inclusions in a range of neurodegenerative disorders in different parts of the brain, the association between increased α-synuclein expression and cell death or susceptibility to stress-induced toxicity in cells, as well as the causative link between α-synuclein overexpression and pathology in various species. While α-synuclein exists in different forms depending on the pathophysiological state, detection of aggregated and/ or phosphorylated α-synuclein in post-mortem brains has been widely accepted as a pathological marker of PD. To further elucidate the connection between α-synuclein and the progressive pathology of PD, the presence of total, phosphorylated as well as aggregated α-synuclein was analyzed in a rat model with virally-mediated overexpression of human wt α-synuclein targeted to the nigro-striatal dopamine system. A progressive loss of dopaminergic neurons in the substantia nigra leading to loss of terminals in the striatum was observed between 3 and 17 weeks post-virus injection, and was associated to progressive motor deficits. In addition, an abnormal firing pattern of neuronal populations in the basal ganglia circuits, including the subthalamic nucleus (STN) and the Substantia Nigra reticulata (SNr), was observed, recapitulating some of the neurophysiological alterations reported in PD patients. The progression of α-synuclein pathology in this animal model was evaluated from 3 to 17 weeks post virus injection, using three different methods: 1) ELISA detection using antibodies with a preferential binding to aggregated α-synuclein, 2)

Western Blotting of enriched fractions of higher molecular weight species of α-synuclein and 3) Immunohistochemistry. Analysis of the correlations between the levels of various pathological forms of α-synuclein and progression of behavioral and electophysiological deficits in our animals models is necessary in order to design studies aimed at investigating the effects of drugs targeting α-synuclein.

[3]Psychological and Physical Sci., Aichi Gakuin Univ., Nisshin, Japan

Abstract: Lewy body diseases (LBDs) are a series of neurodegenerative illness represented Parkinson’s disease (PD), and pathologically characterized by the neuronal inclusion (Lewy Body). Genetical and biochemical studies discovered the disease-related genes especially from the familial cases, but the pathogenesis has not been elucidated yet. On the other hand, the therapy for PD has become available with the modification of neurotransmitters. However, it cannot stop the progressing neuronal cell death. An appropriate model to understand the pathogenesis and to develop the cell therapy is needed. So far, mainly two types of LBDs model have been developed. One is the pharmacological model with neurotoxin like MPTP or rotenone, and another is the genetical model representatively with α-synuclein (α-syn), the major ingredient of Lewy body. The pharmacological model was originally found to cause

Parkinsonism by neurotoxicity, but it cannot explain all LBDs pathogenesis. On the other hand, the genetical model with the wild type of α-syn cannot induce the neuronal death. And so, we newly focused on the point that these diseases develop in elderliness, and are progressing with aging, and started to develop the new LBDs model with aging factor added. Here, we report the functional analysis of the longevity-related gene with the LBDs model cells, and the new model creation trial from the cell level to the mouse level in progress. FOXO3 (Forkhead box O3), which is one of the longevity-related genes, is a multifunctional transcription factor. It functions in stress response, apoptosis, tumor suppression, and etc. Also, it is reported to be colocalized in Lewy body of the patients' autopsied brain, which implicates that it may play a role for the LBD pathology. Therefore, we analyzed the influence of LBD model cells which were made by α-syn overexpression, with the downregulation of FOXO3 by RNA interferance. FOXO3 downregulated cells were more fragile compared with the control. And the α-syn overexpressed cells upregulated FOXO3, and this gene was suggested to have an association with stress response caused byα-syn. We searched the influence of the FOXO3 downregulation biochemically and pathologically with westernblotting, RT-PCR, and etc, and the autophagy system was found to be impaired in the FOXO3 downregulated cells. And α-syn monomer was found to be decreased by the knockdown of the FOXO3 gene. We are now studying more about the impairment of the autophagy, and about the influence for the oxidative stress. If possible, we also want to report about the creation trial of the new LBDs mouse model.

Title: Retinal structural injury in animal models of parkinson's disease and chronic manganese exposure detected by optical coherence tomography

Authors: *D. W. ANDERSON, M. E. AULT, J. S. SCHNEIDER;
Dept Pathol, Anat & Cell Biol, Thomas Jefferson Univ., PHILADELPHIA, PA

Abstract: Optical coherence tomography (OCT) is a non-invasive procedure for analysis of retinal morphology. OCT has been effectively used to assess disease progression in multiple sclerosis (MS) patients and OCT and retinal imaging has been suggested as a surrogate measure for brain damage in MS patients. OCT may also be a valuable tool for longitudinally following other neurodegenerative conditions such as Parkinson's disease (PD) and potentially for monitoring disease progression as well as assessing efficacy of neuroprotective treatments. Recent studies using OCT to assess retinal histology *in vivo* in PD patients have reported significant inverse correlations between foveal or peripapillary retinal nerve fiber layer (RNFL) thickness and Unified Parkinson's Disease Rating Scale scores, and have even suggested the possibility of differentiating between rigid/akinetic and tremor dominant PD patients by differences in retinal morphology between these subgroups. The present study was conducted to investigate the extent to which changes in retinal morphology could be detected *in vivo* using OCT in an established animal model of PD, the MPTP-treated nonhuman primate. We also examined the extent to which OCT could detect retinal changes in a nonhuman primate model of chronic to exposure to manganese (Mn) at levels in the ranges of those reported for human environmental or occupational exposures. Eyes from 10 normal, neurologically intact adult male cynomolgus monkeys, 5 adult male cynomolgus monkeys previously made parkinsonian by chronic administration of MPTP, and 7 adult male cynomolgus monkeys with Mn exposures ranging from were examined from approximately 20 - 72 weeks. MPTP-treated animals were all moderately parkinsonian and exhibited stable parkinsonian signs of at least 4 years duration. Statistically significant reductions in RNFL thickness were found in MPTP-treated animals vs. controls particularly in nasal and inferior RNFL quadrants. Significant foveal thinning and decreases in macula volume were also detected. RNFL thinning was also observed in Mn-exposed animals with changes related to duration of Mn exposure. Foveal thickness and macula volume were not different from controls. These data show that in a nonhuman primate PD model, OCT imaging detects changes in the retina similar to those detected in PD patients. These data suggest that OCT may be a useful measure to employ in preclinical studies of PD and other neurodegenerative conditions and that retinal measurements may have sufficient specificity to be used as biomarkers for different neurodegenerative conditions.

Ctr. for Toxicological Research, US Food and Drug Admin., Jefferson, AR

Abstract: Parkinson′s disease (PD) is a motor system disease characterized by a progressive dopaminergic nigrostriatal degeneration underlying a severe striatal dysfunction, which can be partially recapitulated by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Although etiology of PD is not fully understood, recent data suggest the receptor for advanced glycation endproducts (RAGE), which plays a major role in oxidative stress and gliosis, seems to contribute to the pathogenesis. We aimed to characterize RAGE density and its cellular localization in striatum after a chronic MPTP paradigm (20mg/Kg i.p., 2 i.d-12h apart, 5 days/week for 2 weeks). C57BL/6 mice were euthanized 7 days following this toxic insult after probing their locomotor activity for striatal neurochemical analysis. This new chronic MPTP model triggered striatal dopaminergic nerve terminals toxicity gauged by a mild loss of tyrosine hydroxylase levels, severe dopamine (DA) depletion and by increased DA turnover. This monoamine disruption underlined motor impairments as assessed by the pole test and rota-rod. We provide novel evidence that RAGE-positive immunoreactivity was exclusively observed in striatal neurons of MPTP-treated mice in spite of an intense astrogliosis (GFAP and GS upregulation) and increased oxidative stress (augmented HNE adducts levels). Additionally, this MPTP paradigm failed to change striatal density of RAGE and its astrocytic ligand S100β. These findings demonstrate for the first time that striatal RAGE is quiescent in an astrogliotic and oxidative environment underlying striatal dysfunction in a PD experimental model. Title: Molecular and neural correlates of olfactory dysfunction by paraquat-induced oxidative stress and modeling for Parkinson disease in *Drosophila* melanogaster

Authors: *H. KWON, J. JUNG, H. LEE;
Dept. of Agr. Biotechnology, Major in Biomodulation, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: An environmental toxicant like paraquat is known to induce the increase of oxidative stress, which is likely to lead to various neuropathological symptoms. One of the ultimate questions is what are the molecular and neural target eliciting various neural diseases as time proceeds. Here in this study, using a fruit fly, *Drosophila melanogaster*, as a model animal, we have examined the effect of paraquat on olfactory sensation and behaviors as well as molecular targets based on this phenomenon. Dietary feeding of paraquat with sucrose solution demonstrates that olfactory sensitivity in the periphery was decreased and olfactory behaviors such as food choice and olfactory learning and memory were affected. Present study also demonstrates that the dietary feeding of phytochemicals prior to paraquat exposure has anti-oxidative and neural protective effects, which leads to the recovery of behaviors and lifespan in fruit flies. We will present the more details on molecular and neural correlates associated with this environmental toxicant.

Abstract: Parkinson's disease (PD) is a neurodegenerative disease characterized by the progressive loss of dopaminergic (DA) neurons in the substantia nigra. However, current treatments for PD are mainly palliative. Recently, researchers discovered that neurotoxins can induce Parkinsonian-like symptoms in zebrafish. No study to date has investigated the characteristics of PD, such as neuroinflammation factors, oxidative stress, or ubiquitin dysfunction, in this model. Therefore, the current study was aimed at utilizing commonly used clinical drugs: minocycline, vitamin E, and Sinemet, to test the usefulness of this model. Previous studies had indicated that dopaminergic cell loss was greater with 6-hydroxydopamine (6-OHDA) than with other neurotoxins. Thus, we first challenged zebrafish with 6-OHDA immersion and found a significant reduction in zebrafish locomotor activity, we then reversed the locomotor disruptions by treatment with vitamin E, Sinemet, or minocycline. The present study also analyzed the mRNA expression of *parkin*, *pink1*, and *cd-11b*, because expression of these molecular targets has been shown to lead to attenuation in mammalian models of PD. Vitamin E, Sinemet, and minocycline significantly reversed 6-OHDA-induced changes of *parkin*, *pink1*, and *cd-11b* mRNA expression in zebrafish. Moreover, we assessed tyrosine hydroxylase (TH) expression to confirm the therapeutic effects of vitamin E tested on this PD model and established that vitamin E reversed the 6-OHDA-induced damage on TH expression. Our results provide some support for the validity of this *in vivo* Parkinson's model, and we hope that this model will be more widely used in the future.

Title: Axon guidance molecules in Parkinson's disease

Authors: ***J. A. KORECKA**, J. R. MCLEAN, J. L. JANSSON, J. A. BEAGAN, Z. SCHNEIDER-LYNCH, D. AHMADI, T. M. OSBORN, O. ISACSON;
Neuroregeneration Res. Inst., McLean Hospital/Harvard Med. Sch., Belmont, MA

Abstract: Recently important evidence came to light implicating axonal degeneration as an early hallmark of developing pathology in Parkinson disease (PD). More importantly, gene expression studies, genome wide association studies (GWAS) of single-nucleotide polymorphism variations and pathway analysis studies identified axon guidance signaling pathways to be associated with PD development (Edwards et al., 2011, Plos One;6(2):e16917, Bossers et al, 2009, Brain Pathol;19(1):91-107, Lin et al., 2009, Trends Neurosci;32(3):142-9, Srinivasan et al., 2009, Hum. Mutat;30(2):228-38, Lesnick et al., 2007, Plos Genet;3(6):e98, Maraganore et al., 2005, Am J Hum Genet;77(5):685-93). Based on GWAS and pathway analysis Lin et al. (2009, Trends Neurosci;32(3):142-9) identified five axon guidance genes associated and predictive of PD outcome: DCC, EPHB1, NTNG1, SEMA5A and SLIT3. Axon guidance cues persist to be expressed in the adult CNS maintaining the structural plasticity of the neuronal circuits (Mironova and Giger, 2013, Trends Neurosci;36(6):363-73). It is thought that through this maintained expression of guidance cues in the adult host brain neuronal transplants reconnect their dopaminergic (DA) axons to their specific target- the dorsal lateral striatum (Isacson & Deacon 1996, Neuroscience;75(3):827-37). Mouse ventral midbrain (VM) primary cultures and DA neurons derived form embryonic stem cells are sensitive to Slit and Netrin

signaling (Lin et al., 2005, Mol Cell Neurosci;28(3):547-55, 2006, Stem Cells;24(11):2504-13). For the first time we show that human iPS cell-derived DA neurons may also be sensitive to known DA axon guidance regulators by expressing Ephrin and DDC receptors. Preliminary data from human iPS cell-derived DA neurons indicate that LRRK2 may play a role in neurite outgrowth regulation. IPS cell-derived DA neurons carrying LRRK2 mutations showed increased neurite collapse and lack of recovery after thapsigargin and alcohol stress *in vitro*. These data indicate that axon growth and maintenance is potentially aberrant in PD. We hypothesize that these changes can either take place in the years preceding the clinical diagnosis, or are already present during the development of CNS.

Title: Characterization of G2019S-LRRK2 BAC transgenic rats

Authors: *H. ABDELMOTILIB, X. HU, J. DAHER, T. GROEN, A. B. WEST;
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Mutations in the leucine-rich repeat kinase 2 (LRRK2) gene can cause late-onset Parkinson’s disease (PD). Recently, transgenic rats that express LRRK2 from the human promoter with the pathological mutation G2019S became available. Localization of LRRK2 expression in these transgenic rats revealed high levels of LRRK2 in numerous brain nuclei and neuronal subtypes, strongly divergent from endogenous rat LRRK2 distribution. In initial characterizations, normal neuronal counts of neurons in the substantia nigra were observed, yet deficits in motor co-ordination compared to non-transgenic littermates suggested deficits in motor pathways. Characterization of these rats with a battery of motor and behavioral assays will help reveal the extent to which G2019S-LRRK2 expression alters normal physiology. LRRK2

kinase-activity dependent phenotypes will be defined through exposures to potent and selective LRRK2 inhibitors to begin to understand reversible deficits from neural developmental alterations. These studies may help provide valuable baseline data for a new pre-clinical model useful for the characterization of novel LRRK2-targeting therapeutics.

Title: Overexpression of fragments of the kinase domain of LRRK2 in the rat substantia nigra produces cell disturbances but does not lead to dopaminergic cell loss or motor symptoms

Authors: *E. P. BROUILLET, N. CRESTO, M.-C. GAILLARD, E. DIGUET, D. BELLET, L. LEGROUX, L. FRANCELLE, J. MITJA, G. AURÉGAN, M. GUILLERMIER, D. HOUITTE, G. BONVENTO, C. JAN, F. PETIT, P. HANTRAYE, N. DÉGLON, K. CAMBON, A.-P. BEMELMANS;

Abstract: Mutations in the LRRK2 gene are the most common genetic causes of autosomal dominant Parkinson’s disease (PD). Genetic models of LRRK2 mutations have been developed in animals and cell cultures. They provided new insights in the possible mechanisms underlying mutant LRRK2 toxicity, pointing to a key role of its kinase domain. However, transgenic models in rodents show limited neurodegeneration of dopaminergic neurones in the substantia nigra pars compacta (SNc). An alternative to transgenic models is the use of gene transfer technology with viral vectors. Adenoviral vectors and Herpes Simplex virus amplicons coding for mutant LRRK2 have been successfully used to induce SNc neurodegeneration in rodents. The aim of the present study was to evaluate the potential toxicity of lentiviral vectors (LV) and adeno-associated viral

(AAV) vectors expressing three different fragments of the C-terminal part of wild type (WT) or G2019S mutant LRRK2: the kinase domain (K), the ROC-COR-kinase (RCK) and the RCK-WD40 domain. *In vitro* autophosphorylation assays indicated that only the mutant RCK-WD40 domain had increased kinase activity as compared to the other fragments. Transcriptomic analysis of the rat striatum infected with LV-RCK-WD40 showed that the G2019S mutation produced cellular disturbances as compared to the WT fragment and a G2019S/D1994A double mutant fragment encoding a "dead-kinase". LVs coding the different constructs were stereotaxically injected in the rat SNc. Histological evaluation was carried out 10 and 25 weeks later. Results showed that 20-60% of the tyrosine-hydroxylase-(TH)-positive dopaminergic neurones were transduced with LV coding the WT or G2019S fragments. However, no loss of TH-positive cells could be evidenced at these time points. We also infected the SNc with AAV9 coding wild type RCK-WD40 domain or the RCK-WD40-G2019S mutant. Evaluation of motor performance (Catwalk and the elevated board test) at 3 and 6 months after the AAV injections showed no significant motor alterations in these animals as compared to sham-operated / age matched controls. Histological evaluation indicated no loss of TH positive cells despite high levels of expression of LRRK2 RCK-WD40 fragments. Our data show that sustained overexpression of the active kinase domain of mutant LRRK2-G2019S can produce cellular disturbances in neurons *in vivo*, but is not sufficient to rapidly trigger loss of TH-positive cells or motor changes in adult rats.

Abstract: Leucine-rich repeat kinase 2 (LRRK2) is a large multi-domain protein with known GTPase and kinase domains. Mutations in LRRK2 have been identified as risk factors for Parkinson's disease (PD). Gain-of-function mutations in LRRK2 are the most common genetic cause of familial PD and the mutations are also found in sporadic PD patients, highlighting the importance of LRRK2 in PD pathology. Various animal models including rodent models have been generated to investigate the molecular etiology of PD, and the genetic animal models have provided insights into the neuropathology of LRRK2 mutations. In addition, recent advances in genetic engineering tools and in differentiation techniques for human pluripotent stem cells enable us to generate new PD models with highly enriched human dopamine neurons in culture. To generate a human dopamine neuron PD model with controlled LRRK2 mutant expression, we have generated genetically engineered human embryonic stem cells with an inducible G2019S-LRRK2 overexpression cassette. Expression of the LRRK2 transgene is under the control of the Tet-Off system, which consists of the tetracycline/doxycycline responsive tet-promoter and the tTA transcriptional activator. To avoid transgene silencing and to increase integration efficiency, transcription activator-like effector nucleases (TALENs) were employed to introduce the inducible LRRK2 construct into the AAVS1 safe locus. We expect that this new PD model with inducible LRRK2 expression will allow for a more comprehensive understanding of the molecular mechanisms underlying DA neuron degeneration.

Title: The loss of endogenous parkin causes dopaminergic neurodegeneration in a mouse model of mitochondrial aging

Authors: *A. M. PICKRELL, C.-H. HUANG, R. J. YOULE;
NIH, Bethesda, MD

Abstract: Parkinson's disease is the most common motor deteriorating neurodegenerative disease caused by the loss of a subpopulation of dopaminergic (DA) neurons in the substantia nigra (SN). Early-onset familial cases have identified recessive PARK2 gene mutations encoding the E3 ubiquitin ligase Parkin. Parkin selectively translocates to dysfunctional mitochondria promoting their removal by autophagy (mitophagy) by targeting mitochondria with low mitochondrial membrane potential and/or pathogenic mitochondrial DNA (mtDNA) mutations. Patients with parkin mutations often confer a loss of mitochondrial function, postulated as a consequence due to a defect in the surveillance of mitochondrial quality. To study the role of Parkin *in vivo* in relation to its role in mitochondrial quality control, we utilized an aging mouse model that accumulates dysfunctional mitochondria caused by an accelerated generation of mtDNA mutations (Mutator mice) crossed to a Parkin knockout (KO) mouse. We hypothesized that the loss of endogenous Parkin would exacerbate phenotypes of a mouse model harboring deleterious mtDNA mutations. Mutator Parkin KO mice performed behavioral testing revealing the appearance of L-DOPA (a pharamcological drug used to alleivate PD symptoms) reversible motor coordination defects at 52 weeks-of-age. At this time point, we found 40% of DA neurons in the SN degenerated and a significant reduction in the amount of DA axons projecting into the striatum of Mutator Parkin KO mice. This specific neuronal loss caused a depletion of DA in the striatum, which led to the motor deficits displayed in these mice. Age-matched wildtype, Parkin KO, and Mutator mice exhibited none of these abnormal behaviors or had any DA neurodegeneration present. The gross neuroanatomy and brain weight appeared normal in Mutator Parkin KO mice suggeting that DA neurons are particularly sensitive to mitochondrial defects. Our study provides the first evidence that endogenous Parkin protects DA neurons haboring high levels of deleterious mtDNA mutations implying an important role for Parkin in mitochondrial quality control *in vivo*.

Title: Role of pedunculopontine cholinergic neurons in the vulnerability of nigral dopaminergic neurons in Parkinson's disease

Authors: *M. BENSAID, P. P. MICHEL, E. C. HIRSCH, C. FRANCOIS;
ICM, Paris, France

Abstract: Pedunculopontine nucleus (PPN) cholinergic neurons, which exert excitatory nicotinic control over substantia nigra dopaminergic (DA) neurons, are largely affected in Parkinson's disease and their loss correlates with the level of DA denervation (Karachi et al, J Clin Invest, 2010). This finding and other studies showing that nicotine, the preferential agonist of nicotinic acetylcholine receptors, is neuroprotective in experimental models of Parkinson's disease (Quik et al, Mov Disord, 2013), suggest that PPN excitatory cholinergic inputs might contribute to the survival of substantia nigra DA neurons (Toulorge et al, Faseb J, 2011). To explore this possibility, we used lesion paradigms of DA and/or cholinergic systems in rats and in monkeys. Four groups of rats were used: 1) a group with a bilateral stereotaxic cholinergic lesion of the PPN with diphtheria toxin coupled to urotensin II, 2) a DA lesioned group with unilateral injection of 6-hydroxydopamine (6-OHDA) in the striatum in order to obtain a progressive and significant DA loss in the substantia nigra 3) a doubled lesioned group with unilateral 6-OHDA injection in the striatum followed by a bilateral injection of diphtheria toxin in the PPN, 4) a SHAM group with saline injections in the striatum and in the PPN. Consistent with our hypothesis, we observed that bilateral stereotaxic lesioning of PPN cholinergic neurons in rats resulted in a significant loss of DA neurons in the substantia nigra (27%). Unexpectedly, however, a loss of substantia nigra DA neurons, induced by unilateral striatal injection of 6-OHDA in rats, also produced an important and statistically significant decrease in PPN cholinergic neurons (32%). MPTP intoxication in macaques produced a small (7.2%) but statistically significant reduction in PPN cholinergic neurons compared to control animals. Lastly, when the PPN cholinergic lesion was performed in rats having initially received 6-OHDA in the striatum, i.e., when the process of DA degeneration had therefore already started, losses of DA and cholinergic neurons were more drastic than when each neurotransmitter system was lesioned separately. Thus, our results further highlight the key role of PPN cholinergic neurons in the pathophysiology of Parkinson's disease and suggest strong reciprocal interactions with nigral DA neurons.

Title: Behavioral pharmacological effects of dopaminergic drugs in common marmosets pretreated with subcutaneous MPTP and intra-cerebral 6-OHDA

Authors: *K. ANDO, C. NISHIME, K. KAWAI, R. INOUE, E. NISHINAKA, N. OKAHARA, T. INOUE, T. ITOH, H. TSUTSUMI;
Central Inst. for Exptl. Animals, Kawasaki, Japan

Abstract: The purpose of the present study was to investigate behavioral characterization of MPTP (1-1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine) and 6-hydroxydopamine (6-OHDA) in the common marmoset, a small primate. Behavioral pharmacological effects of dopaminergic drugs were also investigated in the marmosets pretreated with above toxins. MPTP-treated marmosets: MPTP at 2, 2 and 1 mg/kg on day 1, 2 and 3, respectively, was subcutaneously administered to marmosets (MPTP-marmosets). These with marked degeneration of dopaminergic neurons continued to exhibit moving tremor, immobility and other Parkinson's disease (PD)-like signs. In behavioral pharmacological test of apomorphine for observing circling behavior in cylinder-type equipment, four marmosets out of six exhibited either ipsilateral or contralateral circling after apomorphine at 0.125 mg/kg, s.c. Two other MPTP-marmosets and all six intact marmosets exhibited no circling behavior. Hemi-lateral brain infusion of 6-OHDA: 6-OHDA at 3 or 6 μg was infused into the right striatum. These marmosets did not exhibit clear PD-like signs after the infusion. Nevertheless, clear contralateral circling behavior was observed after apomorphine at 0.5 mg/kg, s.c. (n=12). However, marked degeneration of dopaminergic neurons in the striatum was not detected by tyrosine hydroxylase (TH) antibody histology in these marmosets. Bilateral brain infusion of 6-OHDA: The neural degeneration in the striatum was detected by the histology when 6-OHDA was infused into the medial forebrain bundle (MFB). Therefore, 6-OHDA at 30 μg was infused into each side of MFB (n=3). Some marmosets exhibited slight moving tremor after the infusion but no other clear PD-like signs were observed. Spontaneous motor activity of these marmosets in their individual living cages were measured and compared with intact marmosets (n=3) after administration of each dopaminergic drug. Increased levels of motor activity were observed after apomorphine at 0.5 mg/kg, s.c. during 30 - 60 min period and after L-DOPA at 10 mg/kg, p.o. during 60 - 120 min period in comparison with intact marmosets administered the same drug doses. Decreased

level was observed after methamphetamine at 1 mg/kg, s.c. during 0 - 180 min period. Discussion: Unbalanced neural degeneration in both sides of the brain was suggested by apomorphine-induced circling behavior in the MPTP-marmosets received peripheral administration of this toxin. In the preclinical study of PD, 6-OHDA-marmosets can provide bases for understanding actions of the new compounds in comparing with the dopaminergic agonist, dopamine releaser and drug for dopamine synthesis.

Title: Pharmacological validation of a new invertebrate model of Parkinson's disease: The moon jellyfish

Authors: *P. F. ARAVICH[1], V. CHEN[2], A. QUIDORT[2], Z. M. ARAVICH[1], J. H. PAVELA[2], F. A. LATTANZIO[3], D. B. SPANGENBERG[1];
[1]Path/Anat & Med., [3]Physiological Sci., [2]Eastern Virginia Med. Sch., NORFOLK, VA

Abstract: Parkinson's disease (PD) is a complex neurodegenerative disorder that needs simpler animal models. We explored the validity of a new invertebrate model using the ephyra stage of the widely available moon jellyfish (*Aurelia aurita*). It can be seen without a microscope, is inexpensive and easy to maintain, and flew on two space shuttle missions. It also has a full complement of physiological systems in a transparent body that is easily penetrated by toxins/drugs; a simple nervous system with transmitters like dopamine and glutamate; and a known mitochondrial genome. We previously found face validity for this model since the mitochondrial complex-1 inhibitor, rotenone, caused a dose-dependent poverty of movement. However, the validity of a new PD model requires responsiveness to L-DOPA, the classic treatment for PD. L-DOPA efficacy was tested in jellyfish matched for baseline motor activity (swimming pulses/min) and exposed to rotenone (final concentration 1 micromolar in 0.01% DMSO in artificial sea water) according to a 3x4 factorial design: zero, 0.5 & 5.0 nM L-DOPA concentrations (n=15 animals/group); and repeated measures over 1, 12, 24 & 48 hrs). It was found that L-DOPA reliably mitigated rotenone-induced motor deficits in a time and

concentration-dependent fashion: compared to controls, the high concentration significantly increased motor pulses at both 24 & 48 hrs while the low concentration increased pulses at 48 hrs. It was also shown that motor activity improved in all groups when removed from the rotenone, demonstrating a specific and reversible effect of the toxin rather than general malaise. It is concluded that these data show the predictive validity of a new model of PD using one of the evolutionarily oldest nervous systems on earth.

Title: A comprehensive tissue based biomarker approach to explore the roles of oxidative stress, mitochondrial dysfunction, and DNA damage in the pathogenesis of parkinson's disease by using a leucine-rich repeat kinase 2 (LRRK2) knockout rat

Authors: *W. A. SPECKMANN[1], Z. FENG[2], R. BROCKETT[4], F. AHMADI[5], K. LONG[5], J. NUCKOLLS[6], A. MCCOY[6], J. BODE[3];
[1]Millipore, TEMECULA, CA; [2]R&D, [3]Eurofins Pharma Bioanalytics Services US Inc, St. Charles, MO; [4]R&D, [5]Marketing, EMD Millipore, Temecula, CA; [6]SAGE Labs, Saint Louis, MO

Abstract: Parkinson's Disease (PD) is the second most common neurodegenerative disease, affecting ~2% of the population that is 60 years of age or older. Autosomal-dominant mutations in the leucine-rich repeat kinase 2 (LRRK2) gene is associated with both familial and late-onset PD which compose ~13% of PD cases. Oxidative damage, mitochondrial dysfunction, and abnormal protein aggregation have been identified as key players in the pathogenesis of PD and LRRK2 has been implicated in each of these diverse effects in addition to its known functionality in normal cellular activities including neurite outgrowth, vesicular trafficking, phosphorylation, protein translation, and autophagy. Yet, LRRK2's exact etiology in disease progression remains unclear. To further elucidate the role of LRRK2 with PD, we have initiated a comprehensive tissue based biomarker screening analysis of LRRK2 knockout rats. Kidney and brain samples were collected from 11 week old male homozygous LRRK2 knockout rats and

from age matched wild type controls (SAGE Labs). Tissue sections were prepared and stained for histopathology and immunohistochemistry (IHC) and whole slide images were subsequently captured. Histopathological abnormalities in kidneys of the knockout rat were characterized by a loss of tubular architecture, damage to proximal /distal tubule and cast formation. Nissl staining of the brains indicated that there were no observable neuropathological changes. For IHC, a range of targets were analyzed focusing on oxidative stress, mitochondrial function, DNA damage, and kidney function screening both brain and kidney samples. The cellular levels for many of the targets in the panels were essentially unchanged for both wild type and knockout animals, but certain markers showed significant fluctuations in their expression suggesting that the knock out was affecting the normal physiology of the animals. In conjunction with the published data, our results indicate that the kidney abnormality observed in the young LRRK2 knockout rats could be further developed as a potential biomarker for assessing safety liabilities of putative LRRK2 inhibitors as PD therapeutics. Understanding integration of LRRK2 signaling processes and elucidating interaction with other pathways could provide insights for target identification, mechanism study, and ultimately lead to novel therapeutic development for this multiple etiological factors disease.

Title: Underlying mechanisms from motor symptoms of the Alpha-synuclein Parkinson Disease rat model

Authors: *I. BRYS[1,2], R. FUENTES[1], J. NUNES[1,3], B. SCHNEIDER[4], P. AEBISCHER[4], M. A. L. NICOLELIS[1,5];
[1]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil; [2]Psychobiology, Federal Univ. of Rio Grande do Norte, Natal, Brazil; [3]Univ. Potiguar, Natal, Brazil; [4]École Polytechnique Federale de Lausanne, Lausanne, Switzerland; [5]Duke Univ., Durham, NC

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder associated with motor symptoms, progressive loss of dopaminergic neurons in the nigrostriatal pathway and aberrant low-frequency synchronous corticostriatal oscillations. Alpha-synuclein is the major component of Lewy Bodies, the cytoplasmic protein aggregates present in the neurons of PD patients. Mutations in the gene encoding alpha-synuclein have been associated with familial cases of PD. In recent years the injection of viral vectors to overexpress alpha-synuclein in the substantia nigra has been used to reproduce the features of PD in animals. However, the underlying mechanisms of the motor symptoms from this model are still not totally understood. The aim of this work was to investigate the behavioral, histological and electrophysiological features of an AAV6 alpha-synuclein rat model of PD. Sprague-Dawley male rats were injected with empty viral vector suspension AAV6 (Control) or the vector carrying the gene for wild type human alpha-synuclein (Synuclein) in the substantia nigra. Animals were tested for locomotor activity in the Open Field test and asymmetry in the Cylinder test 1 week before viral injections and weekly from weeks 4 - 10 following injection. A separate group of animals was injected with empty viral vector AAV6 in the substantia nigra of one hemisphere and the vector carrying the gene for alpha-synuclein in the other hemisphere. These animals were implanted in both hemispheres with 64 recording electrodes in the motor cortex and striatum. Electrophysiological recordings were performed in freely moving rats for 10 weeks following the viral injection. Animals were perfused at the end of the survival time, the brains were collected and the tissue was used for Tyrosine Hydroxylase (TH), microglial activation (ED1) and alpha-synuclein immunostaining. Animals from the Synuclein group showed a significant decrease in the use of the forepaw contralateral to the lesion after the viral injection [$F(3.8,58.1)=3.4$, $p<0.05$] in the Cylinder test. Alpha-synuclein resulted in ED1 expression in the injection region. TH staining revealed a reduction of 32.9% in the striatal innervation and 43.4% of neuronal loss in the substantia nigra of the synuclein expressing side. Changes in the spectral power components of the local field potential of motor cortex and striatum were assessed. Motor symptoms present in the alpha-synuclein PD model are associated with dopaminergic neuronal loss and inflammatory

response resulting from alpha-synuclein overexpression. The model reproduces the major features of PD and might be useful to study the underlying mechanisms of PD and for preclinical testing.

Title: N-α-synuclein specific CD4+ effector T cell line exacerbates 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine induced neurodegeneration in a mouse model of Parkinson's disease

Authors: R. A. WILSHUSEN, K. M. ANDERSON, A. M. SZLACHETKA, *R. MOSLEY; Dept Pharmacol. and Exp Neurosci., Univ. Nebraska Med. Ctr., OMAHA, NE

Abstract: Inflammation and oxidative stress play critical roles in Parkinson's disease (PD). We have previously shown in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model that adoptive transfer of effector T cells (Teffs) that recognize nitrated α-synuclein (N-α-syn) as non-self exacerbates microglial-mediated neuroinflammation with amplified dopaminergic neurodegeneration as well as accelerated and prolonged MPTP-induced neuropathology. Moreover, Teffs that secrete IL-17 (Th17 phenotype) exacerbate neurodegeneration to greater levels than those Teffs that secret IFNɣ (Th1 phenotype). The specific cellular and molecular mechanisms by which these Teffs modulate neurodegeneration remain enigmatic. However, increasing evidence suggests that neurotoxic inflammatory activities have a profound effect on the pathogenesis and progression of PD. Herein, we report on the generation and long-term culture of an N-α-syn specific CD4+ Teff line that induces increased production of reactive nitrogen species (RNS) from myeloid lineage cells and also intensifies the loss of tyrosine hydroxylase (TH) positive neurons within the SN of MPTP-intoxicated mice. Flow cytometric analysis showed the T cell line exhibited very distinct

expression of CD3 and CD4 cell surface markers and intracellular IL-17a cytokine, moderate staining for surface CD146, and little expression of CD8 and FoxP3. Analysis of secreted cytokines revealed the N-α-syn-specific CD4+ Teff line produced high levels of IL-17, TNF-α and IFN-γ, intermediate levels of IL-10, but low levels of IL-2, IL-6, and IL-4 suggesting characteristics consistent with a Th17 cell line, but also exhibiting attributes of Th1-type T cells. Co-culture of the T cell line with N-α-syn and BV-2 cells increased RNS production by BV-2 cells by 150% compared to BV-2 controls cultured in the absence of T cells. Lastly, adoptive transfer of the cells from the Teff line to MPTP-intoxicated mice increased the loss of TH+ dopaminergic neurons by 63% compared to controls. Together, these results support the notion that effector T cells specific for N-α-syn increase oxidative stress as measured by RNS release from reactive myeloid microglia, increase the loss of TH+ neurons, and thus may play a pivotal role in the tempo and progression of dopaminergic neurodegeneration in PD.

Title: Dysregulation of polycomb repressive complex 2 (PRC2) activity in Huntington's disease

Authors: *R. J. FENSTER[1,2,3], A. M. HEILBUT[1,4], R. KULICKE[1,2], L. J. HACHIGIAN[1,6,2], E. D. KOLACZYK[5,4], J. P. MESIROV[1,4], M. HEIMAN[6,1,2];

Abstract: Huntington's disease (HD) is an autosomal dominant, fatally progressive neurodegenerative disorder caused by the expansion of CAG tri-nucleotide repeats in the *huntingtin* (*HTT*) gene. Although the gene is expressed nearly ubiquitously throughout the brain, some cell types display enhanced vulnerability in HD. The reason for this enhanced vulnerability

is unknown, but offers the potential to identify a therapeutic opportunity. Transcriptional dysregulation is known to be a characteristic of the pathophysiology seen in HD, but whether this dysregulation contributes to the enhanced vulnerability seen for certain cell types in the disease remains unclear. We have used the cell-type specific translating ribosome affinity purification (TRAP) methodology to profile gene expression changes occurring in the most vulnerable cell types in various HD mouse models, at different time points of disease progression. Using these TRAP data, in conjunction with published human HD transcriptional studies, we searched for over-representation of regulatory motifs among the genes whose expression was altered in the most HD-vulnerable cell types: deep-layer cortical neurons and striatal medium spiny neurons. Our analyses revealed an enrichment of genes regulated by the polycomb repressive complex 2 (PRC2) in these most vulnerable cell types, and that a large fraction of those genes with altered expression in HD disease models also contained PRC2 regulatory motifs in their promoters. Given that mutant HTT has been previously shown to activate PRC2 in a CAG-repeat-length-dependent manner, we have further investigated PRC2 function in HD mouse models. By immunostaining, we identified changes to PRC2-dependent histone methylation marks in several mouse models of HD versus control littermates. Of note, the largest of these PRC2-dependent methylation changes were found in the striatum, a region of highest vulnerability in HD. These data together demonstrate that aberrant PRC2 activity is involved in the transcriptional dysregulation that is observed in HD, and that there are brain region-specific differences to changes in PRC2 activity in HD.

Title: Dysregulated cysteine homeostasis mediates neurodegeneration in Huntington’s disease

Authors: *B. D. PAUL, J. I. SBODIO, R. XU, M. S. VANDIVER, J. Y. CHA, A. M. SNOWMAN, S. H. SNYDER;
The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., BALTIMORE, MD

Abstract: Cysteine is a versatile thiol, which is a building block for proteins and the antioxidant glutathione. Cysteine by itself has substantial antioxidant potential and is the substrate for generation of the gaseous signaling molecule, hydrogen sulfide. One of the modes by which hydrogen sulfide acts is by the process of sulfhydration, wherein the -SH group of cysteine is converted to an -SSH. Sulfhydration mediates various cytoprotective functions in the brain. Cystathionine gamma lyase (CSE) is the sole enzyme which synthesizes cysteine via the transsulfuration pathway in mammals. CSE is induced in response to oxidative stress, which confers cytoprotection via cysteine and hydrogen sulfide production. Depletion of CSE causes elevated oxidative stress and susceptibility to stress induced by 3-nitropropionic acid (3-NP) and excitotoxins such as kainate and glutamate leading to a reduction in neuronal glutathione content and hydrogen sulfide production. We show that CSE is depleted in Huntington's disease (HD) which contributes to neurotoxicity. The decrease in CSE levels seems to stem from the inhibitory effect of mutant huntingtin on specificity factor 1 (Sp1), the transcription factor for CSE. Treatment of striatal cells derived from transgenic models of HD or transgenic R6/2 mice with cysteine donors alleviates this stress and improves associated behavioral abnormalities in mice. We propose that stimulation of the transsulfuration pathway could be a therapeutic measure for treatment of neurodegenerative diseases involving oxidative stress such as HD. Taken together, our results unravel a hitherto unrecognized role for CSE in redox homeostasis in the brain.

Title: *In vivo* synthetic lethal screening in the mammalian central nervous system

Authors: *R. SHEMA[1,2,3], R. KULICKE[1,2,3], M. HEIMAN[1,2,3];
[1]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]The Broad Inst. of MIT and Harvard, Cambridge, MA; [3]the Picower Inst. for Learning and Memory, Cambridge, MA

Abstract: Understanding the molecular basis of neurodegenerative diseases (NDDs), and how they interact with the aging process, is one of the greatest challenges in neuroscience. As the most common NDDs, including Alzheimer's, Parkinson's, and Huntington's diseases remain essentially without a cure, the search for therapeutic targets becomes imperative. We have developed a novel platform for the study of NDDs, utilizing the disease-relevant cellular populations in their natural environment. For these screens, which we term SLIC (Synthetic Lethal In the Central nervous system), pooled libraries of lentivirus for knock-down, knock-out, or over-expression of all known genes in the genome are injected into the relevant disease regions in the mouse brain, with one barcoded virus infecting one cell. Comparison, by genomic sequencing, of lentiviruses that are retrieved from wild-type animals, but not from disease model littermates, after various times of incubation in the mouse brain, reveals target genes that function as enhancers of toxicity specific to the disease-associated mutation. We have implemented SLIC for the study of Huntington's disease, the most common inherited neurodegenerative disorder, which is caused by abnormal expansion of a cytosine-adenine-guanine (CAG) tri-nucleotide repeats in the coding region of the huntingtin gene (Htt). Employing SLIC screening across several Huntington's disease mice models, we demonstrate that not only is SLIC capable of identifying enhancers of lethality *in vivo* in the mammalian brain, but that it is able to generate novel hypotheses regarding disease mechanisms and potential therapeutic interventions.

Title: Study of tau expression in Huntington´s disease

Authors: M. FERNANDEZ-NOGALES[1], J. CABRERA[1], M. SANTOS-GALINDO[1], J. HOOZEMANS[2], I. FERRER[3], A. ROZEMULLER[2], F. HERNANDEZ[1], J. AVILA[1], *J. J. LUCAS[1];
[1]CSIC/UAM, Madrid, Spain; [2]VU Univ. Med. Ctr., Amsterdam, Netherlands; [3]IDIBELL-University Hosp. Bellvitge, UB, Barcelona, Spain

Abstract: Tauopathies are a group of neurodegenerative diseases such as Alzheimer's disease (AD), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), Pick's disease (PiD), or frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17) that are characterized by altered metabolism and deposition of the microtubule associated protein tau. Alternative splicing of *tau* exon 10 results in tau isoforms containing either three or four microtubule-binding repeats (3R-tau and 4R-tau). Discovery of silence and intronic mutations leading to increased 4R/3R ratio in FTDP-17 affected families revealed that a disbalance in 4R-tau and 3R-tau in favor of the 4R isoform is sufficient to cause neurodegeneration with personality disturbances, dementia and motor dysfunction. Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder characterized by involuntary movements, psychiatric symptoms and dementia that is caused by an expanded CAG repeat in exon 1 of the *Huntingtin* (*HTT*) gene. HD thus belongs to the group of dominant trinucleotide repeat diseases that include many other CAG repeat disorders such as the spinocerebellar ataxias SCA1, SCA2, SCA3, SCA6, SCA7, SCA12, SCA17, dentatorubropallidoluysian atrophy (DRPLA) and spinobulbar muscular atrophy (SBMA) as well as the CUG repeat disorders SCA8 and myotonic dystrophy 1 (DM1). A key element in the pathogenesis of the latter is the binding of splicing factors by the mutant CUG transcript, thus leading to alternative splicing aberrations in multiple genes. Intriguingly, CAG repeats have recently been shown to mimic CUG repeats in the misregulation of alternative splicing. Since it has also been very recently reported that aberrant splicing contributes to the generation of the highly toxic short N-terminal species of HTT, it is conceivable that splicing alterations significantly contribute to HD pathogenesis. Here we aim to explore whether the neurodegeneration-causing increase in 4R/3R-tau mRNA ratio occurs in HD

by performing quantitative RT-PCR from RNA extracted from striatum and cortex of HD and control subjects.

Title: Inhibition of excessive monoamine oxidase A/B activity protects against increased stress-induced neuronal death in Huntington disease

Authors: ***M. A. POULADI**[1], J. OOI[2], M. R. HAYDEN[3];
[1]A*STAR and Natl. Univ. of Singapore (NUS), Singapore, Singapore; [2]Translational Lab. In Genet. Med., Agency for Science, Technol. and Res. (A*STAR), Singapore, Singapore; [3]Translational Lab. In Genet. Med., Agency for Science, Technol. and Res. (A*STAR), Natl. Univ. of Singapore (NUS), Singapore, Singapore

Abstract: Monoamine oxidases (MAO) are an important component of the homeostatic machinery that maintains the levels of monoamine neurotransmitters, including dopamine, in balance. Given the imbalance in dopamine levels observed in HD, the aim of this study was to examine MAO activity in cellular models of HD and in patient dermal fibroblasts. We show that cells expressing mutant HTT exhibit increased MAO expression and activity. Using cellular stress paradigms, we further demonstrate that the increase in MAO activity in mutant cells is accompanied by enhanced susceptibility to oxidative stress and cell death. Treatment of mutant cells with MAO inhibitors ameliorated oxidative stress and reduced cell death. Consistent with the findings in striatal HD cells, we observe increased MAO expression and activity in patient dermal fibroblasts. Altogether, this study demonstrates abnormal MAO expression and activity and suggests a potential use for MAO inhibitors in HD.

Title: Sphingosine-1-phosphate metabolism/axis as potential therapeutic target in Huntington disease

Authors: *V. MAGLIONE, A. DI PARDO, E. AMICO, M. FAVELLATO, F. SQUITIERI; Ctr. for Neurogenetics and Rare Dis., IRCCS Neuromed, Pozzilli, Italy

Abstract: Background. Sphingosine-1-phosphate (S1P) is a potent signaling lipid that regulates a number of processes essential for cellular homeostasis, differentiation, motility and cell viability. S1P is normally found both in the intracellular and extracellular compartments. When S1P is exported outside of the cell, it acts as a high affinity agonist at five known G protein-coupled receptors, S1PR1-S1PR5, normally expressed in neurons, astrocytes and oligodendrocytes. S1P metabolism is quite complex and involves the action of different enzymes. S1P is synthesized by sphingosine kinase-1 and -2 (SPHK1 and 2 and degraded either by S1P-phosphate (SPP) or by S1P-lyase (SGPL1). Thus, the overall cellular S1P level is determined by a balance between its synthesis and degradation and any alteration in its metabolism is likely to have profound impact on both brain homeostasis and function. Emerging evidence indicates that pharmacological interference with S1P metabolizing enzymes may represent a promising therapeutic approach for multiple disorders including neurological diseases. Aim. Recently, we have demonstrated that chronic administration of FTY720, a synthetic analog of S1P, is neuroprotective and neurorestorative in Huntington disease (HD) R6/2 mouse model. In this study, our aim is to explore whether S1P metabolism/signaling pathway may represent a molecular target for developing new therapeutic strategies for the treatment of HD. Results. Our findings highlight an altered expression of some of the S1P metabolizing enzymes in both cellular and animal models of HD. In particular, we found that immunoblotting analysis on lysate from HD mouse brain tissues revealed increased expression of SGPL1 which might likely result in its increased activity and subsequent alteration of S1P bio-availability. We also demonstrate that the stimulation of specific S1PR subtypes activates pro-survival pathways in HD cells. Conclusion. These results let us suppose an aberrant metabolism of S1P in HD and indicate that modulation of its signaling pathway may be beneficial in HD. We believe S1P axis has the potential of providing the possibility to develop new therapeutic

interventions for treating HD, therefore further studies are warranted. This research is supported by Marie Curie International Incoming Fellowship (PIIF-GA-2011-300197) granted to V.M. within the 7th European Community Framework Programme.

Title: Dendritic loss is an early phenotype in rat cortico-striatal co-cultures expressing mutant huntingtin

Authors: S. DIJKSTRA[1], R. VAN DE BOSPOORT[1], S. LACHIZE[1], S. FRATANTONI[1], J. VEENMAN[1], N. VAN DEN BERG[1], G. MCALLISTER[2], *D. F. FISCHER[1], S.-W. JANG[3]; [1]BioFocus, Leiden, Netherlands; [2]BioFocus, Saffron Walden, United Kingdom; [3]CHDI Mgmt. / CHDI Fndn., New York, NY

Abstract: Phenotypic assays in primary neurons can be used to discover and validate potential novel therapeutic strategies for Huntington's disease (HD). We are using rat primary neuronal cortico-striatal co-cultures based upon Kaltenbach et al 2010, J Biomol. Screen., but with inducible expression of expanded repeat huntingtin (mutHTT) exon 1 fragments. Cortical and striatal neurons are isolated from E18 rat embryos and transfected with a HTT exon 1 fragment containing 73 CAG repeats (Q73), together with a plasmid encoding a fluorescent reporter (different for striatal and cortical neurons), before being plated on a glial cell feeder layer. Striatal and cortical cell populations are identified within the co-cultures by their respective fluorescent reporter signals, using automated high content imaging and analysis. The inducible expression system allows for a period of neuronal maturation *in vitro* before mutHTT expression to explore polyQ dependent phenotypic changes that may be relevant to the neuronal dysfunction found in HD. A unique feature of this inducible system is that it allows candidate compound testing both as a preventive treatment and as a therapeutic treatment. We have previously characterized the time course of mutHTT expression, aggregation and neuronal death in this

system, showing that when mutHTT was induced at 4 days *in vitro* (DIV), cell loss was observed between 11-14 DIV. Here, we describe mutHTT-induced changes in the striatal dendritic tree. To measure the striatal dendritic tree, a MAP2 tag was fused to the striatal reporter to localize the fluorescent signal to dendrites. Using this reporter we observed a gradual reduction in total striatal dendrite area in Q73- compared to non-induced controls, reaching ~50% at DIV12. No dendrite loss was observed in control cultures transfected with a non-expanded HTT fragment (Q8), indicating that the effect was specific for mutHTT. Striatal dendrite loss was evident within days after induction and appeared to precede loss of striatal or cortical cells. The MLK inhibitor CEP-1347, but not the neurotrophin BDNF, was able to significantly ameliorate the Q73-induced dendrite loss at DIV10. We are currently profiling additional compounds targeting pathways implicated in dendritic remodeling.

Title: Age dependent changes in M4-mediated control of striatal glutamate and dopamine signaling in the YAC128 mouse model of Huntington's disease

Authors: *T. PANCANI[1], T. BICHELL[2], D. FOSTER[2], E. BRADLEY[2], M. C. FERGUSON[2], T. BRIDGES[2], S. DANIELS[2], A. BOWMAN[2], C. W. LINDSLEY[2], P. J. CONN[2], Z. XIANG[2]; [1]Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ. Medcenter, Nashville, TN; [2]Vanderbilt Univ., Nashville, TN

Abstract: Huntington disease (HD) is a neurodegenerative disease characterized by severe motor and behavioral alterations. The appearance of a hyperkinetic phenotype (chorea) marks the beginning of the motor symptomatic stage, and is followed by akinesia and progressive loss of striatal medium spiny neurons (MSNs). Changes in signaling of glutamate and other neurotransmitters including dopamine are demonstrated to be responsible for behavioral and neuropathological changes. Interestingly, these changes seem to largely precede the onset of the disease's symptoms. At early age, the YAC128 mouse model of HD shows motor hyperactivity associated with increased striatal glutamate transmission and likely dopamine signaling as well, while late akinesia is accompanied by striatal neuronal loss and decreased glutamatergic/dopaminergic transmission. Striatal cholinergic activity and muscarinic receptor (mAChR) functions seem to be also compromised in HD. A handful of clinical studies show that cholinesterase inhibitors might provide symptomatic relief in HD patients. The M4 mAChR, one of the functionally predominant mAChR subtypes in the striatum, is involved in the modulation of striatal glutamate and dopamine signaling (Pancani et al. 2014, Byun et al. 2014) and is also known to play a pivotal role in locomotor activity and control. Using slice electrophysiology and fast cyclic voltammetry in conjunction with behavioral assay, we found that eEPSC as well as sEPSC amplitude in MSNs and evoked dopamine (DA) release in the striatum are increased in YAC128 compared to WT at a pre-symptomatic stage (2 months). Interestingly, the increased release of neurotransmitters is accompanied by increases in M4 brain expression as well as M4-

mediated inhibition of cortico-striatal glutamate transmission and striatal DA release, suggesting that striatal M4 function is up regulated in HD. Deletion of M4 in YAC128 mice dramatically exacerbates the increase in glutamate release in the striatum. Finally, alterations in Rotarod and open field performance were detected at as early as 5 months of age and were significantly correlated with a decrease in glutamatergic signaling in YAC128 compared to WT mice. Our data suggest that the early increase in striatal glutamate and dopamine release in YAC128 might contribute to the increased neurotoxicity, cortico-striatal "disconnection" and behavioral impairment at later age (5 months). The transient early increase in M4 activity could represent a neuroprotective, compensatory mechanism aimed to decrease glutamate and dopamine tone in the YAC128 mouse.

Title: RTP801 mediates mutant huntingtin-induced cell death

Authors: N. MARTÍN-FLORES[1], J. ROMANÍ-AUMEDES[1], M. CANAL[1], P. SANDERS[2], M. STRACCIA[2], L. RUÉ[2], C. SVENDSEN[3], N. D. ALLEN[4], J. ALBERCH[2], J. CANALS[2], *E. PEREZ-NAVARRO[2], C. MALAGELADA[1];

Abstract: Selective neuronal death is a hallmark in the pathogenesis of Huntington's disease (HD) although the mechanisms underlying the toxicity of mutant huntingtin (htt) are still unclear. RTP801 is a stress responsive protein that has a pro-apoptotic role in non-proliferating differentiated cells such as neurons. The mechanism by which RTP801 triggers neuronal cell death is by a sequential inhibition of mTOR and Akt survival kinases. RTP801 is induced in cellular and animal models of Parkinson's Disease and its expression is elevated in nigral neurons from PD human brains. Thus here we have investigated whether RTP801 is involved in mutant htt-induced neuronal death. Overexpression of exon-1 mutant htt in NGF-differentiated PC12 cells elevated RTP801 protein levels by induction of gene expression, and by lengthening RTP801 protein half-life. RTP801 induction was confirmed in rat cortical neurons in culture. During the differentiation to medium spiny neurons of human induced pluripotent stem cell (iPSC) lines containing either a wild type or mutant htt with 60 CAG repeats, elevation of RTP801 protein levels was observed in the mutant iPSC line in comparison to the wild type control. Consistently in NGF-differentiated PC12 cells, silencing RTP801 expression with shRNAs blocked mutant htt-induced cell death. In HD animal models that display motor deficits but no neuronal death such as the knock-in HdhQ7/Q111 and the exon-1 R6/1 mice, RTP801 levels in the striatum did not differ from their wild type littermates at several stages of the disease. Importantly, RTP801 protein levels were elevated in human HD brains, meaning that the relationship between mutant htt and RTP801 may be relevant to the human disease. Taken together these results indicate that RTP801 is a novel downstream effector of mutant htt toxicity.

Title: Expression of mutant huntingtin in astrocytes suppresses BDNF secretion

Authors: *Y. HONG, T. ZHAO, X.-J. LI, S.-H. LI;
Human Genet., Emory Univ., Atlanta, GA

Abstract: Huntington's disease (HD) is a fatal, inherited, neurodegenerative disease that affects one in every 10,000 Americans. There is no effective treatment for HD to date because of the unknown pathological mechanism. Previous studies mainly focus on neurons, because neuronal loss occurs preferentially in the striatum and then extends to other brain regions as HD progresses. However, astrocyte dysfunction has been found in several neurological disorders, including Epilepsy, ALS and Stroke. In the central nervous system, astrocytes are the largest cell population and play multiple roles in regulating neuronal functions. Among their multiple functions, astrocytes can synthesize and release some important neurotrophic factors including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and glial cell derived neurotrophic factor (GDNF). All of these factors are involved in neuronal survival, development, and function. A large number of studies in HD mouse models indicate that BDNF deficit in the striatum and cerebral cortex occurs before brain pathology, which has led to the idea that reduced endogenous neurotrophic support may contribute to HD onset and/or progression. Mutant huntingtin (mhtt) is found in glial cells in the brains of HD mice and patients; however, little is known about the pathological roles of mhtt in astrocytes. Whether mhtt expressed in astrocytes interferes with BDNF synthesis and release to contribute to selective neuronal degeneration in HD remains unknown. In this study, we used a transgenic HD mouse model (GFAP-160Q) that specifically expresses N-terminal mhtt in astrocytes to study the effect of mhtt on BDNF secretion. Western blot and real-time PCR results show no significant difference of BDNF level in astrocytes between WT and GFAP-160Q mice. However, ELISA results demonstrate that the secretion level of mature BDNF is decreased in the culture medium of astrocytes from GFAP-160Q mice compared with WT. These results indicate that mhtt may impair secretion of BDNF from astrocytes, which might contribute to the neuronal dysfunction and degeneration in HD. The mechanism of decreased BDNF secretion is under investigation

Title: Studying turnover of mutant huntingtin in neuronal and glial cells at subcellular level

Authors: *T. ZHAO, Y. HONG, S.-H. LI, X.-J. LI;
Human Genet., Emory Univ., Atlanta, GA

Abstract: Huntington's disease (HD) is an autosomal dominant, neurodegenerative disease that affects one in every 10,000 Americans. About 200,000 Americans are at risk of inheriting the disease from affected parents. HD patients are characterized by motor, cognitive and neuropsychiatric abnormalities. HD is caused by the expansion of the trinucleotide CAG (>37 units) encoding an expanded stretch of polyglutamine (PolyQ) in the N terminal region of mutant huntingtin (mhtt). Mhtt is neurotoxic and induces neuronal death by disturbing gene expression, axonal transport, and mitochondrial function. Mhtt is prone to forming insoluble aggregates. Appearance of mhtt aggregates is indicative of the accumulation of mhtt. In HD, progressive emergence of mhtt aggregates in neurons is observed. Compared to neurons, fewer and smaller mhtt aggregates are found in astrocytes. Furthermore, the mhtt aggregates preferentially form in neuronal neurites and nuclei, and few aggregates form in the cytosol of soma. This implicates that degradation rates of mhtt in different subcellular compartments are uneven. In order to study degradation rates of mhtt in subcellular compartments, we conjugate dendra2, a photoconvertible fluorescent protein, to the N-terminal fragmented mhtt (N230-130Q) and wild-type htt (N230-23Q) that is used as the control. Dendra2 is irreversibly photoconverted from a green to a red fluorescent state with 405nm light in the neuronal compartments. After photoconversion, decline of red signal over time is used to measure the degradation rates of N230(130/23Q)-dendra2 in the subcellular compartments. In the present study we used brain slice and primary culture models. We found that mhtt is degraded faster than wild-type htt in the cytosol of soma in neurons. However, expanded polyQ stabilizes mhtt in neurites. By contrast, mhtt is cleared faster than wild-type htt in both cytosol of soma and processes of astrocytes. Our data demonstrates

uneven clearance rates of mhtt in distinct subcellular compartments and indicates that astrocytes and neurons cope with mhtt in different ways.

Title: CalDAG-GEFI and CalDAG-GEFII are down-regulated in the R6/2 Huntington's disease mouse model and show reduced H3K4 trimethylation in a pattern typical of dysregulated neuronal genes

Authors: *J. R. CRITTENDEN[1], F. YILDIRIM[2], H. A. BOWDEN[1], T. A. GIPSON[2], C. W. NG[2], E. FRAENKEL[2], D. E. HOUSMAN[2], A. M. GRAYBIEL[1];

Abstract: Huntington's disease is caused by the expansion of a glutamine tract in the Huntingtin protein, resulting in neurodegeneration in the striatum and cerebral cortex and progressively severe psychiatric and motor symptoms. In rodent models that express full-length or pathogenic fragments of mutant Huntingtin, there is notably less cell death than in the human disease, but there is nevertheless a strong overlap in the sets of dysregulated genes observed. This overlap in gene dysregulation appears to be, at least in part, related to shared changes in the function of transcription factors and epigenetic regulators. By genome-wide analyses of an epigenetic mark, histone H3K4 trimethylation, and gene transcription in the R6/2 mouse model of Huntington's disease, we identified the striatum-enriched genes CalDAG-GEFI and CalDAG-GEFII (aka RasGRP2 and RasGRP1) to have lower expression and reduced histone H3K4 trimethylation levels. CalDAG-GEFI is predominantly expressed in the matrix compartment of

the striatum, which receives input from sensorimotor cortices and sends projections to the primary output nuclei of the basal ganglia. By contrast, CalDAG-GEFII is differentially expressed in the striosome compartment, which receives inputs from limbic cortical regions and sends projections to dopamine-containing neurons in the substantia nigra pars compacta, placing striosomes in a circuit involved in mood and motivation. In Huntington's disease, differential degeneration in striosomes, relative to degeneration in the matrix, has been linked to disease onset with prominent mood symptoms. At the protein level, we previously showed that CalDAG-GEFI is reduced in Huntington's disease. We now report that mRNA transcript and protein for CalDAG-GEFII are severely reduced in striatum from aged R6/2 mice. Furthermore, we show that the genes encoding CalDAG-GEFI and CalDAG-GEFII show reduced H3K4 methylation and display a distinct H3K4 trimethylation profile around their transcription start sites that is typical of Class I neuronal genes that are down-regulated in expression in Huntington's disease (Vashishtha et al., 2013). The functional consequences of CalDAG-GEFI and CalDAG-GEFII down-regulation are under evaluation by comparing the phenotypes in CalDAG-GEFI and CalDAG-GEFII knockout mice to those in Huntington's disease models. Title: Mutant huntingtin causes loss of mechanisms underlying early cognitive deficits in Huntington's disease

Authors: *R. P. MURMU[1,2], W. LI[2], J.-Y. LI[2];
[1]Panum Inst., Copenhagen, Denmark; [2]Dept. of Exptl. Med. Sci., Lund Univ., Lund, Sweden

Abstract: In Huntington's disease (HD), cognitive symptoms and cellular dysfunction precede the onset of classical motor symptoms and neuronal death in the striatum and cortex by a decade.

This suggests that the early cognitive deficits may be due to a cellular dysfunction rather than being a consequence of neuronal loss. Abnormalities in dendritic spines and abnormal synaptic plasticity, which are observed in HD patients and in HD animal models are thought to underlie the early cognitive symptoms in HD. However, the exact kinetics of spine alterations and plasticity in HD remain unknown. Experience-dependent synaptic plasticity caused by mechanisms such as LTP or novel sensory experience potentiates synaptic strength, enhances new dendritic spine formation and stabilization and may contribute to normal cognitive processes, such as learning and memory. Although, HD is a autosomal dominant disorder studies show that the disease phenotype is modulated by environmental factors. In this study, we used long-term, two-photon imaging through a cranial window, to track individual dendritic spines in a mouse model of HD (R6/2) as the disease progressed. Additionally, we investigated whether pathological processes of HD interfered with the normal experience-dependent plasticity of dendritic spines in the R6/2 model. Six weeks of two-photon *in vivo* imaging revealed that under baseline condition (without any sensory manipulation) neuronal circuitry in HD mouse model is highly unstable which led to a progressive loss of persistent-type, mature spines in these mice. Although, more new spines formed in the R6/2 mice, the probability that newly formed spines transformed into persistent spines was greatly reduced in these mice. Further, we could show that mutant huntingtin was directly involved in the loss of persistent-type, mature spines. In addition, six-weeks of two-photon imaging before and after whisker trimming revealed that sensory deprivation exacerbates loss of persistent-type, stable spines in R6/2 mice and led to impaired transformation of newly generated spines into persistent spines in these mice thereby reducing synaptic density is barrel cortical neurons of R6/2 mice. Interestingly, dendritic spine alterations in the R6/2 mice were evident before the onset of motor symptoms suggesting that decreased stability of cortical synaptic circuits could underlie the early cognitive deficits in HD. This data also suggests that mutant huntingtin is implicated in maladaptive synaptic plasticity which could be one of the plausible mechanisms underlying early cognitive deficits observed in HD.

Title: Processing deficits in the behavioral modulation of striatal local field potential activity in the YAC128 mouse model of Huntington's disease

Authors: E. S. ZHANG, S. J. BARTON, *G. V. REBEC;
Program Neurosci & Dept. Psychological & Brain Sci.,, Indiana Univ., Bloomington, IN

Abstract: Growing evidence from transgenic mouse models suggests that dysfunctional neural processing in dorsal striatum plays a critical role in the behavioral phenotype of Huntington's disease (HD), a dominantly inherited condition. For example, in freely behaving symptomatic R6/2 mice, which express truncated human mutant huntingtin (mHTT) and develop an early behavioral phenotype, striatal local field potentials (LFPs) are characterized by high frequency oscillations not normally expressed in wild-type controls (Hong, S.L. et al., 2012, PLoS ONE, 7(10): e470246). Here, we recorded striatal LFPs in YAC128 mice, a full-length mHTT mouse model with adult-onset symptoms, and age-matched controls (FvB/N), while each mouse freely explored an open-field arena. We focused on LFP activity when the animals engaged in the following behavioral categories: quiet rest (no overt movement), repetitive grooming (face washing and fore- or hind limb scratching), and active exploration (locomotion, rearing, or climbing). All mice were between 33 and 65 weeks of age, a range in which some neurological signs are evident in the YAC128 model (van Raamsdonk, J.M. et al., 2005, J. Neurosci., 25:4169). We calculated an average power spectrum for each animal for each behavior. Both groups spent similar amounts of time in each behavioral category, but episodes of quiet rest were significantly longer in YAC128s than wild-types. Analysis of resting LFP activity indicated significant group power differences in the theta (4-7 Hz), beta (13-24 Hz), and low gamma range (25-40 Hz), consistent with our R6/2 data. Moreover, active exploration in wild-type and YAC128 mice was accompanied by differential changes in delta (1-4 Hz) and alpha (8-12 Hz) power. Collectively, our results confirm behavior-related striatal processing deficits in HD mice. In the YAC128 model, these deficits occur during quiet rest and active exploration at frequency bands associated with cognitive and motor processing. Thus, our results provide fundamental information on striatal activity that may be central to the HD behavioral phenotype.

Title: *In vivo* characterization of the basal ganglia direct, indirect, and hyperdirect pathways in the zQ175 heterozygous knock-in mouse model of Huntington's disease

Authors: S. ZHONG[1], H. LIN[1], N. KEATING[1], A. GHAVAMI[1], R. CACHOPE[2], *R. F. ROGERS[3], V. BEAUMONT[2];
[1]PsychoGenics, Inc., Tarrytown, NY; [2]CHDI Management, Inc., Los Angeles, CA; [3]CHDI Management, Inc., Princeton, NJ

Abstract: Huntington's disease (HD) is a lethal autosomal dominant neurodegenerative disorder caused by expansion of CAG repeats in the *Huntingtin (Htt)* gene. Post-mortem evaluation of HD patient brains reveal a devastation of both the caudate and putamen, in addition to other progressive grey matter, white matter, whole brain and regional atrophy[1]. Cortico-striatal-thalamo-cortical circuits are particularly affected in HD[2], and choreic symptoms especially have been strongly correlated with the preferential susceptibility of indirect pathway originating striatal medium spiny neurons (MSNs) to mutant Htt insult[3-4]. Impairments in corticostriatal transmission, and dysfunction of medium spiny neuron (MSN) activity has been extensively studied *in vitro* in HD models, but there has been very little functional investigation of the consequences of this on the immediate indirect pathway downstream nuclei, namely the external Globus Pallidus (GPe), and the subthalamic nucleus (STN). The purpose of the current study was to characterize the properties of cortical to basal ganglia transmission in microcircuit-defined neurons in early symptomatic zQ175 heterozygous knock-in mice (6 month old zQ175 HET), a model of HD that carries one allele of expanded CAG repeats contained within the native murine *huntingtin* gene. Under urethane anesthesia, the responses of striatal MSNs were recorded following stimulation of primary motor cortex (M1). MSNs were identified as belonging to either the (putative) indirect pathway (IP) or to the direct pathway (DP) by their (lack of) antidromic activation from electrical stimulation of the Substantia Nigra, respectively. Preliminary data obtained from these recordings indicate that zQ175KI HET mice show a reduced probability of MSN firing in response to M1 stimulation. Furthermore, a higher percentage of spontaneously active MSNs were recorded in zQ175KI HET compared to WT mice. Studies are underway to determine whether the stimulation-response curves are affected in both IP and DP neurons, or whether one pathway is preferentially affected. We have also started to investigate the “hyperdirect” cortico-STN pathway (HP) by recording STN neurons in response to M1 stimulation. Preliminary data indicates a modest reduction in STN responses to M1 stimulation in zQ175 Het mice. Our data together suggests that zQ175KI HET mice exhibit basal ganglia circuitry dysfunction relevant to the human HD condition. These studies may

produce physiological assays for assessing compounds that could rescue these circuitry disturbances.

Title: Ultra-sensitive detection of huntingtin protein in biofluids from Huntington disease patients and model mice using immunoprecipitation followed by flow cytometry

Authors: S. E. P. SMITH[1], A. L. SOUTHWELL[2], T. R. DAVIS[1], E. B. VILLANUEVA[2], *B. LEAVITT[2], A. G. SCHRUM[1], M. R. HAYDEN[2];
[1]Immunol., Mayo Clin. Col. of Med., Rochester, MN; [2]Dept. of Med. Genet., Ctr. For Mol. Med. & Therapeut., Vancouver, BC, Canada

Abstract: Huntington disease (HD) is a progressive neurodegenerative disorder caused by a CAG trinucleotide repeat mutation in the gene encoding for the huntingtin protein (HTT) resulting in the expansion of a polyglutamine tract. Although age of onset in HD can be predicted based on CAG repeat length, this variable accounts for only 50-70% of the variation, while multiple known and unknown genetic and environmental factors account for the remainder. Thus, there is a need for biomarkers that could more accurately predict disease conversion or progression. Levels of mutant HTT protein or of specific species of mutant HTT protein in the brain could be such biomarkers. Additionally, there are multiple HTT lowering therapeutics in clinical development, for which quantification of HTT levels in the brain would be useful to validate and quantify target engagement. Unfortunately, it is not currently possible to directly quantify HTT levels in the living brain of patients. HTT protein is present in cerebrospinal fluid and plasma, though at much lower concentrations than in brain. We propose that cerebrospinal fluid and/or plasma HTT levels could be used as a proxy for brain HTT levels,

but traditional protein quantitation methods have failed to accurately detect and measure HTT protein in biofluids. To overcome this limitation, we have adapted the technique of immunoprecipitation followed by flow cytometry (IP-FCM). IP-FCM is a highly sensitive method of protein detection that has previously been used to quantitatively measure both absolute protein abundance and stable or transient protein-protein interactions. We have screened available anti-HTT antibodies and identified capture-probe pairs that accurately detect HTT protein with enough sensitivity to allow detection of mutant huntingtin protein in the cerebrospinal fluid of HD patients and mice. By using different antibody pairs, specific species of HTT protein relevant to HD pathogenesis and progression, such as total HTT, mutant HTT, full-length HTT, and caspase 6 cleaved HTT, can be rapidly and accurately measured. This technique has potential applications both as a clinical diagnostic and as a research tool to further our understanding of levels and localization of specific HTT protein species over time.

Title: Respiratory activity of isolated mitochondria, cultured neurons, and whole YAC128 mice, a model of Huntington’s disease

Authors: *J. HAMILTON[1], T. BRUSTOVETSKY[1], N. BRUSTOVETSKY[1,2];
[1]Pharmacol. and Toxicology, [2]Stark Neurosciences Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Huntington’s disease (HD) is a hereditary neurodegenerative disorder characterized by severe motor and cognitive abnormalities. It is believed that HD is caused by a mutation in the huntingtin protein. Huntingtin is a ubiquitous 350 kDa protein that is involved in developmental processes and anti-apoptotic defense. In healthy individuals, the N-terminus of huntingtin possesses a polyglutamine stretch containing <35 glutamines. Increased number of

glutamines correlates with development of HD. In recent years, different hypotheses were proposed to explain the mechanism by which mHtt expression leads to neuronal dysfunction and loss. It has been shown that mHtt may affect autophagy, mitochondrial dynamics, and trafficking. In addition, there were reports of mHtt-mediated impairment of mitochondrial respiratory activity, although some investigators failed to find any difference in respiration of mitochondria and neurons derived from HD mice and wild-type (WT) animals. In the present study, we used YAC128 mice and their WT littermates. Each animal was genotyped and tissue samples were analyzed for mHtt using Western blotting. We evaluated respiratory activity and mitochondrial membrane potential in isolated, purified synaptic and non-synaptic brain mitochondria as well as in liver and heart mitochondria from WT mice and 4-5 month old YAC128, which displayed clasping behavior typical for HD mice. We used high-precision respirometry and evaluated mitochondrial membrane potential following tetraphenyl phosphonium (TPP^+) distribution across the inner membrane with a TPP^+-sensitive electrode. In addition, we evaluated respiration in cultured striatal and cortical neurons derived from postnatal day 1 YAC128 mice and their WT littermates. The neurons were grown for 9 days *in vitro*, then their respiration was analyzed in a bath solution containing either 10 mM glucose plus 15 mM pyruvate or 2.5 mM glucose alone, using Seahorse XF24 flux analyzer. Finally, we analyzed respiratory activity of whole YAC128 mice compared to WT littermates, using LabMaster Animal Monitoring System (TSE Systems, Midland, MI). In experiments with isolated mitochondria, we found no difference in respiratory activity and membrane potential between mitochondria from YAC128 mice and WT animals. Similarly, in experiments with cultured neurons no difference in respiratory activity was observed. Lastly, there was no difference in respiratory activity of whole YAC128 mice and WT animals. Thus, our data strongly argue against mHtt-mediated impairment of mitochondrial respiratory activity assessed either with isolated mitochondria, cultured neurons, or whole YAC128 mice.

Title: Activation of axonal JNKs represents an early pathogenic event in Huntington's disease that correlates with axonal degeneration

Authors: *R. G. GATTO[1], E. TAVASSOLI[1], Y. CHU[2], J. KORDOWER[2], G. A. MORFINI[1]; [1]Anat. and Cell Biol., Univ. of Illinois At Chicago, Chicago, IL; [2]Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL

Abstract: Huntington disease (HD) involves degeneration of specific populations of projection neurons within selected areas of the basal ganglia circuit. Nonetheless, the mechanisms underlying differential neuronal vulnerability of selected neuronal populations in HD remain unknown. Results from our previous studies showed that m Htt inhibits axonal transport through a mechanism involving activation of the c-Jun amino-terminal kinase (JNK) pathway and phosphorylation of the motor protein kinesin. Because axonal connectivity critically depends upon appropriate axonal transport, we analyzed the distribution and activation of several JNK pathway components in brains of transgenic R6/2 mice. Using a novel R6/2-YFP reporter mouse model, we present direct evidence that axonal degeneration represents a very early pathogenic event in mutant Huntingtin (mHtt)-affected neurons. Results from quantitative immunohistochemical and immunoblotting studies further revealed heterogeneous cellular distribution of specific JNK isoforms. Additionally, these studies revealed presymptomatic activation of axonal JNK in selected neuronal populations of R6/2 mice, compared to wild type littermates. Immunoblot analysis of control and HD patients confirmed these observations. Taken together, results from our work suggest that axonal degeneration represents a very early pathogenic event in HD. Further, our data suggest that the tissue pattern of JNK activation might contribute to the unique cellular topography of HD.

Title: M-channel activators rescue homeostatic regulation of striatal excitability and ameliorate locomotor deficits in the R6/2 Huntington's mouse

Authors: Y. CAO, D. BARTOLOME-MARTIN, N. ROTEM, C. ROZAS, S. S. DELLAL, M. A. CHACON, B. KADRIU, M. GULINELLO, K. KHODAKHAH, *D. S. FABER;
Albert Einstein Coll Med., BRONX, NY

Abstract: We describe a fast activity-dependent homeostatic (fADH) regulation of the intrinsic excitability of medium spiny neurons in mouse dorsal striatum. It can be induced *in vitro* by repeated brief bursts of evoked impulse activity, for example, by applying 300ms suprathreshold depolarizing pulses at a rate of $1s^{-1}$. With this paradigm, fADH is manifest as a progressive reduction in the number or frequency of stimulus evoked impulses and increased variability in interspike interval. That is, it appears as enhanced accommodation or adaptation. fADH develops and decays with time constants of 10 and 20s, respectively, and thus we hypothesize that it limits repetitive firing and can convert tonic neurons to phasic ones. fADH is not due to a rise in intracellular Ca^{2+}, as it is not affected by chelating this cation with BAPTA in the recording pipette. The properties of fADH are consistent with the hypothesis that it is due to a progressive recruitment or facilitation of the M-current that is mediated by KCNQ2/3 channels and is regulated by the level of phosphatidylinositol 4,5-bisphosphate (PIP2) in the plasma membrane . Three lines of evidence support this notion: 1) fADH is blocked by perfusion with the M-current antagonist XE 991 (6uM), 2) whole cell voltage clamp recordings indicate that fADH induction increases the magnitude of an outward XE 991 sensitive current, and 3) blocking PIP2 synthesis with 10uM Wortmannin reduces fADH. This homeostatic mechanism is significantly depressed in medium spiny neurons of the R6/2 and BAC HD transgenic mouse models of Huntington's Disease, at ages when the affected mice begin to exhibit overt locomotor impairments. This deficit in fADH can be at least partially reversed *in vitro* by superfusion with KCNQ channel activators, such as 10uM retigabine. Finally, to test whether M-current activation could ameliorate the locomotor deficits in the transgenic models, R6/2 mice were treated with daily i.p. injections of retigabine (10mg/kg), for four weeks, starting at 4 weeks of age, and locomotor activity was assessed with the open field test in weeks 5-7. Activity levels in the treated HD mice were significantly improved, in comparison with the untreated transgenic controls. Thus, we suggest that a functional down regulation of the M-current contributes to a neuronal hyperactivity and network dysregulation that may lead to the neurodegeneration observed in these model systems, and that KCNQ2/3 channel regulation may be a target for therapeutic intervention.

Title: Characterization of signature changes mediated by mutant huntingtin expression in cortico-striatal co-culture: Towards a drug screening platform

Authors: *C. BUREN, M. P. PARSONS, L. A. RAYMOND;
Psychiatry, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington disease (HD) is caused by a polyglutamine (polyQ) expansion in the N-terminal region of the huntingtin protein (Htt). This mutation results in synaptic dysfunction and eventual neurodegeneration that particularly affects the spiny projection neurons (SPNs) of the striatum. Several animal models of Huntington's disease (HD) show altered cortical-striatal (C-S) presynaptic glutamate release, glutamate uptake and trafficking/signaling of postsynaptic glutamate receptors. Synaptic changes precede the HD-like motor phenotype, and synaptic proteins form interaction hubs with Htt. Therapy to ameliorate functional deficits in neuronal circuitry may therefore delay HD onset and provide neuroprotection. Here, we aimed to characterize the "signature" changes in C-S synaptic transmission associated with mutant Htt expression in a reduced model system, the C-S co-culture, with the goal of using the model as a platform for testing therapeutics. Our results demonstrate progressive synaptic development on SPNs between day *in vitro* (DIV) 7 to DIV 21 in co-cultures from wild-type mice. Co-cultures from the YAC128 HD mouse model show similar development as wild-type up to DIV 14, after which there is a decline in excitatory, but not inhibitory, synaptic transmission. The reduction in frequency of miniature excitatory synaptic currents (mEPSCs) in YAC128 SPNs is not a result of reduced density of dendritic synapses, since the density of spines and co-localized puncta of postsynaptic (PSD-95) and presynaptic (VGLUT1) proteins were similar for wild-type and YAC128 SPNs at DIV 21. Surprisingly, YAC128 SPNs show significantly shorter total dendritic length by DIV21. In order to determine whether these changes are driven by aberrant cortical activity or secretion of growth factors, versus a cell autonomous effect of mHtt expression in SPNs, we employ "chimeric" co-cultures, comparing the four different combinations of cortical

and striatal neurons from wild-type and YAC128 mice. Potential treatments for recovery of excitatory synaptic transmission in YAC128 SPNs are under investigation.This co-culture system can facilitate mechanistic studies and serve as a drug screening platform for early HD synaptopathy.

Title: Calcium uptake capacity and induction of the permeability transition pore in brain mitochondria from YAC 128 mice

Authors: *J. J. PELLMAN[1], T. BRUSTOVETSKY[1], N. BRUSTOVETSKY[1,2];
[1]Pharmacol. and Toxicology, [2]Stark Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Aberrant mitochondrial calcium handling has been proposed to contribute to mitochondrial damage and neuronal injury in Huntington's disease (HD), a rare hereditary neurodegenerative disorder characterized by motor and cognitive dysfunction. HD pathogenesis is linked to a mutation in the huntingtin protein, a ubiquitous 350 kDa protein involved in developmental processes. The mutant huntingtin (mHtt) protein has an elongated polyglutamine stretch in the N-terminus that is believed to result in HD neuropathology. Despite numerous studies, the mechanisms of deleterious mHtt action are not completely understood. It has been previously reported that mHtt causes bioenergetic deficits, increases likelihood of induction of the mitochondrial permeability transition pore (PTP), and, therefore, decreases mitochondrial Ca^{2+} uptake capacity. However, some investigators found neither a decrease in Ca^{2+} uptake capacity, nor an increase in propensity to PTP induction in mitochondria isolated from brains of HD mouse models. In the present study, we investigated the effect of mHtt on Ca^{2+} uptake capacity and PTP induction in synaptic and non-synaptic brain mitochondria isolated from YAC128 mice and wild-type (WT) littermates. We confirmed that mHtt binds to isolated mitochondria and can be removed by alkali treatment in a medium with pH 11.5. In both

synaptic and non-synaptic mitochondria, mHtt failed to diminish Ca^{2+} uptake capacity. Moreover, addition of mHtt to brain mitochondria isolated from WT mice failed to decrease Ca^{2+} accumulation. In experiments with cultured striatal neurons derived from YAC128 mice and their WT littermates, a short application of glutamate produced similar transient elevations in cytosolic Ca^{2+}. After removal of glutamate and recovery of resting cytosolic Ca^{2+}, FCCP triggered a release of Ca^{2+} from mitochondria and produced similar Ca^{2+} elevations in neurons from both YAC128 and WT mice. This suggests similar amounts of Ca^{2+} accumulated in mitochondria and, consequently, the lack of detectable alterations in Ca^{2+} uptake by neuronal mitochondria exposed to mHtt. The level of cyclophilin D expression, the rate of ROS generation, and an induction of the PTP by Ca^{2+} in mitochondria isolated from both YAC128 and WT mice appeared to be similar. Thus, our experiments do not provide evidence for the decreased Ca^{2+} uptake capacity and argue against increased likelihood of PTP induction in brain mitochondria from YAC128 mice.

Abstract: Huntington's disease (HD) is a neurodegenerative disease caused by the expansion of a poly-glutamine (poly-Q) stretch in the huntingtin (Htt) protein. Gain-of-function effects of mutant Htt have been extensively investigated as the major driver of neurodegeneration in HD. However, loss-of-function effects of poly-Q mutations recently emerged as potential drivers of disease pathophysiology. Early synaptic problems in the excitatory cortical and striatal connections have been reported in HD, but the role of Htt protein in synaptic connectivity was unknown. Therefore, we investigated the role of Htt in synaptic connectivity *in vivo* by conditionally silencing Htt in the developing mouse cortex. When cortical Htt expression was silenced, cortical and striatal excitatory synapses formed and matured faster through postnatal day 21 (P21), but this exuberant synaptic connectivity was lost by 5 weeks. Synaptic decline in the cortex was accompanied with layer- and region-specific reactive gliosis. To determine whether the disease-causing poly-Q mutation in Htt affects synapse development, we next investigated the synaptic connectivity in a full-length knock-in mouse model of HD, the KIQ175 mouse. Similar to the cortical conditional knockouts we found abnormal excitatory synapse formation and maturation in the cortices of P21 KIQ175, which was lost by 5 weeks. Taken together, our findings reveal that cortical Htt is required for the correct establishment of cortical and striatal excitatory circuits, and this function of Htt is lost when the mutant Htt is present.

Title: Imaging the spatiotemporal dynamics of evoked glutamate release in a mouse model of Huntington disease using iGluSnFr

Authors: *M. P. PARSONS, M. P. VANNI, T. H. MURPHY, L. A. RAYMOND;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The cell death that occurs in certain neurodegenerative diseases can be attributed in part to glutamate spillover outside of the synaptic cleft where it can activate extrasynaptic NMDA receptors (eNMDARs). In Huntington disease (HD), there is an early increase in the quantity of eNMDARs on vulnerable neurons in the striatum which contributes to their subsequent death. Moreover, the reported decrease in the expression and function of glutamate transporters in the HD striatum provides a potential means whereby otherwise normal synaptic transmission may activate eNMDARs. Here, we employed a novel fluorescent glutamate sensor, iGluSnFr, to assess its usefulness as a tool to visualize and quantify glutamate spill-over in the acute slice preparation. We then used this sensor to compare the spatiotemporal dynamics of glutamate rise (release) and decay (uptake) in the striatum of wild-type (WT) and YAC128 mice, a well-characterized mouse model of HD. Glutamate indicator expression was obtained by injecting AAV-syn-iGluSnFR virus into the striatum of 1-month old male mice. Acute brain slices were obtained 3 weeks later. Wide field fluorescence recording was performed with a CCD camera. iGluSnFR was excited with a 470nm LED and emission fluorescence was collected using a 530nm bandpass filter. Striatal glutamate release was induced by local electrical stimulation with a tungsten electrode. iGluSnFr responses could not be detected following single pulses (100μA, 0.1 ms), despite the presence of excitatory postsynaptic potentials by whole-cell patch clamp recording. Interestingly, clear fluorescent responses to single pulses were observed at higher stimulation intensities, which may indicate the requirement of glutamate spillover to detect a response under our experimental conditions. Furthermore, at 100 μA, paired pulses or high frequency trains were required to observe a response, and response magnitude was inversely correlated with the inter-pulse interval. Pharmacological inhibition of glutamate transporters dramatically lengthened the response decay, confirming the glutamatergic nature of the signal. Despite previous reports of a glutamate uptake deficiency in HD, our preliminary data show no clear differences in the iGluSnFr decay in the striatum of WT and YAC128 mice. We are currently aging a cohort of animals to test glutamate dynamics in symptomatic HD. Our study demonstrates the usefulness of iGluSnFr to explore glutamate dynamics following electrically evoked release in the acute slice preparation. By using this technique, we expect to gain a better understanding of the contribution of glutamate spill-over to HD pathogenesis.

Title: Vaccinia-related kinase 2 mediates accumulation of polyglutamine aggregates via negative regulation of the chaperonin tric

Authors: *J. LEE;
Integrative Biosci. and Bietechnology, POSTECH, Pohang, Korea, Republic of

Abstract: Misfolding of proteins containing abnormal expansions of polyglutamine (polyQ) repeats is associated with cytotoxicity in several neurodegenerative disorders, including Huntington's disease. Recently, the eukaryotic chaperonin TRiC hetero-oligomeric complex has been shown to play an important role in protecting cells against the accumulation of misfolded polyQ protein aggregates. It is essential to elucidate how TRiC function is regulated to better understand the pathological mechanism of polyQ aggregation. Here, we propose that vaccinia-related kinase 2 (VRK2) is a critical enzyme that negatively regulates TRiC. In mammalian cells, overexpression of wild-type VRK2 decreased endogenous TRiC protein levels by promoting TRiC ubiquitination, but a VRK2 kinase-dead mutant did not. Interestingly, VRK2-mediated downregulation of TRiC increased aggregate formation of a polyQ-expanded huntingtin fragment. This effect was ameliorated by rescue of TRiC protein levels. Notably, small interference RNA-mediated knockdown of VRK2 enhanced TRiC protein stability and decreased polyQ aggregation. The VRK2-mediated reduction of TRiC protein levels was subsequent to the recruitment of COP1 E3 ligase. Among the members of the COP1 E3 ligase complex, VRK2 interacted with RBX1 and increased E3 ligase activity on TRiC *in vitro*. Taken together, these results demonstrate that VRK2 is crucial to regulate the ubiquitination-proteosomal degradation of TRiC, which controls folding of polyglutamine proteins involved in Huntington's disease.

Title: Integrated systems biology approach reveals relationships between age, Htt genotype, and transcriptional dysregulation in knock-in mouse models of Huntington's disease

Authors: *J. R. PEARL[1], S. A. AMENT[2], J. C. EARLS[2], C. PLAISIER[2], N. GOODMAN[2], G. CARLSON[3], A. GRINDELAND[3], V. WHEELER[4], J. CARROLL[5], N. D. PRICE[2], L. E. HOOD[2];

Abstract: Transcriptional dysregulation is an early and progressive phenotype in Huntington's disease (HD), a fatal neurodegenerative disease caused by expanded poly-glutamine (CAG) repeats in the Htt gene. Longer CAG repeat lengths are associated with earlier age of onset in HD patients and mouse models, but the relationships between Htt genotype, transcriptional networks, and pathogenesis remain poorly understood. We generated a comprehensive microarray dataset profiling the effects of Htt CAG repeat length across age and four background strains in a knock-in mouse model of HD. We profiled gene expression in striatal tissue from 827 mice with nominal Htt CAG allele lengths Q7 (wild-type), Q50, Q92, and Q111 harvested between 4 and 20 weeks of age. All of these timepoints precede the onset of overt behavioral deficits. One of the primary aims of the analysis was to identify the earliest perturbations in Htt-related transcriptional networks. By looking at these early changes, we hope to infer the most proximal mechanisms of the disease. Linear modeling revealed a total of 809 genes that were differentially expressed between Q111 and wild-type mice across four genetic backgrounds, with the largest effect size in the C57BL/6J strain. In addition, we found that an increase in the expansion of the CAG repeat tract led to a cascade of transcriptional relationships that occurs earliest in the longer repeat lengths. We used transcriptional network inference approaches and Differential Rank Conservation (DiRAC) to explore specific transcriptional regulatory mechanisms underlying these age- and CAG-length dependent changes in gene expression. Our analysis indicates that progressive reorganization of gene modules related to synaptic dysfunction and chromatin remodeling begins after just 10-12 weeks in the Q111 mice. We identified putative transcriptional regulators involved in these processes. Based on these results,

we are optimistic that mapping premanifest phenotypes of HD will lead to better clinical markers and novel therapeutic targets.

Res., [3]Dept. of Neurol., [4]Dept. of Biostatistics and Epidemiology, Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA; [5]Dept. of Pathology and Lab. Med., [6]Translational Neuropathology Res. Lab., [7]Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: *C9orf72* promoter hypermethylation inhibits the accumulation of pathologies which have been postulated to be neurotoxic. We tested here whether *C9orf72* methylation is associated with prolonged disease in *C9orf72* mutation carriers. *C9orf72* methylation was quantified from brain, blood or saliva using methylation-sensitive restriction enzyme digest-qPCR in a cross-

sectional cohort of 133 *C9orf72* repeat expansion carriers and 37 non-carrier family members. Multivariate regression models were used to determine whether *C9orf72* methylation was associated with age at onset, disease duration, or age at death. Permutation analysis was performed to determine whether *C9orf72* methylation is heritable. While there were differences in *C9orf72* methylation between blood and saliva, there was a high correlation between *C9orf72* methylation in brain versus blood (r_S=0.74, p=0.0012). *C9orf72* methylation was not significantly different between ALS and FTD, and did not predict age at onset. However, brain and blood *C9orf72* methylation was associated with later age at death in FTD (brain: β=0.18, p=0.006; blood: β=0.15, p<0.001). Furthermore, blood *C9orf72* methylation was associated with longer disease duration in FTD (β=0.03, p=0.007). Finally, analysis of pedigrees with multiple mutation carriers demonstrated a significant association between *C9orf72* methylation and family relatedness (p<0.0001). *C9orf72* methylation is associated with prolonged disease in *C9orf72* repeat expansion carriers with FTD. The attenuated clinical phenotype associated with *C9orf72* hypermethylation suggests that slower clinical progression in FTD is associated with reduced expression of mutant *C9orf72*. These results support the hypothesis that expression of the hexanucleotide repeat expansion is associated with a toxic gain of function.

Abstract: Hexanucleotide repeat expansions of C9orf72 are the most common genetic cause of amyotrophic lateral sclerosis and frontotemporal degeneration. The mutation is associated with reduced C9orf72 expression and the accumulation of potentially toxic RNA and protein aggregates. CpG methylation is known to protect the genome against unstable DNA elements and to stably silence inappropriate gene expression. Using bisulfite cloning and restriction enzyme based methylation assays on DNA from human brain and peripheral blood, we observed CpG hypermethylation involving the C9orf72 promoter in cis to the repeat expansion mutation in approximately one third of C9orf72 repeat expansion mutation carriers. Promoter hypermethylation of mutant C9orf72 was associated with transcriptional silencing of C9orf72 in patient-derived lymphoblast cell lines, resulting in reduced accumulation of intronic C9orf72 RNA and reduced numbers of RNA foci. Furthermore, demethylation of mutant C9orf72 with 5-aza-deoxycytidine resulted in increased vulnerability of mutant cells to oxidative and autophagic stress. Promoter hypermethylation of repeat expansion carriers was also associated with reduced accumulation of RNA foci and dipeptide repeat protein aggregates in human brains. These results indicate that C9orf72 promoter hypermethylation prevents downstream molecular aberrations associated with the hexanucleotide repeat expansion, suggesting that epigenetic silencing of the mutant C9orf72 allele may represent a protective counter-regulatory response to hexanucleotide repeat expansion.

Title: Angiogenin is a secreted ribonuclease that cleaves RNAs in paracrine

Authors: M. C. HOGG[1], *J. H. PREHN[2];
[1]Dept. of Physiol. & Med. Physics, [2]Royal Col. of Surgeons in Ireland, Dublin, Ireland

Abstract: Angiogenin is a secreted member of the pancreatic ribonuclease A superfamily. Angiogenin is expressed in motorneurons and secreted under serum deprivation conditions, whereupon it is endocytosed by neighbouring astroglia. Numerous ALS-associated loss-of-function point mutations have been identified in both familial and sporadic forms of the disease. ALS-associated angiogenin mutations either lead to loss of ribonuclease activity or modulate subcellular localisation. We have previously shown that systemic angiogenin delivery increases lifespan and ameliorates symptoms in the SOD1 G93A ALS mouse model. We have established a paracrine cell culture system to further investigate the function of angiogenin using SH-SY5Y neuroblastoma cells overexpressing wild type or mutant angiogenin. In our system the K40I angiogenin mutant is produced at significantly lower levels than wild type angiogenin. Under serum-starvation conditions angiogenin is secreted into the media. The angiogenin conditioned media is then applied to astrocytoma cell line MZ-294 and angiogenin is internalised. We demonstrate that angiogenin expression and treatment generates RNA fragments by PAGE analysis and SYBR Gold staining of small RNAs. Cleavage of tRNAs within the anticodon loop was detected in both neuroblastoma and astrocytoma cell lines using custom taqman assays and northern blotting. However angiogenin uptake into astrocytes induces the cleavage of distinct RNA molecules, in addition to tRNA fragments, suggesting angiogenin has broader substrate specificity than tRNA alone.

Title: The role of the rna binding protein rbm45 and nuclear stress bodies in als and ftld

Authors: *M. A. COLLINS[1], Y. LI[2], R. BOWSER[2];
[1]Neurosci., Univ. of Pittsburgh, Phoenix, AZ; [2]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The aggregation of RNA binding proteins into inclusion bodies is a pathological hallmark of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). Evidence suggests that the aggregation process can be initiated by the incorporation of these proteins into protein-RNA complexes, such as stress granules. We recently demonstrated that the RNA binding protein RBM45 forms intracellular inclusions in neurons and glia in ALS, FTLD, and Alzheimer's disease. The mechanisms by which RBM45 forms inclusions are unclear, as it does not incorporate into cytoplasmic stress granules. In our post-mortem disease tissues, RBM45 staining exhibited a speckled nuclear staining pattern, suggestive of the protein's incorporation into a subnuclear structure. Despite this, RBM45 does not associate with a variety of known subnuclear structures, including nuclear speckles, Cajal bodies, and nuclear gems. During conditions of cellular stress, including oxidative stress, genotoxic stress, and UV light, the distribution of the protein changes to a punctate staining pattern. Using a combined immunocytochemistry/digital deconvolution approach, we show that the RBM45-positive puncta in stressed nuclei correspond to the protein's incorporation into nuclear stress bodies (NSBs). Under conditions of cellular stress, RBM45 exhibits significant colocalization with the NSB marker HSF1 ($p < .05$), but does not do so under basal conditions ($p > .05$). Likewise, the number of RBM45-positive puncta in the nucleus of cells increases in a stress-dependent manner. We also show that the number of these puncta is significantly increased in neurons from ALS and FTLD post-mortem tissue when compared to control ($p < .05$). Overexpression of the protein in cells is, itself, sufficient to cause the formation of these structures. Using a domain mapping approach, we show RBM45's ability to associate with NSBs depends critically upon specific structural elements of the protein, including a putative nuclear localization sequence. Collectively, these results demonstrate that RBM45 is a component of NSBs and NSBs represent a novel disease-associated protein-RNA complex that is a potential therapeutic target for disorders such as ALS and FTLD.

Title: Examining the role of necroptosis signaling in motor neuron dysfunction and death in amyotrophic lateral sclerosis

Authors: K. POLITI[1], D. RE[2], V. LE VERCHE[2], S. PHANI[2], R. PRADHAN[2], *S. E. PRZEDBORSKI[3];
[1]Columbia Univ., New York, NY; [3]Neurolog Inst., [2]Columbia Univ., NEW YORK, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is the most frequent adult-onset paralytic disorder. ALS can be familial (fALS) through inheritance of genetic mutations such as superoxide dismutase-1 (mSOD1) or sporadic (sALS) with no familial history. Transgenic mice expressing mSOD1 develop a phenotype which emulates the clinical and pathological hallmarks of ALS, including motor neuron (MN) degeneration and nerve terminal retraction from the neuromuscular junction (NMJ). Importantly, the molecular mechanisms leading to these two pathogenic events remain unknown and studies suggest they may result from distinct mechanisms. Previously, we reported that wild-type primary or embryonic stem cell-derived spinal MNs show significant death and axonal shortening *in vitro* upon exposure to primary astrocytes from mice expressing fALS-linked mSOD1 or from human sALS patients. We also demonstrated that mSOD1 MNs cell autonomously exhibit a similar axonal length defect. Recently, we reported the death of MN in response to ALS astrocytes is driven by necroptosis, a non-classical form of programmed cell death. Indeed, necrostatin 1 (Nec1), an inhibitor of the kinase activity of the necroptosis initiator, receptor interacting protein kinase (RIP1), prevented MN death in both *in vitro* models. Now, we propose to dissect further the first necroptotic cascade described in non-neoplastic neurons and to determine whether necroptosis also drives the axonal defects we previously observed. A canonical step in necroptosis initiation is the formation of a complex containing RIP1, RIP3 and mixed lineage kinase domain like protein (MLKL). Here, we provide evidence that RIP3 also drives MN death, as RIP3 silencing by shRNA renders MNs resistant to mSOD1 astrocytes. We are currently optimizing the silencing of MLKL in MNs to confirm its involvement. Additionally, our preliminary data suggest that Nec1 may prevent the axonal defects non-cell autonomously mediated by mSOD1 astrocytes. Analysis is ongoing to determine the effect of Nec1 on the cell-autonomous axonal defect in mSOD1 MNs. Our next step will be to genetically confirm the Nec1 results by silencing RIP1 in these two experimental conditions. The validation in our models of RIP3 and MLKL is critical, as in contrast with RIP1, which has several known functions independent of necroptosis, RIP3 and MLKL have not yet been shown to have non-redundant roles independent of necroptosis. Accordingly, they may prove more selective targets to be pursued *in vivo* for the development of

neuroprotective therapies for ALS. Finally, our study will help to predict whether anti-necroptosis strategy can also target muscle denervation in ALS.

Title: The role of HIF-1α and SREBP1 in models of ALS

Authors: *S. DOSHI[1], A. M. JABLONSKI[1], R. G. KALB[1,2];
[1]Univ. of Pennsylvania, PHILADELPHIA, PA; [2]Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: In Amyotrophic Lateral Sclerosis (ALS), degeneration of motor neurons is accompanied with mitochondrial dysfunction, leading to disrupted ATP production and reactive oxygen species (ROS) accumulation. We asked if degenerating neurons could employ alternate pathways for producing ATP and fighting ROS build-up, and if these could be beneficial to disease progression. The two arms of glucose metabolism – glycolysis and the pentose phosphate pathway (PPP) – lead to ATP production and NADPH production to combat ROS accumulation respectively. The mammalian target of rapamycin 1 (mTORC1) is poised to control flux through both arms of glucose breakdown via two transcription factors – hypoxia inducible factor 1α (HIF-1α) and sterol regulatory element binding protein 1 (SREBP1). HIF-1α regulates transcription of key genes in glycolysis (phosphofructokinase, pyruvate dehydrogenase kinase etc.) and SREBP1 regulates transcription of key genes in the PPP (glucose-6-phosphate dehydrogenase) and lipid biosynthesis (fatty acid synthase). We hypothesize that mTORC1, HIF-1α and SREBP1 are downregulated in ALS, preventing motor neurons from combating dysfunctional mitochondria. Additionally, we hypothesize that increasing the activity of these factors will be protective in models of ALS. Preliminary experiments show that constitutive

activation of HIF-1α in the mutant SOD1 background in *C. elegans* is protective against mutant SOD1-induced deficits in worm locomotion. Ongoing experiments will investigate the mRNA and protein levels of HIF-1α and SREBP1 targets *in vitro* and *in vivo* in mammalian models of the disease (cultured rat neurons and mice). Preliminary experiments have also established a pharmacological agent (FG-4497, from Fibrogen, Inc) upregulates HIF-1α function. Ongoing experiments will use this compound to test the role of this compound in protecting against mutant SOD1-induced toxicity in cultured neurons. We have also designed a microRNA against TSC2, a negative regulator of mTORC1 function, and will test the role of this microRNA in protecting against mutant SOD1-induced toxicity. Mitochondrial dysfunction is a key contributor to changes in cellular metabolism observed in ALS. By exploring the role of specific transcription factors aimed at addressing these changes, we hope to gain insight into pathogenesis as well as identify targets for therapeutic intervention in this devastating disease.

Title: Quantitative assessment of endogenous calcium homeostasis in adult hypoglossal motoneurons of wildtype and SOD1-G93A ALS mice

Authors: A. FUCHS[1,2,3], S. KUTTERER[3], B. LISS[4], J. ROEPER[3], *B. U. KELLER[5]; [1]Karolinska Institutet, 17177 Stockholm, Sweden; [2]Univ. of Göttingen, 37073 Göttingen, Germany; [3]Goethe Univ. Frankfurt, 60590 Frankfurt, Germany; [4]Univ. of Ulm, 89081 Ulm, Germany; [5]Univ. Gottingen, 37073 Gottingen, Germany

Abstract: In amyotrophic lateral sclerosis (ALS) hypoglossal (hMN) and spinal motoneurons but not occulomotor neurons (oMN) degenerate, leading to paralysis of skeletal muscles in the whole body, while even terminal patients can still move their eyes. Previous work suggested that differences in calcium homeostasis in spinal and hypoglossal motoneurons compared to oMNs might partially account for this differential vulnerability. Until now, quantitative parameters of calcium homeostasis were determined only in early postnatal mice (up to postnatal day P6) because of methodological limitations. However, as death of hMNs starts not before P60 and disease endstage is reached around P130 in a mouse model of ALS (SOD1-G93A), calcium homeostasis should be studied in this relevant adult age range to assess its direct pathophysiological involvement. Recently, we developed a mouse brainstem slice preparation that allowed patch-clamp recordings of adult hMNs up to disease endstage and filling of the cells with a calcium indicator dye (Fuchs et al. J Physiol 2013). Visualization of the neurons enabled the combination of electrophysiological recordings with fluorometric calcium measurements. Endogenous calcium homeostasis of adult (P130) hMNs in wildtype (wt) and SOD1-G93A mice was quantified by using the "added buffer" approach. In this case, the gradual disruption of endogenous calcium homeostasis by the calcium indicator dye is utilized to quantify endogenous calcium parameters in the cell. Interestingly, we found an endogenous buffering capacity $\kappa s < 70$ in adult wt hMNs. This is small compared to capacities in other central neurons (e.g. hippocampal CA1 pyramidal cells $\kappa s \approx 200$) and provides direct support for the idea that low calcium buffering capacities represent a significant risk factor for selectively vulnerable cells. κs was even lower in SOD1-G93A hMNs ($\kappa s < 50$) compared to wt, indicating that the mutated SOD1-driven disease process further impaired the already constitutively low calcium buffering capacity of vulnerable motoneurons. The extrapolated decay time of calcium transients τ in the absence of indicator dye was 0.29 ± 0.07 s ($n = 52$) for wt and 0.12 ± 0.09 s ($n = 42$) for SOD1-G93A, reflecting rapid somatic calcium dynamics and efficient cytoplasmic clearing by extrusion and calcium uptake into intracellular compartments under physiological conditions. For the first time, our data quantitatively describe the calcium homeostasis in adult motoneurons in health and disease and might help to explain the differential vulnerability of different motor nuclei and even single neurons in ALS.

Leuven, Leuven, Belgium

Abstract: Amyotrophic lateral sclerosis (ALS) is a late-onset progressive neurodegenerative disease affecting motor neurons. This results into fasciculation, muscle atrophy and ultimately paralysis. Denervation of respiratory muscles and diaphragm is often the fatal event and typically occurs between 1 and 5 years after symptom onset. Studies using mutant SOD1 mice have shown that ALS is a non-cell autonomous disease, meaning that non-neuronal cells contribute to motor neuron degeneration. Typically for ALS is the presence of very reactive microglia and astrocytes, so-called microgliosis and astrocytosis, determining disease progression. Recently, also oligodendrocytes were found to actively contribute to ALS pathogenesis, as they degenerate extensively. Although degenerating oligodendrocytes are replaced by newly differentiated oligodendrocytes, differentiation seems to be incomplete. These new oligodendrocytes appear to be immature, unable to myelinate properly and unable to supply neurons with energy substrates. The Notch signaling pathway is important in regulating cell-cell communication, axonal retraction, microgliosis, astrocytosis, proliferation and differentiation of oligodendrocyte precursor cells into mature oligodendrocytes, and even cell death. Notch signaling is also involved in several neurodegenerative diseases, such as Alzheimer's disease and ischemic stroke. This knowledge suggests that the study of Notch signaling is relevant for ALS pathogenesis. We hypothesize that Notch signaling may be disturbed in ALS, thereby contributing to disease progression. More particularly, we hypothesize the involvement of Notch in the non-cell autonomous glial cell contribution to motor neuron degeneration. First, we investigated whether

the expression of components of Notch signaling, such as ligands, receptors and targets, is altered in ALS mice (SOD1G93A), compared to control mice (SOD1WT and non-transgenic), and whether the expression changes with disease progression. We used qRT-PCR, western blot and immunofluorescent staining, and found remarkable changes in the expression of several Notch ligands, receptors and targets, with a clear disease progression dependency. In addition, we studied to what extend modulation of the Notch signaling pathway in the SOD1G93A mice has beneficial effects on ALS pathological hallmarks. A tamoxifen-induced Cre-Lox mediated recombination approach was used for modulating Notch signaling. In conclusion, our data suggest that Notch signaling is severely altered in ALS mice and may play an important role in the non-cell autonomous component of ALS pathogenesis.

Title: Loss of TIA1 impairs development of male reproductive organs in a mouse model of spinal muscular atrophy

Authors: *M. D. HOWELL[1], N. N. SINGH[1], J. SEO[1], E. M. WHITLEY[2], R. N. SINGH[1]; [1]Biomed. Sci., [2]Vet. Pathology, Iowa State Univ., Ames, IA

Abstract: Spinal muscular atrophy (SMA) results from low levels of survival motor neuron (SMN) protein in the central nervous system and peripheral tissues. While death of spinal cord motor neurons and deficits in neuromuscular junctions have been characterized in SMA patients and mouse models of the disease, the consequences of low SMN on many peripheral tissues,

including reproductive organs, is unknown. Low levels of SMN in SMA results from the loss of the SMN1 gene coupled with predominant SMN2 exon 7 skipping that leads to the synthesis of the truncated protein SMNΔ7. We previously reported that depletion and overexpression of TIA1, a RNA-binding protein, promotes SMN2 exon 7 skipping and inclusion, respectively. To assess the impact of the loss of TIA1 on severity of SMA, we generated TIA1 knockout mice on the background of the recently reported allele C mouse model, a mouse that exhibits mild SMA-like symptoms. We examined the gross appearance and histology of testes at six weeks of age in wild type (WT; Smn+/+, Tia1+/+), TIA1-KO (Smn+/+, Tia1-/-), allele C (SmnC/C, Tia1+/+) and allele C-TIA1-KO (SmnC/C, Tia1-/-). Compared to WT mice, we found strikingly smaller testes in allele C mice. Histologically, allele C testes exhibited poorly organized seminiferous tubules and apparent disrupted spermatogenesis. As further evidence of impaired spermatogenesis, sperm count in allele C epididymides was significantly reduced compared to WT males. TIA1-KO testes were slightly larger than WT testes, but there was no difference in histology or sperm count compared to WT mice. Allele C-TIA1-KO mice, however, had significantly reduced testes and further reduced epididymal sperm count compared to allele C mice. Interestingly, SMN protein level in testis remained unchanged in allele C and allele C-TIA1-KO compared to WT and TIA1-KO mice. These results suggest that low levels of SMN in other tissues, particularly the autonomic nervous system that controls testicular blood flow, is responsible for the impaired development of testes. TIA1 is a glutamine-rich protein that regulates stress-granule formation, a critical cellular process involving several factors including SMN. Earlier studies reported that mice lacking Tia1 are hypersensitive to toxic effects of lipopolysaccharides and exhibit dysregulated expression of lipid storage and membrane dynamics factors in nervous tissue. Further, mutations in TIA1 have been associated with Welander distal myopathy, an adult onset autosomal dominant disorder characterized by distal limb weakness. Our results uncover a novel role for TIA1 in modulating testicular development in SMA, a leading genetic disease of children.

Abstract: Amyotrophic lateral sclerosis (ALS) is characterized by progressive degeneration of the motor neuron circuitry. However the spatial and temporal degeneration of sensory nervous system with respect to disease progression has not been studied in detail. We recently generated a novel ALS mouse model reporter line, in which corticospinal and spinal motor neurons, together with sensory neurons, are genetically labeled with enhanced green fluorescent protein (eGFP) expression under the UCHL1 promoter. This mouse model offers, for the first time, a comparative study of peripheral neurons together with motor neurons and allows investigation of the sensory nervous system involvement in motor neuron disease pathology. In this study we investigated the timing and extent of potential sensory nervous system degeneration, using one of the most characterized mouse models of ALS. Qualitative and quantitative analysis of epidermal nerve density of $eGFP^{+}$ distal peripheral nerves in the footpads of the $hSOD1^{G93A}$-UeGFP mice at postnatal days (P) 30, 60, 90, and 120 revealed a significant decrease in epidermal nerve density only by P120, end-stage of the disease. Our preliminary results are in line with previously reported skin biopsy results obtained from ALS patients, and suggest that peripheral nervous system degeneration is most apparent toward the end of the disease.

Abstract: Corticospinal motor neurons (CSMN) receive, integrate and relay cerebral cortex's input towards spinal targets to initiate and modulate voluntary movement. CSMN degeneration is central for numerous motor neuron disorders and neurodegenerative diseases, but the cellular and molecular basis of CSMN vulnerability remains unknown. Mutations in the ubiquitin C-terminal hydrolase-L1 (*UCHL1*) gene have been detected in patients with neurodegenerative disease that affect motor function, and recently three siblings displayed early neurodegeneration, including upper motor neuron dysfunction. There is a need for the generation and characterization of novel

mouse models that recapitulate upper motor neuron loss in patients. Here we report a unique function of UCHL1 in maintaining CSMN viability and cellular integrity. *Uchl1*^{nm3419} (UCHL1 -/-) mice, which lack all UCHL1 function, display motor neuron circuitry defects. Even though spinal motor neurons remain intact with subtle dysfunction, CSMN show early, selective, progressive and profound cell loss. CSMN degeneration is mediated via increased ER stress and becomes evident at pre-symptomatic stages by cytoarchitectural defects primarily involving the apical dendrites. To reveal the importance of UCHL1 function for the motor neuron circuitry, we now generated novel conditional mutant mice in which UCHL1 function is removed either from the corticospinal or the spinal motor neurons, respectively.

Title: The electrophysiological properties of the different motor unit subtypes are not equally affected in adult SOD1-G93A mice

Authors: *M. MANUEL[1], C. HECKMAN[2], D. ZYTNICKI[1];
[1]Ctr. for Neurophysics, Physiol. & Pathology, CNRS / Univ. Paris Descartes, Paris, France;
[2]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: One of the proposed mechanism to explain the death of motoneurons (MNs) in ALS is an excitotoxic process, i.e. an excess electrical activity leading to an overload of intracellular calcium triggering apoptotic death. However, we have recently shown (Delestrée et al., J Physiol

2014) that spinal MNs of adult mice are not intrinsically hyperexcitable in SOD1-G93A mice. Instead, we found that a subpopulation of MNs lost their ability to fire repetitively in response to a stationary input. Yet, at the time, we could not determine whether this hypo-excitability was restricted to a specific physiological type of motor unit. We have developed an *in vivo* adult mouse preparation allowing simultaneously recording intracellularly spinal MNs and recording the force developed by their motor unit. We characterized the properties of motor units (MUs) from the Triceps Surae muscles of SOD1 mice and their non transgenic controls (WT) at the stage preceding their denervation (P35-P65). We classified the motor units in physiological types ("Slow" - S, "Fast fatigue-Resistant" - FR and "Fast Fatigable" - FF) on the basis of their contractile properties (contraction time, twitch force, fatigability, sag in unfused tetanus). During the time frame studied, the contractile properties of the MUs are not affected by the disease, and we could use the same criteria to classify MUs as in WT mice. We found that many electrical properties of SOD1 MNs are unchanged. For example, there was no differences between SOD1 and WT MNs in term of input conductance or rheobase in each of the physiological types taken separately. However, in keeping with our earlier results, we found that a large proportion of MNs (33% vs. 9% in WT mice) lost the ability to produce a sustained firing in response to a stationary input. Interestingly, all of these MUs had a fast contraction time (mean ± stdev 13 ± 3 ms, N=13), and produced twitch forces ranging from 0.4 to 34 mN. Based on their various contractile properties, these MUs were classified as FF (4 MUs out of 6) or FR (9 MUs out of 18). We were therefore able to demonstrate that FF and FR MUs (that are vulnerable in ALS), but not the S type MUs (that are resistant in ALS), become progressively hypoexcitable before they lose their connections to their muscle fibers. We are now investigating if an excitotoxic process could nevertheless arise from changes in excitatory and inhibitory inputs to MNs.

Title: *In vivo* characterization of G93A-SOD1 mouse model of amyotrophic lateral sclerosis by magnetic resonance imaging (MRI) and spectroscopy (MRS)

Authors: K. LEHTIMÄKI, J. OKSMAN, T. LAITINEN, T. AHTONIEMI, A. NURMI, *S. HÄTINEN;
Charles River Discovery Res. Services, Kuopio, Finland

Abstract: Amyotrophic lateral sclerosis (ALS) is a human neurodegenerative disorder that progressively leads to paralysis and death. It is caused by the loss of motor neurons especially in the spinal cord, but brainstem is also affected. In this study, G93A-SOD1 mouse model of ALS was characterized with magnetic resonance imaging (MRI) for brainstem neurochemical metabolite levels (1H-MRS) and for transverse relaxation time changes (T2 MRI) in brainstem nuclei. Non-treated G93A-SOD1 and WT male and female mice, at the age of 110 days, were subjected to MR scanning with 11.7T Bruker system. Brainstem 1H metabolites were acquired using a single-voxel PRESS sequence. Transverse relaxation time (T2) in the brainstem nuclei (Nc. Facialis, Nc. Hypoglossus and Nc. Trigeminus) was determined using a MSME sequence. Additionally, brainstem volume was assessed from MR images at range -8.00 and -5.40 mm from bregma. To confirm disease progression, motor performance and clinical score were evaluated until the imaging end-point. Significant volume decrease (-11.2%) in the brainstem of SOD1 mice was detected as compared to WT mice. This volume decrease was associated with significant T2 relaxation time increase brainstem nuclei Nc. Facialis (+8.9%), Nc. Hypoglossus (+8.1%) and Nc. Trigeminus (+7.5%). Decreased levels of alanine (-40.5%), gamma-aminobutyric acid (GABA, -27.8%), phosphocholine (-45.0%) and N-acetyl acetate (NAA, -25.3%) were detected. In contrast, glutamine (+22.3%), myo-inositol (+11.3%) and taurine (+21.2%) revealed increased concentrations. Our results show significant T2 increase in studied brainstem nuclei in SOD1 mice, which is considered to be associated with appearance of fluid filled vacuoles in place of degenerated motor neurons (Bucher et al. 2007). In addition to T2 changes, reduction in total volume of brainstem in SOD1 mice likely reflects the degeneration of motor neurons. *In vivo* neurochemical fingerprint for affected brainstem revealed several changes from which the reduction of NAA (neuronal health/number) and GABA (GABAergic neurotransmission) has been previously reported in G93A SOD1 model by use of high-resolution *in vitro* 1H-MRS (Niessen et al. 2007). Results obtained in this study highlight the importance of non-invasive *in vivo* imaging modalities. MR imaging parameters shown here can complement longitudinal drug investigational studies in G93A SOD1 mouse model that conventionally have concentrated on motor behavior, survival, biochemical and histological read-outs.

Title: Characterization of the astroglial gap junction protein Connexin 43 in Amyotrophic Lateral Sclerosis

Authors: *A. A. ALMAD[1], A. DORESWAMY[2], X. TANG[2], S. GROSS[2], N. MARAGAKIS[2]; [2]Dept. of Neurol., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a primary motor neuron (MN) disease manifesting with progressive muscle atrophy and paralysis. Astrocytes in ALS can exert toxicity on MNs both in *in vitro* and *in vivo* model systems. Astrocytes form a highly coupled intercellular network in the central nervous system (CNS) through gap junctions. Gap junction in astrocytes, specifically connexin43 (Cx43) conducts important homeostatic functions in the nervous system such as regulation of the excitatory neurotransmitters, providing metabolic support to neurons, regulation of neurovasculature and synaptic events. However, under pathological conditions connexins are altered and their functions are compromised as observed in numerous neurological trauma/diseases such as spinal cord injury Alzheimer's disease, Parkinson's, ischemia, and others. This prompted us to investigate if the expression level of the major astrocyte connexin, Cx43 is altered in patients with ALS as well as animal models. We characterized the expression level of Cx43 in the SOD1G93A mice and notably in human post-mortem tissue from ALS patients. We examined Cx43 protein levels in the cervical, thoracic and lumbar spinal cord segments in the endstage SOD1G93A mice and observed a significant increase in Cx43 expression levels in all three regions compared to their wild-type litter mates. The histological study revealed Cx43 increase predominantly in the gray matter co-localizing mainly with astrocytes and a few microglia. Interestingly, when we examined the human post-mortem tissue for total Cx43 protein levels from ALS patients compared to their age-matched controls, we observed a significant increase in the motor cortex and cervical and lumbar spinal cord segments. Similar to the mouse model, Cx43 localized primarily to astrocytes and in the gray matter of human cervical spinal cord. This finding potentially implicates aberrant connexin biology in ALS either as an astrocytic response to neuronal injury or possibly as a mediator of disease. Future studies to investigate these contributions may be helpful in understanding glial responses in motor neuron disease.

Title: Presymptomatic dysfunction in glial cells at the NMJ may impact reinnervation in SOD1G37R mice

Authors: *E. MARTINEAU, R. ROBITAILLE;
Univ. De Montréal, Montréal, QC, Canada

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the loss of motoneurons. Glial cells are known to play a major role in disease progression. However, the contribution of Perisynaptic Schwann cells (PSCs), glial cells at the neuromuscular junction (NMJ), is still ill-defined in ALS despite that they regulate both synaptic and structural plasticity of the healthy NMJ. We previously reported an alteration of PSC properties at a presymptomatic (P120) and pre-onset (P370) stage of the disease in the Soleus, a muscle exhibiting a delayed progression. These properties were consistent with an impaired repair ability of PSCs. Since fast-twitch muscles are more vulnerable in ALS, we tested whether PSC properties were also altered in the fast-twitch Sternomastoid muscle. Using Ca2+ imaging on isolated nerve muscle preparations, we found that glial Ca2+ responses to endogenous neurotransmitter release evoked by motor nerve stimulation were unaltered at P120 but greatly diminished at P180. Furthermore, PSCs on a single NMJ displayed heterogeneous responses suggesting that PSCs are unable to accurately decode synaptic activity. PSCs displayed an improper balance between purinergic and muscarinic signals as revealed by selective pharmacological agonists and antagonists of PSC receptors. Since adequate PSC decoding of synaptic activity is required for proper maintenance of the NMJ, these presymptomatic glial abnormalities suggest that PSCs may not respond adequately to denervation in symptomatic animals. Unlike wild-type littermates, and consistent with this possibility, PSCs at denervated NMJs of end-stage animals failed to upregulate Mac-2, a marker of glial activation, while PSCs

at innervated NMJs upregulated it. Furthermore, fewer process extension by PSCs at denervated NMJs and fewer nerve terminal sproutings at innervated NMJs were observed. These features are essential for reinnervation and are modulated by PSCs. Interestingly, these defects were less pronounced in the Soleus muscle which is consistent with the partial resistance of slow-twitch muscles. Together, these results show that neuron-glia communication is altered early in ALS which may result in a disorganised glial response to denervation during disease progression.

Abstract: Recent evidence suggests that not only immune reactions but also glia-immune interactions contribute to disease processes of neurodegenerative diseases. Microglial cells are responsible for innate immune responses against a traumatic injury and a bacterial infection in the central nervous system. Although adaptive immune system was shown to be involved in disease process of amyotrophic lateral sclerosis (ALS), the role of innate immune system in ALS was unclarified. We have demonstrated that the innate immune pathway was activated in inherited ALS model mice (mSOD1 mice) and TRIF, an essential adaptor for Toll-like receptor

signaling, was identified as determinant of disease progression in mSOD1 mice. TRIF-deficient mSOD1 mice exhibited the acceleration of disease progression with decreased expression level of chemokines in microglia and fewer infiltrating immune cells in the spinal cord. We also show that the activation of TRIF signaling in microglia serves as a bridge between innate immunity and adoptive immunity and the infiltrating immune cells attracted by microglia actively involve in neuroprotection in the mSOD1 mice spinal cords. Finally, in contrasts to the previous reports, we identified that infiltrating immune cells, mainly cytotoxic T-lymphocytes, natural killer T-lymphocytes, and natural killer cells, confer novel role in maintaining glial environment surrounding the motor neurons.

Title: Early-onset neuropathology and neuroinflammation in motor and sensory brain areas and their association with CGRP abundance in the SOD1-G93A mouse model of amyotrophic lateral sclerosis

Authors: *B. SCHUETZ[1], C. RINGER[2], H. SCHWARZBACH[1], S. TUNE[2], E. WEIHE[1]; [1]Philipps Univ., Marburg, Germany; [2]Dept. of Neurol., Univ. of California, Irvine, CA

Abstract: Introduction: Amyotrophic lateral sclerosis (ALS) is a lethal neurodegenerative disease affecting primary motor neurons in cortex, and secondary motor neurons in brain stem and spinal cord. Progressive loss of these motor neurons results in denervation of skeletal muscles, paralysis, and finally death. Neuronal vacuolization accompanied by pronounced neuroinflammation is the neuropathological hallmark in the superoxide dismutase 1-G93A (SOD1-G93A) mouse model of ALS. Methods and results: using histological staining (Giemsa) and immunohistochemistry for vacuolization (human SOD1), astrocytes (GFAP), microglia

(Iba1), and neuropeptides (calcitonin gene-related peptide, CGRP) we discovered that vacuolization begins in the pre-symptomatic stage at post-natal day 50 in diverse motor and non-motor brain areas, including olfactory bulb and retina. In the olfactory bulb vacuoles were restricted to the external plexiform layer and apparently originated from satellite-like neurons. In the retina vacuoles were confined to the internal plexiform layer and most likely originated from amacrine cells. In the brainstem, cholinergic, dopaminergic and noradrenergic neurons were affected. Following vacuolization with a delay of 10-20 days, astrogliosis also started pre-symptomatically and simultaneously throughout the brain. Only in the pyramidal motor system a dying forward progression to cortical primary motor neurons was observed, where vacuolization and astrogliosis in the motor cortex emerged not until symptomatic disease stages. Across all brain regions analyzed, the degree of astrogliosis did not correlate with the number and size of vacuoles, but with CGRP abundance. Conclusion: SOD1-G93A-related ALS vacuolization pathology prominently affects limbic, autonomic and other non-motor areas including sensory circuits in the olfactory bulb and the retina lending support to the concept that ALS is a multisystem disorder well beyond the motor system. The observed correlation between astrogliosis and CGRP abundance in most affected regions suggests that neuroglial CGRP signaling is involved in ALS disease progression. We propose to test CGRP receptor antagonists to mitigate ALS disease progression.

Title: Oxidative stress expands the repertoire of alternatively spliced transcripts of spinal muscular atrophy gene

Authors: *J. SEO, S. SIVANESAN, M. D. HOWELL, E. W. OTTESEN, N. N. SINGH, M. SHISHIMOROVA, R. N. SINGH*;

Abstract: Loss of Survival Motor Neuron 1 (SMN1) gene coupled with the skipping of SMN2 exon 7 causes spinal muscular atrophy (SMA), a leading genetic cause of infant mortality. With the consequence to the increased severity of SMA, recent cell-based studies have revealed oxidative stress (OS)-induced enhanced skipping of SMN2 exons. However, effect of OS on tissue specific splicing regulation of SMN2 remains unknown. Taking advantage of a transgenic mouse expressing SMN2, here we report a comprehensive analysis of SMN2 transcripts expressed in different tissues under normal and OS conditions. Our findings supported by exon-trapping PCR, quantitative real-time PCR and a multi-exon skipping detection assay (MESDA) capture tissue-specific signatures of splicing events of SMN2. Our results underscore that the occurrence of co-skipping of SMN2 exons 5 and 7 in response to OS is a signature event that climaxes during the first 24 h of a high-dose treatment of paraquat (PQ). Regarding tissue-specific differences in response to OS, we observed a relatively high proportion of Δ5,7 transcripts in brain and spinal cord followed by kidney, liver, lung, muscle and heart. Notably, proportion of Δ7 transcripts remained unchanged during PQ-induced OS in liver, lung and muscle. Brain and kidney showed an OS-induced decrease in levels in Δ7 transcripts, whereas, heart and spinal cord showed a slight increase in the proportion of Δ7 transcripts in response to OS. Levels of Δ5 splice variant remained very low during OS in all tissues examined. We also observed differential expression of several exons including co-skipping of exon 3 with other exons. Interestingly, effect of OS on testis was found to be distinct from other tissues. We examined effect of OS on levels of several proteins including human SMN, mouse SMN, TIA1 and TIAR. Our results suggest a unique role of the alternatively spliced transcripts in regulation of SMN translation.

Title: Direct conversion of spinal astrocytes into functional neurons with defined transcription factors and small molecules

Authors: *L. ZHANG[1], J. YIN[2], H. YEH[2], N. MA[2], G. LEE[2], G. WU[2], G. CHEN[2];

Abstract: Neurons can be induced from glial cells by overexpression of proneuronal genes. Neurogening 2 (Ngn2) and NeuroD1 have been reported to convert glial cells into glutamatergic neurons both *in vitro* and *in vivo*. Here we report that defined small molecules facilitated Ngn2 to reprogram cultured mouse spinal astrocytes directly into functional motor neurons. The converted neurons were immunopositive for motor neuron markers Hb9, Isl1 and cholinergic markers CHAT and VACHT. Electrophysiological analysis demonstrated that these converted neurons were fully functional as they were capable of firing repetitive action potentials and showed large ionic currents. In addition, small molecules could facilitate Ngn2 to convert cultured human astrocytes into functional motor neurons. Interestingly, a defined combination of small molecules was able to convert cultured human astrocytes into functional neurons without overexpression of proneural genes. Taken together, our studies suggest that defined combination of small molecules can facilitate glia-neuron conversion and help to guide the converted neurons into specific subtype.

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating, uniformly fatal adult-onset neurodegenerative disorder with no clear etiology. Patients experience worsening symptoms of weakness as the motor neurons (MNs) that govern voluntary movement degenerate, and typically die within 3-5 years of diagnosis. Most cases of ALS are sporadic; however, a minority of patients develop a familial form involving a disease-triggering mutation in one of several known genes, including C9ORF72, SOD1, TDP-43, FUS, and ANG. The downstream events that culminate in MN degeneration are largely unknown, but there are early increases in MN excitability that make ALS MNs more likely to respond to incoming stimulation from the excitatory neurotransmitter glutamate. Accordingly, by comparing iPS-derived MNs from familial ALS patients with isogenic control lines, where the disease-causing mutation has been corrected by TALENS, we have shown that ALS MNs respond more strongly to and are slower to recover from glutamatergic stimulation than controls. One possibility is that hyperexcitability could make MNs more vulnerable to excitotoxic cell death, in which excessive glutamatergic stimulation causes fatal Ca2+ imbalances within the cell. In several models of ALS, we have uncovered selective down-regulation of RBFOX1, an RNA-binding protein that is known to regulate neuronal excitability. We have also found that mice lacking RBFOX1 showed robust motor impairments that mirror those in ALS mice. Importantly, they also exhibited hyperexcitability in the MNs involved in hindlimb movement. The goal of this project is to evaluate the causal relationship between changes in RBFOX1 expression and changes in MN excitability, and to determine how changes in MN excitability ultimately lead to MN death. To accomplish these goals, we are taking advantage of a broad range of iPS lines, enabling high-throughput analyses in live human ALS MNs that would otherwise be inaccessible in patients.

Title: Characterization of β-methylamino-L-alanine (BMAA) as a tool to study environmental-linked sporadic amyotrophic lateral sclerosis

Authors: *B. IKIZ[1], S. D. CROLL[2], A. J. MURPHY[2], L. E. MACDONALD[2], M. L. LACROIX-FRALISH[2];
[1]Neurobio. and Behavior, [2]Pain, Addiction & Neurol., Regeneron, Tarrytown, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is the most frequent adult-onset paralytic disorder, characterized by the loss of upper and/or lower motor neurons through a pathological mechanism that is not completely understood. While ALS is mostly a sporadic disease, for about 90% of the cases, the majority of the research done in the field had focused on modeling the familial form, which necessitates tools to model the sporadic form of ALS. β-methylamino-L-alanine (BMAA) is an environmental neurotoxin that has been linked to a significantly higher ALS incidence in a population in Guam. To test whether BMAA can be used to study environmental-linked sporadic ALS *in vitro*, we generated mouse embryonic stem cell-derived motor neurons and exposed these neurons to differing concentrations of BMAA over 14 days in culture. In these studies, we have found that BMAA induces motor neuron death in a dose-dependent manner after seven days in culture and this degeneration is not reversible even after the BMAA is removed from the neuronal cultures and replaced with fresh medium. We have also observed that the exposure to BMAA results in early oxidative stress in motor neurons. Moreover, given that the addition of AMPA/kainate receptor antagonist (NBQX), but not NMDA receptor antagonist (MK-801), to culture rescues motor neurons, we believe that the AMPA/kainate receptor-mediated glutamate excitotoxicity might be involved in this BMAA-induced motor neuron degeneration. These findings suggest common pathogenic pathways between the familial and BMAA-induced ALS, which may provide further information on the disease mechanisms involved in sporadic ALS.

Title: Characterization of angiogenin-induced, trna-derived stress-induced rnas

Authors: *S. SUSDALZEW, M. C. HOGG, J. H. M. PREHN;
Physiol. & Med. Physics Dept, Royal Col. of Surgeons In Ireland, Dublin, Ireland

Abstract: Amyotrophic lateral sclerosis (ALS) is an incurable neurodegenerative disorder affecting motoneurons. Mutations in angiogenin, encoding a member of the pancreatic RNase A superfamily, segregate with ALS. We have previously shown that angiogenin is secreted from motoneurons under stress conditions and is taken up by astrocytes where it induces RNA cleavage and mediates neuroprotection in paracrine. Under stress conditions, Angiogenin has been shown to cleave tRNAs within the anticodon loop to produce tRNA-derived, stress-induced RNAs (tiRNAs). In reconstitution assays, tiRNAs have been shown to suppress cap-mediated global protein translation, but not internal ribosome entry sequence (IRES)-mediated translation which is often used by pro-survival and anti-apoptotic genes. 5' tiRNAs have also been shown to promote the assembly of stress granules (SGs), cytoplasmic foci at which untranslated mRNPs are transiently concentrated. We identified several tRNAs produced by Angiogenin in human astrocytoma cells. To characterise the effect of tiRNAs generated by Angiogenin, corresponding synthetic tRNA fragments (tiRNAs) labeled with a fluorophore were transfected in a neuronal cell line (SH-SY5Y), and their ability to protect against stress conditions analyzed in survival assays via flow cytometry. A broad range of stress treatments was chosen: Epoxomycin (proteasomal stress), Thapsigargin (ER stress and Ca2+ depletion) and sodium arsenite (oxidative stress), a commonly used stressors which induce apoptosis and lead to the formation of SGs. We verified that the transfected tiRNAs were internalised using confocal microscopy. However we did not detect significant neuroprotection induced by 5' or 3' aspartic acid or 5' alanine tiRNA in SH-SY5Y cells. Collectively these data suggest that 5' nor 3' tiRNAs generated by Angiogenin are not cytoprotective in this setting.

Title: Astrocytes derived from Amyotrophic Lateral Sclerosis patients upregulate ABC drug efflux transporters at the endothelial cell layer

Authors: *M. R. JABLONSKI, S. MARKANDAIAH, P. PASINELLI, D. TROTTI; Thomas Jefferson Univ., PHILADELPHIA, PA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a slowly progressing neurodegenerative disease, characterized by motor neuron degeneration. ALS is characterized by non-cell-autonomous components with astrocytes contributing to toxicity and selective loss of motor neurons. The blood-brain barrier (BBB) is formed by endothelial cells in association with pericytes and astrocytes, forming the neurovascular unit. Astrocytic end-feet encapsulate approximately 90% of endothelial cells and maintain homeostasis of the barrier. ABC drug efflux transporters, highly localized in endothelial cells, prevent a wide range of neurotoxicants and therapeutics from entering the CNS. We recently reported a disease-driven increase in expression and function of P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP) in spinal cord capillaries of the SOD1-G93A mouse model of ALS and expression increases in human spinal cord tissue (Jablonski et al. 2012; Neurobiol Dis), suggesting these transporters could cause pharmacoresistance in ALS. The ability to produce neuronal cell types from induced pluripotent stem cells (iPSCs) allows the differentiation of astrocytes and endothelial cells from both ALS patients and controls. We hypothesized that astrocytes derived from iPSCs impart alterations in ABC drug efflux transporters in iPSC-derived endothelial cells. To examine this hypothesis, we implemented a co-culture system whereby iPSC-derived endothelial cells were plated on a transwell above a layer of iPSC-derived astrocytes from ALS patients or controls. P-gp protein expression is increased in endothelial cells, which are co-cultured with astrocytes differentiated from ALS patient compared to iPSC-derived control astrocytes. Furthermore, NFkB inhibition (SN50) in endothelial cells prevented the endothelial P-gp expression increases seen from iPSC-derived ALS astrocytes. These results are an important step towards understanding drug efflux transporter regulation in ALS.

Title: Aberrant release of netrin-1 by astrocytes is toxic to motor neuron in ALS

Authors: ***L. T. ROSENBLUM**[1], A. BOGUSH[2], X. WEN[1], P. PASINELLI[1], D. TROTTI[1]; [1]Thomas Jefferson Univ., Philadelphia, PA; [2]Temple Univ., Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a rapidly progressive and fatal neurodegenerative disease primarily affecting the corticospinal tract. In ALS, astrocytes cause toxicity to upper and lower motor neurons in a process known as non-cell autonomous toxicity. It has previously been shown that accumulation of a sumoylated C-terminal fragment (CTE-SUMO1) derived from caspase-3 cleavage of EAAT2 occurs in spinal cord astrocytes of the SOD1-G93A mouse model of ALS as disease progresses. Furthermore, mimicking the *in vivo* astrocytic accumulation, expression of an artificialCTE-SUMO1 construct by astrocytes causes secretion of one or more factors that are toxic to motor neurons in *in vitro* experiments. Astrocytes expressing CTE-SUMO1 substantially upregulate Ntn-1 and the corresponding secreted axonal guidance protein, Netrin-1. In addition to its extensive developmental functions, Netrin-1 functions in local axonal homeostasis, cell-cell contact, and myelin organization and has recently been implicated in neurodegenerative diseases. We present evidence that astrocytes expressing either the ALS-causative mutation SOD1-G93A or the CTE-SUMO1 construct are toxic to motor neurons via netrin-1 secretion and indications that astrocytic netrin-1 secretion is a pathogenic mechanism in ALS. Netrin-1 is expressed by astrocytes only during the symptomatic stage in mice, increasing with disease course, and in post-mortem samples of affected areas of the human CNS. Furthermore, Netrin-1 is directly toxic to primary motor neurons, as measured by decreased neurite length and by increased death, but is not toxic to non-ALS susceptible cortical neurons. We also show that Netrin-1 mediates the toxicity of astrocytes expressing theCTE-SUMO1 construct or the ALS-causative SOD1-G93A mutation, both in a co-culture cell

model and from astrocyte-conditioned media, as shown with the addition of neutralizing antibodies.

Title: Modeling disease-specific axonal defects of hereditary spastic paraplegia with human pluripotent stem cells

Authors: ***K. R. DENTON**[1], L. LEI[1], J. GRENIER[1], V. RODIONOV[2], C. BLACKSTONE[4], X.-J. LI[1,3];
[1]Neurosci., [2]Ctr. for Cell Analysis and Modeling and Dept. of Cell Biol., [3]The Stem Cell Inst., Uconn Hlth. Ctr., Farmington, CT; [4]Cell Biol. Section, Neurogenetics Br., Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Hereditary spastic paraplegias (HSPs) comprise a large and diverse group of genetic neurodegenerative disorders (SPG1-71). The hallmark of all HSP subtypes is the length-dependent distal axonopathy, mainly affecting long projection neurons, especially cortical spinal motor neurons (CSMNs). The most common form of HSP is SPG4, which is caused by dominant mutations to the SPAST gene that encodes the microtubule-severing ATPase spastin. Here, we generated a model of SPG4 using human induced pluripotent stem cells (iPSCs) and examined differentiated forebrain glutamatergic neurons. The SPG4 neurons displayed a significant increase in axonal swellings, which stained strongly for mitochondria and tau, indicating the accumulation of axonal transport cargoes. Analysis of fast axonal transport revealed a significant reduction in mitochondrial transport indicating that these patient iPSC-derived neurons recapitulate disease-specific axonal phenotypes. Interestingly, spastin protein levels were

significantly decreased in SPG4 neurons, supporting a haploinsufficiency mechanism. Furthermore, cortical neurons derived from spastin-knockdown human embryonic stem cells (hESCs) exhibited similar axonal swellings, confirming that the axonal defects can be caused by loss of spastin function. Vinblastine, a microtubule-destabilizing drug, rescued this axonal swelling phenotype in neurons derived from both SPG4 iPSCs and spastin-knockdown hESCs. Thus, this study demonstrates the successful establishment of human pluripotent stem cell-based models of SPG4, which will be valuable for dissecting the pathogenic cellular mechanisms and screening compounds to rescue the axonal degeneration in HSP.

Title: Amyotrophic lateral sclerosis linked mutations in fused in sarcoma (fus) cause non-cell autonomous toxicity to motor neurons

Authors: *A. T. KIA, K. MCAVOY, K. KRISHNAMURTHY, S. SHAMAMANDRI MARKANDAIAH, D. TROTTI, P. PASINELLI;
Jefferson Hosp. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: It has become well established that astrocytes contribute to motor neuron degeneration and disease progression in Amyotrophic Lateral Sclerosis (ALS), an incurable neurodegenerative disease. Mutations in fused in sarcoma/translocated in liposarcoma (FUS/TLS, FUS) account for approximately 4% of familial (fALS) cases and FUS-positive pathological inclusions have been identified in sporadic ALS (sALS) cases as well. It is important then to elucidate what role is played by mutant FUS in driving astrocytic toxicity to motor neurons. Using primary astrocytes infected with N-terminally tagged GFP-FUS (WT or R521G), we show that R521G expressing astrocytes, but not controls, are in fact toxic to wild-

type motor neurons. Further, we show that conditioned medium from these astrocytes is sufficient to induce a neurotoxic effect on motor neurons. We identified one of the toxic molecules released in the medium of FUS-containing astrocytes and show that neutralizing that molecule affords protection to motor neurons. We also show that mutant FUS infected astrocytes display classical cytoplasmic inclusions seen in patients and, while they undergo changes in cellular phenotype, they do not die. Thus, like for SOD1-ALS but not for TDP-43-ALS (Serio et al., PNAS 2012), our data highlight a non-cell autonomous glial effect in disease and provide a viable *in vitro* system to further understand how mutations in different genes differentially affect glia-neurons interactions. This work was supported by NINDS-RO1 NS051488 and the Farber Family Foundation.

Title: The involvement of glial cells in FUS-related ALS/FTLD pathophysiology -FUS knock-down glial cells have a neuro-protective effect.-

Authors: *Y. FUJIOKA[1], S. ISHIGAKI[1], T. SHIROMIZU[2], T. UDAGAWA[1], D. HONDA[1], S. YOKOI[1], K. IKENAKA[1], M. KATSUNO[1], T. TOMONAGA[2], G. SOBUE[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is one of the most common neurodegenerative disorders, characterized by selective motor neuron degeneration in the primary motor cortex, brainstem and spinal cord. FUS is the causative gene of familial ALS and pathologically linked to sporadic ALS and frontotemporal lobar degeneration (FTLD). FUS is an RNA binding protein which was reported to function in transcription, RNA splicing, and RNA transport in various cells including neurons and glial cells. Recently, non-cell autonomous toxicity has been thought to be involved in the pathophysiology of SOD1-related ALS. However, it has not been clear whether glial cells have effects on neurons in FUS-related ALS/FTLD pathology. To elucidate the effects of FUS-silenced glial cells to neurons, the neurite outlength of primary cortical neurons (PCN) co-cultured with glial cells with/without FUS was measured by the autoimage

scanner. Surprisingly, the neurite outlength of PCN were elongated after the co-culture with FUS knock-down glial cells, indicating that FUS knock-down glial cells have a protective effect. Next, we identified some proteins specifically elevated in the culture supernatant of FUS-silenced glial cells using LC-MS/MS analysis as candidates for protective factors. Thus, glial cells which lost the function of FUS countervail the progression of the pathology of FUS related ALS/FTLD through the expression of protective factors.

Title: Impact of *in vitro* and *in vivo* modulation of ALS C9ORF72 gene

Authors: ***P. J. MULCAHY**, A. HIGGINBOTTOM, G. HAUTBERGUE, P. J. SHAW, M. AZZOUZ;
Neurosci., Sheffield Inst. For Translational Neurosci., Sheffield, United Kingdom

Abstract: Theme: **C.04. Neurodegenerative Disorders and Movement Disorders** C.04.g. Motor neuron disease: *in vitro* studies **Rationale & Objectives:** Since the recent discovery of the relationship between the C9ORF72 gene and Amyotrophic Lateral Sclerosis (ALS), much research efforts have focused on understanding the role of this particular protein and modelling the disease. Repeat GGGGCC expansions located in the intronic region have been linked to the disease in familial ALS cases. Here, we attempt to elucidate the role of C9ORF72 in terms of both its role in normal function and also in ALS. The function of the C9ORF72 was assessed by gene silencing both *in vitro* and *in vivo*. Repeat expansion induced cellular disruptions were also investigated to determine the mechanistic pathways involved with the aim of potential gene therapy development. **Methodology:** To determine the role of C9ORF72, knockdown miRNA sequences were designed to target mouse gene and were cloned into lentiviral and adeno-associated viral vectors. Transduction of cell lines and primary neurons were carried out and

C9ORF72 silencing was assessed at mRNA and protein levels. To assess the effect of GGGGCC repeat expansions, lentiviral and adeno-associated viral vectors with repeat sequences from 10 to 102 repeats were generated. Transduction assays were carried out using cell lines and primary neuronal cells (cortical neurons and spinal motor neurons). Cell viability and apoptosis were assessed and C9ORF72 associations with RNA binding proteins analysed. *In situ* evaluation of RNA foci development, as noted in the human condition, following viral expansion transduction was carried out using both sense and antisense probes. To examine the effects associated with C9ORF72 knockdown or repeat expansion *in vivo*, neonatal mice were infused with the viral vectors and behavioural testing was performed. **Findings:** Results have shown that viruses generated to silence C9ORF72 showed significant knockdown following cell transduction compared to scrambled control *in vitro*. RNA foci development following transduction with lentiviral-mediated repeat expansions has been observed in neurons. Behavioural and histological data from animals injected with AAV9 expressing GGGGCC are being analysed. Our current studies will allow many avenues to open up in terms of C9ORF72 research into the causes and potential treatments for ALS.

Title: SUMO3 accelerates aggregation of ALS-linked SOD1 mutants

Authors: *T. NIIKURA[1], Y. KITA[2], Y. ABE[3];
[1]Information and Communication Sci., Sophia Univ., Tokyo, Japan; [2]Ctr. for Res. and Develop. of Bioresources, Osaka Prefecture Univ., Osaka, Japan; [3]Dept. of Pharmacol., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Mutations in superoxide dismutase 1 (SOD1) are the major cause of familial amyotrophic lateral sclerosis (FALS) and have been widely used for *in vitro* and *in vivo* models to investigate the pathomechanisms of ALS. FALS-linked mutant SOD1 proteins are misfolded and aggregated into intracellular inclusions both *in vitro* and *in vivo*. It is generally accepted that the propensity for aggregation is associated with the pathobiology of SOD1 mutants. Sumoylation, a post-translational protein modification, involves covalent attachment of small ubiquitin-like modifier (SUMO) proteins to target proteins. The astrocytic expression of sumoylated EAAT2 fragment induces cytotoxicity in motoneuronal NSC34 cells and primary motor neurons, suggesting the involvement of sumoylation in ALS pathogenesis. Here, we investigated the effect of sumoylation on ALS-linked mutant SOD1 proteins in motoneuronal NSC34 cells. We found that both SUMO1 and SUMO2/3 modify ALS-linked SOD1 mutant proteins at lysine75 in these cells. The modification of ALS-linked SOD1 mutant proteins by SUMO3, rather than by SUMO1, significantly increased the stability of the proteins and accelerated intracellular aggregate formation. These findings suggest the contribution of sumoylation, particularly by SUMO3, to the protein aggregation process underlying the pathogenesis of ALS.

Title: Mechanistic study of oligodendrocyte degeneration in ALS *in vitro*

Authors: ***Y. LI**[1], B. DWIGHT[2], J. D. ROTHSTEIN[2];
[1]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]the Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult onset degenerative disease characterized by the death of motor neurons. Both macroglia and microglia play a role in disease development. However, oligodendrocyte (OL) lineage, in contrast to other glial types, has been found to significantly affect disease onset in mouse models. OLs indeed die at pre-symptomatic

stage in animal models. Remarkably, OLs degeneration is common in ALS patients, including both familial and sporadic cases. All these data indicate that OL lineage cells play a critical role in ALS pathogenesis. To further investigate the mechanisms involved in OL degeneration and how it affects motor neuron survival, we generated *in vitro* models. In two-dimensional (2-D) pure mouse OPC (msOPC) culture, no differences in cell proliferation and death have been seen between SOD1-msOPCs and wild type (WT)-OPCs, while SOD1-msOPCs showed slightly enhanced differentiation to myelinating OLs after triiodothyronine (T3) treatment. As similar to 2-D culture, when msOPCs were cultured on nanofibers (3-D), no difference in cell proliferation was observed. In contrast, T3 treatment induced more myelinating SOD1-OL differentiation and death compared to WT-OLs, indicating that overexpression of mutant SOD1 affects mouse OL differentiation and survival. We further cocultured mouse SOD1-OLs with human neurons that were differentiated from human control- or ALS-specific induced pluripotent stem cells (iPSCs). Abnormal OL differentiation was seen in the co-cultures with mouse SOD1-OLs as indicated by abnormal myelin basic protein (MBP) expression. Those OLs with abnormal MBP expression had cleaved caspase 3 expression or condensed nuclei, indicating they were degenerating. Given that human OPCs (huOPCs) have reactive morphology and gray matter OL degeneration are common in ALS patients, we further set out to investigate human ALS-specific oligodendrocytes. We differentiated ALS-specific iPSCs to OPCs, myelinating OLs, and also cocultured differentiated huOPCs with human neurons. We did not see significant differences in huOPC differentiation between control- and ALS-iPSCs. When human neurons were cocultured with human oligospheres, axonal degeneration was readily seen in the cultures with ALS-oligospheres compared to that with control-oligospheres. These *in vitro* models are being used to study the mechanisms involved in OL degeneration in ALS.

Title: Selective Neurodegeneration in Alzheimer’s Disease and Parkinson’s Disease

Authors: *J. WANG, W. SONG;
UBC, Vancouver, BC, Canada

Abstract: A hallmark of Alzheimer's Disease (AD) is neuritic plaques, primarily consist of extracellular deposits of amyloid β (Aβ) cleaved from β-amyloid precursor protein (APP). Parkinson's Disease (PD) is characterized by intracellular Lewy bodies (LBs), primarily consist of aggregated alpha-synuclein protein (αSyn), encoded by SNCA gene. Both AD and PD are characterized by extensive neuronal loss within certain brain regions. An invariant feature of AD is cholinergic dystrophy and dopaminergic neurodegeneration in substantia nigra is characteristic in PD. Previous studies suggested that AD-associated Swedish APP mutation promoted Aβ generation and neuronal loss, whereas PD-associated SNCA A53T mutation caused αSyn more prone to aggregate. In this study, we used cholinergic SN56 cells and dopaminergic MN9D cells to stably overexpress wildtype (WT)/ mutant APP or WT/ mutant SNCA gene, followed by performing whole-genome expression profiling in these stable cell lines as well as two background cell lines. There were 213 probes identified as having an interaction between APP mutation's effect and cell line's effect. There were 1422 probes having an interaction between SNCA mutation's effect and cell line's effect. As for gene set enrichment analysis, the difference of Swedish APP gene overexpressing in SN56 and MN9D cell lines has the strongest effect on ECM-receptor gene expression, while the difference of overexpressing SNCA A53T gene in two cell line has the strongest effect on spliceosome gene expression. Our data supports the hypothesis that APP and SNCA mutations change gene expression in a cell type-dependent way, which may contributes to selective neurodegeneration in AD and PD.

Title: Selenoprotein P mediates modification of synaptic physiology and plasticity

Authors: *E. D. NGUYEN-WU;
Cell and Mol. Biol., Univ. of Hawaii At Manoa, John A. Burns Sch. of Med., Honolulu, HI

Abstract: Selenoprotein P (Sepp1) is an extracellular protein with multiple selenocysteine residues involved in interorganal selenium transport. Sepp1 is part of the unique family of selenoproteins obtained mainly through dietary selenium, an essential micronutrient. Association of Sepp1 with pathology in neurodegenerative disorders and neurological impairments in Sepp1 knockout (Sepp1 KO) animals highlight the importance of Sepp1 for brain function. However, the direct actions of Sepp1 in brain remain poorly understood. We investigated expression of Sepp1 in the cortex, substantia nigra and putamen, as well as cuboidal cells of the choroid plexus in human postmortem Alzheimer's and Parkinson's disease brain samples. Our published data demonstrated for the first time, that Sepp1 is associated with both Alzheimer's and Parkinson's brain pathology. These neurodegenerative diseases involve memory loss and motor dysfunction similarly exhibited by Sepp1 KO mice. We are currently investigating the role of Sepp1 in synaptic physiology using Sepp1 KO mice. Deletion of Sepp1 results in bidirectional changes in synaptic plasticity, learning and memory deficits, and neuromotor defects. Long-term potentiation (LTP) is a well-established cellular model for learning and memory. LTP deficits observed in Sepp1 KOs can be reversed by applying Sepp1 directly onto the hippocampus. Altogether, these studies underscore the importance of Sepp1 in maintaining normal synaptic integrity and plasticity. These novel findings strongly support our hypothesis that Sepp1 has direct actions on neuron physiology besides its role in transporting selenium.

Title: Introducing MAPT mutation into human iPSC-derived neural stem cells using CRISPR/Cas systems

Authors: *Y. IMAIZUMI, H. OCHIAI, K. YAMAZAKI, K. SAGANE, M. ITO;
Eisai Co., Ltd., Ibaraki, Japan

Abstract: To understand the pathogenic mechanisms in patients with neurological disorders, induced pluripotent stem cell (iPSC)-based human neuronal disease models could be helpful application tools. For more precise analysis, recent development of the genome editing technology, such as zinc-finger nuclease (ZFN) and transcription activator-like effector nuclease (TALEN), enabled us to generate monogenic iPSCs from wild-type iPSCs and rescue disease phenotypes on patient derived-iPSCs. However, use of ZFNs or TALENs on iPSCs is still a challenge, because of low efficiency of genome editing. Here, we used a novel genome editing technology "clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated (Cas) systems" on human iPSC-derived neural stem cells (NSCs) due to the following two reasons. (1) Recently, Ding *et al.,* demonstrated that efficiency of iPSC genome editing was enhanced using CRISPR/Cas systems compared with TALENs (Ding, *et al.*, 2013). (2) NSCs might show higher viability and transfection efficacy, and shorter neural differentiation period, compared with iPSCs. NSCs were induced from 201B7 iPSCs (iPSC from a healthy donor) by using Gibco's NSC induction medium. Double-strand DNA repair template, guide RNA (gRNA) and Azami green fused Cas9 vector were designed to generate microtubule-associated protein tau (MAPT) mutation. After 48 hrs from transfection, Cas9-activated NSCs were sorted by fluorescence-activated cell sorting (FACS) system and expanded. Then, some NSC clones with MAPT homozygous mutation were established. Finally, MAPT NSCs were able to differentiate into neurons and showed marked accumulation of phosphorylated tau. In conclusion, we succeeded to generate human iPSC-derived NSCs with MAPT mutation using CRISPR/Cas systems. Moreover, this study suggests that NSCs will be one of good host cells for genome editing to establish neurological disease models efficiently.

Title: Targeted induction of endogenous TRPML2 (Mucolipin-2) or TRPML3 (Mucolipin-3) expression for use as potential therapy for Mucolipidosis type IV

Authors: J. A. VALADEZ, *M. P. CUAJUNGCO;
BIOLOGICAL SCI, CALIFORNIA STATE UNIV FULLERTON, FULLERTON, CA

Abstract: There is currently no therapy or cure for Mucolipidosis type IV (MLIV). A previous study in *Caenorhabditis elegans* has shown that the loss of CUP5 protein, a Mucolipin-1 (TRPML1) orthologue, could be rescued by genetic complementation using human TRPML1 or TRPML3. The high degree of sequence and functional similarities between TRPML1 and its related proteins, TRPML2 and TRPML3, make them an excellent candidate to potentially substitute for the loss of TRPML1 function in MLIV. In order to consider this possibility, we first focused on studying the mechanisms that control the expression of *TRPML2* (*Mucolipin-2*) gene. We cloned DNA regions of varying size upstream of the *TRPML2* gene transcriptional start site (TSS) into a dual luciferase reporter (DLR) assay. We identified a putative core promoter region between -320 and -287 of the TSS containing a consensus sequence for six transcription factors (TFs). Heterologous expression of the candidate TFs conferred an effect on the expression of endogenous *TRPML2* transcripts compared to controls. To determine post-transcriptional regulators of endogenous *TRPML2* transcripts, we screened and identified a micro-RNA that modulates the expression of endogenous *TRPML2* transcripts using real-time quantitative PCR (qPCR) technique. Meanwhile, we use the DLR assay to screen a drug library to identify compounds that up-regulate the expression of *TRPML2* and *TRPML3* genes. Using real-time qPCR, we found several candidate drugs that significantly increased the transcript levels of endogenous *TRPML2* and *TRPML3* genes. These results show that we could induce the expression of the *TRPML2* and *TRPML3* genes through exogenous manipulation of transcriptional activators, or post-transcriptional regulators. Understanding the mechanism of TRPML2 or TRPML3 protein expression brings us a step closer to our goal of manipulating the expression of either protein as a potential therapeutic substitute for the loss of TRPML1 function in MLIV disease.

Title: Evidence for lysosomal membrane permeability and protein aggregate formation in Mucolipidosis type IV

Authors: *L. C. BOUDEWYN, M. C. MICSENYI, S. U. WALKLEY;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Mucolipidosis type IV (MLIV) is a rare autosomal recessive lysosomal disease that presents early in life with progressive neurological symptoms, including intellectual disability, delayed developmental and motor milestones, ophthalmologic abnormalities, and premature death. There is currently no cure or corrective therapy. MLIV stems from mutations in the MCOLN1 gene, which encodes the late endosomal/lysosomal transient receptor potential channel, mucolipin-1. Its dysfunction leads to a host of metabolic abnormalities, most notably the accumulation of glycosphingolipids and acid mucopolysaccharides in neurons and other cells throughout the central nervous system (CNS) and periphery. In addition to the accumulation of storage material in Mcoln1-/- mice, our lab has previously reported the presence of large inclusion bodies comprised in part of the autophagic adaptor protein p62. Confocal microscopy has revealed that these inclusions are in fact lysosomal storage bodies where p62 is localized in a shell-like pattern around the periphery of lysosomal membranes. Our lab recently identified that p62 responds to a novel pathophysiological event known as lysosomal membrane permeability (LMP) in the lysosomal disease, late-infantile neuronal ceroid lipofuscinosis. We found that LMP, a known mechanism of cell death, stimulates a coordinated response by macroautophagy adaptor proteins including p62 to sequester damaged lysosomes and their content as cytosolic protein aggregates. Our recent findings of p62-positive aggregates in MLIV disease and the distinct localization of p62 to the periphery of lysosomal storage bodies in both neuronal and glial cell types suggests LMP and a similar response may be occurring. Notably, recent reports have shown that LMP induction stimulates an autophagy mechanism known as lysophagy. Lysophagy involves the recruitment of ubiquitin, p62 and LC3-II to lysosomes undergoing LMP to engulf these damaged organelles within nucleating autophagosomes to be redelivered to intact lysosomes. This mechanism prevents the release of lysosomal cathepsins and lysosomal-mediated cell death. Evidence in MLIV and other lysosomal diseases for p62 sequestration of lysosomes and lysosomal storage material suggests that LMP is occurring in these disorders. Importantly, the persistent presence of p62-aggregates in these diseases may indicate a failure in lysophagy to adequately respond to LMP. Here we are using Mcoln1-/- mice to clarify the pathophysiological events that occur in MLIV disease progression. Addressing this issue is central to understanding the cellular abnormalities leading to MLIV's clinical manifestations.

Title: Deoxysphingolipids: A new biomarker in peripheral neuropathy?

Authors: ***E. A. JOHNSON**[1], N. WEI[1], T. HORNEMANN[2], F. EICHLER*[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Inst. for Clin. Chem., Univ. Hosp. Zurich, Zurich, Switzerland

Abstract: Deoxysphingolipids (deoxySLs) are neurotoxic lipids that have been shown to accumulate as a byproduct of aberrant sphingolipid synthesis (Penno et al 2010). It was originally recognized that they were toxic in various cancer cell lines (Cuadros et al 2000) but their role in normal physiology and disease remained poorly understood. Interestingly, *in vitro* studies also showed that dSL are toxic to cultured sensory neurons. Our recent studies examined the accumulation of dSL *in vivo* in patients with Hereditary Sensory Autonomic Neuropathy Type I (HSAN1) as well as in diabetic patients (T1DM and T2DM, with and without neuropathy). Studies were conducted on both retrospectively and prospectively collected samples. For sphingoid base analysis the samples were shipped on dry ice overnight to the University of Zurich. The sphingoid base profile was analyzed by LC-MS after hydrolyzing the N-acyl and O-linked headgroups as described earlier (Zitomer et al 2009). Marked accumulation of two atypical deoxy-sphingoid bases (1-deoxy-sphinganine and 1-deoxymethyl-sphinganine) were found in HSAN1 patients (N=18) consistent with our prior reports (Garofalo et al., 2010). Next we compared the long chain base profile in plasma from individuals with T1DM (N=27), T2DM (N=30) and healthy controls (N=23). 1-deoxySLs were significantly higher in the groups with T2DM but not different between T1DM and controls. In contrast to patients with T2DM, 1-deoxSL levels are not elevated in T1DM. Our studies provide further evidence that aberrant dSL are a biomarker for particular metabolic disorders that cause neuropathy. It appears that in diabetes the 1-deoxySL formation is not per-se caused by hyperglycemia but rather specifically

associated with metabolic changes in T2DM. Ongoing studies are assessing whether the degree of neurologic impairment is correlated with dSL levels in both HSAN1 patients and T2DM diabetic patients.

Title: Dynamic palmitoylation of H+-transporting V-ATPase subunit a1 regulates lysosomal acidification and is disrupted in Ppt1-/- mice

Authors: M. B. BAGH[1], G. CHANDRA[3], Z. ZHANG[1], S. PENG[2], *A. B. MUKHERJEE[4]; [1]NICHD (National Inst. of Child Hlth. and Human Development), [2]NINDS (National Inst. of Neurolog. Disorders and Stroke), NIH, Bethesda, WA; [3]Dept. of Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL; [4]NICHD (National Inst. of Child Hlth. and Human Development), Natl. Inst. of Hlth., Bethesda, MD

Abstract: Neuronal ceroid lipofuscinoses (NCLs) are the most common childhood neurodegenerative lysosomal storage disorders (nLSDs). The infantile NCL (INCL) is caused by mutations in the CLN1 gene encoding palmitoyl-protein thioesterase-1(PPT1). Dynamic palmitoylation (palmitoylation-depalmitoylation) is critical for regulating the functions of many proteins, especially in the brain, and involves palmitoylation by palmitoyl-acyltransferases (PATs) as well as depalmitoylation by palmitoyl-protein thioesterases (PPTs). PPT1-deficiency impairs degradation of palmitoylated proteins (constituents of ceroid) by lysosomal hydrolases causing lysosomal ceroid accumulation leading to INCL. However, lysosomal hydrolases require acidic pH for enzymatic activity and in virtually all LSDs the lysosomal pH is elevated and the molecular mechanism(s) of this defect remains unexplained. The vacuolar H+-transporting ATPase (V-ATPase) is a multi-subunit protein-complex that regulates endosomal/lysosomal pH. It is suggested that the reversible assembly of its membrane-bound V0 sector and a cytosolic V1 sector regulate the acidification of intracellular compartments including the lysosomes. Accordingly, we tested a hypothesis that one or more subunits of V-ATPase require dynamic

palmitoylation for lysosomal targeting and are disrupted in INCL. Using Ppt1-/- mice, a reliable animal model of INCL, we found that the a1 subunit of V0-ATPase (V0a1) requires palmitoylation on Cys-25 for localization to endosomal/lysosomal membranes. Unexpectedly, we found that in brain tissues of Ppt1-/- mice V0a1 is mis-targeted to the plasma membrane instead of lysosomal membrane.Moreover, V0a1 is transported via clathrin/AP2-dependent pathway from plasma membrane to early endosomes where lack of PPT1 suppressed depalmitoylation impairing dissociation of V0a1 from clathrin/AP2/V0a1 complex. Failure of V0a1 dissociation prevented its repalmitoylation essential for binding AP3, required for its transport to lysosomes. Consequently, clathrin/AP2/V0a1 complex was transported to the plasma membrane via the recycling endosomes. This defective trafficking of V0a1 disrupted V0V1 assembly on lysosomal membrane, essential for pH regulation. Importantly, a PPT1-mimetic small molecule, NtBuHA, which we recently identified, ameliorated these defects. Our findings for the first time demonstrate that PPT1-deficiency impairs dynamic palmitoylation (palmitoylation-depalmitoylation) of V0a1 which elevates lysosomal pH in INCL and suggest that varying mechanism(s) impairing V0ATPase may underlie elevated lysosomal pH in other LSDs.

Title: Intrathecal or intravenous recombinant human alpha-iduronidase improve brain myelination in canine mucopolysaccharidosis I

Authors: *P. DICKSON[1], J. M. PROVENZALE[2], S. CHEN[2], I. NESTRASIL[3], J. YEE[4], S.-H. KAN[4], S. Q. LE[4], J. JENS[5], E. SNELLA[5], M. A. GUZMAN[6], C. VITE[7], E. G. SHAPIRO[3], N. ELLINWOOD[5];

Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Objectives: Children with mucopolysaccharidosis I (MPS I) show reduced fractional anisotropy (FA, a measure of white matter integrity) on diffusion tensor imaging (DTI) of the corpus callosum (CC) that correlates with diminished attention on neurocognitive tests (Shapiro et al., 2012). Our neuroimaging and neuropathological studies in MPS I dogs suggest that reduced volume and FA in the CC are caused by abnormal myelination (Provenzale et al., in preparation). We therefore studied the impact of enzyme replacement therapy with recombinant human alpha-L-iduronidase (rhIDU) on abnormal myelination in the canine CC. Methods: MPS I dogs received intrathecal (IT) rhIDU 0.05 mg/kg every 3 months and/or intravenous (IV) rhIDU 0.58-2.0 mg/kg weekly. Untreated MPS I and unaffected carriers were used as controls. Dogs underwent brain magnetic resonance imaging and DTI. CC was evaluated using sandwich ELISA for myelin basic protein (MBP), RT-PCR for myelin-related gene expression, lipidomics, and electron microscopy. Results: Mean whole CC volumes were lower in MPS I dogs vs. carriers ($p=0.02$). CC volume was preserved with IT rhIDU ($p=0.006$ vs. untreated MPS I). FA was reduced in MPS I dogs vs. carriers ($p=0.004$). MBP in CC of treated MPS I, untreated MPS I, and carrier dogs correlated with FA ($r2=0.56$, $p=0.01$) and inversely correlated with radial diffusivity ($r2=0.51$, $p=0.02$), demonstrating a relationship between CC myelination and DTI. We found decreased myelination in MPS I dogs ≥6 weeks. Myelin composition was abnormal in MPS I dogs. Neuroimaging findings, MBP and myelin lipid composition in the CC was improved with administration of IT rhIDU, even if started at 4 months. Expression of myelin-related genes in CC improved in MPS I dogs treated with IT and/or IV rhIDU beginning at ≤30 days of age. Conclusions: Reduced CC volume and FA in MPS I dogs may be caused by abnormal myelination. IT and/or IV rhIDU improves abnormal myelination in the CC, especially if treatment begins early.

Title: The mechanism of HspB1 and its mutants on the regulation of RhoA activity

Authors: *X. SUN[1,2], D. J. FINK[1,2], M. MATA[1,2];
[1]Neurol., Univ. of Michigan, Ann Arbor, MI; [2]VA Ann Arbor Healthcare Syst., Ann Arbor, MI

Abstract: Heat shock protein B1 (HspB1) is an ATP-independent molecular chaperone belonging to a family of small heat shock proteins with a conserved α-crystalline domain in the C-terminalregion. A number of mutations in HspB1 have been identified in families with Charcot Marie Tooth type IIF (CMT-IIF) disease or with distal hereditary motor neuropathy II (dHMN II). CMT is a clinical heterogeneous group of diseases characterized by progressive nerve degeneration causing distal muscle weakness and atrophy and sensory loss; in dHMNII phenotype the degeneration affects motor nerves but sensory abnormalities are absent. Mutations outside the crystalline domain (P39L, G84L, P128S, P182L) appear to associate with dHMN, while mutations within the crystalline domain may associate with either phenotype We previously observed that wild type HspB1 reduces RhoA activation by translational inhibition of PDZ-RhoGEF, a RhoA specific GEF. Decreased expression of PDZ-RhoGEF by HspB1 was accomplished by enhancing expression of specific microRNAs (miR20a and miR128) that inhibit the translation of PDZ-RhoGEF and resulted in an increase neurite growth response in cortical neurons. To determine whether this signaling pathway may be altered in HspB1

mutations causing disease, we studied three different mutations (S135F, R136W and R127W) that are closely localized in the α-crystalline domain of HspB1 and that are associated with an AD CMT-IIF phenotype. Mutants R136W and R127W behave as wt HspB1 in the regulation of RhoA activity by translation inhibition of PDZ-RhoGEF, but mutant S135F did not increase expression of miR20a and miR128 to modify PDZ-RhoGEF levels nor decrease RhoA activity in Neuro-2a cell line and cortical neurons Our results suggest that either these HspB1 mutations alter independent cellular mechanisms or that their effects may converge downstream of RhoA GTPase signaling to cause similar disease phenotype.

Title: Investigating SPTLC1 mutations on protein profiles in HSN-I patient lymphoblasts

Authors: *S. STIMPSON, J. COORSSEN, S. MYERS;
Univ. of Western Sydney, Campbelltown, Australia

Abstract: Axonal degeneration is the final common path in many neurological disorders. Subsets of neuropathies involving the sensory neuron are known as hereditary sensory neuropathies (HSN). Hereditary sensory neuropathy type I (HSN-I) is the most common subtype with autosomal dominant inheritance. It is characterized by the progressive degeneration of the DRG and an onset of clinical symptoms between the second or third decade of life. Heterozygous mutations in the serine palmitoyltransferase (SPT) long chain subunit 1 (SPTLC1) were identified as the pathogenic cause of HSN-I. Previous studies have shown that in HSN-I patient lymphoblasts, mitochondria play a role in HSN-I. Transmission electron micrographs studies have shown that the mitochondria in the HSN-I mutant cells are morphologically challenged, cluster to the perinucleus and are wrapped by the endoplasmic reticulum (ER). This investigation has shown that mutant SPTLC1 alters the expression of and potentially interacts with a set of proteins that associate with the mitochondria and ER. Using mitochondrial and ER protein isolates from control and patient lymphoblasts, via 1 and 2-dimensional gel electrophoresis, we have confirmed up regulation of a number of proteins by mass spectrometry caused by the SPTLC1 mutations. In conclusion, previous studies have shown alterations to the

mitochondrial and ER protein profiles in patient-derived lymphoblasts, with this investigation confirming changes and has identified novel proteins which may help further the understanding of HSN-I and establish a basis for treatment. The regulation of these proteins may prove a new route to understanding the cellular mechanisms underlying HSN-I.

Title: Axonal transport disruption and cytoskeletal restructuring in retinal ganglion cells following elevated intraocular pressure

Authors: *A. NUSCHKE[1], X. WANG[4], C. SMITH[2], V. DANTHUREBANDARA[3], N. O'LEARY[5], B. CHAUHAN[2];
[2]Physiol. and Biophysics, [3]Ophthalmology and Visual Sci., [1]Dalhousie Univ., Halifax, NS, Canada; [4]Natl. Eye Institute, Natl. Inst. of Hlth., Bethesda, MD; [5]Ctr. for Biostatistics, Inst. of Population Hlth., Univ. of Manchester, Manchester, United Kingdom

Abstract: **Introduction:** Disruption of axonal transport (AT) and changes in structural proteins within the retinal ganglion cell (RGC) axon are associated with RGC response to injury, both in human optic neuropathies and experimental models of RGC loss. A time-course of such changes following a transient injury is not well characterized. Here we examine AT and the expression of cytoskeletal proteins within the RGC axon following transient retinal ischemia induced by elevated intraocular pressure (IOP). Responses to an IOP elevation for durations known to cause (90 mins) and not cause (30 mins) progressive RGC loss are compared. **Methods:** The anterior chamber of right eyes of Brown Norway rats was cannulated with a 30 G needle attached to a saline reservoir, which was raised to induce an IOP of 120 mmHg. The left eye was used as control. Anterograde AT was monitored via injection of the tracer cholera-toxin B-subunit (CTB) Alexa488 conjugate into the vitreous of the eye immediately prior to IOP increase. Elevated IOP was maintained for 30 or 90 mins. Rats were sacrificed at 3, 6 and 24 hours following IOP increase for AT analysis, and 1 week for quantification of RGC loss. Average

fluorescence within optic nerves (ONs) was measured from confocal images of longitudinal ON sections along their entire length. These data were analysed using a linear mixed-effects model. RGC loss was quantified in retinal wholemounts using the RGC marker Brn3a. Immunohistochemistry for phosphorylated and non-phosphorylated neurofilament heavy, as well as markers of glial activation (GFAP and Iba-1) was performed in longitudinal sections of the optic nerve head (ONH). **Results:** A 90-min increase in IOP caused 98±0.9% (N=2, P=0.004) RGC loss 1-week post injury, as well as retrograde accumulation of CTB in the ONH. In ON sections there was a mean 56% (N=12, P<0.001) decrease in AT compared to control. The 30-min injury caused no detectable RGC loss (1.2±2.5%, N=2, P=0.002) and no evidence of AT blockade at the ONH. However, analysis of ONs after the 30-min injury demonstrated a mean 8% (N=12, P<0.001) decrease in AT. There was no effect of recovery time following either injury. Analysis of neurofilament expression suggested an increase in phosphorylated neurofilament at 6 hours following 90 mins of IOP elevation, while no change is observed following 30 mins. **Conclusions:** Despite no detectable RGC loss following 30 mins of elevated IOP, there was a significant blockade in AT evident in the ON. Evidence of cytoskeletal restructuring was only present in the case of severe injury causing RGC loss. It is possible that mild disruptions of AT are less determining than cytoskeletal modifications in RGC survival.

Title: Progranulin haploinsufficiency causes pre-clinical retinal thinning and NCL-like pathology in humans

Authors: *M. E. WARD[1], R. CHEN[2], A. TAUBES[2], S. MINAMI[1], Y. LI[1], B. MILLER[2], B. SEELEY[2], H.-Y. HUANG[2], H. BOUDIN[2], E. HUANG[2], S. COTMAN[3], J. STAROPOLI[3], A. GREEN[2], L. GAN[1];

Abstract: Reduced expression of progranulin (PGRN) via heterozygous mutations in the *GRN* gene causes frontotemporal dementia (FTD), a neurodegenerative disorder typified by behavioral and/or language abnormalities. Complete loss of PGRN expression due to homozygous *GRN* mutations was recently discovered in two siblings. Unexpectedly, these siblings developed symptoms and pathologic features consistent with Neuronal Ceroid Lipofuscinosis (NCL), a group of related pediatric neurodegenerative disorders characterized by vision loss, retinal atrophy, seizures, and the presence of autofluorescent intracellular storage material. Here, we provide the first evidence of NCL-like clinical and pathological features in humans with heterozygous *GRN* mutations. Using optical coherence tomography, we measured retinal thickness in 12 living *GRN* mutation carriers and 24 age- and sex-matched controls. We discovered substantial retinal thinning in *GRN* mutation carriers, including those who were cognitively asymptomatic. Autofluorescent aggregates were also present in the retinas of several *GRN* mutation carriers. Electron microscopy (EM) studies of post-mortem brain tissue from *GRN* mutation carriers revealed a significant increase in electron-dense intraneuronal storage material. Aggregates of mitochondrial subunit C, characteristic findings in NCL, were present in post-mortem brain tissue from *GRN* mutation carriers. EM analysis of human lymphoblasts isolated from five separate *GRN* mutation carriers showed significant increases in NCL-like storage material compared to non-mutation sibling controls. This storage material phenotype could be rescued by overexpression of PGRN. Our findings indicate that heterozygous *GRN* mutations cause early retinal thinning, a clinical feature of NCL, and NCL-like pathology in humans. Taken together, they suggest that *GRN*-associated FTD and the NCLs may share similar mechanisms.

Title: Identification of transcription factors necessary for re-establishing retinotectal connections after optic nerve transection in zebrafish

Authors: *I. VENKATESH, R. TEAL, A. UDVADIA;
Biol. Sci., Univ. of Wisconsin, Milwaukee, WI

Abstract: Damage to the central nervous system (CNS) circuitry of adult mammals results in permanent disability. In contrast, the ability to regenerate damaged CNS nerves and achieve functional recovery occurs naturally in fish. The ability of fish to successfully regrow damaged CNS nerves is in part a consequence of their ability to re-express key neuronal growth-associated genes in response to CNS injury. However, our knowledge of the molecular mechanisms regulating growth-associated gene expression during successful CNS regeneration in fish remains limited. We have focused our initial efforts on a well-charaterized growth associated gene encoding Growth-Associated Protein-43 (GAP-43), a protein highly enriched in axonal growth cones during CNS development and regeneration. Our studies demonstrate that knockdown of *gap43* gene expression during optic nerve injury in fish obstructs regenerative axon outgrowth *in vivo.* This prompted us to investigate regulatory pathways responsible for *gap43* gene activation during CNS regeneration in fish. Using *in vivo* reporter assays, we identified select transcription factors involved in activation of *gap43* transcription during optic nerve regeneration in fish. We have also utilized *in vivo* regeneration assays to determine the impact of these same transcription factors on the ability of damaged retinal axons to re-establish tectal connections after optic nerve transection. We are currently performing chromatin immunoprecipitation (ChIP) assays in regenerating zebrafish retina, to determine if the identified candidate transcription factors directly regulate *gap43* expression by binding to the previously identified regeneration-specific promoter regions during optic nerve regeneration. Using *gap43* as a model we have identified transcription factors necessary for re-activation of growth-associated gene expression and axon regrowth during CNS regeneration in fish, thereby revealing potential targets for therapeutic strategies designed to improve regenerative capability in mammals

Title: Cytoskeletal alterations and abnormal protein accumulation in the primary visual projection of the DBA/2J mouse model of glaucoma

Authors: *S. D. CRISH, G. N. WILSON, M. A. SMITH, C. M. DENGLER-CRISH; Pharmaceut. Sci., NEOMED, Rootstown, OH

Abstract: In neurodegenerative disorders, cytoskeletal defects and abnormal protein accumulation in the brain are early pathologies that occur prior to neuronal loss. For example, hyperphosphorylation of neurofilament (pNF-H) and/or site-specific hyperphosphorylation of the microtubule associated protein tau are thought to destabilize the cytoskeleton, interrupting axonal transport. Additionally, abnormal accumulation of Amyloid-beta not only creates structural blockades that hinder transport but can also activate kinases that can drive pathological phosphorylation of tau and NF-H. We used ELISA to quantify pNF-H, Aβ(1-42), total tau, and two phosphoisoforms of tau: RZ3 (ptau231), and CP13 (ptauS396/404) in retina, optic nerve (ON), and superior colliculus (SC) of pre-glaucomatous, early, and late glaucomatous DBA/2J mice. To assess the relationship between protein concentration and axonal transport outcome, we injected the anterograde tracer, cholera toxin-B (CTB) into the eye to trace the retinofugal projection. The SC was microdissected and analyzed based on presence/ absence of CTB; corresponding retina and optic nerve were also analyzed based on transport outcome. Significant elevations in Aβ(1-42) were observed in the retina of all DBA/2J age groups, even the preglaucomatous age, while elevations were not present in the SC until early glaucomatous ages. Aβ(1-42) elevations occurred prior to transport loss. There were also significant age-dependent and tissue-specific increases in pNF-H in the retina, ON and SC of DBA/2J mice. While retinal pNF-H concentrations were not elevated until transport deficits were evident, a significant increase in pNF-H was observed in the SC and ON beginning at the earliest, pre-glaucomatous stage and persisting throughout all ages - providing support for a distal axonopathy model. Furthermore, elevated pNF-H in SC and corresponding projections with compromised/absent axonal transport was observed. Surprisingly, no clear relationship between total or phosphorylated tau levels and age or transport outcome was found. Understanding the progression of these structural alterations in glaucoma may present new therapeutic avenues for this debilitating disease.

Title: The number of photoreceptors is reduced in postmortem human retinas after short durations of diabetes

Authors: *A. J. BARBER[1], S. MOHR[2], W. F. ROBINSON[1];
[1]Dept Ophthalmol,H166, Penn State Univ. Col. Med., HERSHEY, PA; [2]Physiol., Michigan State Univ., East Lansing, MI

Abstract: Objective: Diabetic retinopathy is a common complication of diabetes that causes vision loss in working-age adults. The disease is progressive and generally diagnosed between 5 and 15 years after diabetes onset. Clinical indications of retinopathy include macular edema due to blood-retinal barrier breakdown, and vascular lesions such as microaneurysms and vascular cell drop-out. People with diabetes often report vision loss such as reduced night vision and acuity, but the underlying cause is unclear. Evidence from animal models indicates that neurodegeneration leads to cell death in retinal ganglion cells and other neurons. This study examined the effect of diabetes on retinal thickness, as an indicator of neuronal cell number, as well as the abundance of photoreceptors, in postmortem eyes collected from human donors with relatively short durations of diabetes (3 to 5 years). Methods: Postmortem tissue was collected from donors with no diabetes (ND; n=7), non-insulin dependent diabetes ((-)Ins; n=6), or insulin-dependent diabetes ((+)Ins; n=6). Donor ages were closely matched and averaged 55 ± 12 years old. Retinal cell layer thickness was measured in H&E stained paraffin sections by bright field microscopy. The density of the nuclei in the outer nuclear layer was also measured in peripheral and central retina. Cone photoreceptor density was measured in these regions using

immunofluorescence to 7G6 (all cones) and red/green opsin (red and green cones). Vascular microaneurysms and acellular capillaries were counted in contralateral retinas by whole-mount elastase digest, to expose the entire vascular structure. Data were analyzed by one-way ANOVA with multiple comparisons test. Results: There was no significant difference in the thickness of retinal cell layers in (-)Ins and (+)Ins donors, compared to ND. The (-)Ins and (+)Ins retinas, however, contained significantly fewer nuclei in the outer nuclear layer of peripheral retina compare to the ND tissue ($p<0.05$). There was no significant difference in the number of cones in each group. Quantification of vascular lesions in the elastase-digested retinas suggested a trend towards more microaneurysms in the (+)Ins retinas compared to ND, but this was not a statistically significant difference. Conclusions: The results indicate that outer nuclear layer cells in the peripheral retina are depleted during the early stages of diabetic retinopathy, in the absence of gross vascular lesions. Since the number of cone photoreceptors was unchanged, the reduction in cell number must be due to a loss of rods. These data may explain some of the early vision loss in diabetes.

Title: Aberrant homeostasis of the dopamine D2-like receptor subtypes mediating inhibition of the vasopressor sympathetic outflow in diabetic rats

Authors: *A. H. ALTAMIRANO-ESPINOZA, G. MANRIQUE-MALDONADO, E. RIVERA-MANCILLA, B. VILLANUEVA-CASTILLO, C. M. VILLALON; Farmacobiología, Dept. De Farmacobiología Cinvestav Sede Sur, Mexico DF, Mexico

Abstract: Dopamine plays an important role in the modulation of several physiological functions, including cardiovascular homeostasis, via dopamine D_1-like and D_2-like receptors. Based on the conjunction of structural, transductional and operational criteria, dopamine D_2-like receptors consist of the D_2, D_3 and D_4 subtypes. Our group has recently reported that activation of dopamine D_3 and, to a lesser extent, of D_4 receptor subtypes inhibit the vasopressor

sympathetic outflow in healthy pithed rats. Moreover, other studies have shown alterations in the expression and/or function of D_2-like receptors in the central nervous system in diabetic animals; nevertheless, it remains unknown whether these alterations encompass the perivascular sympathetic neurons innervating resistance blood vessels. Hence, this study investigated with selective antagonists the specific role of the dopamine D_2, D_3 and D_4 subtypes in the inhibition of the sympathetic vasopressor outflow in diabetic pithed rats. For this purpose, male Wistar rats were pretreated intraperitoneally with streptozotocin (50 mg/kg, i.p.; n=60) or vehicle (citrate buffer; 1 ml/kg, n=20) and kept for 4 weeks; then they were pithed and artificially respired with room air. Under these conditions, electrical stimulation (0.03, 0.1, 0.3, 1 and 3 Hz; 50 V and 2 ms) of the thoracic spinal cord (T_7-T_9) or i.v. bolus injections of exogenous noradrenaline (0.03, 0.1, 0.3, 1 and 3 μg/kg) resulted in frequency-dependent and dose-dependent vasopressor responses, respectively. Moreover, i.v. continuous infusions of quinpirole (1 μg/kg.min) inhibited the electrically-induced, but not the noradrenaline-induced, vasopressor responses in both healthy and diabetic rats. This quinpirole-induced sympatho-inhibition in diabetic rats was: (i) unchanged after vehicle or L-741,626 (a D_2 receptor antagonist; 300 μg/kg); and (ii) partially blocked after SB-277011-A (a D_3 antagonist; 300 μg/kg), L-745,870 (a D_4 antagonist; 100 μg/kg) or the combination of SB-277011-A + L-745,870 (300 and 100 μg/kg, respectively). These doses of antagonists did not affect per se the sympathetically-induced vasopressor responses and were high enough to completely block their respective receptors, as previously reported in pithed rats. These findings in diabetic rats suggest: (i) differences in the pharmacological profile of the D_2-like receptor subtypes mediating inhibition of the sympathetic vasopressor outflow (as compared to healthy rats); and (ii) that quinpirole might interact with other receptors (probably α_2-adrenoceptors) besides the D_3 and D_4 subtypes.

Title: Characterization of cerebrovascular function in mice developing cerebral small vessel disease

Authors: *M. BALBI, N. PLESNILA;
Inst. For Stroke and Dementia (ISD)University, Munich, Germany

Abstract: Background: CADASIL - cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy - is the most common form of hereditary small vessel disease. It is caused by mutations of the Notch 3 gene, located on chromosome 19 (1). Transgenic mice overexpressing mutated Notch3 (TgNotchR169C) replicate the disease and are therefore the only available model for small vessel disease. This study aims to identify early microvascular dysfunctions in the CADASIL model in order to facilitate the development of therapeutic strategies. Methods: Pial microvascular reactivity to CO2 (5 and 10%) was investigated in 7.5 (n=21) and 11 (n=16) months old TgNotchR169C and control mice using intravital fluorescence microscopy. Cerebral blood flow (CBF) was measured with a laser Doppler probe over the territory of the middle cerebral artery. Neurovascular coupling was investigated in a second group of 8.5 (n=25) and 12.5 (n=15) months old mice, via electrical stimuli to the forepaw and simultaneous recording of CBF over the associated somatosensory cortex. Results: Vessels of 20 to 30 micrometers in diameter were selected for analysis. All groups show an increase in vessel diameter in response to CO2. Estimating the cumulative increase in vessel diameter and CBF, significant differences were found: at 11 months, TgNotchR169C mice show increased vessel dilation at 5% CO2, and decreased CBF response at 10%. In the second group, CBF responses were analyzed sorting the first four and last six stimuli separately. While there was no significant difference in reaction between TgNotchR169C and control mice, older mice - 8 and 11.5 months old - exhibited a significant decrease in reaction over time compared to younger controls (n=7) - 6 weeks old. Conclusion: We conclude from these findings, that aging reduces neuro-vascular coupling, i.e. vasodilatation to neuronal activation, and that mice suffering from progressive small vessel disease develop endothelial dysfunction. Accordingly, aging and small vessel disease may result in completely different pathophysiologies. [1] Joutel A, Corpechot C, Ducros A, et al. (October 1996). Title: Altered structural white matter patterns in children with perinatally acquired HIV are associated with processing speed

Authors: *T. M. NIR[1], N. JAHANSHAD[1], V. G. VALCOUR[2,3], W. PRASITSUEBSAI[4], A. DESAI[2], S. CATELLA[2], S. LERDLUM[5], P. VISRUTARATNA[5,6], K. PRUKSAKAEW[4], L. AURPIBUL[7], T. Jackson Fndn., Bethesda, MD

Abstract: Worldwide, about 330,000 infants are infected with HIV each year because they are born to mothers living with HIV. Cerebral atrophy and cognitive impairment are common in HIV-infected patients; however, the neurobiological consequences of perinatal HIV infection and ART exposure on brain development are not well understood, and the effect of HIV and ART on the brain's structural connectivity has yet to be studied. One of the most frequent cognitive abnormalities in HIV infection is slowing of mental processing speed. To identify whether impaired anatomical networks in HIV+ youth are associated with information processing speed index (PSI), we used 1.5T MRI-based cortical parcellations (Fig1a) and 25-direction whole-brain DTI-based tractography (Fig1b) to evaluate the white matter connection density in cortico-cortico connectivity maps (Fig1d); 46 HIV- children (mean age: 10.4+/-2.4; 23M/23F) and 18 HIV+ children (mean age: 10.8+/-1.8; 9M/9F) from Thailand were imaged. The fiber density between each pair of cortical regions was evaluated to identify connections that showed changes with respect to disease status, PSI, or their interaction (Dis*PSI). Linear regressions were used, adjusting for the linear and non-linear effects of age, sex, and their interactions. While PSI was significantly lower in HIV infected youth than uninfected youth ($p<0.02$), we found no overall effects of PSI or disease status on the connectivity network. However, an increase in the density of connections between the left entorhinal cortex and insula was significantly associated with an increased interaction score ($p<9.8*10^{-5}$). As seen in Figure 1d, this suggests that HIV status affects the relation of white matter connectivity and PSI, with *better* cognition being associated with *fewer* fiber connections in uninfected youth and *more* fiber connections in HIV+. Compensatory mechanisms in temporal lobe network connections, thought to mediate many cognitive functions like PSI, may allow for normal cognitive function. Ultimately, perinatal HIV infection may alter network developmental trajectories.

Title: Functional connectivity revealed an isolated cingulate cortex due to aging and HIV-infection

Authors: *X. JIANG[1], C. LIU[2], C. WANG[2], M. YOUNG[2];
[1]Dept Neurosci, [2]Dept Med., Georgetown Univ. Med. Ctr., WASHINGTON, DC

Abstract: **Background:** Despite the widening use of combination antiretroviral therapy (cART), HIV-associated neurocognitive disorders, or HAND, remains as one of the most common disorders in people with HIV infection. However, the neuropathogenesis of HAND is

still poorly understood. Recently, using a combination of a task-switching paradigm and functional magnetic resonance imaging (fMRI) technique, we have found that reduced executive function in HIV+ older adults is linked to reduced brain activations in the anterior cingulate cortex (ACC), suggesting that ACC might be one of key regions affected by HIV-infection (*Magnus et al., CROI, 2014*). Here we hypothesized that the disrupted activations in ACC might reflect a disconnection of ACC and posterior cingulate from other brain regions due to HIV-induced synaptodendritic injury (*Ellis et al., 2007*). To test this hypothesis, resting state functional connectivity between cingulate cortex and other brain regions was examined. **Method:** Twenty-three women (50.2±6.8 years old, 13 HIV+) participated in the study. They were recruited from the Washington DC site of the Women's Interagency HIV Study and had no major psychiatric disorders or other confounding health problems. One run of resting state fMRI data was collected from each subject. After standard MRI preprocessing, the nuisance factors that include head motion, signal from white matter and cerebrospinal fluid, global signal, and linear trend, were regressed out. We then obtained two sets of voxel-wise correlations: R_{within}, the mean pairwise correlations between voxels in the cingulate cortex; and $R_{between}$, the mean pairwise correlations between voxels in the cingulate cortex and voxels in the rest of brain (gray matter). The isolation of cingulate cortex from the rest of brain was measured as $I_{cc} = (R_{within} - R_{between}) / (R_{within} + R_{between})$. **Results:** Pearson's correlation analysis revealed a significant positive correlation between age and I_{cc}, ($r=0.60$, $p<0.005$), and two-sample t-test revealed that I_{cc} is higher in HIV+ women than in HIV-negative controls ($p<0.05$, one-tailed). **Conclusion:** Cingulate cortex, one of most interconnected regions with other parts of brain, is involved in many important cognitive functions, including executive function. Here we provided preliminary evidence suggesting that connections between cingulate cortex and the rest of brain are affected by both aging and HIV-infection. This may be due to age- and/or HIV-related synaptodendritic injury, leading to a more "isolated" cingulate cortex, which might be responsible for the high prevalence of reduced executive function with the aging HIV-positive populations in the cART era.

Title: Antemortem diagnosis of Neuronal intranuclear inclusion disease

Authors: *J. SONE[1], N. KITAGAWA[2], T. INAGAKI[1], Y. IWASAKI[3], M. YOSHIDA[3], F. TANAKA[4], G. SOBUE[1];
[1]Nagoya Univ. Sch. of Med., Nagoya / Aichi, Japan; [2]Neurol., Kosei Chuo Gen. Hosp., Tokyo, Japan; [3]Neuropathology, Inst. for Med. Sci. of Aging, Aichi Med. Univ., Nagakute/Aichi, Japan; [4]Neurol., Yokohama City Univ. Grad. Sch. of Med., Yokohama, Japan

Abstract: Neuronal intranuclear inclusion disease (NIID) is a progressive neurodegenerative disease characterized by widespread presence of eosinophilic hyaline intranuclear inclusions in neuronal cells and somatic cells in H&E slides. NIID has been considered to be a heterogeneous disease with highly variable clinical manifestations such as neuropathy, cerebellar ataxia and dementia etc, which may occur concomitantly in certain cases. Sporadic and familial cases have been reported, and the onset of disease varies from the infantile stages to late middle age. These factors made the antemortem diagnosis of NIID difficult. So, we investigated the capability of skin biopsy for antemortem diagnosis of NIID, and reported that skin biopsy is a useful antemortem diagnostic tool for familial neuronal intranuclear inclusion disease because it detects intranuclear inclusions in the dermal cells. Recently, some autopsies of sporadic NIID patients with leukoencephalopathy which showed high-intensity signal in MRI diffusion-weighted imaging (DWI) in the corticomedullary junction have been reported. So, we studied skin biopsy samples of normal volunteers and sporadic NIID suspected patients who presented leukoencephalopathy and DWI high-intensity signal, and investigated the capability of skin biopsy for antemortem diagnosis of sporadic NIID. Skin biopsy samples were collected under local anesthaesia. A 3-mm-diameter punch biopsy specimen was obtained at 10 cm above the lateral malleolus. Biopsy samples were fixed in 10% formalin and treated. We performed an immunohistochemical analysis using a Ventana DISCOVERY system with anti-ubiquitin antibody. The samples for electron microscopy were fixed with glutaraldehyde in cacodylate buffer and embedded in epoxy resin. In skin biopsy samples from sporadic NIID, intranuclear inclusions were found in sporadic NIID patients with leukoencephalopathy and DWI high-intensity signal. Inclusions were found in adipocytes, fibroblasts and sweat gland cells. Electron microscopy revealed that intranuclear inclusion in cutaneous cells have no limiting membrane and consist of haphazardly arranged filaments. These inclusions were positively stained with anti-ubiqutin antibody. These features of inclusion were identical with those of reported familial NIID inclusions in neuronal cells and dermal cells. In normal control and other neurodegenerative disease samples, no intranuclear inclusion was found in adipocytes, fibroblasts and sweat gland cells. Skin bipsy is available, less invasive and safe tool for the antemortem diagnosis of NIID.

Title: Proteasome impairment and protein aggregation in the nervous system of *Drosophila*

Authors: M. JANSEN[1], E. LEMPERT[1], R. ADEROGBA[2], *T. SCHMIDT-GLENEWINKEL[2]; [1]Biol. Sci., Hunter Col. and Grad. Ctr. of CUNY, New York, NY; [2]Biol. Sci., Hunter Col. of CUNY, NEW YORK, NY

Abstract: The etiology of aging and neurodegeneration is associated with impairment of the ubiquitin proteasome pathway and the accumulation of protein aggregates in the brain. Under normal circumstances the proteasome mediates the proteolysis of short-lived, mutated, miss-folded, and aberrantly-modified proteins. However, during the aging process and in the progression of neurodegenerative disorders, proteasome function is inexplicably inhibited, leading to the production of proteinaceous aggregates. To further elucidate the relationship between proteasome impairment and protein aggregate formation, we used the inducible binary Geneswitch system in *Drosophila* melanogaster to express an RNAi against the pros-β5 subunit of the proteasome. The β5 subunit confers the rate limiting chymotrypsin-like proteolytic activity to the proteasome, making it an ideal target for RNA interference in our proteasome disruption studies. We detected a significant decrease in proteasome activity accompanied by an increase in protein aggregates in the brains of our knockdown flies compared to the controls. To better characterize the mechanisms involved in aggregate formation, we will analyze protein aggregate formation in neurons, glia, and the fly neuropil. In addition we will employ mass spectrometry to identify proteins that are more susceptible to being miss-folded and included in aggregates.

Title: HIV-1 Tat activates a RhoA/ROCK signaling pathway to reduce NMDA-evoked calcium increases in hippocampal neurons via an actin-dependent mechanism

Authors: ***K. A. KROGH**, E. A. LYDDON, S. A. THAYER;
Univ. of Minnesota, Minneapolis, MN

Abstract: Almost half of the 33 million people currently infected with HIV will develop HIV-associated neurocognitive disorder (HAND). Cognitive decline in patients with HAND correlates with synaptodendritic damage and loss of dendritic spines. HIV-infected cells in the brain shed viral proteins, such as the transactivator of transcription (Tat), which causes synapse loss via an NMDA receptor (NMDAR)-dependent mechanism. Here we report that following Tat-induced potentiation of NMDARs, a RhoA/Rho-associated protein kinase (ROCK) signaling pathway is activated; a subsequent rearrangement of the actin cytoskeleton results in a reduction in NMDAR function. Tat-induced changes in NMDA-evoked increases in [Ca2+]i were measured using fura-2-based Ca2+ imaging of rat hippocampal neurons in culture. Ca2+ influx was triggered by the transient application of NMDA (10 μM) following 0 to 24 h exposure to Tat (50 ng/mL). Tat induced a time-dependent potentiation of the NMDAR that peaked by 8 h and then adapted back to control levels by 24 h. Tat-induced NMDAR potentiation was unaffected by inhibition of RhoA by C3 transferase (1 μM) or by inhibition of ROCK by Y27632 (10 μM) or H1152 (10 μM). However, inhibition of either RhoA or ROCK prevented adaptation of the NMDAR. Expression of dominant-negative RhoA (T19N) also prevented adaptation following Tat-induced NMDAR potentiation, confirming Tat-induced activation of this pathway. RhoA/ROCK

signaling is known to affect the actin cytoskeleton. Stabilization of actin with phalloidin (10 μM) or depolymerization of actin with cytochalasin D (10μM) had no effect on Tat-induced NMDAR potentiation, but prevented adaptation of NMDAR function. Preliminary data suggest that Tat causes loss of dendritic spines expressing EGFP-actin, which may arise following activation of RhoA/ROCK. Together, these findings indicate that Tat activates a RhoA/ROCK signaling pathway resulting in actin rearrangement with a subsequent reduction in NMDAR function. Adaptation of NMDAR function and loss of dendritic spines may be a mechanism to protect neurons from excessive Ca2+ influx and excitatory input and could reveal targets for the treatment of HAND.

Title: Effect of adipose derived mesenchymal stem cells administration on hypoglycemia-induced neuronal death

Authors: ***J. KIM**[1], H. KIM[1], B. LEE[1], B. CHOI[1], I. KIM[1], S. LEE[1], M. SOHN[2], S. SUH[1]; [1]Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of; [2]Inha Univ., InCheon, Korea, Republic of

Abstract: Diabetic patients who attempt tight control of blood glucose levels frequently experience hypoglycemia. Acute and prolonged hypoglycemia results in neuronal death and cognitive dysfunction. Recently, therapeutic stem cell transplantation has been highlighted because stem cells ability to promote tissue regeneration, neuroprotection, and improvement of endogenous repair. Human adipose derived mesenchymal stem cells (MSC) can be easily attained from liposuction tissue following plastic surgery. In a previous study, MSC have shown neuroprotective effects on ischemia-induced brain injury. MSC has never been tested for its therapeutic effect on hypoglycemia-induced brain injury. To investigate the therapeutic potency of MSC on hypoglycemia-induced neuronal death, we used an animal model of insulin-induced hypoglycemia. Acute hypoglycemia was induced by intraperitoneal injection of human insulin

(10 U/kg), and then iso-electricity was maintained for 30 minutes. MSC (1x10^6) intravenous injection was started immediately after hypoglycemia. Histological test for neuronal death, microglia activation, oxidative injury and blood brain barrier (BBB) disruption were evaluated at 1 week after hypoglycemia. Hippocampal neuronal death was evaluated by Fluoro Jade-B. Activated microglia were evaluated by immunostaining for CD11b. IgG immunostaining was performed to detect BBB disruption and 4HNE immunostaining was performed to detect oxidative injury. Neuronal death, microglia activation, oxidative injury and BBB disruption were significantly reduced by MSC administration when evaluated at 1 week after hypoglycemia compared with vehicle treated group. The present study suggests that MSC may have therapeutic potential to reduce hypoglycemia-induced brain injury in diabetic patients.

Title: Analysis of FET and stress granule related proteins in frontotemporal lobar degeneration (FTLD)

Authors: *R. BANDOPADHYAY, J. BRELSTAFF, C. PERSAD, T. LASHLEY;
Inst. of Neurol., London, United Kingdom

Abstract: The neuropathological hallmark of FTLD-FUS is extensive FUS aggregate pathology demonstrated by cytoplasmic and intranuclear inclusions. Transportin-1(TRN1) is a nuclear transporter that shuttles FET proteins (FUS/TLS, EWS and TAF15) and other cargoes back into the nucleus. We have recently shown that TRN1 is also present in the pathological lesions of FTLD-FUS cases (Brelstaff et al 2011). Here we have investigated the presence of FET proteins, EWS, TAF15 and NUP98 (a nuclear-pore complex protein) in our cohort of FTLD-cases along

with healthy control brain tissue from Queen Square Brain Bank using standard immunohistochemistry and immunoblotting protocols. We also examined the presence of FET proteins and TRN1 in Huntington's disease (HD) and spinocerebellar ataxia. We show EWS and TAF15 within a variety of morphological inclusions in the FTLD-FUS cases that mirrors those observed under FUS and TRN1 immunohistochemistry by our group (Lashley et al, 2011; Brelstaff et al 2011). Inclusions are observed in frontal cortex, hippocampal formation, medulla and the motor neurons of spinal cord. We also noted that NUP98 is present in the cytoplasmic inclusions in a NIFID case and which overlapped with FUS pathology. The stress granule markers, PABP1 and G3BP label a variety of cytoplasmic inclusions in FTLD. Cytoplasmic EWS and TAF15 levels are increased in FTLD-FUS cases compared to controls as seen by immunoblotting. We conclude that in our cohort of FTLD-FUS cases, the typical pathological lesions were also positive for EWS, TAF15 and stress granule markers. The link between SG and FET proteins warrant further investigations. Refs: Brelstaff J et al 2011; Acta Neuropathol, 122(5):591-600. Lashley T et al 2011; Brain, 134(9):2548-2564.

Title: MicroRNA-21 influences the progression of Cervical Spondylotic Myelopathy by altering astrocyte reactive state and onset of symptoms

Authors: *A. M. LALIBERTE[1], S. K. KARADIMAS[1], M. G. FEHLINGS[2];
[1]Genet. and Develop., Univ. of Toronto, TORONTO, ON, Canada; [2]Neurosurg., Krembil Neurosci. Centre, Toronto Western Res. Institute, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Background: Cervical Spondylotic Myelopathy (CSM), the most common form of adult spinal cord dysfunction, is a progressive neurodegenerative disease that is caused by compression of the cervical spinal cord by spontaneously generated bony osteophytes. Progressive compression and loss of spinal cord microvessels is thought to cause regional hypoxia, leading to gray matter degeneration. Recently, our laboratory has developed a model of CSM that reproduces the compression and resulting neurological deficits of the human disease,

finally allowing in depth examinations of CSM molecular pathology. A screen of microRNAs expressed in CSM animals determined that microRNA-21 (miR-21) was highly expressed, particularly in the advanced stages of disease. MiR-21 has previously been identified as a molecule of interest in both spinal cord injury and hypoxia; however, relatively little is known about its role in these conditions. Recent findings in spinal cord injury have implicated miR-21 in suppression of astrocyte hypertrophy. Since astrocytes are important regulators of neurovascular interactions, inflammation, and synaptic integrity, we sought to investigate the effect of miR-21 in the progression of CSM symptoms and pathology. Methods: MiR-21 knockout (KO) CSM animals were acquired and compared to wild type CSM animals. Gradual compression of the spinal cord occurred over 2, 6, or 12 weeks (consistent with no, moderate, or severe behavioral deficits, respectively). Catwalk gait analysis system was used to periodically measure motor deficits. Immunohistochemistry and stereology were used to monitor progression of CSM pathology Results: Using CatWalk gait analysis, miR-21 KO appeared to have altered gait from wild type animals, displaying decreased stride length and swing speed in both forelimbs and hindlimbs as early as 2 weeks from the start of compression. As predicted, astrocyte morphology was much more hypertrophic in miR-21 KO animals. Surprisingly, lesion size was generally smaller in the miR-21 KO animals. Conclusions: Knockout of miR-21 appears to dramatically increase astrocyte hypertrophy in CSM animals, a finding consistent with other spinal cord pathologies. Interestingly, this phenomenon appeared to have contradictory effects on behavior and tissue integrity, possibly due to differing cell-specific mechanisms.

Title: Sentizaitation of trigeminal nervous system by infraorbital nerve injury exacerbates the pathophysiology of migraine

Authors: M. TOOYAMA[1], *C. KUDO[1], C. MUKAI[1], Y. MORIMOTO[2], H. NIWA[1]; [1]Dept. of Dent. Anesthesiol., Osaka Univ. Grad. Sch. of Dent., Suita, Osaka, Japan; [2]Kyusyu Univ. Hosp., Fukuoka、Fukuoka, Japan

Abstract: Background and Aims: Migraine is a chronic neurological disorder by recurrent of severe unilateral headache. It has recently been reported that migraineurs are often suffering from headache attacks accompanying with the cutaneous allodynia in the craniocervical region, and this allodynia is supposed to be a risk factor for migraine chronification. In addition, some migraineurs experience the non-odontogenic toothache instead of headache during the migraine attack period. These clinical findings suggest that branches of trigeminal nerve interact and sensitize each other. Here, we examined the influence of the sensitization of 2nd branch of trigeminal nerve on migraine attack by using the capsaisin-induced migraine animal model to demonstrate the correlation between the pathophysiology of migraine and the sensitization of the trigeminal nervous system. Methods: Male Sprague-Dawley rats (250-300g) were divided into three groups: (a) the chronic constriction injury of the infraorbital nerve (CCI-ION) and capsaicin administration (CCI-ION+cap), (b) CCI-ION and vehicle administration (CCI-ION+vehicle), (c) sham operation and capsaicin administration (sham+cap). The sensitization of ION was induced by CCI, and the allodynia in the region of the 2nd branch of the trigeminal nerve developed in 14 days. At day 14, rats were anesthetized, and 10 mM capsaicin was applied to the dura mater on the right transverse sinus to induce the migraine attack. Four minutes later, the brainstem and trigeminal ganglion (TG) were harvested. We performed the immunohistochemical staining in the trigeminal spinal subnucleus caudalis (Vc), upper cervical spinal cord (C1-C2) and TG to examine the expression of phosphorylated extracellular signal regulated kinase (pERK), as a marker of the excitability of nociceptive neurons after noxious stimulation of peripheral tissues. Results: The number of pERK immunoreactive cells (pERK-IR) in Vc and C1-C2 in CCI-ION+cap group significantly increased at 3600 and 4320 μm caudal from the obex compared to sham+cap group and CCI-ION+vehicle group. In the TG, pERK-IR neurons tended to increase in CCI-ION+cap group compared to sham+cap group. Conclusions: Our data showed that the sensitization of 2nd branch of the trigeminal nerve (ION) by CCI caused the sensitization of 1st branch, resulting in the enhancement of pERK expression in capsaicin-induced migraine rats peripherally and centrally in the trigeminal nociceptive pathway. From these results, it is suggested that the existence of the sensitization of a branch of trigeminal nerve can be the one of the exacerbation factors of the pathophysiology of migraine.

Title: Magnetic field and induced electrical field distributions of Figure-Eight TMS

Authors: *I. BASALDUA;
UMBC, BALTIMORE, MD

Abstract: Currently transcranial magnetic stimulation (TMS) has been widely accepted and used for laboratory experiments and clinical applications. Among different TMS structures the figure-8 type of stimulator has the advantage of having a better focused field as most people intuitively believed. However, even though it may be better focused than other types of stimulators the exact magnetic field distribution and the corresponding induced electrical field (or current) have not been revealed by vendors. To most users knowing the exact peak field location and the field distribution, which provides information about the desired and possibly unexpected excitation locations, is important for their applications. In this work we measured both the magnetic field and induced electrical distributions of a figure-8 stimulator. The magnetic field is measured by a 3-dimension magnetic meters from the vendor Trifield model VGM. Projection of magnetic field to al x-y, x-z, z-x planes and an overall 3-D plot of magnetic field vectors were generated and will be presented in the meeting. The distribution provides a clear view not only the strength but also direction of the magnetic field. To study the induced current distribution we use a twisted wire pair with negligible physical foot print to measure the electrical field instead. The measured voltage difference cross two spatial points with a fixed length provides initial recorded data of the induced electrical field. As we can theoretically prove that it doesn't matter what kind of resistance is used inbetween the two points, using a low resistance resistor to hold the two points will create higher induced current and potentially distorted TMS created field. So, it is important to minimize the induced current during the measurement of the field distribution. We have obtained a trustworthy measurement of the induced field distribution using transient magnetic field created by an electrical pulse generator and high current amplifier setup. The measured results match well with the 3-D magnetic field distribution driven by DC current. Besides learning from the measured results that the maximum induced field is indeed right at the center location of the figure 8 stimulator and immediately below the center on the surface, we also can see clearly how fast the field attenuated when the location is gradually away from the center.

Abstract: Shank3 is a scaffolding protein that forms a key structural part of the postsynaptic density (PSD) of excitatory synapses. Haploinsufficiency of SHANK3 causes a monogenic form of autism spectrum disorders (ASD). Characterization of mouse models with Shank3 mutations provided evidence for impaired glutamatergic synaptic function in hippocampal and striatal brain slices and deficits in several behavioral measures related to ASD. Yet, our knowledge about the affected molecular pathways, the alterations in brain circuitries and their relation to the behavioral deficits observed in ASD is scanty. The aim of our study is to analyze the effect of Shank3 deficiency on ASD associated behaviors and to uncover the alterations in synaptic plasticity in brain regions and circuitries associated with the impaired behaviors. At the molecular level, we aim to identify the affected pathways that underlie the behavioral and synaptic deficits. For this purpose we have developed the Shank3-deficient rat, a genetically modified rat model for ASD. We are using electrophysiological, biochemical and genome wide transcriptional analyses to study the effect of the disruption in Shank3 on synaptic functioning and are applying behavioral analysis to relate changes to higher order processes. Our results reveal that Shank3 deficiency leads to attentional and social behavioral deficits, both of which are prevalent in subjects with ASD. These behaviors are highly dependent on the intact function

of brain regions associated with ASD; the hippocampus, the PFC or both. Our *in vitro* electrophysiological analysis demonstrated impairment in long-term potentiation (LTP) and depression (LTD) in the hippocampus while the *in vivo* analysis showed impaired mPFC LTP in response to hippocampal stimulation. Finally, our high-throughput RNA sequencing, unbiased proteomic analysis, and functional enrichment analysis, showed that decreased Shank3 levels affect distinct biological mechanisms, including actin remodeling and that Shank3 perturbed signatures map to frontal and fetal developmental periods, consistent with previous findings indicating that many ASD genes map to these time periods. By further characterizing this ASD rat model we will be able to investigate the perturbed pathways to define molecular and cellular components that could be targeted for developing therapies for SHANK3-haploinsufficiency syndromes and for ASD more broadly.

Title: The Tube Co-occupancy Test (TCOT): A novel way to measure affiliative behaviour among laboratory mice

Authors: *A. H. TUTTLE[1,2], K. DOSSETT[1], L. GERSTEIN[1], L. STEIN[1], R. PEARL[1], M. SUKOSD[1], P. LEGER[1], D. YACHNIN[1], J. S. AUSTIN[1], J. S. MOGIL[1,2];
[1]Dept. of Psychology, McGill Univ., Montreal, QC, Canada; [2]Alan Edwards Ctr. for Res. on Pain, Montreal, QC, Canada

Abstract: Empathy for another's physical pain has been previously demonstrated in humans and mice, and is shown to be dependent on familiarity between individuals. Our recent efforts indicate that social stress may be responsible for the absence of empathy for the pain of

strangers, as well as a contributing factor to prosocial behaviors in rodents. Previous attempts to explain prosocial rodent behaviour have implicated sex-specific hormones and candidate autism genes. However, the corresponding neurobiological mechanisms mediating rodent familiarity behaviour, or the initial social interactions between mice, are unknown. Here we propose a novel and fully automated behavioural test, the Tube Co-Occupancy Test (TCOT) as a way to study the effects of stress on rodent social behaviour. Our assay quantifies rodent willingness to co-occupy a "safe" PVC tube placed in a brightly lit open field. Prior to testing mice are either housed together (familiars) or separately (strangers). Preliminary results show that outbred strangers demonstrate significantly reduced co-occupancy behaviour when compared to familiar mice. Furthermore, we show that autistic-like rodent models (Fmr1 -/-, BTBR strain) show decreased co-occupancy behaviours when compared to C57BL/6 controls. Our assay features a new way to test social behaviours in laboratory rodents that we hope will be useful in understanding dysfunctional social affiliation in autism spectrum disorders.

Title: Consistency between the neuroanatomical and behavioural phenotype in the 15q11-13 duplication mouse model

Authors: *J. ELLEGOOD[1], N. NAKAI[2], J. NAKATANI[3], T. TAKUMI[2], J. P. LERCH[1]; [1]Mouse Imaging Ctr., Hosp. For Sick Children, Toronto, ON, Canada; [2]RIKEN Brain Sci. Inst. (BSI), Wako, Japan; [3]Shiga Med. Univ., Shiga, Japan

Abstract: Background - Copy number variations (CNVs) are thought to account for ~20% of autism cases (Beaudet et al. 2007). A very large CNV (6.3Mb) located at 15q11-13 is a common

chromosome abnormality (Takumi, 2010). The 15q11-13 region contains several maternal (Mat) and paternal (Pat) imprinting genes. 15q11-13 Mat and Pat duplications (Dp) have both been associated with Autism and occur in ~5% of autism patients (Takumi, 2010). The behavioural phenotypes for both the MatDp/+ and PatDp/+ have been thoroughly investigated (Nakatani et al. 2009), and several autism-like behaviours were found in the PatDp/+ but not in the MatDp/+. Objectives - The purpose of this study is to use magnetic resonance imaging (MRI) in both the PatDp/+ and MatDp/+ 15q11-13 mouse models to investigate the neuroanatomical phenotype and see how it relates to the behavioural phenotype. Methods - Twenty mice were included for the 15q11-13 PatDp/+ (10 PatDp/+ and 10 WT littermates) and 17 mice for the MatDp/+ (9 MatDp/+ and 8 WT littermates). Imaging was performed ex-vivo using a 7T MRI with a T2 weighted, 3D fast spin echo sequence which acquires data at an isotropic resolution of 56 μm (Lerch et al. 2011). Using image registration the brains were aligned, and the volumes of 62 different regions (Dorr et al. 2008) were calculated. Multiple comparisons were controlled using False Discovery Rate (FDR, Genovese et al. 2002). Results and Discussion - Mirroring the previously reported behavioural findings (Nakatani et al. 2009), multiple significant differences were found in the PatDp/+ mice, and no differences were found in the MatDp/+ mice. For the PatDp/+ mice, 15 of the 62 regions were found to be significantly smaller in absolute volume (mm3). The majority of differences were localized to subcortical structures. The hypothalamus, the inferior and superior colliculi, the granular layer of the hippocampus, and thalamus were all significantly decreased in volume (-5-6%). Contrary to previous reports on autism related mouse models involving neuroligin3 and integrinβ3 (Ellegood et al. 2010, 2012) no differences in the large white matter tracts were found in the 15q11-13 implying the structural integrity of the white matter is unaffected. Further, the reported behavioural findings highlighted a reversal learning impairment in the PatDp/+ mice, which could be related to the 6% smaller granular layer found in the hippocampus of the PatDp/+. Conclusions - This study highlights the complimentary benefit of examining the neuroanatomy in conjunction with behaviour, and can also provide a explanations for some of the reported behavioural findings.

Title: Automated variant scoring for the prioritization of candidate genes in the autism genetic database AutDB

Authors: *E. LARSEN[1], M. ZIATS[2], S. BANERJEE-BASU[1];
[1]Mindspec Inc., McLean, VA; [2]Baylor Col. of Med., Houston, TX

Abstract: A major focus of research in the post-genomic era is to decipher the heterogeneous genetic landscape underlying the pathogenesis of complex human diseases such as Autism Spectrum Disorders (ASD). Hundreds of candidate genes containing ASD-associated rare and/or common genetic variants have been identified, and the advent of new techniques such as next generation sequencing (NGS) has significantly accelerated the discovery of candidate genes containing ASD-linked rare variants. With the rapid growth of genetic data obtained from ASD individuals adding to the already complex genetic landscape of this disease, there is a critical need for resources that not only specialize in the storage of this data, but that also provide tools for assessing the strength of evidence for a given gene in ASD and identifying high-priority candidate genes for further investigation. The Human Gene module of the autism genetic database AutDB (http://autism.mindspec.org/autdb/Welcome.do) was developed to serve as a publically available web-based modular database for the ongoing curation and visualization of ASD candidate genes, which are systemically extracted from peer-reviewed primary scientific literature and manually curated for inclusion. The number of ASD susceptibility genes in the Human Gene Module of AutDB has increased from 304 genes in December 2011 to 604 genes in March 2014, which demonstrates both the continued discovery of ASD candidate genes and the ongoing curation of these genes into AutDB. In addition, NGS techniques have contributed to a dramatic increase in the number of rare variants identified in ASD candidate genes (from 1202 in Dec 2011 to 3652 in March 2014) compared to common variants (from 534 to 878 over the same period). We have developed an automated gene scoring strategy that takes advantage of the richly-detailed annotation available in the Human Gene module to score candidate genes based on the strength of evidence of individual ASD-associated rare or common variants for a given gene. ASD-associated rare variants are scored based on the degree of variant specificity and segregation with ASD, whereas common variants are scored based on the degree of association with ASD and replication of association. Furthermore, the functional effect of a given variant (rare or common) is factored into determining the overall variant score. This strategy has allowed us to identify a number of high priority ASD candidate genes. Moreover, ongoing annotation of ASD-associated gene variants in the Human Gene module will allow candidate gene scores to be frequently updated, providing users with up-to-date gene prioritization information.

Title: Changes in prefrontal microcircuit organization increase repetitive network activity in two mouse models of autism

Authors: *F. LUONGO, C. ZIMMERMAN, A. BRUMBACK, M. HORN, V. SOHAL; UCSF, San Francisco, CA

Abstract: Pathological changes in neocortical microcircuits are believed to instigate neuropsychiatric disorders including autism, but measuring such circuit-level changes remains challenging. Deficits associated with disorders such as autism often extend across multiple cognitive, behavioral, sensory, and affective modalities, suggesting that these diseases may comprise common information processing phenotypes at the level of neuronal networks. Such network-level phenotypes might be missed by studies of individual cells and instead require studies of datasets that probe patterns of network activity. Here, we use single-photon GCaMP imaging to measure activity patterns within isolated prefrontal circuits from two etiologically distinct models of autism: FMR1 knockout mice and mice exposed to valproic acid *in utero*. Both models exhibit enhanced functional interactions between prefrontal neurons and an increase in repetitive patterns of network activity that could plausibly contribute to perseveration and stereotyped behavior. Notably, these changes occur despite the absence of increased network excitability. Furthermore, these changes do not occur in mice which model schizophrenia (DISC1 mutant mice), nor in mice that have undergone chronic treatment with Fluoxetine, an SSRI which may ameliorate symptoms of autism. This suggests that the changes observed in VPA-exposed and FMR1 KO mice may be specifically associated with prefrontal microcircuit dynamics in models of autism. We develop a novel computational method for generating surrogate datasets with matching activity statistics but arbitrary correlation matrices and show that the increased primary and higher order interactions drive the increased repetitive activity in these mouse models. Lastly, we show that cholinergic modulation normally decorrelates activity, possibly contributing to attention, while defects in this mechanism underlie the abnormalities we

observed and may thereby contribute to attentional deficits in autism. Studies of this sort could provide a foundation for understanding common phenotypes at the level of circuits and thus inform circuit-level remedies for ASD and other neuropsychiatric diseases.

Title: Brain structure volumes as a means of measuring changes in neuron gene expression

Authors: *D. J. FERNANDES, J. P. LERCH, J. ELLEGOOD;
Mouse Imaging Ctr., Toronto, ON, Canada

Abstract: Autism Spectrum Disorders (ASD) are characterized by social deficits, communication difficulties, and repetitive behaviours. The genetics behind autism is heterogeneous; with over 250 genes implicated in susceptibility of autism. Genetic defects lead to changes in protein expression at the synapse, which in turn causes changes in the volumes of brain structure during development and to behaviours associated with autism. A better understanding of how mutations in genetics lead to changes in protein expression could help develop potential therapies for autism. We measured the volume of brain structures with single gene knockouts and found significant differences in the volumes of certain structures when compared to wild-type mice. We then used the Allen Brain Atlas to find which genes are preferentially expressed in these regions in wild-type mice. For example, in mice with Intersectin-1 knockout, we found significant differences in the volumes of certain structures: such as the cerebral peduncles and the dentate gyrus. As expected, the Allen Brain Atlas showed Intersectin-1 was found to be preferentially expressed in these regions. However, other genes expressing synaptic proteins -- such as adhesion regulating molecule 1, myotubularin related protein 2, synaptic vesicle glycoprotein, etc. -- were also found to be preferentially expressed. While only Intersectin-1 was knocked out, the expression of several proteins involved with synaptic function was altered. Further investigation is currently being undertaken to look at other gene knockouts and how they alter protein expression at the synapse. This investigation could help create a network of gene expression, where the knockout of one gene leads to changes in

expression of other genes and further our understanding of genetically diverse disorders, such as autism.

Title: Behavioral characterization of an ephrin-a knockout mouse model for autism spectrum disorders

Authors: *R. WURZMAN[1,2], P. FORCELLI[3], L. F. KROMER[2];
[1]Rachel Wurzman, Arlington, VA; [2]Neurosci., [3]Pharmacol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: EphA receptors and ephrin-A ligands play important roles for neural development and also synaptic plasticity in select cases where expression persists into adulthood. Recently, EPHA3 and EPHA7 gene mutations were linked with Autism Spectrum Disorders (ASDs) and developmental neurological delays, respectively. Ephrin-A2 and ephrin-A3 are two high affinity binding partners for EphA3 and EphA7, and which are expressed on astrocytic processes at glutamatergic synapses. As binding partners to EphA3, we propose that these ephrins also could be implicated in ASD. Supporting this hypothesis, deletions of ephrin-A2 or ephrin-A3 have each been associated with isolated deficits in learning and memory behavior in rodents. To better characterize a potential role for these ligands in ASDs, we performed a comprehensive behavioral characterization of sensorimotor, learning, social, and anxiety-like behaviors in ephrin-A2/-A3 double knockout (DKO) mice. These behaviors included the open field, elevated plus maze, morris water maze, and assays of prepulse inhibition of startle response, marble burying, social approach, and grooming. The predominant phenotype in ephrin-A2/A3 DKO mice was repetitive and self-injurious grooming behaviors, such as have been associated with corticostriatal circuit abnormalities in other rodent models of neuropsychiatric disorders. However, despite the self-injurious grooming phenotype, analysis of striatal dendritic spine morphology failed to detect abnormalities in spines at excitatory corticostriatal synapses.

Therefore, we are currently investigating dendritic spine changes in other brain regions known to be associated with the observed behavioral abnormalities as a possible alternative explanation for abnormal sensorimotor behaviors in these mice. Consistent with an ASD phenotype, ephrin-A2/-A3 DKO mice also exhibited decreased preference for social interaction, a shift towards self-directed activity (e.g., grooming) in novel environments, and increased prepulse inhibition of acoustic startle. Although there were no gross deficits in cognitive assays, subtle differences in performance on learning and memory tests resembled traits observed in humans and other rodent models of ASD. We therefore conclude that ephrin-A2/-A3 DKO mice have utility as a novel ASD model with an emphasis on sensory abnormalities and restricted, repetitive behavioral symptoms.

Title: Enhancing AMPA signaling improves sociability in an autism mouse model

Authors: *M. HAN[1], R. M. MEJIAS-ESTEVEZ[2], R. L. HUGANIR[3], T. WANG[2];
[2]McKusick-Nathans Inst. of Genet. Med., [3]The Solomon H. Snyder Dept. of Neurosci., [1]The Johns Hopkins Univ., Baltimore, MD

Abstract: Despite rapid advancement in the understanding of the causes to autism, little progress has been made toward developing effective therapies. No drugs are currently available to target social behavioral deficits in autism. Glutamate, which mediates the majority of excitatory neurotransmission through the ionotropic and metabotropic (mGluR) receptors, has been previously implicated in the pathophysiology of autism. More specifically, disturbances in mGluR signaling have been implicated in Fragile X syndrome and autism, but the role of AMPA glutamate signaling in this disorder is unknown. We recently investigated the role of AMPA signaling disturbance in autism and identified mutations in glutamate receptor interacting protein 1/2 (GRIP1/2) that contribute to social behavioral deficits in patients with autism. These mutations alter dynamic AMPA-receptor synaptic recycling and synaptic strength. We

hypothesized that drugs modulating AMPA receptor function could improve social deficits in autism. We tested S18986, a positive allosteric modulator of AMPA receptors, on social behaviors using adult male BTBR mice, a well-characterized mouse model of autism in a cross over study. Acute administration of S18986 at an optimized dose results in a significant improvement in sociability in BTBR mice as measured by the ratio of the time spent sniffing a novel mouse to the time spent sniffing an empty cage in a modified three chamber sociability test (n=25; carrier only: 2.50+/-0.41; S18986: 4.78+/-0.90, p =0.023). We observed similar improvement in the preference to social novelty using the same study cohort. Results from these studies indicate that AMPA signaling pathway should be further investigated as a potential drug target for the correction of social deficits in autism.

Title: Learning delays in a mouse model of autism spectrum disorder

Authors: ***A. R. RENDALL**, D. T. TRUONG, R. H. FITCH;
Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Autism Spectrum Disorder (ASD) is a heterogeneous neurodevelopmental disorder with core symptoms of atypical social interactions, language impairments, and repetitive behaviors. It has also been reported that individuals with ASD have difficulty with multisensory integration, and this may disrupt higher-order cognitive abilities such as learning and social communication. Impairments in the integration of sensory information could in turn reflect diminished cross-modal white matter connectivity, as reported in some DTI/MRI studies. To date, causal mechanisms in ASD remain poorly understood, but likely include a combination of genetic and environmental risk factors. Indeed, the genetic contribution in ASD appears to be

strong, with heritability estimates as high as 90%. However, no single gene has been identified, and over 100 risk genes have been reported. Most of these genes play a critical role in neurodevelopment. One of these genes -- contactin-associated-like-protein 2 (*CNTNAP2*) -- was first associated with Specific Language Impairment, and more recently has been linked to ASD. *CNTNAP2* is located on ch7, and encodes a cell adhesion protein regulating synaptic signal transmission. Human *CNTNAP2* variants have also been specifically associated with difficulties with non-word repetition, a measure of working memory. To better understand the behavioral and biological underlying mechanisms of ASD, a transgenic mouse model was created with a genetic knockout (KO) of the rodent homolog *Cntnap2*. Initial studies of this mouse (Peñagarikano et al., 2011) found poor social interactions, behavioral perseveration, and reduced vocalizations -- all strongly resembling the human symptoms. *Cntnap2* KO mice also show abnormalities in myelin formation, consistent with a hypo-connectivity model of ASD. Furthermore, these mice showed abnormal cortical neural synchrony, fewer inter-neurons, and atypical neuronal migration. The current study was designed to further assess the intermediate behavioral phenotype of this mouse model, with a focus on learning and memory. *Cntnap2* KO and wild-type mice were tested on a 4/8 radial arm water maze for 14 consecutive days. Results showed that *Cntnap2* KO mice exhibited significant deficits in working and reference memory during the acquisition period of the task. During the retention period (i.e., after an asymptote in errors), *Cntnap2* KO mice performed comparably to wild-type mice. These findings suggest that *CNTNAP2* may play an underlying role in the development of neural systems important to learning and cross-modal integration, and disruption of this function could be associated with delayed learning in ASD.

Title: Morphological changes in the medial geniculate nucleus of Cntnap2 KO mice

Authors: *D. T. TRUONG, A. R. RENDALL, R. H. FITCH;
Behavioral Neurosci., Univ. of Connecticut, Storrs, CT

Abstract: Atypical cell morphology in the medial geniculate nucleus (MGN) of the thalamus has been reported in dyslexic brains (Galaburda et al., 1994), and it has been suggested that these anomalies could relate to impairments in rapid auditory processing seen in infants, children and adults with (or at risk for) language-based disorders. Associated research with genetic and injury-based rodent models of language-related neurodevelopmental disorders (e.g., developmental dyslexia) has confirmed evidence of simultaneous impairments in rapid auditory processing, and anomalies in MGN cell morphology, in several of these models. *CNTNAP2* is a gene that has been implicated in autism spectrum disorder (ASD) as well as specific language impairment -- two neurodevelopmental disorders associated with language deficits. Interestingly, behavioral examination of *Cntnap2* knock-out (KO) mice conducted in our lab showed atypical auditory processing behaviors, including impaired silent gap detection, as well as an unexpected enhancement frequency discrimination. These patterns are in fact consistent with behavioral findings from ASD populations, and may relate to the language deficits that often occur with ASD. To investigate whether differences in MGN morphology could be related to the abnormal pattern of auditory processing behaviors observed in *Cntnap2* KO mice, we examined the MGN from male KO and matched wildtype mice that were previously tested on our auditory battery. Numbers and sizes of neurons were estimated in the MGN using optical fractionator and nucleator probes, respectively. We found significantly fewer neurons in the MGN of *Cntnap2* KO mice. In addition, cumulative cell size distribution in the MGN indicated that *Cntnap2* KO mice had more small than large neurons in the MGN in comparison to congenic controls. These findings suggest that changes in MGN morphology may contribute to the atypical auditory processing behaviors observed in *Cntnap2* KO mice, and could have relevance for auditory and language anomalies in human language-disordered populations including ASD.

Title: Functional characterization of Itgb3 promoter gene variants associated with elevated serotonin blood levels

Authors: *S. GABRIELE[1], C. LINTAS[1], R. SACCO[1], A. M. PERSICO[1,2];
[1]Univ. Campus Biomedico, Rome, Italy; [2]Mafalda Luce Ctr. for Pervasive Developmental Disorders, Milan, Italy

Abstract: Genetic factors contribute significantly to autism spectrum disorders (ASD). The ITGB3 gene, located on human chr. 17q21.32, encodes integrin beta 3, the beta subunit of the platelet membrane adhesive protein receptor complex GP IIb/IIIa. Integrin beta 3 interacts with the serotonin transporter SERT, coded by the SLC6A4 gene, regulating its trafficking on the plasma membrane of platelets and serotonin (5-HT) uptake in synapses. ITGB3 and SLC6A4 genes were both identified as quantitative trait loci (QTLs) for 5-HT blood levels, which are known to be elevated in a consistent subgroup of ASD patients. We have previously reported that the *rs2317385* G allele at the 5' end is significant associated with 5-HT blood levels in 293 Italian families with an autistic proband (Napolioni et al., Eur J Hum Genet. 2011). To identify functional ITGB3 variants contributing to elevated 5-HT blood levels, we sequenced the ITGB3 promoter region, exons and exon-intron junctions in twenty individuals selected on the basis of known genotypes, and we detected six SNPs in linkage disequilibrium with *rs2317385* and all located in the promoter region of ITGB3. Four different haplotypes involving these SNPs were selected, two associated with "high" and two with "low" 5-HT alleles at *rs2317385*. Each haplotype was cloned into pGL4.10, transfected into two hematopoietic cell lines, K-562 and HEL 92.1.7, and analysed by luciferase assay. ITGB3 promoter activity is strongly modulated in HEL 92.1.7 cells, where luciferase expression is significantly increased by the presence of a G allele at *rs55827077* ($P<0.05$), but not in K-562 cells. Functional experiments to explain this cell specificity are ongoing, as well as similar experiments in neuronal cell lines, Neuro2A and SH-SY5Y. These results support a cell type-specific modulation of ITGB3 promoter activity by genetic variants linked to high 5-HT blood levels in families with autistic probands.

Title: Common functional genetic variants support Th2 and NK immune pathway contributions to the pathogenesis of Autism Spectrum Disorder

Authors: *I. PIRAS[1,2], S. GABRIELE[1], V. NAPOLIONI[1], R. SACCO[1], A. M. PERSICO[1,2]; [1]Unit of Child and Adolescent Neuropsychiatry & Lab., Rome, Italy; [2]Mafalda Luce Ctr. for Pervasive Developmental Disorders, Milan, Italy

Abstract: Converging evidence suggests that immune system dysregulation is involved in the pathophysiology of Autism Spectrum Disorder (ASD) both in children and adults. Altered immune processes include ongoing neuroinflammation in post-mortem brains, elevated pro-inflammatory cytokines in cerebrospinal fluid and blood, altered immune cell function, presence of brain-specific auto-antibodies, and dysregulated immune transcriptome. Previous studies have highlighted SNPs located in immune genes, such as *CD99L2*, *JARID2* and *TPO*, as well as genetic variation at *MHCII*, *C4B* and *MIF*, as risk factors for ASD. Another strategy to assess whether dysimmunity contributes to ASD pathogenesis or represents a collateral by-standing effect is to investigate the association of ASD with common SNPs known to influence immune gene expression or function (e.g cytokine levels) affecting several distinct immune cascades. To this aim, we genotyped 484 simplex and 18 multiplex Italian families with an ASD proband at 34 known functional SNPs located in 26 immune genes involved in all major immune pathways. SNPs yielding significant associations involved two immune pathways: [A] Statistically significant opposite transmission patterns between ASD and unaffected siblings were evident for rs2243250, located in the promoter of the *IL4* gene, and rs231775, a missense variant located in the *CTLA4* gene). The combination of high *IL4* expression and low *CTLA4* function alleles was associated with autism and the opposite alleles were overtransmitted to unaffected siblings. IL-4 is mainly produced by Th2 cells and at the same time is the key signal to induce Th2 differentiation from naïve T cells, whereas CTLA-4 is a critical and potent inhibitor of Th2 differentiation. [B] Similarly, the combination of high expression alleles at rs361525 and rs2430561*,* functional SNPs located in the promoter and in intron 3 regions of the *TNFA* and *IFNG* genes*,* respectively, was associated with autism, while the opposite alleles were protective. Among various functions, TNF-α and IFN-γ enhanced the cytolytic function of Natural Killer (NK) cells. These results indicate that common variants conferring hyper-responsive Th2 (*IL4* and *CTLA4*) and NK (*TNFA* and *IFNG*) activity also confer autism vulnerability. Hence previously-reported increases in plasma Th2 cytokine levels and NK cell activation do not appear to represent mere by-standing effects, but may be instead part of the pathophysiological cascade resulting in autistic disorder in a sizable subgroup of patients.

Title: Linguistically deprived children: Meta-analysis of published research indicates mental synthesis disability - Implications for novel intervention strategies for children with language delay

Authors: *A. VYSHEDSKIY[1,2], R. DUNN[2];
[1]Boston Univ., Boston, MA; [2]ImagiRation LLC, Boston, MA

Abstract: We analyzed published reports of individuals not exposed to a syntactic language until puberty: two feral children, who grew up without hearing any language, and eight deaf linguistic isolates, who grew up communicating to their families using homesign, a system of gestures which allows them to communicate simple commands, but lacks much in the way of syntax. This is typical of families with deaf children, which are isolated from a sign language community; instead of learning a formal sign language, they normally spontaneously develop a homesign system. All tests performed on these individuals were sorted by their reliance on the subject's ability to actively create novel mental images (a function we are calling *mental synthesis*). For example, a subject's ability to follow a direction to "put the bowl *behind/in front of/on/under* the cup," has significant indication of their capacity towards *mental synthesis*. To correctly place a bowl *behind* or *in front* of a cup, one first needs to mentally synthesize the novel image of a bowl behind or in front of a cup. Someone who cannot simulate the process mentally would have no mental image of a bowl *behind* or *in front* of a cup and would therefore just use trial and error and probably place the cup and bowl into an incorrect arrangement. According to our analysis, feral children and deaf linguistic isolates performed poorly in all tests of *mental synthesis*. The consistent observation of *mental synthesis disability* within these individuals stands in stark contrast to their performance in memory as well as semantic tests: they could easily remember hundreds of newly learned words and recall previously seen images from memory but had real difficulty in any tasks requiring them to combine these images into novel configurations. Myelination and electrophysiological studies suggest that the likely problem of these individuals is the reduced connectivity between the PFC and the posterior cortex. The *PFC-posterior cortex* connection model indicates that syntactic language exercises in neurotypical children provide the necessary input for fine-tuning those connections. The model predicts that *mental synthesis* relies on synchronous networks, whereby fiber conduction velocity

is equilibrated by increased myelination of longer fibers. A lack of exposure to a syntactic language before the end of the critical period appears to result in reduced myelination and asynchronous connections between the PFC and the posterior cortex. Exposure to a syntactic language past the critical period can improve semantic content but not *mental synthesis* ability. Implications for novel intervention strategies for children with language delay are discussed.

Title: Bidirectional changes in ube3a gene dosage reciprocally regulate aggression in models of angelman syndrome and idic15

Authors: *D. C. STOPPEL[1], J. TODOROVIC[2], M. P. ANDERSON[1];
[1]Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Univ. of Texas, Austin, TX

Abstract: Reciprocal changes in UBE3A gene dosage cause two neurodevelopmental disorders. Maternally inherited deletions of UBE3A cause Angelman syndrome, characterized by intellectual disability, motor defects, seizures, and a pathognomonic increased social motivation. Whereas maternally inherited triplications of UBE3A as in Idic15 Autism underlie decreased sociability and increased repetitive restrictive behaviors of this disorder. Aggression is a

common comorbidity in Autism but is not widely studied in mouse models. To study the regulation of aggression by Ube3a we compared mice with two extra copies of Ube3a (Ube3a-2x) that model Idic15 to maternal Ube3a knockout mice (Ube3a-mKO) in the resident intruder paradigm. Ube3a-2x mice showed increased aggression compared with wild-type animals while Ube3a-mKO mice had decreased aggression. These findings indicate that disturbances in Ube3a gene dosage reciprocally regulate aggression behavior in two mouse models of human developmental disorders.

Title: Pax6 haploinsufficiency affects maternal separation-induced ultrasonic vocalization by advanced paternal age in the offspring

Authors: *N. OSUMI[1], R. KIMURA[1], K. YOSHIZAKI[1], K. KOIKE[1], V. TUCCI[2], H. INADA[1]; [1]Dept Devel Neurosci, Tohoku Univ. Grad Sch. Med., Sendai, Japan; [2]Dept. of Neurosci. and Brain Technologies, Inst. Italiano di Tecnologia, Genova, Italy

Abstract: Human genetics and epidemiological studies have indicated that a neurodevelopmental gene PAX6 and advanced paternal age are genetical and environmental risk factors for autism. Here we examined a role of Pax6 in an advanced paternal age-related behavior impairment in mice. To obtain F1 offspring, young C57BL6/J (3-month-old) female mice were mated with male wild type (WT) or Sey/+ mice at three different ages, i.e., young, middle-aged (6-8-month-old) and advanced aged (>12-month old). F2 offspring were obtained from crossing young C57BL6/J female mice with young F1 WT offspring derived from young or advanced aged F0 WT father. Maternal separation-induced ultrasonic vocalization (USV) of both F1 and F2 offspring was measured at postnatal day 6. The number of USV in WT offspring derived from advanced-aged WT was dramatically decreased by 32.7% and 33.1% compared to that in WT offspring derived from young and middle-aged WT, respectively. In contrast, the number of USV was not different between the groups in F2 offspring, implicating that the USV

phenotype would be canceled in the next generation. Interestingly, the number of USV in Sey/+ offspring derived from middle-aged Sey/+ was significantly decreased by 58.8% compared to that in WT offspring. In contrast, the number of USV was not statistically altered between WT and Sey/+ offspring derived from young Sey/+, indicating that Pax6 haploinsufficiency accelerates behavioral abnormalities such as maternal separation-induced USV. To explore molecular mechanisms, histone methylation moieties were compared between young and advanced aged or middle aged WT and Sey/+ spermatocytes, in which Pax6 is predominantly expressed. We found significant changes in global methylation in advanced aged spermatocytes and middle-aged Sey/+ spermatocytes. Our results suggest an intriguing possibility that epigenetical changes in spermatogenesis may cause behavioral abnormalities such as maternal separation-induced USV in the offspring. We are testing whether these altered histone methylation remains in sperm and the developing brain.

Title: AutDB: Integrator of diverse data related to autism

Authors: ***S. B. BASU**[1], E. C. LARSEN[1], I. DAS[2], S. MUEND[1], R.-S. LIN[1], W. PEREANU[1]; [1]Mindspec Inc., McLean, VA; [2]MindSpec Inc., McLean, VA

Abstract: Although a genetic component underlying Autism Spectrum Disorders (ASD) has been firmly established from various lines of evidence, the identification of multitude of genes and chromosomal loci associated with ASD has made elucidation of pathophysiology difficult to resolve. A range of methodologies have identified both rare and common genetic variants in ASD candidate genes. Moreover, the recent development of high-throughput next generation sequencing technologies and the increasing usage of chromosomal microarray analysis has led to a significant expansion in the number of single nucleotide variants (SNVs) and copy number variants (CNVs) associated with ASD. To facilitate visualization and analysis of the vast genetic

heterogeneity underlying ASD, we have created the Autism Database (AutDB*; http://autism.mindspec.org/autdb/Welcome.do), a publicly available, manually curated, web-based, and searchable database for genes linked to ASD. Evidence regarding ASD candidate genes is systematically extracted from peer-reviewed, primary scientific literature and manually curated by our researchers for inclusion in AutDB. We have recently expanded AutDB utilizing a systems biology approach, implementing a modular framework that integrates diverse types of evidence about ASD candidate genes. Current modules within AutDB include: 1) Human Gene, which annotates both common and rare variants in ASD-linked genes; 2) Copy Number Variant (CNV), which catalogs deletions and duplications of chromosomal loci identified in ASD; 3) Animal Model, which catalogs behavioral, anatomical, and physiological data corresponding to genetic, induced, inbred and rescue models of ASD and 4) Protein Interaction (PIN), which builds interactomes of all known direct relationships for protein products of ASD-linked genes, documenting six major types of direct interactions: 1) protein binding, 2) DNA binding, 3), RNA binding, 4) protein modification, 5) direct regulation, and 6) autoregulation. To provide high-resolution view of diverse data linked to ASD, we have developed detailed annotation rules based on the biology of each data type and generated controlled vocabulary for data representation. In AutDB, we have seemlessly integrated ASD-specific genetic information to the corresponding data in Animal Model and Protein Interaction (PIN) modules. AutDB has grown rapidly; as of March 2014, it contains detailed annotations for 604 ASD associated genes with relevant evidence linking the gene to autism. AutDB is widely used by the autism research community as a reference resource for accelerating ASD research. * AutDB is licensed to Simons Foundation as SFARI Gene

Title: Analysis of forebrain MEF2C function in autism-like behaviors

Authors: *A. J. HARRINGTON[1], J. KUMAR[1,2], J. RADUAZZO[1,3], C. W. COWAN[1];
[1]McLean Hosp., Belmont, MA; [2]Mstp, UT Southwestern, Dallas, TX; [3]Harvard Univ., Cambridge, MA

Abstract: Autism Spectrum Disorders (ASDs) are thought to result from brain synapse dysfunction. Emerging evidence indicates that rare, deleterious mutations increase the risk for developing autism, and many of these identified genes have known functions in the formation, pruning or plasticity of brain synapses. The myocyte enhancer factor 2 (MEF2) family of transcription factors regulates a gene expression program involved in activity-dependent synapse elimination in the developing brain. We found that MEF2 promotes synapse elimination through a process involving the RNA-binding protein, Fragile X Mental Retardation Protein (FMRP), the causal gene in the ASD, Fragile X Syndrome. More recently, mutations in MEF2C have been identified in patients with severe intellectual disability, epilepsy and autism, further supporting the critical link between MEF2 and normal brain development and function. To examine the role of MEF2 in brain development and autism-related phenotypes, we generated a conditional knockout (cKO) of the MEF2C gene within excitatory neurons of the forebrain in early brain development of mice. The MEF2C cKO mice are viable and healthy, but they display significant autism-like behavioral phenotypes, including reductions in social behaviors, restricted and repetitive motor behaviors, and deficits in social communication (ultrasonic vocalizations). Moreover, the mice are hyperactive, and they display robust deficits in reward-related behaviors. Ongoing studies are exploring the cellular, synaptic, and forebrain circuit abnormalities that accompany these behavioral abnormalities. Taken together, our findings reveal that genetic deletion of MEF2C in excitatory forebrain neurons in the mouse brain results in behaviors reminiscent of the three core diagnostic criteria for autism in humans, and as such, provide a new mouse model for studying potential brain dysfunctions that underlie autism-like behaviors.

Title: Predictable enriched environments reduce hyper-emotionality in the VPA rat model of autism

Authors: *M. R. FAVRE, D. LA MENDOLA, J. MEYSTRE, D. CHRISTODOULOU, M. COCHRANE, H. MARKRAM, K. MARKRAM;
EPFL, Lausanne, Switzerland

Abstract: Autistic people present a spectrum of symptom severities and comorbidities, and are not equally responsive to treatment. Environmental stimulation and structured behavioral therapy are among the most effective treatments, but few studies have investigated the effects of predictability in the neurobiology autism, and individual differences. In rodents, environmental enrichment (EE) improves health, cognitive and emotion functions relevant for autism. In the present study, we investigate if EE predictability reduces hyper-emotionality, in the VPA rat model of autism, as proposed by the Intense World Theory of autism. We weaned male rats embryonically exposed either to VPA or to saline into a standard, or an unpredictable enriched, or predictable enriched home cage environment. Our univariate effects and multivariate Cronbach's alpha coefficients analyses corroborate to indicate that predictability is required for reversal of hyper-emotional behaviors in the VPA-exposed animals as a group. Correlations between a multivariate emotionality score and protein content support contributions from plasma corticosterone and glutamatergic-related proteins in the primary somatosensory cortex, dorsal and ventral hippocampus, and amygdala. Behavioral clustering of individual rats with Agglomerative Hierarchical Cluster Analysis further indicates that subgroups with lower emotionality form after predictable environment and also present particular levels of neurobiological proteins. Together, our results suggest that autistic-like individual rats are more sensitive to the environment than "neurotypical"-like rats and require a highly predictable type of enrichment for beneficial outcomes. These observations support autism as an intense world syndrome and have important implications for future research and personalized treatment.

Title: Individually specially targeted supplement and dietary intervention shows promising results in a cohort of children with autism spectrum disorder (ASD)

Authors: *H. B. WALKER;
Biomed Clin., Oslo, Norway

Abstract: The most important developmental phase in any person's life is the 1000 first days from conception.1, when basic genetic and epigenetic programming take place. Influences from different factors during this phase may change the way genes are expressed, even in generations. For most biochemical pathways there are different "security pathways", which in an exposed first generation may impose a shut-down or activation of genes with other consequences than in second generation. Current scientific data suggests that many illnesses may stem from the similar, underlying patho-physiological process as autism. Since the 1950's infants have been exposed to more xenobiotics before the age of 2 than before (new xenobiotics -vaccines, additives, paracetamol, antibiotics, etc.). An exposure for second generations like for the first - can influence epigenetics more. Feeding of infants has changed since the 1950's. Infant formula may differ in ingredients from mothers' milk. Children diagnosed with ASD have been rising in the past 20 years. It may indicate that people with a certain genetic DNA profile are more vulnerable to xenobiotics, and may develop an unbalance in their biochemistry manifesting itself as autism. We are born germfree. Microbiota will develop in specific order-in a window of establishment - during the first two years of life. If a window is missed, it may give lifelong consequences. Based upon principals summarised at the meeting at Nobel Forum, Karolinska Institute, May7th 2012.2,3,4. Biomed Clinic, Oslo, Norway has followed a cohort of ASD children age 2-10 years and tried successfully to regulate relevant factors. We use questionnaires going through a child's history, information from parents and observe the child. Urine tests showing 94 different markers and blood tests following 60 markers are evaluated. Thereafter, we design a specific plan for each child with follow-ups. Most start with a change in diet. Acetyl-L-carnitine and taurine are most commonly used for a year, thereafter in intervals. Essential minerals are supplemented depending on diet and/or test results. Vitamins- particularly B and D are evaluated. Other factors may be used. Improvement are found in all children and relevant cases will be presented. Autism can be treated. 1.Shenderov BA, Midtvedt T. Epigenomic programming. A future way to health? Title: Methylome and synaptic gene impacts of an organic pollutant in Dup15q syndrome

Authors: *M. S. ISLAM[1], K. DUNAWAY[1], D. SCHROEDER[1], I. PESSAH[2], M. HORIKE[3], S.-I. HORIKE[3], J. LASALLE[1];
[1]Med. Microbiology and Immunol., [2]Univ. of California, Davis, Davis, CA; [3]Kanazawa Univ., Kanazawa, Japan

Abstract: Chromosome 15q11-13 duplication syndrome (Dup15q) is one of the most common copy number variations observed in autism-spectrum disorders. Unexpectedly, Dup15q human brain samples showed both DNA hypomethylation measured by LINE-1 pyrosequencing and significantly higher levels of the persistent organic pollutant PCB 95 than controls or idiopathic autism cases (Mitchell et al, 2012). Based on these prior observations, we investigated whether PCB 95 plays a causal or compounding role in DNA methylation differences observed in human Dup15q neurons using epigenomic approaches. Human SH-SY5Y neuroblastoma cells containing an additional maternal chromosome 15 (SH-15M, Meguro-Horike et al, 2011) were used to probe Dup15q and PCB 95 interactions. Whole genome bisulfite sequencing (MethylC-seq) revealed that SH-15M cells exhibited 2-14% higher frequency of large genomic domains of partial methylation (PMDs, Schroeder et al, 2011) compared to parental SH-SY5Y cells across all autosomes. Genes within SH-15M-gained PMDs were enriched for functions at the postsynaptic cell membrane, but were more specifically enriched for ion channels, neurotransmitter, and synaptic functions with PCB 95 exposure. Transcript levels of 48 autism candidate genes hypomethylated in SH-15M exposed to PCB 95 were compared across 48 different cell lines, single-cell clones, and postmortem brain samples in the Fluidigm Biomark.

Aberrant transcript levels were observed for multiple glutamate, serotonin, and GABAA receptor genes, with a significant compounding effect of SH-15M + PCB 95 for GRIA1, encoding ionotropic glutamate receptor AMPA1. The combination of a large chromosomal duplication (Dup15q) and exposure to a persisting organic pollutant (PCB 95) resulted large-scale genomic changes to the neuronal DNA methylome and synaptic gene transcript levels. These results have implications for understanding and treating complex gene x environment interactions in autism-spectrum disorders.

Title: A hypothesis regarding the molecular mechanism underlying soy-induced seizures

Authors: *C. J. WESTMARK;
Univ. Wisconsin, MADISON, WI

Abstract: Numerous neurological disorders including fragile X syndrome, Down syndrome, autism and Alzheimer's disease are comorbid with epilepsy. We have observed elevated seizure propensity in mouse models of these disorders dependent on diet. Specifically, soy-based diets exacerbate audiogenic-induced seizures. We have also found associations between the consumption of soy-based infant formula and seizure incidence, epilepsy comorbidity and autism diagnostic scores in autistic children by retrospective analyses of the Simons Foundation Autism Research Initiative (SFARI) medical record database. There were seizure and infant formula data available for 1,949 autistic subjects (87% males) in the SFARI database. We found a 2.6-fold increase in the incidence of febrile seizures and a 4.8-fold increase in the incidence of simple partial seizures in autistic children fed soy formula. The soy-based formula was not associated

with statistically higher rates of infantile spasms, atonic (drop attack), grand mal (generalized tonic clonic), petit mal (absence) or complex partial seizures. There was a 2.1-fold increased incidence of epilepsy. In aggregate, these data demonstrate that soy-based diets are associated with increased seizure incidence in both mouse models of neurological disease and in autistic children. These data raise important questions regarding the neurological side effects of a soy-based diet during postnatal development. We evaluated autism testing scores in the SFARI autism population dependent on soy-based infant formula. We found exploratory associations between the consumption of soy-based infant formula and several autistic behaviors as assessed by sub-score and line-item analysis of the Aberrant Behavior Checklist (ABC), Autism Diagnostic Interview-Revised (ADIR) and Autism Diagnostic Observation Schedule (ADOS). Of note, subscale 5 scores (inappropriate speech) increased one grade from 3.4 ± 2.9(SD) in the non-soy female cohort to 4.4 ± 3.2(SD) in the soy cohort ($P \leq 0.05$). Likewise, subscale 1 scores (irritability) increased from 11 ± 8.7(SD) to 12 ± 9.0(SD) in males, which approached statistical significance ($P \leq 0.07$). In total, these data suggest that consumption of high levels of soy protein during postnatal development may affect neuronal excitability. We now present our theory regarding the molecular mechanism underlying soy-induced effects on seizure propensity. We hypothesize that soy phytoestrogens interfere with metabotropic glutamate receptor signaling through an estrogen receptor-dependent mechanism, which results in elevated production of key synaptic proteins and decreased seizure threshold.

Title: Influence of pediatric vaccines on CNS development and behavior in the rhesus macaque: Relevance to autism

Authors: *B. GADAD[1], W. LI[1], U. YAZDANI[1], B. CURTIS[2], V. YUTUC[2], C. FERRIER[2], G. SACKETT[2], K. A. YOUNG[3], J. A. DARDEN[3], L. HEWITSON[4], D. C. GERMAN[1];

[1]Psychiatry, UT Southwestern Med. Ctr., Dallas, TX; [2]Washington Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA; [3]Psychiatry and Behavioral Sci., Texas A&M Hlth. Sci. Ctr., Temple, TX; [4]Johnson Ctr. for Child Hlth. and Develop., Austin, TX

Abstract: Autism spectrum disorders (ASDs) are a heterogeneous group of neuro-developmental disorders characterized by impairments in social interaction and communication, and restricted stereotyped behaviors that manifest in early childhood. The etiology of ASDs is unknown but involves interactions between genetic and environmental factors. Some reports suggest that exposure to ethyl mercury, in the form of thimerosal, in childhood vaccines play a causative role in ASDs (*Austin et al., 2008*). In ASD post-mortem brains, reductions in the number of cerebellar Purkinje cells (*Skefos et al., 2010*) and amygdala lateral nucleus cells (*Schumann & Amaral*, 2006), and reductions in the cell size of CA1 hippocampus cell (*Kemper & Bauman*, 1993) have been reported. Using male rhesus macaques, receiving thimerosal-containing vaccines (TCVs) following the pediatric schedule from the 1990's (e.g., Hep B, DTaP, Hib, MMR) and from 2008 (with fewer TCVs) administered at 6 different time points (from birth to 12 months of age, and animals sacrificed at ~18 months), we examined cerebellar cells, amygdala cells and hippocampus cells (n=8-16/group). In the same animals we also examined learning, cognition and social behavior in vaccinated and control animals. Social behaviors from 8 to 18 months of age are currently being analyzed. There were no significant changes in Purkinje cell number or cell size, CA1 cell size, dentate gyrus volume, hippocampal neurogenesis, or lateral nucleus of the amygdala volume/cell number in animals in the 1990's vaccination group vs. saline controls. These data do not support a role for TCVs in the neuropathology of ASDs

Title: Prenatal fluoxetine exposure does not increase autism-related behaviors in adult mice

Authors: *F. MALARKEY[1,2], E. I. MESHREKY[3], N. J. MCGOVERN[3], J. P. HEAD[3], M. P. LEUSSIS[3];
[1]Emmanuel Col., Fullerton, ; [2]Psychology, [3]Emmanuel Col., Boston, MA

Abstract: SFN 2014 – Prenatal fluoxetine permanent effects Prenatal fluoxetine exposure does not increase autism-related behaviors in adult mice. Francis J. Malarkey, Elaria I. Meshreky, Nathan J. McGovern, Joshua P. Head, Melanie P. Leussis Although autism is a highly heritable disorder, the role of environmental factors in autism spectrum disorder has recently received increased attention. Relatively little is known about which environmental factors contribute to the ontogeny of autism. The current study examined the role of prenatal exposure to fluoxetine on subsequent behaviors relevant to autism in adulthood. C57BL/6J dams were administered the selective serotonin reuptake inhibitor (SSRI) fluoxetine (0.6mg/kg/day, IP) or vehicle from embryonic days 8 to 18. Adult male progeny were subsequently tested in a behavioral test battery designed to examine changes in social/communicative behaviors and repetitive behaviors. Mice were also tested for anxiety-related behaviors, as previous studies indicate that prenatal fluoxetine exposure increases anxiety. The test battery included tests such as social preference, scent marking in response to an estrus female stimulus, self-grooming, marble burying, elevated plus maze, and novelty-suppressed feeding. The results indicate that mice treated with fluoxetine prenatally were significantly more anxious in the elevated plus maze, but not in a novelty-suppressed feeding paradigm. Fluoxetine-treated mice did bury significantly more marbles than controls, but this increase in repetitive behavior did not extend to the self-grooming task as control and fluoxetine-treated mice did not differ on this measure. Further, prenatal fluoxetine treatment did not appear to alter social behavior in either the social preference task or a scent-marking task. These findings suggest that, at least in mice, prenatal exposure to fluoxetine does not significantly increase the risk of developing autistic-relevant behaviors in adulthood.

Title: Blood biomarkers for Autism: Peptoids and proteins

Authors: *D. C. GERMAN[1], U. YAZDANI[1], S. SINGH[1], Y. DENG[1], S. ZAMAN[1], L. HEWITSON[2];
[1]Psychiatry, U Texas Southwestern Med. Cntr., DALLAS, TX; [2]Johnson Ctr. for Child Hlth. and Develop., Austin, TX

Abstract: Autism spectrum disorders (ASDs) are a heterogeneous group of neuro-developmental disorders characterized by impairments in social interaction and communication, and restricted stereotyped behaviors that manifest in early childhood. Research findings have identified widespread changes in the immune system of children with autism, at both systemic and cellular levels. In order to identify individuals with ASDs and treat them at the earliest possible age, biomarkers for the disorder are desirable. A blood biomarker would be ideal because it is non-invasive and inexpensive. To identify blood biomarkers of ASDs we have used two approaches - peptoids and proteins. We have used on-bead displays of thousands of different peptoids (N-substituted oligoglycines) to screen for candidate IgG antibody biomarkers for ASDs. This approach represents a *high-throughput screening* approach with a *combinatorial peptoid library* to identify antibodies in the serum that are sensitive and specific for the identification of ASD. We have identified several peptoids (ASD1, ASD19-22) that uniformly bind lower levels of IgG in serum from ASD boys compared to typically developing (TD) boys (n=50/group; p=0.06). These peptoids also binds low levels of IgG in unaffected siblings from ASD families (pooled serum from n=10). Currently we are working to identify the antibody/antibodies that are recognized by the ASD1 peptoid. We have also used the Myriad Rules Based Medicine Luminex platform to determine whether there are differences in the levels of inflammatory proteins in the blood of ASD individuals (DiscoveryMAP 175+). Comparing serum from 30 ASD boys and 30 TD boys (ages 2-8 yrs.) we found 8 proteins that were significantly different between the two groups (<0.05). These proteins include alpha-fetoprotein, ferritin, interleukin-8 and thyroid stimulating hormone. We are cross-validating these findings on the Meso Scale Discovery platform to determine whether this panel of 8 protein biomarkers will have high sensitivity/specificity for the identification of ASDs.

Title: Aluminum-induced gene expression alterations in mice brains

Authors: *D. LI, Y. LI, C. SHAW;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The consensus regarding the mode of inheritance of autism is that it is a polygenic model with multiple gene-gene and gene-environment interactions. However, how genes interact with environmental factors remains to be discovered. In young children, a highly significant correlation exists between the number of pediatric aluminum-adjuvanted vaccines administered and the rate of autism spectrum disorder (ASD). Furthermore, increased anxiety and reduced exploratory behavior and locomotor activities have been observed in aluminum-injected mice in our previous study. Aluminum, as a commonly known toxin, could possibly drive the immune response by being carried into the central nervous system by circulating macrophages and further disturb prenatal or postnatal neural system development. In this study, we propose a "two-hit model" to explain the potential interaction between aluminum and ASD-related genes, in which genetic predisposition (first insult) can sensitize children's neural system to toxic aluminum (secondary insult), and together they trigger downstream immune dysfunction and eventually result in developmental delay. To test this hypothesis, we selected 17 candidate genes which have implied function in both ASD and innate immune response. By measuring the expression level of these 17 genes in mice brains after repetitive subcutaneous administration of aluminum in amounts comparable to those children receive via routine vaccinations, a spectrum of expression change was detected in comparison with control mice. Some of the activators and effectors of macrophage, such as CCL2, IFNG and TNF, were significantly up-regulated, while the inhibitor of NF-κB, NFKBIB, and the excitatory neurotransmitters, ACHE, were remarkably down-regulated in aluminum-injected male mice. The down-regulation of NFKBIB led to

activation of NF-κB. Therefore, the immune system was activated and the synaptic function was decreased in male brains as a result of aluminum injection. Unlike male, female mice were less responsive to environmental insult. Fewer genes with altered expression level were discovered in females. These results strongly suggest that aluminum could impair brain function by penetrating brain and further interacting with key players of immune and neural system in males, while females may be protected from the aluminum toxicity by their more robust neurobiological system. Our results shed new lights on the etiology of ASD, gene-toxin synergy and vaccine safety.

Title: Epigenetic modulation of BDNF transcription in the valproic acid model of autism

Authors: M. KONOPKO[1], A. DENSMORE[2], C. D. ROBY[3], *B. K. KRUEGER[2];
[1]Program in Neurosci., [2]Dept Physiol., [3]Dept Pharmacol., Univ. Maryland Sch. of Med., BALTIMORE, MD

Abstract: Valproic acid (VPA) is an anti-epileptic and mood-elevating drug that increases the risk of autism in the offspring of mothers who use it during pregnancy. Fetal exposure to VPA has been extensively used as an animal model of autism. Previously, we showed that administration of VPA to pregnant mice at E12.5 transiently increases BDNF expression in the fetal brain by activating promoters 1, 4 and 6 (P1, P4 and P6). Based on the activity of VPA as a histone-deacetylase inhibitor, we utilized chromatin immunoprecipitation to determine whether

histone-3 acetylation at one or more of these promoters was affected by fetal exposure to VPA. VPA administered to the dam at E12.5 increased acetylation of lysine 9 and/or 14 (H3K9/14ac) at P1, P4 and P6 2−4-fold in the fetal brain. We also examined the CpG methylation patterns in P1, P4 and P6 in response to VPA. Only 4 of the 106 CpGs in or near P1, P4 and P6, analyzed by bisulfite sequencing, were significantly methylated in the control fetal brain (35−60% methylated). No methylation of non-CpG Cs was observed. The four methylated sites were located in P4, in a cluster consisting of two individual CpGs and one CpG doublet within a 96 bp sequence. Overall methylation of this cluster was reduced by about 20% (11−31% at individual CpGs) in fetal brains exposed to VPA. This methylated CpG cluster is located just upstream from previously-described calcium-dependent regulatory elements and contains CpGs implicated in MeCP2 silencing of BDNF transcription in cultured neurons. Additionally, one of the individual CpGs and the doublet are immediately followed by an identical 7 bp sequence, conserved in humans, which was identified as a potential Elk-1/ETS regulatory element not previously implicated in BDNF transcription, raising the possibility that CpG methylation may directly suppress binding of a transcription factor to these sites. These data suggest that the stimulation of BDNF expression induced by VPA in the fetal brain may be mediated in part by increased H3K9/14ac at P1, P4 and P6 and by reduced methylation of a cluster of four CpGs in P4.

Title: Prenatal fluoxetine exposure does not alter ultrasonic vocalizations but does improve performance on some neuromotor coordination tasks in 3-11 day-old mouse pups

Authors: *J. M. THANOS, E. M. WEBER, N. J. MCGOVERN, M. P. LEUSSIS; Emmanuel Col., Boston, MA

Abstract: The present study examined the effects of prenatal fluoxetine exposure on isolation-induced ultrasonic vocalizations and neuromotor coordination in 3-11 day old mouse pups. C57BL/6J dams were administered the selective serotonin reuptake inhibitor (SSRI) fluoxetine

(0.6mg/kg/day, IP) or vehicle from embryonic days 8 to 18. Pups were then tested on postnatal days (P) 3,5,7,9, and 11. Neuromotor developmental paradigms included surface righting, negative geotaxis, and forelimb grip. Ultrasonic vocalizations were recorded in pups on P8, P10, and P12 after a five-minute separation from the dam. Mice were also weighed every other day to examine growth from P3-P13 and at P21. There was no significant effect of prenatal fluoxetine treatment on ultrasonic vocalizations during development in either male or female pups. Prenatal fluoxetine treatment did alter some measures of neuromotor development, including decreasing surface righting time and increasing forelimb grip strength. Negative geotaxis was not affected by prenatal fluoxetine treatment. It is possible these effects reflect a change in weight in the fluoxetine-exposed mice as weight increased from P3-P13 for all, but males were not significantly different across drug conditions while females exposed to fluoxetine were heavier than saline-treated females. This still held true at weaning (P21) when females treated with fluoxetine were heavier than controls, while in males there was no difference in weight. The results suggest there are no significant effects of prenatal fluoxetine treatment on communication and anxiety during development, as measured in the isolation-induced ultrasonic vocalization paradigm. This suggests prenatal fluoxetine exposure does not increase autism-related behaviors during early postnatal development.

Title: Prostaglandin E2 promotes earlier differentiation of neuroectodermal stem cells: A link to Autism

Authors: *C. T. WONG[1,2], N. USSYSHKIN[3], H. LI[1], D. A. CRAWFORD[1,2,3];
[1]Kinesiology and Hlth. Sci., [2]Neurosci. Grad. Diploma Program, [3]Dept. of Biol., York Univ., Toronto, ON, Canada

Abstract: Background: Prostaglandin E_2 (PGE_2) is a metabolite of membrane phospholipids and serves as a bioactive signalling molecule. It binds to four EP receptors (EP1-4) to regulate physiological functions in early development. Existing literature provides evidence that the prostaglandin pathway is an autism candidate signalling pathway[1]. The levels of PGE_2 can be altered through genetic changes along the pathway or exogenous factors such as dietary intake, oxidative stress, and exposure to infections or chemical agents, which have all been associated with Autism Spectrum Disorders (ASD) [1]. Our previous work in undifferentiated neuroectodermal (NE-4C) stem cells showed that PGE_2 interacts with Wnt signalling[2]. Addition of PGE_2 increased Wnt-dependent cell migration, speed and distance travelled. PGE_2 also modified the expression of Wnt-target genes including *Ctnnb1*, *Ptgs2*, *Ccnd1* and *Mmp9*. These genes have been previously linked to ASD. This study examines the effect of PGE_2 on NE-4C cell differentiation. **Objective**: To elucidate the mechanisms of how increases in PGE_2 may elicit functional changes in prenatal development of the nervous system and to study how PGE_2 may affect the differentiation behaviour and gene expression of NE-4C stem cells. **Methods**: Mouse NE-4C cells were differentiated into neurons through a continuous serum-free media protocol *in vitro*. Time-lapse microscopy was used to collect images over an 8 day differentiation period. Cell behaviour such as neurosphere (NSp) formation (area, perimeter and roundness) was quantified. Real time PCR was used to measure the expression of target genes. **Results**: We showed that NE-4C cells undergo distinct stages of differentiation: proliferation, inward migration, aggregation, and NSp formation. We found that 1μM PGE_2 treatment accelerates differentiation through earlier expression of neuronal marker (*Tau*) and formation of NSp. Moreover, during the stage of NSp formation, PGE_2 treatment resulted in changes to the expression level of adhesion molecules: higher levels of *Ncad* and lower levels of *Ncam*. Wnt-target gene expression was also modified by PGE_2: *Wnt8a*, *Wnt3*, *Tcf4*, and *Ccnd1* increased while *Wnt2* and *Mmp9* decreased. Interestingly, *Ncam*, *Tcf4*, *Ccnd1*, *Wnt2* and *Mmp9* have been linked to ASD. **Conclusions**: Our results show that elevated levels of PGE_2 alters NE-4C cell differentiation *in vitro* such as progression and gene expression. We also demonstrate that PGE_2 and Wnt signalling pathways likely collaborate with each other in early development. Our data suggests that prenatal increase of PGE_2 could affect developmental processes and result in pathologies of the nervous system that lead to ASD.

Title: Effects of thimerosal on the expression levels of ghrelin and its receptor genes in immature neuronal cells

Authors: *E. M. SAJDEL-SULKOWSKA;
Psychiatry, Harvard Med. Sch/BWH, Boston, MA

Abstract: Ghrelin is an important orexigenic peptide synthesized by gastric mucosa and involved in gut-brain communication. A number of recent studies have reported ghrelin synthesis in specific neuronal populations in the brain; its biological effects in CNS include modulation of membrane excitability, neurotransmitter release, neuronal gene expression and neuronal survival and excitability. These actions are mediated by an interaction between ghrelin and a growth hormone secretagogue receptor (GHSR1). The present study was undertaken to: (1) confirm the expression of ghrelin and GHSR1 genes in the neuronal stem cells and primary brain culture of immature neurons; and (2) examine the effects of thimerosal (TM) on the expression of these genes. TM, an ethyl mercury containing preservatives, is used in a variety of biological products, including some vaccines, and reported as cytotoxic to neural tissue. We have shown previously that *in vivo* perinatal TM exposure in rats resulted in neurobehavioral abnormalities that were associated with changes in expression of TH-dependent genes in several regions of rat brain. In the present study we examined the effect of TM (17 nM) in neuronal stem cells prepared from Wistar rats, and wild type and p53 knockout mice. We also examined the chronic effect of TM on the expression of ghrelin/GHSR1 in the primary cerebellar cultures prepared from P1 rats. Gene expression was determined by qRT-PCR and the relative gene expression values were calculated using the $2(-\Delta\Delta Ct)$ method. We report that the addition of TM resulted in growth inhibition in rat (72.5%) and mice stem cells (57%), and a smaller inhibition (38%) in p53 knockout mouse cells, suggesting that the TM effect is mediated by the p53 protein. The addition of TM to primary cerebellar cultures, resulted in altered expression of several genes. Notably, expression of ghrelin was increased twofold and expression of GHSR1 gene was increased fourfold in TM-treated cultures. The results of the present study demonstrate that ghrelin and its receptor GHSR1 are expressed in immature cerebellar neurons. Furthermore, TM affects neuronal cell growth and the expression of ghrelin and GHSR1 genes at equivalent concentrations. These results further support developmental effects of TM. Future studies will establish effect of TM on ghrelin and GHSR1 expression in the gastric mucosa. Altered

expression of ghrelin/receptors in the gut as well as the brain may contribute to the disturbance of the brain-gut axis observed in various pathologies, including autism.

Title: Brain-derived estrogen exerts anti-inflammatory and neuroprotective actions in the rat hippocampus

Authors: *Q.-G. ZHANG[1,2], R. WANG[3,2], H. TANG[3], Y. DONG[1], A. CHAN[1], D. BRANN[1,2]; [1]Georgia Regents Univ., Augusta, GA; [2]Charlie Norwood Dept. of Veteran Affairs Med. Ctr., Augusta, GA; [3]Neurobio. Inst. of Med. Res. Center,Hebei United Univ., Tangshan, China

Abstract: The ovarian steroid hormone 17β-estradiol (E2) functions as a critical mediator of neuroprotection in several neurodegenerative diseases. Besides acting as a neuroprotective agent, E2 plays a role in synaptic plasticity and cognition. Much of this work has focused on the role of gonadal-derived E2, but recent studies have demonstrated a potential neuroprotective role for E2 produced in the brain by the cytochrome p450 aromatase, which catalyzes the conversion of androgens to E2. Results revealed aromatase is highly expressed in hippocampus of the brain, particularly in the CA1 region, an area critical for learning and memory. Aromatase co-localized primarily in neurons in non-ischemic animals. However, following global cerebral ischemia (GCI), aromatase became highly expressed in GFAP-positive astrocytes in the hippocampal CA1 region at 2-3 days post GCI reperfusion. An ELISA for E2 and IHC for E2 confirmed the GCI-induced elevation of local E2 in the CA1 region and that the increase in local E2 occurred in astrocytes. A role for brain-derived E2 in neuroprotection in the hippocampus was implicated by the finding that central inhibition of aromatase by administration of an aromatase inhibitor (letrozole, 30 μg/10μl) resulted in a significant decrease of E2 levels in CA1 region, and increase in hippocampal neuronal cell death following GCI in ovariectomized rats. Furthermore, central administration of aromatase antisense (AS) oligonucleotides, but not missense (MS) oligonucleotides, blocked the increase in aromatase and local E2 in astrocytes after GCI, and

resulted in a significant increase in GCI-induced hippocampal CA1 region neuronal cell death and neuroinflammation. As a whole, these results suggest that brain-derived E2 exerts important neuroprotective and anti-inflammatory actions in the hippocampal CA1 region following GCI.

Title: Prolonged exposure to ketamine but not thiopental sodium might potentiate glutamate-induced neurotoxicity in rat primary cultured cortical neurons

Authors: *S. SHIBUTA, T. MORITA, T. KAMIBAYASHI, Y. FUJINO;
Osaka Univ. Grad Sch. Med., Osaka 565, Japan

Abstract: A number of the studies have shown that anesthetics administration during perinatal period exhibits a neurotoxicity afterwards. Especially, an NMDA receptor antagonist, ketamine-induced neurotoxicity in the developing brain is thought to associate with the upregulation of NMDA receptors. In the present study, we examined whether a long time exposure to the most widely-used intravenous anesthetics, ketamine and thiopental, during perinatal development periods would intensify glutamate-induced neurotoxicity which occurs later using rat primary cultured neurons *in vitro*. Primary cultures of cortical neurons from E16 Wistar rats were prepared. During the first 72 hr in the primary culture, the neurons were exposed to 1, 10 or 100 μM ketamine or thiopental, respectively. As a control, sister culture dishes were exposed to the same amount of PBS or distilled water without anesthetics. Cultured neurons were exposed to glutamate at the concentrations of 3, 30 or 300 μM 13-14 days later. The survival rate of neurons was analyzed after a 24-hr period of glutamate exposure. Survival rates were calculated using the following formula; the amount of unstained cells at the end of the experiment divided by the amount of whole cells shortly before the experiment. Survival ratios (SR) were calculated as follows; a survival rate of a certain dish divided by a survival rate of the control sister culture

dish. Therefore, SR of control neurons was defined as 1. Without exposure to glutamate, the SR of the neurons, which was exposed to 100μM ketamine in the first 72 hr of the culture, was not significantly attenuated (0.923). When neurons were exposed to 3μM glutamate, the SR of the neurons, which were exposed to ketamine 100μM in the first 72 hr of the primary culture, was 0.839. This SR was significantly lower than control (ket=0, glu=0), however, was not significantly lower than the SR of the neurons of ket=0, glu=3 (SR=0.9033). When neurons were exposed to 30 or 300μM glutamate, the SR of the neurons were significantly lower compared to control without regard for the exposure to ketamine in the first 72 hr of the primary culture. Moreover, the concentration of ketamine in the first 72 hr of the primary culture did not affect the SR of the neurons significantly. In contrast to ketamine, thiopental, exposed in the first 72 hr of primary culture, did not show any significant difference in the SR at any dose. In E16 rat primary cortical cultured neurons, prolonged exposure to high concentration of ketamine but not thiopental for the first 72 hr might alter the sensitivity against glutamate-induced neurotoxicity marginally two weeks later.

Title: Estrogen administration modulates parvalbumin expression during trimethyltin-induced hippocampal neurodegeneration

Authors: *F. MICHETTI[1], V. CORVINO[2], E. MARCHESE[2], V. DI MARIA[2], F. BIAMONTE[3], M. GELOSO[2];
[2]Anat. and Cell Biol., [3]Histology and Embryology, [1]Univ. Cattolica S. Cuore, Roma I-00168, Italy

Abstract: Parvalbumin (PV) interneurons are known to give a crucial contribute to cognitive processes, being also responsible for a peculiar form of experience-related plasticity, involved in

learning and memory processes. They are modulated in several conditions of neural injury, and their dysfunction severely impairs brain functions, thus representing a potential target for neuroprotective strategies (1-3).The neurotoxicant trimethyltin (TMT) induces severe hippocampal neurodegeneration, selectively sparing PV interneurons, accompanied by behavioural alterations including cognitive deficit and seizures, and is regarded to be an useful model for the study of neurodegenerative processes and neuroprotective strategies (4-6). Since beta-estradiol (E2) is known to play a role in neuroprotection and to modulate PV expression in different models of brain damage (7,8), we explored the role of E2 on neuronal death and PV expression in the hippocampus of TMT-treated rats. Animals (n=6/group) received i.p. E2 (100 microg/rat) for 2 consecutive days starting from the day of TMT or saline administration, and were sacrificed on post-treatment day 7. Unbiased stereological analysis of Fluoro-Jade- or PV-stained hippocampal sections evidenced that E2 administration induces in TMT-treated rats a significant increase in the number of PV interneurons in CA1, which correlates with the degree of neuronal degeneration ($p<0.05$),while the extent of neuronal death in CA1 and CA3 did not appear to be significantly influenced. The present data add information to depict a possible role for *in vivo* E2 administration in the modulation of mechanisms of cell plasticity and neuroprotection in the adult brain. -1 Andrioli A,Alonso-Nanclares L, Arellano JI, DeFelipe J Neuroscience 2007,149:131-43 -2 Donato F,Rompani SB, Caroni P Nature 2013, 504:272-6 -3 Cabungcal JH, Steullet P, Kraftsik K, Cuenod M, Do KQ Biol Psychiatry 2013, 73:574-82 -4 Geloso MC,Corvino V, Michetti F Neurochem Int 2011, 58:729-38 -5 Corvino V,Marchese E,Giannetti S,Lattanzi W,Bonvissuto D,Biamonte F,Mongiovì AM,Michetti F,Geloso MC J Neurochem 2012, 122:415-26 -6 Corvino V,Marchese E,Podda MV,Lattanzi W,Giannetti S,Di Maria V,Cocco S,Grassi C,Michetti F,Geloso MC PloSOne 2014DOI:10.1371/journal.pone.0088294 -7 Rewal M, Wen Y, Wilson A, Simpkins JW, Jung ME Alcohol Clin Exp Res 2005,29:1837-44 -8 Macrì S,Biamonte F,Romano E,Marino R,Keller F,Laviola G Psyconeuroendocrinology 2010,35:1374-87

Title: Characterisation of corticospinal tract termination patterns originating from the intact hemisphere following recovery from ischaemic stroke in the rat

Authors: *E. J. MITCHELL, D. DEWAR, D. J. MAXWELL;
Inst. of Neurosci. and Psychology, Glasgow, United Kingdom

Abstract: A limited degree of functional recovery commonly occurs in the first few weeks following stroke but the neural basis of this is poorly understood. Previous reports have implicated plasticity of the corticospinal tract (CST) in this process where motor recovery was correlated with crossing of intact (contralesional) CST fibres into the contralateral denervated spinal grey matter. The present study was conducted to determine if new CST axonal terminals arising from the non-ischaemic hemisphere form in the impaired half of the spinal cord replace synaptic connections lost after stroke. We also investigated whether new or enhanced connections are formed between the contralesional CST and specific spinal interneuron populations with known commissural projections. Sprague-Dawley rats underwent occlusion of the left middle cerebral artery (MCAo) or sham occlusion surgery. Behavioural testing was conducted prior to MCAo and postoperatively for 28 days to monitor functional deficit and recovery. CST terminals from the non-ischaemic hemisphere were visualised by injecting cholera toxin B (CTb) subunit into the right forelimb motor cortex at day 28 and quantified in the impaired (right) half of the cervical spinal cord. Termination patterns to spinal interneurons were investigated using immunofluorescence: antibodies against CTb, choline acetyltransferase (ChAT), calbindin and calretinin were used to identify terminals and spinal neuron populations. All MCAo rats exhibited a sensorimotor deficit that spontaneously recovered over 28 days. MCAo did not alter the number of labelled terminals in the impaired half of the spinal cord. ChAT, calbindin and calretinin expressing neurons were rarely contacted by labelled CST terminals in both sham and MCAo rats. The results suggest that terminal remodelling from the CST originating in the non-ischaemic hemisphere does not contribute to spontaneous recovery following MCAo.

Title: An open-label treatment with valproate for patients with acute middle cerebral artery infarction: evidence for improved functional recovery

Authors: *G.-S. PENG[1], J.-T. LEE[2], C.-H. CHOU[3], Y.-F. SUNG[3], C.-M. CHU[4], J.-S. HONG[5], D.-M. CHUANG[6];
[1]Neurol., Tri-Serv Gen Hosp, Taipei, Taiwan; [2]Neurol., [3]Tri-Service Gen. Hosp., Taipei, Taiwan; [4]Natl. Def. Med. Ctr., Taipei, Taiwan; [5]Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC; [6]NIH, Bethesda, MD

Abstract: Introduction: Increasing evidence from studies using animal stroke models suggests that valproate comprises multiple neuroprotective mechanisms against ischemic brain damage and functional deficits. This study tested whether valproate could improve functional recovery in patients suffered from acute middle cerebral artery (MCA) infarction. Methods: An open-label trial was performed by treating patients with valproate 3 to 24 hours after acute MCA infarction, and with confirmation by brain MR imaging. A total of 34 eligible patients were evenly distributed into the valproate and non-valproate groups. All patients were examined for neurological function, laboratory data and brain MR imaging at stroke onset, as well as 2 weeks and 3 months of follow-up. Results: There was no significant difference in demographics and baseline characteristics between the valproate and non-valproate groups. All patients were elderly having high score of pretreatment National Institutes of Health stroke scale (NIHSS) and slow stroke lesion growth with a final large infarct volume at the 2nd week of follow-up (71.5±12.3, years;17.7±8.2; 110.7±137.1 cm3 in the valproate group; 72.7±9.1, years; 17.4±8.6; 106.5±84.5 cm3 in the non-valproate group). The infarct volume and function outcome showed no difference when compared between the valproate and non-valproate groups at 3 months of follow-up. Notably, comparison of functional outcome between pre-treatment and post-treatment at 3 months of follow up showed that the valproate group had highly significant improvement in all the modalities, including NIHSS (17.0±2.3 vs. 9.6±2.3, p=0.004), modified Rankin scale (mRS;4.3±0.3 vs. 3.1±0.5, p=0.007), and Barthel index (BI;11.1±4.0 vs. 48.9±10.7,p=0.001), while the non-valproate group showed no significant improvement in NIHSS and mRS, and had only mild improvement in the BI scale (9.2±3.5 vs. 37.1±12.3,p=0.022). Conclusions: This open-

label trial demonstrated for the first time that patients with acute MCA infarction receiving valproate treatment had marked improvements in functional outcome at 3 months of follow-up compared to those at pre-treatment. This study suggests the potential use of valproate in the treatment of patients suffered from acute ischemic stroke.

Title: Bilateral cortical hyperactivity detected by functional MRI associates with improved motor function following intravenous administration of mesenchymal stem cells in a rat stroke model

Authors: ***S. OKA**[1], M. SASAKI[1], J. SUZUKI[2], J. D. KOCSIS[3], O. HONMOU[1];
[1]Neural Regenerative Med., [2]Radiology, Sapporo Med. Univ., Sapporo, Japan; [3]Yale Univ., New Haven, CT

Abstract: Intravenous administration of mesenchymal stem cells (MSCs) derived from bone marrow improved motor function in rat cerebral infarction models. In this study, MSCs were intravenously infused 6 hours after right middle cerebral artery occlusion (MCAO) induction in rat. Functional MRI (fMRI) during electrical stimulation of the left forepaw and behavioral testing (treadmill stress test) were performed at day 1, 4, 7, 14, 21, 28 and 42 following MCAO. In medium infused group (n=20) electrical stimulation of the left forepaw elicited a unilateral (right cortex) activated signal detected by fMRI in the infarcted somatosensory cortex. In the MSC infused animals two fMRI patterns were observed: unilateral (n=17) and bilateral (n=19) activation of sensorimotor cortex. In the MSC group both unilateral and bilateral cortical activated animals displayed significantly improved motor function compared to the medium infused group. The bilateral activated pattern in the MSC group, however, demonstrated the greatest functional recovery. Lesion volume as evaluated from high intensity signals using T2WI was less in the MSC groups as compared to the medium group, but the lesion volume for the

unilateral and bilateral signals in the MSC group was the same. These results suggest that the presence of a bilateral signal in sensorimotor cortex as detected by fMRI was more predictive of improved functional outcome than lesion volume alone.

Title: Nogo-A neutralization improves visual recovery after partial excitotoxic damage of the retina

Authors: *N. JORDI, V. PERNET, S. JOLY, M. E. SCHWAB;
Brain Res. Inst., Zürich, Switzerland

Abstract: Ischemic insults like those occurring in glaucoma or after artery or vein occlusions cause irreversible vision deficits. At the molecular level, ischemic injuries induce retinal neuronal cell death in a manner thought to depend on excessive N-methyl-D-aspartate (NMDA) receptor activation, a process called excitotoxicity. In the present study, we hypothesised that the inactivation of the neuronal plasticity inhibitor Nogo-A could improve visual recovery at the functional and anatomical level after NMDA-induced excitotoxicity of retinal ganglion cells (RGCs) in adult mice, a model mimicking ischemic damage. WT and Nogo-A KO mice were intraocularly injected with increasing doses of NMDA. The visual function was longitudinally assessed by measuring the spatial frequency threshold using the optokinetic response (OKR). The cell death of RGCs was examined three weeks after NMDA injection in WT and Nogo-A KO retina flat-mounts by immunohistochemistry for β3-tubulin, a specific marker for RGCs. After injection of 0.25mM NMDA into WT eyes, the OKR was rapidly abolished; recovery started at 2 wks to reach 80% at 3 wks.. In contrast, Nogo-A KO mice only showed a transient

loss of OKR at 1 day and a rapid recovery starting as early as two days post injection. At the end of the experiment (3 weeks), the recovery was complete (95%) in the Nogo-A KO mice. At higher concentration of NMDA (2.5mM) the OKR was absent and neither WT nor Nogo-A KO mice showed significant behavioural improvements over the course of the experiment. The density of surviving β3-tubulin-labelled RGCs did not differ between the two genotypes after administration of NMDA, suggesting that neuronal cell death was not affected by the ablation of Nogo-A and cannot explain the difference of OKR improvement in Nogo-A KO mice. However, neuronal cell death is likely to prevent OKR recovery at 2.5 mM NMDA for the two groups of animals: at 0.25 mM NMDA, 25% of RGCs died in the two genotypes while at 2.5mM NMDA, the RGC population was reduced by 80%. Using the OKR behaviour test, our data revealed that the effect of NMDA-induced excitotoxicity on the visual function can be strikingly improved by inactivating the neuronal plasticity repressor Nogo-A in adult mice, provided that cell death is limited. The cellular and molecular mechanisms underlying the visual recovery in Nogo-A KO mice are currently under investigation and could be relevant to treat a large spectrum of visual affections.

Ctr., UZH ETH Zurich, Zurich, Switzerland

Abstract: Animal studies have demonstrated that most recovery occurs within a limited time window after stroke that lasts about 4 weeks. Human studies, which have largely relied on

clinical measures of recovery like the Fugl-Meyer score, also show that most recovery occurs in the first 4 weeks after stroke. In this study, we sought to characterize the time window for recovery of arm motor control after stroke using kinematic measures. Our kinematic planar reaching task was designed to be an assay of basic motor control that minimizes both the effects of strength and the possibility of compensatory strategies. Using functional principal components analysis (FPCA), reaching deficits can be quantified in terms of increased trajectory bias (differences in mean trajectories) and variance (differences in variability around those means), compared to healthy age-matched controls. We studied patients with newly diagnosed ischemic stroke (n=12, mean age=58.3 yrs, 6M, 4 dominant side affected) with residual unilateral arm impairment. Patients were evaluated at four time points during the first six months after the stroke (within 2 weeks of stroke, at week 5, week 13, and week 26 post-stroke). Subjects performed visually-guided, center-out, gravity-supported planar reaching movements to eight radially-arrayed targets (8 cm distance) for each arm. Initial trajectories with both the affected and unaffected arms showed greater bias and variance compared to healthy controls. From the first time point to week 5, we found significant improvements in both bias and variance for the affected arm (p=0.00065 and 0.0345, respectively, Fig.1). For the unaffected arm, there was improvement in trajectory variance (p=0.003) but not in bias (p=0.0065). After week 5, we saw no further improvements in our kinematic measures for either arm. We conclude that there is a limited, approximately five-week time window for spontaneous recovery of proximal arm motor control.

Title: The effects of targeted intracerebral saporin injection on recovery from stroke

Authors: *A. BECKER[1], M. GOLDBERG[2];
[1]UT Southwestern, Dept. of Neurol. and Neurotherapeutics, Dallas, TX; [2]Dept. of Neurol. and Neurotherapeutics, UT Southwestern, Dallas, TX

Abstract: It is well known that the diffuse neuromodulatory systems of the brain play a role in cortical plasticity that may extend to cortical reorganization after brain injury. The basal forebrain cholinergic system in particular is necessary for both cortical plasticity and behavioral recovery from cortical electrolytic lesions. The role of the cholinergic system in recovery from stroke has never been directly investigated. In this experiment, we asked the question: is the basal forebrain cholinergic system in the mouse necessary for behavioral recovery from stroke? To answer this question, we administered intracerebral injections of the selective immunotoxin mu p75-saporin bilaterally to the cholinergic nucleus basalis in young adult mice. Using choline acetyltransferase immunohisochemistry, cresyl violet staining, and fluoro-jade B staining we discovered a dose at which these injections eliminate local cholinergic neurons while leaving other cell types and cholinergic cells outside the nucleus basalis unharmed. We report the effects of these injections on behavioral recovery from a subsequently induced photothrombotic cortical ischemic stroke.

Title: Neuroprotection of the cembranoid 4R compound against stroke

Authors: *A. H. MARTINS[1], P. A. CORDOLIANI[1], L. A. LLOPART[1], D. PEREZ[1], Y. LI[2], B. D. FORD[2], V. A. ETEROVIC[1], P. A. FERCHMIN[1];

Abstract: Ischemic stroke is an important cause of death and disabilities. There are none neuroprotective agents available and just one drug named tPA approved by FDA, leaving the search for new drugs an important segment of research. Here we present a new compound named 4R-cembranoid, which has been shown neuroprotective characteristics in different *in vitro* and *in vivo* models of neuronal injury. In the present work, 6mg/Kg of 4R injected subcutaneously 2 hours after transient middle cerebral artery occlusion (MCAO) decreased the infarct volume in male rats, as measured by 2,3,5-triphenyltetrazolium chloride 24 hours after ischemia. The average of infarct area in vehicle treated rats was 31.67% ± 4.19 and 13.99% ± 9.2 ($n=5$, $p<0.01$) in 4R treated rats. On the other hand we analyzed the 4R-induced neuroprotection in hippocampus since significant memory impairment has been observed with delayed neuronal hippocampal death after MCAO. We analyzed the 4R-induced neuroprotection using the recovery of population spikes as measurement of functional neurons. Hippocampal slices submitted to 10 min of OGD were superfused with 10 μM of 4R immediately or 30 minutes after the initiation of deprivation. We observed a significant recovery of population spikes in both treatments; 27.024± 5.2% (OGD), 56.7 ± 7.2 (immediately after) and 65 ± 7.1 (30 minute after). On the other hand, a possible mechanism of action was evaluated. Although, in experiments using NMDA as a model of injury in hippocampal slices, the PI3K-Akt kinase were used as neuroprotective pathway, 4R-induced neuroprotection does not was abolished when 10 μM of LY294002, an PI3K-Akt, inhibitor was added, showing possible independence of PI3K in OGD model. In summary, experiments have shown that 4R decreased the neuronal death using different models of action.

Title: Neurorestorative therapy of stroke in type two diabetes rats treated with human umbilical Cord blood cells

Authors: *P. VENKAT[1,2], T. YAN[1,3], M. CHOPP[1,2], A. ZACHAREK[1], R. NING[1], Y. CUI[1], C. ROBERTS[1], N. KUZMIN-NICHOLS[4], C. SANBERG[4], J. CHEN[1];

Abstract: Background and Purpose: Diabetes mellitus (DM) is a high risk factor for ischemic stroke. Patients with DM stroke have worse outcomes, poor long term recovery, risk of recurrent strokes and extensive vascular damage. We investigated the neurorestorative effects and the underlying mechanisms of stroke treatment with human umbilical cord blood cells (HUCBCs) in Type two diabetes mellitus (T2DM) rats. Methods: Adult male T2DM rats were subjected to 2h of middle cerebral artery occlusion (MCAo). Three days after MCAo they were treated via tail-vein injection with: 1) phosphate-buffered-saline (PBS); or 2) HUCBCs (5x10^6); n=10/group. Results: HUCBC treatment of stroke initiated at 3 days after MCAo in T2DM rats significantly improved long term functional outcome ($p<0.05$), but did not significantly decrease brain hemorrhage ($p=0.22$), blood glucose level and body weight, marginally decreased lesion volume ($p=0.078$) and BBB leakage ($p=0.1$) in the ischemic brain when compared to the non-treatment T2DM-MCAo control group. HUCBC treatment significantly promoted white matter remodeling as indicated by increased expression of Bielschowsky silver (axons marker), Luxol fast blue (myelin marker), SMI-31 (neurofilament) and Synaptophysin in the ischemic border zone (IBZ). HUCBC treatment of stroke in T2DM rats significantly increased M2 macrophage polarization (increased M2 macrophage CD163, decreased M1 macrophage ED1 expression) in the ischemic brain compared to non-treatment T2DM-MCAo controls ($p<0.05$). HUCBC promoted vascular remodeling, and significantly increased arterial density and diameter (αSMA expression). HUCBC treatment significantly increased Angiopoietin-1 expression and decreased pro-inflammatory factors i.e., Angiogenin, matrix metalloproteinase 9 (MMP9), receptor for advanced glycation end-products (RAGE) and TLR-4. However, HUCBC treatment of T2DM rats also significantly increased arteriosclerosis-like changes, identified by increased internal carotid artery thickness and intima thickness (Trichrome staining analysis). Conclusion: HUCBC treatment initiated 3 days after stroke significantly increased WM and vascular remodeling in the ischemic brain as well as decreased neuro-inflammatory factor expression in the ischemic brain in T2DM rats and promoted M2 macrophage polarization. HUCBC reduction of neuroinflammation and increased vascular and WM-axonal remodeling may contribute to the

HUCBC induced neurorestorative effects in T2DM rats. However, HUCBC treatment in T2DM rats also induces potential adverse effects, e.g. atherosclerosis.

Title: Gender influences early gene expression after subarachnoid hemorrhage

Authors: F. A. SEHBA[1], D. KIM[2], *V. L. FRIEDRICH JR[2];
[1]Neurosurg., [2]Icahn Sch. of Med. At Mount Sinai, NEW YORK, NY

Abstract: Early mortality after aneurysmal subarachnoid hemorrhage (SAH) is significant, with 45% deaths occurring within 48 hrs. More women than men suffer from SAH and their age at SAH on average is greater by 5 years than males, yet prognosis is similar. We previously hypothesized that gender affects prognosis, and have studied the influence of gender on acute physiology and early brain injury after experimental SAH. We found that increases in intracranial pressure and in systemic blood pressure at SAH, anatomical damage to small cerebral vessel, and neuronal apoptosis all are greater in males than in females. We are currently pursuing this effect at on levels of particular gene transcripts and of proteins. The genes studied include two groups. Genes in group-1 encode products essential for maintaining blood vessel integrity and function: thrombomodulin (TM), endothelial nitric oxide Synthase (eNOS), intracellular adhesion molecule-1 (ICAM-1), vascular endothelial growth factor (VEGF), and vasopressin (VSP). Genes in group-2 encode cytokines involved in cerebral inflammation;

interleukin-1beta (IL-1 β) and tumor necrosis factor-alpha (TNF- α). SAH is induced in three month old male and female rats by endovascular puncture and animals are sacrificed at 3 hrs later. Gender and age matched sham surgery animals are controls. We have found significant gender differences in the expression of group-1 but not of group-2 genes. In group-1 expression of TM, eNOS, ICAM-1 and VSP increased in SAH males and only of VSP increased in SAH females; in group-2 expression of IL-1 β but not of TNF- α increased in males and females after SAH. Our results, though preliminary, suggest that gender influences expression after SAH of genes whose products are essential for maintaining blood vessel integrity.

Title: Assessment of cortical vascular responsivity to calcium channel blockers in the context of vasospasm after subarachnoid hemorrhage

Authors: *D. Y. CHUNG[1], M. A. SHAIK[2], S. H. KIM[2], M. G. KOZBERG[2], E. M. C. HILLMAN[2];
[1]Columbia Univ., New York, ; [2]Columbia Univ., New York, NY

Abstract: Delayed cerebral ischemia (DCI) and cerebral vasospasm after subarachnoid hemorrhage (SAH) is an important problem in survivors of aneurysm rupture. It was previously thought that DCI resulted exclusively from large vessel spasm, and the calcium channel blocker nimodipine was developed in order reverse this spasm. Nimodipine was found to be effective in

preventing DCI and remains the standard of care today. However, it has been noted that nimodipine does not need to reverse radiographic large vessel vasospasm in order to exert its effect. Conversely, other calcium channel blockers have been found to improve radiographic large vessel vasospasm, yet fail to improve outcomes in patients with DCI secondary to SAH. The mechanism of action of these drugs on the brain's microvasculature is still unknown. Here, we present work in an exposed-cortex in-vivo rodent model using simultaneous high-speed, high-resolution multispectral optical intrinsic signal imaging (MS-OISI) and laser speckle flowmetry. These methods allow us to assess the acute vascular response to administered vasoactive drugs in-vivo, including careful characterization of the relative dilation of large and small vessels, as well as hemoglobin oxygenation and flow rates in cortical vessels. 2-photon microscopy permits examination of diving arterioles and capillary dynamics. Mean arterial blood pressure and arterial blood oxygenation levels are simultaneously monitored over the course of 2-3 hours post-administration, along with successive assessment of the brain's hemodynamic response to somatosensory stimulation. Our initial results suggest differential action of the two different calcium channel blocker drugs tested of the different vascular compartments of the cortex, providing a basis for clinical improvement in the nimodipine case. Our latest results will be presented.

Title: PTEN-induced kinase 1 (PINK1) and protein kinase A (PKA) form a new neuroprotective signaling axis

Authors: *R. K. DAGDA[1], T. DAS BANERJEE[1], R. Y. DAGDA[1], G. L. CRAVISO[2], A. PHAM[2];
[1]Pharmacol., [2]Univ. of Nevada Sch. of Med., Reno, NV

Abstract: Background and Objective: PINK1, a kinase associated with familial Parkinson's disease (PD), and PKA are two cytoprotective kinases that are localized to cytosolic and mitochondrial compartments to regulate critical physiological functions in neurons. In developing neurons, PINK1 amplifies downstream PKA signaling to enhance dendritic complexity, mitochondrial dynamics and survival. We hypothesize that PINK1 activates distinct subcellular pools of PKA to confer neuroprotection against chemical models of PD. Methods/Results: Morphometric analyses of neurites (axons and dendrites) suggests that conditions of pharmacological activation of PKA by cyclic AMP (cAMP) and forskolin, transient overexpression of wild-type PINK1, untargeted PKA, mitochondrially-targeted catalytic subunit of PKA or the mitochondrial targeted protein scaffold of PKA (D-AKAP1) but not a PKA binding deficient mutant of D-AKAP1 significantly prevent the loss of neurites in primary neurons induced by the Parkinsonian toxin 6-hydroxydopamine. Treating primary neurons with cAMP, transient overexpression of untargeted or mitochondrial PKA in SH-SY5Y cells increases the basal oxygen consumption rates and partially protects cells against toxin-induced decreases in mitochondrial respiration as measured by a XFE24 Analyzer. Conversely, transient expression of PD-associated mutations in PINK1 show impaired neurite outgrowth in primary neurons and in bovine primary chromaffin cells. PD-associated mutations in PINK1 show impaired PKA signaling in primary neurons. Mechanistically, PINK1 amplifies downstream PKA signaling by elevating the catalytic subunits of PKA, increasing the levels of cytoskeletal associated PKA, and enhancing transcriptional activation of PKA-regulated promoters as demonstrated by Western blot analyses and luciferase reporter assays of transfected cells. Discussion and Conclusions: Overall, PINK1 and PKA form a signaling axis that confers protection of neurites against chemical models of PD, elevates mitochondrial function, and promotes neurite outgrowth by relocating and activating PKA holoenzymes. Therefore, enhancing PKA signaling may be a therapeutic strategy for treating PD.

Title: Isoform-specific NOS inhibition preserves axon function against ischemia in an age-dependent manner by enhancing free radical scavenging and preserving mitochondrial structure and function

Authors: *C. BASTIAN, J. ZALESKI, A. RUNKLE, S. BRUNET, S. BALTAN;
Dept. of Neurosci., Cleveland Clin. Fndn., Cleveland, OH

Abstract: White matter (WM), which comprises half of the human brain, is frequently damaged during stroke. In young WM, injury mechanisms follow a temporal pattern starting with loss of ionic homeostasis followed by excitotoxicity and oxidative stress. The incidence of stroke increases with aging. The susceptibility of aging WM to ischemia increases because of enhanced excitotoxicity, oxidative stress and mitochondrial dysfunction. The role of oxidative stress mechanisms in WM ischemic injury remains unexplored. We hypothesized that nitric oxide synthase (NOS)-mediated oxidative stress contributes to ischemic injury by generating free radicals, which impair mitochondrial structure and function in an age-dependent manner. We confirmed that mouse optic nerves (MON) express all three isoforms of NOS (nNOS (neuronal), eNOS (endothelial) and iNOS (inducible)) in an age- and cell-specific manner. We recorded evoked compound action potentials (CAPs) from MONs treated with L-NAME (L-NG-nitroarginine methyl ester, pan-NOS blocker) before or after oxygen glucose deprivation (OGD) and observed improved axon recovery in young MONs. L-NAME promoted axon function only when applied before OGD in aging MONs. SMT (S-methyl-isothiourea, iNOS blocker) and 3-Br7NI (3-bromo-7-nitroindazole, nNOS blocker) before OGD protected aging MONs at lower doses of drugs compared to young MONs. In addition, 3-Br7NI administered after OGD protected only aging MONs. SMT administered after OGD failed to protect either age group. Unlike other isoform-specific inhibitors, L-NIO (N5-(1-iminoethyl)-L-ornithine, eNOS inhibitor) applied before or after OGD improved axon function recovery in both young and aging MONs. L-NAME treatment before OGD preserved levels of reduced glutathione, a free radical scavenger. Moreover, fluorescent imaging and 3-dimensional electron microscopy studies of axonal mitochondria revealed that L-NAME treatment preserved mitochondrial structure and preserved ATP levels against OGD. Our studies demonstrate that NOS inhibition promotes axon recovery by increasing free radical scavenging and preserving mitochondrial structure and function. Age- and isoform-specific NOS inhibition is therefore a potential therapeutic target for stroke victims.

Title: mitoNEET agonist NL-1 promotes cell proliferation in hippocampal dentate gyrus

Authors: *A. MDZINARISHVILI, R. T. CARROLL, W. J. GELDENHUYS;
Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: The discovery of neurogenesis in the adult brain and the regenerative potential of neural stem cells hold the promise for restoration and regeneration of neural population and regeneration of neural circuits necessary for cerebral functions. Pharmacological compounds that enhance hippocampal neurogenesis could provide new therapeutic approaches for many neurodegenerative diseases (Alzheimer's, Parkinson's, MS, stroke and etc.). mitoNEET is a novel mitochondrial protein which belongs to a zinc-finger group of proteins that is conserved throughout evolution. mitoNEET is an iron-sulfur containing protein located on the outer mitochondrial membrane of mitochondria which regulates mitochondrial bioenergetics. Recently, the anti-diabetic drug pioglitazone (a thiazolidinedione) was found to be a ligand for mitoNEET, and has been also shown *in vivo* to be neuroprotective against ischemia-reperfusion injury after brain stroke. In this study, our goal was to evaluate a mitoNEET ligand NL-1, a derivative of pioglitazone, with its pro-neurogenic activities in the adult mice hippocampal dentate gyrus (DG). In our prior studies we have shown that NL-1 has neuroprotective effects in MCAO murine stroke models. In this study, CD-1 mice (25-27g) were treated with NL-1 (10 mg/kg) or vehicle control; 30-40 min later 5-bromo-2-deoxyuridine (BrdU; 300 mg/kg, i.p.) a marker of cell division was injected. Mice were sacrificed after 5 h of BrdU injection. Immunohistochemical assay was used to determine the number of BrdU-labeled progenitor cells in the hippocampal DG. After a single injection of NL-1 the number of BrdU-labeled neural progenitor cells had increased significantly by 39% compare to vehicle control. These results clearly demonstrated that mitoNEET ligand NL-1 increases and promotes proliferation of neural progenitor cells in hippocampal DG. We did not find any significant difference in cell proliferation process in subventricular zone (SVZ) the other neurogenic zone, after drug administration. These data suggest that a positive neurogenic effect of NL-1 in hippocampal DG is probably implemented through the mitoNEET. Positive effects of NL-1 on neural progenitor cells proliferation in hippocampal DG also suggests that mitoNEET ligand NL-1 is a new

candidate for developing of novel neuroprotective and neurorestorative therapies in neurodegenerative diseases.

Title: Investigation of desferrioxamine-induced adaptive responses in human neuronal cells

Authors: J. CANDELORA, F, L. RASMUSSEN, A. HERRERA, *J. L. KO;
Dept. of Biol. Sci., Seton Hall Univ., South orange, NJ

Abstract: Cancer, diseases, surgery, or traumatic injury can trigger hypoxia condition, which can further provoke pain sensation mediated by the mu-opioid receptors (MOR). Effect of hypoxia on MOR expression was therefore examined using human neuronal cells treated with desferrioxamine (DFO) to create a hypoxic-mimic condition. The transcription regulator PCBP-1 is known to modulate the MOR gene expression, and its interacting protein RACK-1, identified by two hybrid system recently, can negatively regulate MOR gene expression. RT-PCR analysis revealed a decrease of MOR expression under DFO treatment, whereas the RACK-1 expression was increased. Results from DFO-induced hypoxia supported the notion that RACK-1 participates in the regulation of MOR expression. Neuronal cells surviving under DFO challenge also displayed an activation of JAK/STAT pathway via Western blot analysis. An increase of the expression of suppressors of cytokine signaling proteins, negative regulators of the JAK/STAT pathway, was also detected using RT-PCR, suggesting that an up-regulation of suppressors of cytokine signaling proteins under hypoxia may play a role in a form of neuroprotection by aiding in the decrease of inflammation associated with JAK/STAT pathway.

Title: BNIP3 interacting with LC3 triggers excessive mitophagy

Authors: *R. SHI[1], S. ZHU[2], V. LI[4], S. B. GIBSON[3], X. XU[5], J. KONG[1];
[1]Dept. of Human Anat. and Cell Sci., [2]Dept. of Pharmacol. & Therapeut., [3]Dept. of Biochem. and Med. Genet., Univ. of Manitoba, Winnipeg, MB, Canada; [4]Fac. of Med., Univ. of British Columbia, Vancouver, BC, Canada; [5]Inst. of Neurosci., Soochow Univ., Suzhou, Jiangsu Province, China

Abstract: A basal level of mitophagy is essential in mitochondrial quality control in physiological conditions while excessive mitophagy contributes to cell death in a number of diseases including ischemic stroke. Signals regulating this process remain unknown. BNIP3, a pro-apoptotic BH3-only protein, has been implicated as a regulator of mitophagy. Here, using *in vivo* and *in vitro* models of stroke, we show that BNIP3 and its homologue BNIP3L (NIX) are highly expressed in a 'delayed' manner and contribute to delayed neuronal loss following stroke. Deficiency in BNIP3 significantly decreases both neuronal mitophagy and apoptosis but increases non-selective autophagy following ischemic/hypoxic insults. The mitochondria-localized BNIP3 interacts with the autophagosome-localized LC3, suggesting that BNIP3, similar to NIX, functions as a LC3-binding receptor on mitochondria. Although NIX expression is upregulated when BNIP3 is silenced, upregulation of NIX cannot functionally compensate for the loss of BNIP3 in activating excessive mitophagy. Therefore, NIX primarily regulates basal level of mitophagy in physiological conditions, whereas BNIP3 exclusively activates excessive mitophagy leading to cell death.

Title: The impact of metabolic syndrome on cortical microvasculature - form and function

Authors: *M. GOMEZ-SMITH[1,3], C. NGUEMENI[2,3], M. JEFFERS[2,3], A. DORR[4], B. STEFANOVIC[4,5,3], D. CORBETT[3,2,7,6,1];

Abstract: Metabolic syndrome (MetS) is a leading risk factor for ischemic stroke. Given that nearly 25% of the world population has MetS, the number of stroke patients needing treatment will rise considerably in the coming years. As it stands, the only post-stroke therapy available to patients is rehabilitation. Animal models are extensively used to optimize human rehabilitation by developing therapies aimed at enhancing neuroplastic mechanisms. Nonetheless, the majority of animals used in stroke rehabilitation studies are young and healthy - they lack the co-morbidities of stroke patients. To better approximate the clinical condition, our lab is using a model of MetS, the Cafeteria (CAF) diet. Before initiating rehabilitation studies with this model, we will confirm that this diet exerts effects on the cerebral vasculature at the structural and, even more importantly, at the functional level. CAF rats were provided with free access to standard rodent pellets and water as well as a varied daily supply of highly processed human junk food items (i.e. chips, cookies, bacon, etc.) and a 12% sucrose solution. Several histological analyses were performed to determine whether intact CAF animals have an impaired blood brain barrier or exhibit structural vascular abnormalities. In others, strokes were surgically induced using endothelin-1 injected into forelimb motor cortex. Infarct size was evaluated in both CAF and standard diet (SD) animals. After 3 months of treatment, CAF animals exhibit 4/5 criteria for MetS. CAF animals are overweight (CAF=767±16g, SD=676±13g), have increased circulating triglycerides (CAF=183±21mg/dl, SD=95±9mg/dl), reduced HDL cholesterol (CAF=70±4mg/dl,

SD=94±3mg/dl) and impaired glucose tolerance (insulin: CAF=7.1±1ng/ml, SD=3.3±0.5ng/ml; blood glucose two hours after i.p. GTT test: CAF=8.5±0.7mmol/L, SD=6.7±0.3mmol/L). Preliminary histological analysis indicates that CAF animals trend towards larger infarcts and increased blood brain barrier leakage. There is also some indication that CAF animals have increased erythrocyte aggregation. We have succeeded in generating a rat model of MetS that closely approximates the clinical condition. Preliminary results indicate that the vasculature of CAF animals may be compromised. Further analysis is being performed to determine whether or not structural damage to the vessels is accompanied by functional deficits, as assessed via *in vivo* two-photon fluorescence microscopy. Future directions involve testing our animals on cognitive tasks to determine whether they exhibit signs of emerging vascular cognitive impairment.

Title: Degradation of collagen XV by tissue plasminogen activator may be protective after stroke

Authors: H. DHUNGANA[1], M. HUUSKONEN[1], T. PIHLAJANIEMI[2], R. HELJASVAARA[2], J. PARCQ[3], Y. POMESHCHIK[1], P. KORHONEN[1], T. MALM[1], K. KANNINEN[1], V. KEKSA-GOLDSTEINE[1], M. PRUVOST[3], D. VIVIEN[3], *J. KOISTINAHO[1], S. LEMARCHANT[1]; [1]Univ. of Eastern Finland, Kuopio, Finland; [2]Univ. of Oulu, Oulu, Finland; [3]Univ. of Caen Basse-Normandie, Caen, France

Abstract: Recombinant tissue plasminogen activator (rtPA) is the only acute treatment for ischemic stroke in patients eligible for thrombolysis. The ability of rtPA to dissolve the stable fibrin meshwork of blood clot formed at the site of the injury depends on its ability to convert the fibrin-bound plasminogen to active plasmin. Chondroitin sulfate proteoglycans (CSPGs) are

another substrate of tPA. In this study, we aim to study weather collagen XV, a type of CSPGs, could represent a putative substrate for rtPA, thereby having impact on the outcome of stroke. In order to determine the effect of tPA on collagen XV *ex vivo*, protein extract isolated from perfused cortex of C57BL/6J mice was incubated at 37°C for 2 h with or without increasing doses of rtPA. The degradation of collagen XV was then monitored by Western blotting. We further carried out *in vivo* thromboembolic ischemic study on 8-month-old female wild-type (WT) and collagen XV knock-out (KO) mice where the representative groups received intravenous infusion of either rtPA (10 mg/kg) or saline for 40 minutes. Infarct volumes were determined with MRI 48 h after the surgery. Protein levels of vascular endothelial growth factor A (VEGF-A) were determined by western blot. *Ex vivo* analyses demonstrated a significant ($P < 0.05$) dose-dependent degradation of collagen XV in the presence of rtPA when compared to controls without rtPA. Following stroke, Collagen XV KO mice exhibited significantly smaller lesion ($P = 0.0179$) compared to WT mice. Even though, early thrombolysis was beneficial in rtPA treated WT mice compared to saline treated WT counterparts ($P = 0.0161$), no added beneficial effect was observed in rtPA treated collagen KO mice compared to saline treated counterparts. In addition, we also observed 2-fold increase in VEGF-A in ipsilateral hemisphere of rtPA treated ischemic WT mice compared to vehicle treated ischemic and sham counterparts. Similar increase of VEGF-A was also evident in both rtPA and vehicle treated ischemic collagen KO mice compared to sham KO mice. This study indicates that collagen XV is a novel substrate for rtPA and that the lack of collagen XV is protective after stroke. The neuroprotection observed in collagen XV KO animals might be attributed to the increased VEGF-A production following stroke in the ischemic territory. The findings also suggest a possible beneficial effect of rtPA-induced collagen XV degradation after stroke. Further studies will be carried out to determine the mechanism involved in neuroprotection following collagen XV degradation using several molecular approaches.

Neuromed, Sapienza University, Italy, and Univ. of Lille, France, LIA (International Associalted Laboratories), Roma, Italy

Abstract: Dickkopf-3 (Dkk-3) is a member of the dickkopf protein family acting as a pro-apoptotic factor on cancer cells and as a differentiation factor in remodelling the tumor vasculature in endothelial cells. Remarkably, dkk-3 gene maps within the chromosome 1 region linked to stroke phenotype in the model of stroke-prone spontaneously hypertensive rat (SHRsp), which develops stroke after high-salt/low potassium diet (Japanese diet, JD). This raises the intriguing possibility that Dkk-3 gene may be considered as a candidate gene for stroke susceptibility in this strain. Our preliminary data showed that: (i) Dkk-3 is upregulated in cerebral blood vessels of SHR stroke resistant (SHRsr) but not in SHRsp rats after one month of JD, (ii) the Dkk-3 upregulation in cerebral blood vessels of SHRsr rats is associated to a vascular endothelial growth factor (VEGF) upregulation, and (iii) VEGF is upregulated in human endothelial cells cultures following incubation with human recombinant Dkk-3 peptide (hrDkk-3). Here, we performed double fluorescence immunoistochemical analysis to described the cellular localization of Dkk-3 in cerebral blood vessels of striatal, hippocampal and cortical brain regions of SHRsr rats. Our results showed that Dkk-3 expression is localised at endothelial level, as suggested by the co-localization with the endothelial marker reca-1. In order to establish a causal relationship between Dkk-3 blood vessel expression and occurrence of stroke exists, we used SHRsr rats on JD subjected to cerebral lentiviral dkk-3 silencing which were monitored for motor disability by the rotarod test. Results showed that Dkk-3 silencing in cerebral blood vessels is associated with a greater motor disability in SHRsr rats maintained for 7 weeks on JD. Taken together these data suggest that in response to hypertension the glycoprotein Dkk-3 is upregulated in endothelial cells of cerebral blood vessels. This glycoprotein may acts by enhancing the VEGF expression which could play a protective role against the hypertension mediated endothelial damage. Lack of vascular expression of Dkk-3 in spontaneous hypertensive stroke-prone rats may represent a novel mechanism favoring stroke occurrence.

Title: Ethyl pyruvate inhibits HMGB1 phosphorylation and release by chelating calcium

Authors: *J.-K. LEE, H.-K. LEE, I.-D. KIM, L. LUO, H.-B. LEE, S.-W. KIM;
Dept Anat, Inha Univ. Sch. Med., Inchon 400-712, Korea, Republic of

Abstract: Ethyl pyruvate (EP), a simple aliphatic ester of pyruvic acid, has been shown to have anti-inflammatory effects and to confer protective effects in various pathological conditions. Recently, a number of studies have reported EP inhibits highmobility group box 1 (HMGB1) secretion and suggested this might contribute to its anti-inflammatory effect. Since, EP is used in a calcium-containing balanced salt solution (Ringer's solution), we wondered if EP directly chelates $Ca^{2+}$and it is related with the EP- mediated suppression of HMGB1 release. Calcium imaging assays revealed that EP significantly and dose-dependently suppressed high K^{+}-induced transient $[Ca^{2+}]_i$surges in primary cortical neurons and similarly,fluorometric assays showed that EP directly scavenges Ca^{2+}, as the peak of fluorescence emission intensities of Mag-Fura-2 (a low-affinity Ca^{2+}indicator) was shifted in the presence of EP at concentrations of $\geq$13 mM. Furthermore, EP markedly suppressed the A23187 (a calcium ionophore)-induced intracellular Ca^{2+}surge in BV2 cells (a microglia cell line) and under this condition, A23187-induced activations of Ca^{2+}-mediated kinases (protein kinase C alpha and calcium/calmodulin-dependent protein kinase IV), HMGB1 phosphorylation, and subsequent secretion of HMGB1 were also suppressed. Moreover, the above-mentioned EP-mediated effects were independent of cell death or survival, which suggests that they are not indirect outcomes of the protective effect of EP, but rather direct effects. Together these results indicate that EP directly chelates Ca^{2+}, and that it is, at least in part, responsible for the suppression of HMGB1 release by EP.

Title: Human cerebral microvascular endothelium: Linoleoyl ethanoliamide, a novel natural lipid substance, is a potential vasodilator

Authors: P. CASTRI[1], T. KINO[2], Y. CHEN[2], R. ABUTARBOUSH[2], F. LENZ[3], E. SHOHAMI[4], R. MECHOULAM[4], R. MCCARRON[2], *M. SPATZ[1];
[1]Stroke Br., NIH-NINDS, BETHESDA, MD; [2]Neuro Trauma Dept., Naval Med. Res. Ctr., Silver Spring, MD; [3]Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Surgery, Hebrew Univ., Jerusalem, Israel

Abstract: INTRODUCTION Linoleoyl Ethanoliamide (LEA) is one of the endogenous lipids structurally related to endocannabinoids, specifically to arachidonoyl ethanoliamide (also known as anandamide). This agent was found in plant and animal tissues as well as in human plasma. Reports indicate that it is a biologically active substance which has anti-inflammatory properties. This study examines whether LEA is able to induce cellular activities involved in vasorelaxation. It will evaluate if LEA reorganizes cytoskeleton in control and endothelin-1 (ET-1) stimulated endothelial cells derived from human brain microvessels (HBEC). It will also assess LEA induction of phosphorylation of various kinases (MAPK, Akt, JNK, c-Jun, and VASP) and the possible mediation by CB1, CB2 and TRPV1 receptors. METHODS Cultured HBEC which were >95% Factor VIII+ were exposed to LEA for 15 min alone or pre-treated with selective antagonists for CB-1, CB-2 and TRPV1 receptors (SR141716A, SR141728A and capsazepine, respectively). The levels of phosphorylation of p44/42 MAPK, Akt, JNK, c-Jun and VASP were determined by Western blot analysis. RESULTS 1.LEA activates CB1 and CB2 receptors in HBEC. 2.LEA induces reorganization of cytoplasmic actin fibers in control and ET-1 treated HBEC. 3.LEA stimulated stress-linked kinases (MAPK, Akt, JNK, c-Jun, and VASP) up to 3 fold. 4.All the above mentioned HBEC responses to LEA were mediated by CB1, CB2, TRPV1 receptors and involved the Rho/PI3/Akt pathway. 5.LEA inhibited Rho kinase activity (40%). CONCLUSION The results indicate that LEA is able to induce the reorganization of cellular-actin fibers and the phosphorylation of stress-linked kinases. All these HBEC responses were mediated by cannabinoid (CB1, CB2) and vanilloid (TRPV1) receptors, since they were inhibited by their respective antagonists. The reactions all involved the Rho/PI3/Akt signal

transduction pathway. The findings indicate that LEA may act as a Rho kinase inhibitor and strongly suggest that LEA may act as a relaxing agent *in vivo*.

Title: *In vivo* mir-155 inhibition supports recovery after mouse stroke

Authors: *E. CABALLERO-GARRIDO[1], J. PENA-PHILIPPIDES[1], Y. YANG[2], D. BRAGIN[1], T. ROITBAK[1];
[1]Neurosurg., Univ. of New Mexico, Albuquerque, NM; [2]Univ. of New Mexico BRaIN Imaging Ctr., Albuquerque, NM

Abstract: Recently identified small molecules microRNAs (miRNAs) regulate the expression of genes and proteins in many tissues, including brain and vasculature. Based on our experiments involving inhibition and overexpression of specific miRNAs, in combination with *in vitro* morphogenesis assay and cell signaling pathway analysis, the miRNA miR-155 was identified as the potential primary regulator of endothelial morphogenesis. We found that the specific inhibition of miR-155 subsequently altered the expression of major components of the mTOR and TGF-β signaling pathways in the endothelial cells (ECs). Overexpression of this miRNA in ECs suppressed, while inhibition activated, the *in vitro* endothelial morphogenesis. Our animal studies suggest that miR-155 could also mediate vascular remodeling after stroke: *in vivo* injections of specific miR-155 inhibitor after distal/direct middle cerebral artery occlusion (dMCAO) in mice, supported post-ischemic revascularization. Using two-photon laser scanning microscopy technique, we detected increased vascular density and blood flow velocity in the peri-infarct area of the injured mouse brain. Similar to miR-155 inhibition in the ECs, the *in vivo*

injections of anti-miR-155 resulted in the activation of mTOR and TGF- β signaling pathways in the mouse brain tissue, detected by the increase in Smad-2 protein expression and phosphorylation, as well as mTOR phosphorylation at Ser-2448. In addition, intravenous anti-miR-155 injections resulted in a significant increase of anti-inflammatory (Interleukin 1 receptor antagonist Il1rn) and decrease of pro-inflammatory (macrophage colony stimulating factor Csf1) cytokine gene expression. Our preliminary studies including MRI measurements and behavioral assessment ("adhesive removal" and "cat walk" tests) indicate that these effects of miR-155 inhibition also correlated with decreased infarct size and improvement of the animal functional recovery after stroke. Based on our findings and preliminary results, we hypothesize that miR-155 inhibition following ischemia supports cerebral vasculature, as well as improves the animal post-stroke recovery process. In addition, we propose that *in vivo* inhibition of specific miRNAs could be utilized to manipulate the revascularization process following stroke in order to improve post-ischemic recovery in the brain.

Title: Scanning and transmission electron microscopy of the glial scar after stroke

Authors: T.-V. V. NGUYEN[1,2], J. BEISCHEL FRYE[1,2], O. M. HUSSEIN[1,2], *K. P. DOYLE[1,2]; [1]Departments of Immunobiology and Neurol., Univ. of Arizona, Tucson, AZ; [2]Arizona Ctr. on Aging, Tucson, AZ

Abstract: "It is the pervading law of all things organic and inorganic, of all things physical and metaphysical, of all things human and all things superhuman, of all true manifestations of the head, of the heart, of the soul, that the life is recognizable in its expression, that form ever follows function. This is the law." The American Architect Louis Sullivan coined the phrase "form ever follows function" to encapsulate the principle that in architecture the shape of an object should reflect it's intended function or purpose. In nature form also "ever follows

function", and so to extend our knowledge about the function of the astroglial scar that forms in the brain after stroke we used electron microscopy to reveal its ultrastructure. BALB/cJ mice underwent distal middle cerebral artery occlusion and the structure of the glial scar was evaluated one and four weeks later. We discovered that hypertrophied astocytic processes form a dense mesh that is effective at keeping large phagocytic immune cells away from adjacent healthy tissue, but is porous to smaller immune cells that by electron microscopy strongly resemble lymphocytes. To uncover the identity of these cells we used immunohistochemistry, and discovered that for weeks after stroke CD3+ T lymphocytes leak out of the lesion and home to areas of degenerating white matter. Furthermore, immunohistochemistry revealed that immunoglobulin also leaks out of the glial scar into adjacent non-infarcted tissue, where its presence correlates with progressive dysfunction in the hippocampus and delayed loss of neurons between weeks one and seven after stroke. Together, these findings indicate that the astroglial scar is an effective border at containing larger inflammatory cells, but is porous to smaller immune cells such as T lymphocytes, and to immunoglobulin.

Title: Myeloperoxidase inhibition improved neuroprotective and beneficial effects after ischemic stroke

Authors: *H. KIM[1], J. CHEN[1], G. WOJTKIEWICZ[2], L. BURE[3], W. YING[4], M. MOSKOWITZ[4], J. LEE[5];
[1]center for system biology, Mass Gen. Hosp. Harvard Med. Univ., Boston, MA; [2]Massachusetts Gen. Hosp. Ctr. for Systems Biol., boston, MA; [3]Massachusetts Gen. Hosp., boston, MA; [4]Neurosci. Ctr. at Massachusetts Gen. Hosp., boston, MA; [5]George Washington Med. Washington, washington DC, MD

Abstract: Myeloperoxidase, a key inflammatory enzyme, is markedly elevated after stroke. We had reported that 4-aminobenzoic acid hydrazide (ABAH), a specific irreversible MPO inhibitor, increased neurogenesis after stroke. Here, we investigated whether post-insult ABAH treatment in wildtype (WT) and MPO-/- mice can exert neuroprotective effects after transient middle cerebral artery occlusion (tMCAO) in mice. Additionally, we asked whether ABAH treatment only during subacute stroke can reduce brain infarct volume and improve behavioral deficits. We found that post-insult ABAH treatment significantly reduced brain infarct volume ratio (D21/D1) on MRI imaging compared with saline-treated control mice ($P<0.05$). ABAH treatment in WT mice and MPO-/- mice robustly reduced cell loss and Fluoro-Jade B (FJ-B) immunostaining in the ischemic brains compared with saline-treated WT mice on day 7 after stroke. ABAH treatment in WT mice and MPO-/- mice both showed decreased loss of oligodendrocytes as detected by myelin basic protein (MBP) immunostaining in the ipsilateral white matter at 7 days after stroke. Stroke-induced activation of microglia (CD11b+, Iba-1+) and macrophages/monocytes (ED1+) and matrix metalloproteinase-9 (MMP-9+) cells, were decreased by ABAH treatment. ABAH treatment also increased cytoprotective proteins such as heat shock protein 70 (HSP70), HSP27, and p-AKT (Ser 473) in the ipsilateral striatum and cortex on day 3 after tMCAO. HSP70 has multiple roles including anti-apoptotic, neuroprotective, and anti-inflammatory effect after stroke, and ABAH treatment in WT mice and in MPO -/- mice on day 7 after stroke increased the number of HSP 70+/NeuN-positive cells in the brain. Notably, ABAH treatment starting in the subacute stage of stroke still significantly reduced brain infarct size ratio (D21/D1) compared with acute ABAH treatment on day 21 after stroke ($P<0.05$). While treatment during the acute phase mildly improved functional outcome, treatment during the subacute phase exhibited marked improvement in behavioral outcome ($P<0.05$). Taken together, our results show that inhibition or lack of MPO contributes to the prevention of cell death, oligodendrocyte loss, and upregulation of anti-apoptotic and anti-inflammatory proteins that lead to improved outcome. Therefore, post-insult MPO inhibition may provide a potential therapeutic target for subacute stroke therapy. Key words: Stroke; neuroprotection; myeloperoxidase; MRI; 4-aminobenzoic acid hydrazide (ABAH)

Title: The gene silencing transcription factor REST represses miR-132 expression in hippocampal neurons destined to die

Authors: *J.-Y. HWANG, N. KANEKO, K.-M. NOH, F. PONTARELLI, R. S. ZUKIN; Dept Neurosci, Albert Einstein Col. Med., New York, NY

Abstract: The gene silencing transcription factor REST/NRSF (Repressor Element-1 (RE1) Silencing Transcription Factor/Neuron-Restrictive Silencer Factor) actively represses a large array of coding and noncoding neuron-specific genes important to synaptic plasticity including miR-132. miR-132 is a neuron-specific microRNA and plays a pivotal role in synaptogenesis, synaptic plasticity and structural remodeling. However, a role for miR-132 in neuronal death is not, as yet, well-delineated. Here we show that ischemic insults promote REST binding and epigenetic remodeling at the miR-132 promoter and silencing of miR-132 expression in selectively-vulnerable hippocampal CA1 neurons. REST occupancy was not altered at the miR-9 or miR-124a promoters despite the presence of RE1 sites, indicating REST target specificity. Ischemia induced a substantial decrease in two marks of active gene transcription, dimethylation of lysine 4 on core histone 3 (H3K4me2) and acetylation of lysine 9 on H3 (H3K9ac) at the miR-132 promoter. RNAi-mediated depletion of REST *in vivo* blocked ischemia-induced loss of miR-132 in insulted hippocampal neurons, consistent with a causal relation between activation of REST and silencing of miR-132. Overexpression of miR-132 in primary cultures of hippocampal neurons or delivered directly into the CA1 of living rats by means of the lentiviral expression system prior to induction of ischemia afforded robust protection against ischemia-induced neuronal death. These findings document a previously unappreciated role for REST-dependent repression of miR-132 in the neuronal death associated with global ischemia and identify a novel therapeutic target for amelioration of the neurodegeneration and cognitive deficits associated with ischemic stroke.

Title: Role of serum- and glucocorticoid-regulated kinases in stroke

Authors: *K. INOUE, T. YANG, Z. ZENG, Z.-G. XIONG;
Neurosci. Institute, Morehouse Sch. of Med., Atlanta, GA

Abstract: Stroke is one of the most common causes of disability and death in US. Despite the long history of effort in the search of effective treatment, tissue plasminogen activator is still the only FDA approved agent for stroke. However, it has limited therapeutic time window and potential side effect of intracranial hemorrhage. Serum- and glucocorticoid-inducible kinases (SGKs) encode serine/threonine kinases and regulate the function of many proteins including ion channels and transporters. One of the important roles of SGKs is associated with blood pressure control, mediated through its regulation of renal epithelial Na+ channels. Regulation of most channels/transporters by SGKs acts through E3 ubiquitin ligase Nedd4-2, and subsequently surface expression of the targets are influenced. SGKs are also expressed in the brain. Recent studies have revealed the contribution of SGKs to physiological functions such as fear retention, learning and memory. However, the role of SGKs in neurological disorders such as stroke remains elusive. We therefore examined the effect of SGK inhibition on the outcome of stroke. SGK inhibitors, gsk650394 and EMD638683, were applied through intracerebroventricular injection 30 min prior to 1h middle cerebral artery occlusion (MCAO). Volumes of brain lesion were evaluated 24h after MCAO. We showed that both SGK inhibitors significantly reduced the infarct volumes. Because excessive intracellular Ca2+ increase via N-methyl-D-aspartate (NMDA) receptors is a main cause of neuronal injury under oxygen/glucose-deprivation condition and because SGKs are known to facilitate response of NMDA receptors, we examined the effect of SGKs on NMDA toxicity in cultured mouse cortical neurons. We demonstrated that SGK inhibitors ameliorate NMDA-induced neurotoxicity, suggesting that the beneficial effect of the SGK inhibitors on ischemic brain injury is, at least in part, mediated by the inhibition of NMDA channels. Indeed, we found that SGK inhibitors significantly decrease the amplitude of NMDA current. In summary, our studies suggest that SGKs play an important role in stroke and that the effects of SGKs are mediated in part through NMDA receptors.

Title: Contribution of the contralesional sensorimotor cortex to the motor recovery in the rat brain after focal ischemia

Authors: *S. MOMMA[1], M. GOTO[1], S. TOMOKO[1], T. MIKAMI[2], A. MITANI[1];
[1]Kyoto Univ., Kyoto, Japan; [2]Biotex Res. Lab., Kyoto, Japan

Abstract: Functional recovery following stroke is significantly improved with rehabilitation. It has been reported that the rehabilitative training enhances neuronal reorganization and alters the cortical maps in the affected hemisphere(Nudo et al., 1996). However, little is known about the contribution of contralesional hemisphere to motor recovery. In the present study, we examined the functional changes induced in the rat contralesional sensorimotor cortex following training of affected forelimb using intracortical microstimulation (ICMS), multi-unit recording and injection of biotynilated dextran amine (BDA). Following pre-infarct training of skilled reaching, rats were randomly divided into three groups: training, non-training and sham. Stroke was produced on the sensorimotor cortex of the training and non-training groups by photothrombosis method to affect trained forelimb, and only the training group received the skilled reaching training in which rats were forced to use their affected hand for 6 weeks. Skilled reaching was used as a behavioral test to evaluate their motor function. As a result, the training group scored significantly higher than the non-training group. ICMS applied to the contralesional hemisphere showed that the threshold for ICMS-evoked affected hand movements decreased in the training group. In addition, we recorded multi-unit activities in the contralesional sensorimotor cortex with a telemetry system during a series of reaching movement. The firing rate in the training group significantly increased as they reached their affected hand to a pellet. We finally injected BDA into the contralesional sensorimotor cortex to investigate the morphological changes that would underlie the reorganization. These results suggested that the contralesional sensorimotor cortex might contribute motor recovery of affected hand following rehabilitative training.

Title: Optogenetic inhibition of striatum neurons promotes neurogenesis after ischemic stroke through GABA-A receptor

Authors: *Y. WANG[1], X. HE[2], Y. LU[2], L. JIANG[2], Z. ZHANG[2], G.-Y. YANG[2];
[1]Med-X Res. Inst., [2]Med-X Res. Institute, Sch. of Biomed. Engin., Shanghai Jiao Tong Univ., Shanghai, China

Abstract: Introduction: Endogenous neurogenesis occurs after cerebral ischemia in response to hypoxia-induced stress. However, how this process is regulated remains unclear. We use suture-induced middle cerebral artery occlusion (MCAO) model as stroke model, use optogenetic tool to regulate the activity of striatum neurons after stroke and investigated their roles in neurogenesis and neural functional recovery after ischemic stroke. **Methods:** Lentivirus carrying ChR2-YFP or NpHR-YFP fusion protein under CaMKII promoter control were injected into the striatum of experimental mice. Optical fiber or optrode was implanted in the same position at 7 days after gene transfection. MCAO surgery was performed at 14 days after gene transduction. Four days after MCAO surgery, mice were treated with 473nm or 594nm laser twice a day for 15 minutes each session for 4 consecutive days. Electrophysiology recording confirmed the validity of ChR2 and NpHR channels *in vivo*. Neurological behavior tests were performed at 3, 7 and 35 days after MCAO. BrdU/NeuN and BrdU/DCX double staining were used to quantify neurogenesis. Bicuculline was used as a specific GABA-A receptor antagonist. Cresyl violet staining of brain sections was used to evaluate brain atrophy at 35 days after MCAO. **Results:** When stimulated by 473nm laser, the firing rate of striatum neuron was enhanced in ChR2 transduced mice. When stimulated by 594nm laser, the firing rate of striatum neuron was reduced in NpHR transduced mice. The number of BrdU/DCX double positive cells significantly increased in the NpHR group comparing to GFP control group and ChR2 group in the sub-ventricular zone. Nestin positive cells were increased both in SVZ and peri-infarct area 7 days after MCAO in the NpHR group. The number of BrdU/NeuN double positive cells also increased at 35 days after MCAO. Brain atrophy was reduced in the NpHR group compared with ChR2 or GFP group. Neural behavior tests showed that inhibition of striatum neuron activity promotes motor function at 7 days and 35 days after MCAO. ChR2 transduced mice showed less

neurogenesis and worsened neurological function compared to GFP control group. Administration of bicuculline to ChR2-transduced mice rescued the inhibition of neurogenesis by ChR2, suggesting that the regulation of neurogenesis by striatum neurons is likely through GABA-A receptor. **Conclusion:** Activation of striatum neurons inhibits neurogenesis after ischemic stroke, while inhibition of these neurons promotes neurogenesis and recovery. Such effects on neurogenesis by striatum neurons are likely regulated through GABA-A receptor.

Title: CLIC4 translocation is implicated in the development of Perinatal Brain Injury

Authors: *C. THORNTON[1], U. RUETSCHI[2], R. VONTELL[1], P. GRESSENS[1,3], H. ZETTERBERG[2], H. HAGBERG[1,2];

Abstract: Perinatal cerebral hypoxic-ischaemic injury (HI) is a major cause of neurological damage and underlies the development of human disorders such as epilepsy and cerebral palsy. HI results in an initial cellular energy depletion, followed by a recovery phase and a secondary energy failure during which the majority of brain injury occurs. The mitochondrion may act as a convergence point for mechanisms underlying the pathological damage; mitochondrial outer membrane permeabilisation (MOMP) may represent the switch between reversible and irreversible injury. Previously, we showed that Bax-mediated apoptosis leading to MOMP is a critical pathway for the development of injury in neonatal brain. In the current study, we carried out an unbiased proteomics screen using Stable Isotope Labeling by Amino acids in Culture

(SILAC) to identify mitochondrial proteins differentially regulated in response to a Bax-mediated apoptotic stimuli. In addition to alterations in both individual proteins and pathways (e.g. ubiquitination proteins, voltage dependent anion channels) we identified the downregulation (0.37 fold) of chloride intracellular channel protein 4 (CLIC4) at the mitochondria. Interestingly, we found that in a cell line exposed to oxygen-glucose deprivation (OGD) and in mouse brain exposed to HI there was a time-dependent increase in CLIC4 mRNA expression, in contrast with the SILAC data. However, protein fractionation studies and immunofluorescence in the same models revealed that CLIC4 was rapidly translocated from the mitochondria, accumulating in the nucleus. In experiments modulating CLIC4 expression by siRNA knockdown and plasmid upregulation we find that CLIC4 alters the ability of cells to survive OGD and apoptotic insult. Finally we are currently examining the interaction between histamine H3 receptor and CLIC4 as in addition to apoptosis, a recent publication suggests that this pathway may regulate autophagy. Our study provides a new target implicated in HI-mediated apoptosis and may yet contribute to the emerging field of autophagy/mitophagy in the development of perinatal brain injury.

Title: Negative regulation of autophagic cell death by calpain upon proteasome inhibition in adult hippocampal neural stem cells

Authors: *K. CHUNG, H. PARK, S. JUNG, S. HA, S. YOO, H. WOO, E.-K. KIM, C. MOON, S.-W. YU;
Brain Sci., Daegu Gyeongbuk Inst. of Sci. & Technol., Daegu, Korea, Republic of

Abstract: The mechanism by which autophagy interrelates with apoptosis remains one of the key unanswered questions in programmed cell death. We have previously reported that adult

hippocampal neural stem (HCN) cells undergo autophagic cell death (ACD) following insulin withdrawal. Autophagy is the central cell death mode of insulin-deficient HCN cells in spite of their intact apoptotic capability. Autophagy and ubiquitin-proteasomal system (UPS) are two major cellular degradation systems and their interplay is critical in regulation of cellular homeostasis and demise. Proteasome inhibition by lactacystin or MG132 induced apoptosis in insulin-deficient HCN cells defaultly undergoing ACD, but with different levels of autophagy. Lactacystin dampened the insulin withdrawal-mediated autophagy whereas MG132 further enhanced the level of autophagy. Genetic silencing of calpain 2 or ectopic expression of calpastatin increased ACD. Conversely, calpain over-expression decreased autophagy level. The expression level of calpain 2 and its protease activity were significantly reduced by MG132 while intracellular calcium concentration was significantly elevated to similar levels upon both lactacystin and MG132 treatment, suggesting that balance of calpain-calpastatin system is more important for regulation of autophagy than overall intracellular calcium level. These findings demonstrate the concurrent, yet uncomplementary regulation of UPS and autophagy; and unveil a molecular mechanism governing an interconversion between apoptosis and autophagic cell death through calpain.

Biochem., Catholic Univ. of Rome, Rome, Italy; [5]Radiology and Psychiatry, [6]Radiology, Univ. of California San Diego, La Jolla, CA

Abstract: Ischemia tolerance can be achieved by the oxidative chain inhibitor 3-nitropropionic acid (NPA). We have previously shown that rats pre-treated with a sub-lethal dose of NPA 72 h before transient middle cerebral artery occlusion (MCAO) have smaller infarct lesions and less severe functional deficits compared to saline-treated controls. In order to characterize mechanisms of NPA induced ischemia tolerance, our goal was to find out if NPA preconditioning induces vascular remodeling or long-term changes in energy metabolism. We induced ischemia tolerance by a single 20mg/kg NPA i.p. injection in adult male Wistar rats and performed quantitative cerebral blood flow (CBF) measurements using arterial spin labeling (ASL)-MRI along with structural (T1- and T2w) imaging 72 hours later. After MRI analyses, animals were sacrificed and brains subjected to histological analysis including the expression of the neuronal marker NeuN, the endothelial cell marker RECA-1, and the mitochondrial respiratory chain marker cytochrome c-oxidase (COX). High-Performance liquid chromatography (HPLC) analyses were performed in brains of another subset of animals 72h after NPA vs. saline injection. NPA preconditioning did not result in any structural damage. HPLC analysis revealed a shift in the proportion of adenosine nucleotides towards a lower energy charge potential with a tendency to decrease the rate of ATP synthesis with a concomitant increase in its dephosphorylated products (AMP). There was a global CBF reduction of approximately 30% in NPA preconditioned animals compared to controls. Blood vessel density was not altered upon NPA treatment. However, the COX immunofluorescence signal was reduced in cortical and subcortical regions in NPA preconditioned animals. Our data suggest a novel link between NPA induced reduction in oxidative phosphorylation indicated by the reduced COX expression, a lower energy charge potential, and a global reduction in CBF as a potential mechanism underlying ischemia tolerance.

Title: Myeloperoxidase increases risk of formation and rupture of cerebral aneurysms

Authors: *Y. CHU[1], G. L. PIERCE[1], G. CHENG[2], L. WEGMAN-POINTS[1], H. GU[1], K. WILSON[1], R. A. PENA SILVA[1,3], F. M. FARACI[1], D. D. HEISTAD[1], D. HASAN[1]; [1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Alabama Sch. of Med., Birmingham, AL; [3]Univ. de los Andes Sch. of Med., Bogota, Colombia

Abstract: Myeloperoxidase (MPO) is increased in many inflammatory diseases. MPO is associated with elevated risk for vascular disease in humans. We hypothesized that MPO is increased locally in human intracranial aneurysms (IA), and is critical for aneurysm formation and progression to rupture in a mouse model of IA. Blood, from the lumen of IA and femoral artery, was obtained from 17 patients who underwent endovascular coiling of IA. Tissues were collected from the wall of IA and from a superficial temporal artery in 12 patients who underwent microsurgical clipping of IA. We utilized a mouse model of IA in which aneurysmal rupture with subarachnoid hemorrhage (SAH) occurs spontaneously and causes neurological signs. Two groups of mice (12 WT and 12 MPO KO) underwent IA induction. Cerebral arteries from the mice were analyzed for inflammatory molecules and MMPs using qPCR. Plasma concentrations of MPO were 3-fold higher in aneurysms (100±15 ng/ml) (mean±SE) than in femoral blood (33±10; p=0.0007), whereas vascular peroxidase 1 (VPO1), a homolog of MPO, was not increased in aneurysm (384±51 μg/ml) vs. femoral blood (513±65; p=0.12). mRNA expression of MPO and VPO1 was similar in leukocytes recovered from aneurysmal blood and femoral blood. There were significantly more MPO-positive cells in aneurysm tissue (69±8 positive cells/field) than superficial temporal artery (6±3 positive cells/field, $p<0.001$). Incidence of aneurysms was significantly lower in MPO KO mice (50%) than WT control (92%, $p<0.05$). SAH was significantly lower in KO (8%) than WT (83%, $p<0.001$) mice. In cerebral arteries, neutrophil elastase, TNFα, CXCL1, COX2, MCP1, CD68 and arginase 1, MMP3, MMP13, and MMP9 were significantly lower, and both SM22 alpha and alpha smooth muscle actin significantly greater, in MPO KO mice. These findings suggest that MPO plays a critical role in the formation and rupture of IA in a mouse model of IA through inflammation/MMP/SMC mechanisms. A localized increase of MPO may contribute to IA in humans.

Title: Protease activated receptor-mediated mechanisms of axon injury and neuron degeneration

Authors: *H. YOON[1], M. RADULOVIC[2], I. A. SCARISBRICK[1];
[1]Physical Med. & Rehabilitation, Rehabil. Med. Res. Ctr., [2]Neurobio. of Dis. Program, Mayo Grad. Sch., Mayo Clin., Rochester, MN

Abstract: Serine protease-driven cascades are recognized to play important roles in CNS physiology during development and in adulthood, although knowledge regarding the scope of their physiologic actions and the consequences of their deregulation with injury or disease remains limited. We discovered that an important subset of serine proteases expressed endogenously in the CNS or upregulated therein after injury, such as thrombin, plasmin or select kallikreins, exert their cellular effects by selective activation of a family of G-protein coupled receptors referred to as Protease Activated Receptors (PARs). All 4 identified PARs were shown to be expressed in the adult brain and spinal cord and are therefore positioned to rapidly translate the dynamic changes that can occur in the proteolytic microenvironment with CNS injury or disease into rapid cellular responses. PARs are uniquely activated by specific serine proteases that selectively hydrolyze the extracellular N-terminus of the receptor resulting in differential recruitment of G-proteins and activation of discrete signaling cascades that have multiple downstream targets including gene transcription, cell motility, cytoskeletal rearrangement and secretion. For example, thrombin is the canonical activator of PAR1, whereas a more recently identified serine protease expressed at high levels in the CNS, neurosin (kallikrein 6), activates both PAR1 and PAR2. We hypothesize that serine protease-PAR signaling occurring at sites of CNS pathogenesis promotes axonopathy and neuron degeneration. Supporting this, we show that thrombin and neurosin, in addition to their cognate receptors, are elevated at sites of CNS injury, including murine spinal cord trauma and inflammatory demyelinating disease. Recombinant neurosin activated the ERK1/2 signaling cascade in primary neurons in a PI_3K and MEK-dependent fashion. Novel lipopeptide inhibitors specific for the intracellular loops of PAR1 or

PAR2, in addition to neurons derived from PAR deficient mice were utilized to demonstrate both receptors play a role in neurosin-elicited signaling, including activation of ERK1/2 and the pro-apoptotic protein Bim. Moreover, both neurosin and thrombin promoted axon injury in dissociated neurons and in organotypic spinal cord slice cultures with the effects in each case potentiated by excess glutamate. Importantly, protease-mediated neurotoxicity was significantly reduced in neurons and organotypic slices derived from PAR deficient mice. Together, these data point to a novel neurosin-PAR1 and -PAR2 mediated signaling axis in CNS neurons that is positioned to mediate neurotoxicity in cases of CNS injury and disease.

Title: Dysfunction, recovery, and hyperexcitability in the acute phase of ischemic stroke

Authors: *E. G. WANN, N. S. JACOBS, R. D. FROSTIG;
Neurobio. and Behavior, Univ. California Irvine, Irvine, CA

Abstract: We monitored spontaneous neuronal activity during the acute phase of ischemic stroke to map the time course of spontaneous activity patterns in the minutes and hours after an ischemic event. Spontaneous activity within the middle cerebral artery (MCA) region was measured using multi-site recordings across multiple cortical depths following permanent MCA occlusion (pMCAO). Infarct was assessed 24 hours after pMCAO using Nissl staining, and electrodes were then categorized based on their relative location to the infarct. Within the infarcted region in all cortical layers, spontaneous activity decreased directly after pMCAO and remained diminished for the five hour period sampled. In contrast, spontaneous neuronal activity at all cortical depths in regions adjacent to the area of subsequent infarct decreased initially but became hyperexcitable within two to three hours after pMCAO. An initial reduction in activity occurred even in electrodes distant to the infarcted region where activity recovered. Previous studies have shown that sensory stimulation delivered within two hours after pMCAO completely protects the cortex from impending stroke damage; however, the same sensory

stimulation results in additional damage if delivered three hours after pMCAO. Interestingly, the time window of sensory stimulation efficacy is consistent with the timing of hyperexcitability seen in the peri-infarct region. We are currently investigating whether sensory stimulation affects spontaneous activity directly after pMCAO and if hyperexcitability is blunted when sensory stimulation is delivered early. Title: Intra-arterial delivery of mesenchymal stem cell protects brain from stroke injury via brain-derived growth factor (BDNF) signaling

Authors: *D. R. YAVAGAL[1], P. BHATTACHARYA[2], R. LOPEZ[2], A. KHAN[3], M. PEREZ-PINZON[2], J. M. HARE[2], A. P. RAVAL[2];
[1]Neurol., Univ. of Miami, Miami, FL; [2]Neurol., [3]Stem Cell Inst., Univ. of Miami Miller Sch. of Medicine,, Miami, FL

Abstract: Stroke remains a leading cause of disability worldwide and ischemic stroke (occlusive clot-induced) accounts for almost 85% of total stroke cases. Although ischemic stroke patients are treated more often with thrombolytic agents, all neuroprotection trials for stroke have been unsuccessful and therefore, new pharmacological interventions are greatly needed. In last decade, laboratory studies suggest that stem cell therapy is a prospective treatment for stroke. There are multiple routes of stem cell delivery to the brain in ischemic stroke. Among these, the intra-arterial (IA) route of stem cell delivery has a high potential for clinical translation, in view of the increasing clinical application of endovascular therapy in the treatment of ischemic stroke. Recently, our study demonstrated that the intra-arterial delivery of mesenchymal stem cell (IA MSCs) at 24h after a reversible middle-cerebral artery occlusion (MCAo; for 90 min) reduces the infarct volume and improves neurological score in female rats at one month post-treatment. However, our study did not identify the mechanism by which IA MSCs protect female brain from ischemic damage. Identifying the mechanism by which IA MSCs protect the brain could be

of future implication in extending the period of beneficial effects of MSCs in recovery of stroke. Studies from various laboratory demonstrated that the growth factors play important role in preserving brain function after ischemia. Therefore, we propose to test the hypothesis that the IA MSCs treatment after MCAo increase brain-derived neurotrophic factor (BDNF) release and tyrosine kinase receptor sub-type B (TrkB) signaling in the female brain. To test proposed hypothesizes, ovariectomized rats were exposed to MCAo and treated intra-arterially either MSCs or phosphate buffered saline (PBS; vehicle control) a day later. Mesenchymal stem cells or PBS treated rats were sacrificed at 2, 4 8 or 30 days. The core, penumbra and contralateral regions of the brain were harvested to check protein levels of BDNF, TrkB and phosphorylated TrkB by Western blot analysis. We observed significant increase in the protein levels of BDNF and pTrKB in the penumbra region. IA MSCs increased protein levels of BDNF by two folds ($p < 0.05$) on days 2 and remain high until day 8, as compared to PBS treated groups. Similarly, we observed increased protein levels of pTrKB by one fold ($p <0.05$) on days 4 and 8 respectively, as compared to PBS treated groups, suggesting activation of BDNF-TrkB signaling after IA MSCs treatment. BDNF signaling is known to promote neuronal survival and stimulate neurogenesis in ischemic brain and direction of our future research.

Title: The role of the NOD-like receptor, Nlrx1 in neuroprotection and neuronal cell death

Authors: *E. IMBEAULT[1], T. M. MAHVELATI[2], D. GRIS[2];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Neuronal cell death is a phenomenon that occurs during brain development as well as in pathological diseases. Depending on the environment in which the cells are; apoptosis, necrosis or autophagic cell death can contribute to neuronal cell death. Basal autophagy plays a

key role in homeostasis by degrading damaged organelles, proteins, and even pathogens. Thus, an unbalanced process in autophagy can lead to neuronal cell death by a mechanism called autophagic cell death. It is crucial for the brain to have a basal level of autophagy to maintain neurons intact and prevent neurodegenerative diseases. A recently discovered NOD receptor, Nlrx1, is thought to play a role in autophagy and in innate immunity by sensing viral RNA at the mitochondria. Therefore, we hypothesize that Nlrx1 plays a neuroprotective role in attenuating inflammation by inhibiting apoptosis in neurons. To determine the protective mechanism of Nlrx1 *in vitro*, a Knock-Down, a Knock-In and a Scrambled control of Nlrx1 in N2a cells have been generated. LDH assays for cell death detection with hypoxic conditions or treatments with rotenone and staurosporine have been done. After 24h treatment of rotenone or hypoxia, N2a Knock-In cells showed higher cell death than N2a Knock-Down. When cells are pre-treated with Z-VAD for 1h prior to staurosporine or rotenone treatments, there was a decrease in cell death in all cells, regardless of the treatment. Pre-treatment with Z-VAD, followed by rotenone treatment demonstrated that N2a Knock-In cells undergo less cell death compared to N2a Knock-Down. Z-VAD pre-treatment decreases cell death in N2a Knock-In cells compared to N2a Knock-Down cells and can be explained by the increase in the number of mitochondria seen in N2a Knock-In cells by electron microscopy. Thus, having more mitochondria promotes the apoptotic pathway mediated by mitochondria in N2a Knock-In cells. Finally, *in vitro* results show that Nlrx1 Knock-In cells are more sensitive to oxidative stress and more prone to apoptosis and N2a Knock-Down cells are more resistant to cell death. Further investigations will be done to determine the exact mechanism of apoptosis within the type of cell.

Title: Roles of oxygen treatment in the development of ischemic brain injury, signal transduction and brain microcirculation after focal cerebral ischemia

Authors: *M. C. BEKER, A. B. CAGLAYAN, T. KELESTEMUR, E. YALCIN, G. OZTURK, E. KILIC;
Physiol., Istanbul Medipol Univ., Istanbul, Turkey

Abstract: Brain injury following ischemic stroke develops from a complex series of pathophysiological events, including over-activation of glutamate receptors, disruption of cellular calcium homeostasis, generation of reactive oxygen species (ROS) and spreading depression, which causes vasoconstriction in the penumbra. It is a matter of debate and an important issue in clinical aspect whether normobaric oxygen (NBO) treatment worsens ischemic stroke outcome. Here, we were interested whether different concentration of NBO treatment combined with free radical scavenger melatonin promotes neuronal survival, DNA fragmentation, brain oedema, blood-brain barrier (BBB) permeability, neurological outcome, broad spectrum of protein analysis, including Bcl-XL and eNOS activities. Furthermore, we have analyzed real time cerebral microcirculation by using laser speckle flowmetry before, during and after ischemia, including NBO treatment. For this aim, male 9 weeks old balb-c mice were anesthetized with 1% isoflurane (30% O2; rest N2O), and subjected to 30 min or 90 min of intraluminal middle cerebral artery occlusion (MCAo) and 72 hours or 24 hours reperfusion, respectively. Animals were treated with 21-, 70-, or 100% NBO alone or combined with melatonin (4mg/kg) just after reperfusion. NBO treatment was continued for the first 90 min of reperfusion. As compared with animals treated with 21% NBO treatment, 70% but particularly 100% NBO treatment. Seventy- but especially 100% NBO treatment decreased infarct volume, brain swelling, neurological outcome, neuronal survival and DNA fragmentation significantly, which was associated with improved BBB permeability, cerebral microcirculation and increased significant expressions of anti-apoptotic Bcl-XL and eNOS. Furthermore, melatonin treatment further improved neuroprotective effects of NBO treatment. Here, we provide evidence that NBO treatment is beneficial after ischemic stroke which was associated with improved brain microcirculation, BBB permeability and Bcl-XL and eNOS activities. Furthermore, free radical scavenger melatonin potentiates the effects of NBO treatment.

Title: Aerobic exercise is as effective as skilled reach training in improving functional recovery following ischemic insult in C57BL/6 mice

Authors: *A. L. KERR[1], T. MUELLER[2], M. DOMINGUEZ[1], R. HOLDEN[1], M. CURTIS[1], B. WALL[1];
[1]Psychology, [2]Illinois Wesleyan Univ., Bloomington, IL

Abstract: Stroke is a leading cause of serious, long-term disability with upper limb impairment among the most common, chronic deficits reported in survivors. Current rehabilitative strategies employed in humans are often ineffective in restoring pre-stroke behavioral performance. It has been found that focused rehabilitative training of the impaired limb effectively improves functional outcome in rodent models of ischemic stroke. However, the benefits reported with this training require intensive therapy with relatively long sessions implemented daily. Additional rehabilitative strategies that may be easier to implement in other populations (including humans) need to be established to promote better behavioral recovery following injury. Aerobic exercise has been found to have beneficial effects for both the brain and behavior in humans and rodents, with exercise improving learning and memory in aged populations. The current study investigates the role of aerobic exercise in functional recovery following focal ischemic insult in C57BL/6 mice. A total of 40 mice were trained to criterion on a skilled reaching task, the Pasta Matrix Reaching Task (PMRT), prior to receiving a unilateral ischemic stroke. Following four days of recovery, mice were divided evenly into one of four groups: skilled reach training of the impaired limb (on the PMRT), aerobic exercise, skilled reach training with aerobic exercise, or control procedures. Animals in aerobic exercise conditions had free access to running wheels, while control animals received no direct training of any limb. All mice were in their respective conditions for a total of two weeks and received weekly probe trials of their impaired limb. Our results indicate that aerobic exercise is as effective as skilled reach training in improving functional recovery of the impaired limb. The combined therapy of skilled reach training and exercise was no more beneficial than either condition alone. These findings suggest that aerobic exercise may be a feasible rehabilitative strategy for individuals with persistent upper extremity impairment following stroke.

Title: Mechanisms of p75NTR-dependent peri-infarct denervation

Authors: D. C. PARRISH[1], B. L. HEMPSTEAD[2], A. NYKJAER[3], *B. A. HABECKER[1]; [1]Physiol. & Pharmacol., OHSU, Portland, OR; [2]Weill Cornell Med. Col., New York, NY; [3]Aarhus Universitet, Aarhus, Denmark

Abstract: Several recent clinical trials revealed that the amount of sympathetic denervation of the heart after myocardial infarction (MI) predicts the risk for arrhythmias and sudden cardiac death. We previously showed that the p75 neurotrophin receptor (p75NTR) is required for denervation of the peri-infarct zone after cardiac ischemia-reperfusion injury. Both mature brain-derived neurotrophic factor (BDNF) and proneurotrophins, such as pro-nerve growth factor (proNGF) and proBDNF, can signal through p75NTR to initiate axon degeneration. We have shown that proNGF is elevated in the heart following MI. We quantified proBDNF protein in the left ventricle of BDNF-HA/HA mice 24 hours following ischemia-reperfusion or sham surgery by western blotting. ProBDNF was elevated in the infarcted left ventricle compared to sham-operated controls. We asked if the denervation of viable myocardium was caused by proneurotrophins. Because proneurotrophin signaling through p75NTR requires a sortilin family co-receptor, we quantified sympathetic innervation density by tyrosine hydroxylase immunohistochemistry in 12-18 week old sortilin -/- and wild-type control mice (C57Bl6/J) that were subjected to sham or ischemia-reperfusion surgery. The infarct and peri-infarct zones were largely denervated in wild-type mice 3 days after MI, and denervation of both the infarct and peri-infarct regions in sortilin -/- mice was identical to wild-type. BDNF signals through p75NTR to cause axon degeneration in sympathetic neurons, in part by increasing expression of tumor necrosis factor-alpha converting enzyme (TACE), an alpha-secretase that cleaves p75NTR. We examined expression of TACE in the stellate ganglia of wild type mice subjected to sham or ischemia-reperfusion surgery and found that TACE mRNA was elevated 3 days post-MI. We treated mice with either vehicle or the secretase inhibitor Marimastat (25mg/kg/day) for 3 days after MI and examined the innervation density of the peri-infarct area. Marimastat-treated mice lacked peri-infarct denervation compared to vehicle-treated controls, suggesting that TACE may play a role in peri-infarct axon degeneration.

Title: Hydrogen peroxide impairs GABA-dependent motor behavior in Caenorhabditis elegans

Authors: *L. HERNANDEZ[1], G. CAMARGO-HERNANDEZ[2], A. LOMELI-SILVA[3], M. A. RAMIREZ-HERRERA[1], A. HERNANDEZ-CHAVEZ[1];
[1]Dept. de Fisiologia, Univ. de Guadalajara, Guadalajara, Jalisco, Mexico; [2]Dept. de Botánica y Zoología, Univ. de Guadalajara, Zapopan, Jalisco, Mexico; [3]Lic. QFB CUCEI, Univ. de Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Background: Oxidative stress (OS) is an imbalance between production of free radical (FR), reactive oxygen species (ROS) and endogenous antioxidant defense mechanisms where is favored the oxidant environment. In these conditions, could produce adverse modifications to cell component, such as lipids, proteins, and DNA. Thus, OS have been associated to many pathological conditions and diseases, including atherosclerosis, cancer, diabetes mellitus, neurodegenerative and psychological diseases, some of them, related to GABAergic activity. GABAergic activity is focused in synthesis and release of gamma-aminobutyric acid (GABA) and its postsynaptic receptors, which set up the primary inhibitory neurotransmission system in vertebrate and invertebrate animals. In this sense, the main aim of this work was to evaluate the effect of oxidative damage induced by hydrogen peroxide on GABAergic system, using *Caenorhabditis elegans (C. elegans)* as an *in vivo* model organism. *C. elegans* is a saprophyte nematode that recently it has been employed in oxidative stress studies. In *C. elegans*, GABA acts on neuromuscular junction by inducing relaxing of locomotion and foraging muscles, and contracting muscles implied in defecation. Particularly, GABAergic system is essential for stereotyped behaviors, such nose touch response (NTR). In this study, we examined this behavior after oxidative damage induced by hydrogen peroxide (H_2O_2), in presence or not of GABA or Curcumin (CUR). **Methods:** WT (Bristol N2) strain of *C. elegans*, age synchronized and cultured in NMG-agar plates seeded with E. coli OP50, were used in this study. They were transferred to 12-well plates and were exposed to different concentrations of H_2O_2 (0.1, 0.35 and 0.5 mM) for 30 min. Then, worms were relocated to Agar-NMG plates with no food, and individually were stimulated by touching their noses with an eyebrow hair. A reversal sinusoidal movement was considered as a normal motor behavior and a shrinking movement was scored as defective. This protocol was repeated by adding GABA as $GABA_A$

receptor agonist or CUR as antioxidant. **Results and Conclusions:** Concentrations of H_2O_2 0.35 mM and above induced an impairment of normal NTR in 39%, a statically significant change in relation to non-exposed animal, consequently we inferred that oxidation produces damages in GABAergic system. We confirm this when this effect was partially reversed in the co-exposure of H_2O_2 and GABA. On the other hand, the impairment of NTR could not be completely prevented with co-exposure of CUR and H_2O_2.

Title: An introduction of photothrombotic focal cerebral ischemia model in the adult zebrafish

Authors: *X. YU, Y. V. LI;
Biol. Sci., Ohio Univ., Athens, OH

Abstract: As the more commonly used models (suture model and distal middle cerebral artery occlusion) for focal cerebral ischemia are often technically challenging, using simpler models to induce a predictable focal ischemic lesion have been developed as an alternative. One of these methods consists of the photothrombosis, which is induced by the illumination of the brain after the systemic delivery of a photosensitive dye, Rose Bengal. Rose Bengal releases singlet oxygen, which breaks the endothelial cells of the blood vessel under light exposure, and triggers the coagulation pathway in the location of the irradiated tissue. The zebrafish (Danio rerio) has shown a good correlation between zebrafish and rodent data and has demonstrated similarity to mammalian models in tests of toxicity. In this study, we developed a method to use adult zebrafish as a model of focal cerebral ischemia. During anesthesia, Rose Bengal was intraperitoneally delivered to zebrafish according to the body weight (50 μg/g, 100 μg/g, 200 μg/g and 500 μg/g) with different doses of light exposure. The recovery and behavioral changes after photothrombosis were recorded daily for 3 days. The mortality rate of each group was also measured. The results showed the photothrombosis effect is dose-dependent with Rose Bengal and light exposure. High dose of Rose Bengal (500 μg/g) was lethal for zebrafish without light exposure. However, smaller doses of Rose Bengal (50 μg/g, 100 μg/g) and light exposure

introduce brain damage on zebrafish. The optimal dose of Rose Bengal (100 μg/g) and light exposure (intensity of 800 μW/cm2 for 30 minutes) yielded significant brain damage. Quantified 2,3,5-triphenyltetrazolium chloride (TTC) staining showed the significant damage of the optic tectum in the photothrombotic treated zebrafish. Data suggest that Rose Bengal with light exposure induces reproducible photothrombotic brain damage in zebrafish, and that zebrafish can be used as a model of focal cerebral ischemia.

Title: Mitochondrial and cytosolic hydrogen peroxide and glutathione in pyramidal cells and astrocytes in hippocampal area CA1 respond to oxygen-glucose deprivation

Authors: B. YIN[1], N. POVYSHEVA[2], G. BARRIONUEVO[2], *S. WEBER[3];
[1]Chem., [2]Neurosci., [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A good model for studying cerebral ischemia is oxygen glucose deprivation (OGD). Abundant evidence supports the damaging nature of excess reactive oxygen species (ROS) in cells, which can be converted into less reactive H2O2; then H2O2 can be scavenged by glutathione (GSH), which is oxidized to glutathione disulfide (GSSG). Monitoring H2O2 level and glutathione redox potential (GSHRP) during OGD-reperfusion is a promising way to investigate the course of ischemic injury. We are unaware of single-cell investigations in tissue though there is a rich literature on this problem. Thus we have developed an approach using the organotypic hippocampal slice culture (OHSC), and employ green fluorescent protein (GFP)-based sensors, which are selectively sensitive to H2O2 level or GSHRP. Real-time O2 level inside OHSC (10 - 40 μm depth) is measured with a Clark-type electrode. Our study focuses on the H2O2 level and GSHRP in mitochondrial and cytosol from pyramidal cells and astrocytes in OHSC. We treated OHSCs with OGD-reperfusion (pre-oxygenation, 10 min/ OGD, 20 min/ reperfusion, 30 min), followed by fully oxidizing and reducing them for calibration. We performed ratio-metric imaging of the H2O2 and GSHRP sensors (Ex 405/488 nm; Em 500-530

nm). Fluorescence signal ratio (FSR) 405/488 is normalized to 1 at the sensor's fully oxidized state. FSR is 0.17 or 0.24 for fully reduced GSH or H2O2 sensors, respectively. For pyramidal cell mitochondria, FSRGSH is 0.46 ± 0.01, 0.37 ± 0.01, 0.55 ± 0.01, for pre-, during, post- OGD, respectively (n=6); while FSRH2O2 is 0.53 ± 0.01, 0.43 ± 0.02, 0.57 ± 0.01, for pre-, during, post-OGD, respectively (n=6). These values are statistically significant different suggesting that ROS generation is suppressed during OGD. The situation is reversed during reperfusion. Notably, the GSRRP is stable over the observation time, showing no evidence of a "burst". The peroxide sensor does not respond quickly enough to see a "burst". We also find similar changes in astrocyte mitochondria. However, cytosolic sensors, in either pyramidal cells or astrocytes do not show significant changes during OGD and reperfusion (ANOVA). Supported by NIH Grant R01 GM066018.

Title: Oxidative stress and neuronal death in non-coma hypoglycemia

Authors: *N. G. LANGUREN, T. MONTIEL, A. JULIO-AMILPAS, L. MASSIEU;
Inst. De Fisiologia Celular , UNAM, Mexico, Mexico

Abstract: Type 1 diabetic patients are exposed to insulin treatment in order to regulate blood glucose levels. However, intensive insulin tretment increases their risk to present episodes of moderate and even severe hypoglycemia. Severe hypoglycemia leading to blood glucose levels below 20 mg/dl can lead to the coma state both in animals and humans, which is associated with neuronal death in vulnerable brain regions such as the cortex, the hippocampus and the striatum. However, the presence of neuronal death has also been observed in rats exposed to non-coma hypoglycemia, particularly in the cerebral cortex. The consequences of non-coma hypoglycemia in brain have not been completely elucidated and the mechanisms leading to the death of cortical neurons are unknown. The aim of the present study was to investigate whether severe non-coma hypoglycemia induces oxidative stress in discrete regions of the brain and wheter it correlates to

their vulnerability to neuronal death. Male Wistar rats were subjected to severe hypoglycemia (< 20 mg/dl) by insulin administration and were rescued with glucose before the coma, as monitored by EEG recording. Four and 24 h after insulin injection, the levels of lipoperoxidation (TBARS method), reduced glutathione (GSH, fluorometric method), and superoxide production (oxidation of dihydroethydium (DHE) were determined, while neuronal death was evaluated by Fluoro Jade B 24 h after insulin injection. Results indicate that lipoperoxidation was significantly increased in the parietal and frontal cortices, the hippocampus and the striatum of severe hypoglycemic animals at the end of the hypoglycemic period (4 h after insulin), while GSH levels were significantly diminished at this time in all brain regions. At 24 h lipoperoxidation levels remained elevated in frontal cortex but returned to control levels in the parietal cortex, the hippocampus and the striatum. Consistently, the levels of GSH remained low in frontal cortex while it recovered in the parietal cortex, the hippocampus and the striatum. The production of superoxide was increased in both cortices and the hippocampus at 24 h and the frontal cortex showed the largest increase. Consistent with these observations, degenerating neurons were observed only in the frontal cortex. These results suggest that a differential regulation of the antioxidant defense and a differential production of ROS contributes to selective brain damage induced by non-coma hypoglycemia.

Title: The beta-pix - rac1 - cofilin pathway after brain ischemia

Authors: T. LUO, C. LIU, Y. PARK, I. SABIRZHANOVA, *B.-R. HU;
Univ. of Maryland Sch. of Med., Univ. of Maryland, Baltimore, MD

Abstract: The beta-PIX - Rac1 - cofilin pathway plays a key role in synaptic networking after brain injury. Ultimately, functional recovery, which requires synaptic networking, is a key issue for stroke patients. For that reason, understanding of the beta-PIX - Rac1 - cofilin pathway is essential for developing therapeutics to prevent brain injury and to facilitate functional recovery after brain ischemia. However, how this pathway is regulated following brain ischemia remains largely unknown. This study utilized a rat transient cerebral ischemia model to investigate this pathway. The results showed that the Rac1 GTPase was significantly upregulated and translocated to the synaptic and nuclear fractions after brain ischemia. Cool1/beta-PIX (beta-PIX hereafter), a Rac1 guanine nucleotide exchange factor, was dramatically activated by translocation to the synaptic membrane and nuclear structure initially, and then depleted during the recovery phase after brain ischemia. Correspondingly, an episode of brain ischemia led to transient activation of cofilin, a Rac1 downstream effector by dephosphorylation. This cascade of events suggests that the beta-PIX - Rac1 - cofilin pathway is transiently upregulated, which may be responsible for the excitotoxicity in the initial phase after brain ischemia. Furthermore, the depletion of beta-PIX of this pathway during the recovery phase may play a negative role in functional recovery during the late postischemic phase. Therefore, transient inhibition of the beta-PIX - Rac1 - cofilin pathway before or immediately after the onset of brain ischemia may prevent excitotoxicity, but activation of this pathway in the late postischemic phase may facilitate functional recovery.

Title: Effect of cerebral ischemia on behavioral outcomes in insulin-treated diabetic rats exposed to recurrent hypoglycemia

Authors: V. SHUKLA, P. FUCHS, A. LIU, K. SERDAHELY, P. REDDY, *K. DAVE; Neurol., Univ. Miami Sch. Med., MIAMI, FL

Abstract: The International Diabetes Federation estimates that 382 million people suffer from diabetes worldwide. The major side effect of intensive therapy to control blood glucose levels in both type 1 and type 2 diabetics is recurrent hypoglycemic (RH) episodes. Recurrent hypoglycemia in a rat model of insulin-dependent diabetes exacerbates cerebral ischemic damage, as indexed by the number of surviving neurons in the CA1 region of the hippocampus. The goal of the present study is to determine the effect of cerebral ischemia on behavioral outcome in RH-exposed diabetic rats. Streptozotocin-induced diabetic rats were used as an animal model. Four experimental groups were examined: 1) naïve (non-diabetics), 2) insulin-treated diabetics (ITD) (diabetics on insulin therapy), 3) ITD + RH (diabetics on insulin therapy experiencing RH), and 4) ITD + RH + Glucose (control for additional insulin injected to induce hypoglycemia). Moderate RH was induced once a day for five consecutive days. Global cerebral ischemia (8 min, 2VO + hypotension) was induced the day after the last hypoglycemia treatment. Sham operated rats for each group were used as controls. Behavior was assessed using the open field test (day 13 post-ischemia), contextual fear conditioning test (day 13-14 post-ischemia), zero maze test (days 4 and 12 post-ischemia), and Barnes maze test (days 4-11). Brains were harvested on day 14 post-ischemia for histological assessments. Open field test showed no significant difference in distance traveled among four ischemia groups when compared to respective sham operated groups. Currently we are evaluating effects of ischemia in above mentioned experimental groups on contextual fear conditioning, zero maze and Barnes maze test. We are also evaluating histological outcomes in these animals. Characterization of RH on cerebral ischemia-induced behavioral impairments may help understand the nature of cerebral ischemic injury in diabetic patients.

Title: Behavioral, physiological and neuroanatomical changes following a focal ischemic damage in the mouse motor cortex

Authors: *C. ALIA[1,2], C. SPALLETTI[3], S. LAI[4], A. PANARESE[4], A. GHIONZOLI[4], S. MICERA[4,5], M. CALEO[1];
[1]CNR - Inst. Di Neuroscienze, Pisa, Italy; [2]Scuola Normale superiore, Pisa, Italy; [3]Inst. of Life Sci., [4]The Biorobotics Inst., Scuola Superiore Sant'Anna, Pisa, Italy; [5]Ctr. for Neuroprosthetics, Ecole Polytechnique Federale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Stroke is one of the leading causes of long-term motor disabilities and re-acquisition of motor skills is a priority for stroke survivors. To develop new effective rehabilitation protocols, it is critical to achieve a more complete understanding of the spontaneous cortical reorganization that occurs following injury. In this study, we have assessed behavioral, physiological and neuroanatomical changes in a mouse model of focal photothrombotic injury in the forelimb motor region (caudal forelimb area, CFA). At the behavioral level, spontaneous motor tasks such as the Gridwalk Test, the Schallert Cylinder Test and the Swim Test indicated robust deficits that were selective for the contralesional forelimb and persisted for at least 30 days after stroke. Reconstruction of paw trajectories during a skilled reaching task indicated that several kinematic parameters were altered by focal ischemia, and these changes persisted up to 30 days. However, the percentage of successful grasps significantly recovered starting from the third week after stroke, pointing to the development of compensatory strategies. To identify physiological and morphological underpinnings of compensation, we used intracortical microstimulation to map motor representations and immunostaining to measure levels of plasticity markers in the perilesional areas at 30 days. Intracortical microstimulation revealed significant rewiring of cortical regions posterior to the lesion, i.e. the hindlimb motor cortex. In addition, the percentage of sites producing combined, forelimb/hindlimb/tail movements was enhanced in the peri-infarct zone. Neuroanatomical analyses in the peri-infarct cortex showed a decrease in the density of perineuronal nets, as well as of somatostatin- and parvalbumin-positive interneurons. Perineuronal nets are well known plasticity brakes and a reduction in intracortical inhibition has been previously shown to promote adult cortical plasticity. Thus, reductions in these markers may underlie spontaneous reorganization of the perilesional areas. These data provide baseline information on the behavioral, physiological and neuroanatomical changes triggered by a focal cerebral ischemia in mice. Ongoing experiments in our laboratories are applying these quantitative measures to the study of post-stroke rehabilitation. In particular, we are measuring functional recovery and cortical rewiring following rehabilitation with a robotic device that we have recently described (Spalletti et al., Neurorehabil Neural Repair, 2014).

Title: A non-ionotropic activity of GluN2A-containing NMDA receptor confers neuroprotection

Authors: *B. J. LUJAN[1], R. HU[1,2], Q. WAN[1,2,3];
[1]Dept. of Physiol. and Cell Biol., Univ. of Nevada Med. Sch., Reno, NV; [2]Dept. of Neurosurg., Southwest Hosp., Chongqing, China; [3]Dept. of Physiol., Wuhan Univ., Wuhan, China

Abstract: Function of N-methyl-D-aspartate receptor (NMDAR) is believed to depend on its channel activity. GluN2A- and GluN2B-containing NMDARs GluN2ARs and GluN2BRs) are the major subtypes of NMDARs, whose activations require agonist glutamate and co-agonist glycine. Here we show that glycine alone acts through an ifenprodil-sensitive binding site in the GluN1 subunit of GluN2ARs to enhance Akt phosphorylation independent of the channel activity of GluN2ARs, indicating that the ionotropic GluN2AR has a non-ionotropic property. The non-ionotropic GluN2AR mediates a neuroprotective effect of glycine against glutamate neurotoxicity-induced neuronal death *in vitro*. In a rat cerebral ischemia model, glycine prevents neuronal death and improves functional recovery in a NMDAR channel activity-independent manner. These results suggest that as a co-agonist of ionotropic NMDAR, glycine serves as an agonist to trigger a non-ionotropic activity of GluN2ARs and confers neuroprotection. This study uncovers a previously unknown mechanism whereby GluN2AR, through its non-ionotropic activity, exerts a different effect than GluN2BR in neuronal survival.

Title: The multi-herbal mixture HT047 improves functional recovery after focal cerebral ischemia in rats

Authors: *J. SONG, D. LEE, H. KIM, H. LEE, H. KIM;
Dept. of Herbal Pharmacol., Kyunghee Univ., Soeul, Korea, Republic of

Abstract: HT047 is a multi-herbal mixture consisting of Pueraria lobata and Scutellaria baicalensis which have been used together to treat stroke in traditional Korean medicine. In the present study, the effects of HT047 on functional recovery after focal cerebral ischemia were investigated. Sprague-Dawley rats were subjected to 90 min of middle cerebral artery occlusion (MCAO) followed by reperfusion. HT047 were orally administered to rats for 14 days at a dose of 30 mg/kg or 100 mg/kg, starting 3 days after MCAO. Functional recovery was assessed at weekly intervals using the rotarod test and modified Neurological Severity Score (mNSS). In rotarod test, rats were trained for 7 days prior to induction of MCAO. The latency to fall on the accelerating rotarod was recorded for 5 min at 7, 14, 21, and 28 days after MCAO. The mNSS which includes both motor and sensory tests was scored from 0 (normal) to 7 (maximal deficit) at 7, 14, and 21 days after MCAO. Rats were weighed daily the day before MCAO and over 4 weeks after MCAO. At 14 days after MCAO, treatment with HT047 100 mg/kg significantly prolonged the time that rats remained on the rotarod by 62.6% compared with the control group (210.2 ± 23.5 vs. 129.3 ± 20.8 sec, $p<0.05$). HT047 100mg/kg-treated rats showed significantly lower mNSS scores than saline-treated rats at 21 days after MCAO (3.1 ± 0.4 vs. 4.5 ± 0.5, $p<0.05$). The body weights of rats treated with HT047 100 mg/kg continued to increase and were significantly different from those of control group over time from 3 days to 28 days after MCAO. In conclusion, HT047 treatment improves functional recovery and prevents weight loss after experimental stroke.

Title: Third ventricle neural stem cell niche dynamics following focal ischemic lesion

Authors: R. BRONSTEIN[1], *S.-A. E. TSIRKA[2];
[1]Neurobio. and Behavior, [2]Stony Brook Univ. Med. Ctr., STONY BROOK, NY

Abstract: In addition to the well established neural stem cell reserves in the adult mammalian brain located in the dentate gyrus (DG) of the hippocampal formation and the sub-ventricular zone (SVZ) lying along the lateral ventricle wall, the 3rd ventricle lying proximal to the hypothalamus has also been shown to house limited-potential progenitors. Local α or β tanycytes (a radial glia-like cell population), which slowly differentiate in response to leptin and insulin-growth factor (IGF) signaling, add neuronal and glial cells (NG2+) to the arcuate and paraventricular nuclei. The proliferative zone of the 3rd ventricle also extends into thalamic territory, though whether adult neurogenesis occurs in these dorsal reaches of the 3rd ventricle remains an open question. We studied the response of 3rd ventricle neural stem cells (NSCs) to focal thalamic lacunar ischemia in wild-type (WT) C57Bl6/J mice and in mice lacking the high mobility group B2 (HMGB2) gene - loss of which leads to heightened neurogenesis in the adult SVZ NSC niche. We have previously reported a role for this chromatin protein (HMGB2) in the modulation of embryonic neurogenesis and in the adult SVZ. We examine the response of HMGB2-associated transcriptional and epigenetic changes following ischemia, which could lead to insights into changes occurring in conditions such as Dejerine-Roussy syndrome (thalamic pain syndrome) or heat shock/exhaustion (hypothalamic in origin) - as both are caused by injury to those particular brain regions. Title: Differential CSF-derived microparticle protein expression in humans with cerebral vasospasm after aneurysmal subarachnoid hemorrhage

Authors: *M. M. SZYMANSKA, W. W. ASHLEY, JR;
Neurolog. Surgery, Loyola Univ. Med. Ctr., Maywood, IL

Abstract: Cerebral vasospasm (CVS) and related ischemic injury is a major contributor to death and disability after aneurysmal subarachnoid hemorrhage (aSAH). Our goal is to understand the molecular mechanisms underlying CVS in order to facilitate the rational development of safe, effective and reliable diagnostic and treatment paradigms. Our hypothesis is that there are specific early changes in protein expression related to endothelial injury and inflammation that induce CVS. Cerebro-spinao fluid (CSF) was collected daily from patients with aSAH. Microparticles (MPs), micromolecules released by vesicles, red and white blood cells, platelets and endothelial cells, were isolated using serial ultracentrifugation. Differential protein expression in CSF-MPs was analyzed by a mass spec (MS) based system using isotopically tagged peptides to profile the proteins and determine their relative concentrations in individual patient samples. These proteins were correlated with patient's clinical data and used to identify candidates for biomarkers predictive of CVS. More than 150 proteins were isolated from CSF-MPs. Proteomic and molecular pathways analysis revealed marked differential expression of proteins in patients with CVS. We identified specific candidate proteins that could potentially serve as early biomarkers for CVS. ApoE, ApoD, prostaglandin D5, synaptic nuclear envelope protein 1, clusterin, α-1-acid glycoprotein, plasma protease C1 inhibitor, and prostaglandin H2 D isomerase were downregulated in patients who developed CVS. Haptoglobin, fibrinogen α and γ chain, synaptic nuclear envelope protein 2, and hemoglobin subunits α and β were upregulated. Some of these proteins are associated with immune and metabolic processes and some have been specifically associated with cerebrovascular disease states. This is the first demonstration that there is differential protein expression in CSF-MPs from VS patients.. Alone or in combination, these and other proteins may be useful as biomarkers to guide in stratifying patients into categories of risk to develop CVS. They may also deepen our understanding of the mechanisms and facilitate the development of safer and more effective therapies for CVS.

Title: Glial responses and neuroregeneration in a pediatric model of ischemic stroke

Authors: *J. T. AHRENDSEN[1], H. GREWAL[2], R. J. TRAYSTMAN[3], P. S. HERSON[2], W. B. MACKLIN[1];
[1]Cell and Developmental Biol., [2]Anesthesiol., [3]Pharmacol., Univ. of Colorado, Aurora, CO

Abstract: Pediatric arterial ischemic stroke affects more than 1,000 children in the United States each year, with a vast majority of surviving children suffering long-term neurologic deficit with varying degrees of disability. Initial studies suggest that recovery from stroke is greater among juveniles compared neonates or adults. We have therefore developed a middle cerebral artery occlusion (MCAO) model of pediatric stroke in order to understand repair mechanisms and cellular responses that are unique to this juvenile developmental time period. One strikingly understudied aspect of stroke, especially in juvenile subjects, is its impact on glial cells, in particular myelinating glia. Therefore, the glial responses following experimentally-induced stroke in juvenile mice (20-25 days old) were investigated. GFAP immunoreactivity steadily increased in the lesioned striatum from 24 hours to 30 days following MCAO. Similarly, Iba1-positive microglia and NG2-positive cells proliferated in the lesioned area 24 hours after stroke, and remained increased after 30 days. Surprisingly, mature oligodendrocytes and gross myelin production were unaffected during the acute (24 hours and 3 days post MCAO) and subacute (7 days) recovery phases. However, during the chronic (30 days) phase, some myelin debris and signs of axon pathology were detected in the lateral striatum, where gliosis was most severe. Taken together, these results suggest that myelinating oligodendrocytes in the pediatric brain are resistant to the initial ischemic insult but that ongoing astrogliosis and microgliosis could be harmful. Extensive neuronal cell death occurred during acute phases of recovery throughout the lesioned striatum. During subacute and chronic phases, neuronal cell death continued in the lateral striatum. However remarkable recovery of the neuronal population was observed in the medial striatum, starting 7 days after stroke and continuing at 30 days. Consistent with this, we observed increased proliferation of doublecortin-positive cells in the ipsilateral subventricular zone and increasing numbers of doublecortin-positive neuroblasts were found in medial striatum. These data suggest that partial recovery in the juvenile brain occurs after experimentally induced stroke, and that recovery may be correlated with the degree of ongoing gliosis and the proximity to germinal centers, such as the subventricular zone. Understanding the unique cellular responses in the juvenile brain could yield valuable insight into enhancing cellular resistance to ischemia as well as promoting recovery after ischemia.

Title: Lymphocytes bioenergetics after stroke: A functional proteomic study

Authors: *F. FERRARI[1], D. GEROLDI[2], A. GORINI[1], G. PERO[3], R. F. VILLA[1];
[1]Dept. of Biol. and Biotech., Univ. of Pavia, Pavia, Italy; [2]Dept. of Intrnl. Med., San Matteo Hosp. - Univ. of Pavia, Pavia, Italy; [3]Dept. of Neuroradiology, Niguarda Hosp. Ca' Granda, Milan, Italy

Abstract: BACKGROUND - Modulation of molecular and cellular inflammatory responses is a potential target of neuroprotection but an in-depth understanding of their therapeutic implications in the brain ischemia is still lacking [1]. Moreover, stroke leads to important metabolic alterations and energy availability is required for molecular and cellular brain functions [2]. This in progress, systematic research studies the catalytic properties of cytoplasmic and mitochondrial enzymes of stroke patients' lymphocytes, indicative of cellular-molecular mechanisms of immune system engagement and predictive markers of neuronal energy transduction abnormalities. METHODS - Controls and stroke patients were divided by sex and age and the catalytic properties of these regulatory enzymes were assayed: hexokinase (HK), lactate dehydrogenase (LDH) for glycolysis; citrate synthase (CS), malate dehydrogenase (MDH) for Krebs' cycle (TCA); NADH-cytochrome c reductase (Complex I-III), succinate dehydrogenase (SDH, Complex II), cytochrome oxidase (COX, Complex IV) for Electron Transfer Chain (ETC); glutamate dehydrogenase (GlDH), glutamate-oxaloacetate- (GOT) and glutamate-pyruvate- transaminase (GPT) for amino acids/glutamate metabolism. RESULTS - Because of the little number of patients enrolled so far, results are referred only to the gender effect; even so, stroke changed lymphocytic enzyme activities of patients, particularly in females, reflecting the metabolic dysfunction of ischemic brain, like for other pathologies [3, 4]. Overall, the glycolytic and the aerobic flux in TCA and at the ETC entry level points were increased, although the COX activity was decreased because of the lack of O2 as electron terminal acceptor. Moreover, GlDH was decreased explaining on functional basis the glutamate accumulation in the early ischemic phase [5]. CONCLUSIONS - The biochemical machinery of lymphocytic bioenergetics suggests

different responses to ischemia in males and females and this functional proteomic approach may be a suitable model to study drug actions. In the research progress, we will increase the number of enrolled patients, taking into account also the age factor and considering the recovery phases, when inflammation become more relevant for patients' outcome, REFERENCES - [1] Iadecola C, Anrather J. 2011. Title: Pharmacological evaluation of the antinociceptive and anti-inflammatory activities of limonene and nerol in the oxazolone-induced colitis model

Authors: ***A. E. GONZÁLEZ-RAMÍREZ**[1], F. LOPEZ MUÑOZ[1], M. GONZALEZ TRUJANO[2], M. GONZALEZ TRUJANO[2], M. GONZALEZ TRUJANO[2], M. GONZALEZ TRUJANO[2], M. GONZALEZ TRUJANO[2], M. GONZALEZ TRUJANO[2];
[1]Delegación Tlalpan, Ctr. De Investigación Y De Estudios Avanzados Del IPN, Mexico, Mexico; [2]Instituo Nacional de Psiquiatria Ramon de la Fuente Muñiz, Mexico DF, Mexico

Abstract: Monoterpenes are natural products and main constituents in essential oils, plant resins and citrus. Antinociceptive, anti-inflammatory and antioxidative activities have been attributed to this kind of compounds. In a chronic inflammatory condition like ulcerative colitis, a painful disease with clinic manifestations as diarrhea, pain and abdominal cramps, ulcers, weight and

appetite loss and fatigue; it has been involved the nociceptive and inflammatory reactions linked to a Th2 immune response that leads to release of cytokines such as: IL-4, IL-5, IL-13 and IFN-γ. Because of this, the aim of this investigation was to analyze the antinociceptive and anti-inflammatory effects of the monoterpenes limonene and nerol by using oxazolone-induced colitis model in BALB/c mice. The evaluation of pathological characteristics considered Disease Activity Index (DAI) and Colonic Damage Index (CDI) as pathological markers that were used to evaluate the effect of monoterpenes and a positive control treatments; as well as secondary hyperalgesia which was determined by using Von Frey filaments as a mechanical stimulus and histological estimation in colon sections performed with hematoxylin-eosin staining. Results demonstrated that individual administration of limonene and nerol reduced the oxazolone-induced colonic damage markers with a significant decrease in DAI at a 100 mg/kg dosage and in CDI at 177.8 and 300 mg/kg. In addition, these monoterpenes reduced hyperalgesia from a dosage of 30 mg/kg. Finally, the histological analysis gave evidence that monoterpenes treatment prevented the oxazolone-induced colonic damage in lamina propia, a highly vascular layer of connective tissue under the basement membrane lining a layer of epithelium, previously observed in control subjects. In conclusion, this study gives preclinical pharmacological evidences of therapeutic properties of nerol and limonene in a painful disease like ulcerative colitis.

Title: Diosmin reverses hyperalgesia in a model of neuropathic pain in rats involving the opioidergic system

Authors: *A. CARBALLO[1], M. GONZÁLEZ-TRUJANO[2], F. J. LÓPEZ-MUÑOZ[1];
[1]Ctr. De Investigacion Y De Estudios Avanzados Del IPN, Mèxico Distrito Federal, Mexico;
[2]Unidad de Neurociencias, Inst. Nacional de Psiquiatría Ramón de la Fuente Muñiz, Mexico DF, Mexico

Abstract: Despite of the discovery of new drugs and their possible involved mechanism of action, the treatment for neuropathic pain remain unclear; there is not single treatment that works in all conditions of neuropathic pain and its underlying mechanisms. Conventional therapy such as non-steroidal anti-inflammatory drugs, opioids, tricyclic anti-depressants, anti-convulsants and topical medicine have been associated with various adverse effects, withdrawal syndromes and multiple pathological mechanisms that are not suitable for all types of neuropathy. In psychiatric medicine, it is developing phytomedicines, including analgesics with the purpose of using complementary and alternative therapies. Diosmin (Diosmetin-7-O-rutinoside) is a flavonoid that possesses anti-diabetic, antioxidant, anxiolytic and anti-inflammatory activities. These properties suggest that diosmin is a possible candidate for the relief of neuropathic pain, which antinociceptive effect could be mediated through of an opioid pathway. In this investigation, painful neuropathy was induced in male rats using the Constriction Chronic Injury (CCI) model in order to investigate the involvement of opioid pathway in diosmin-induced effects. We tested the non-selective opioid receptors naloxone given 10 min before to diosmin or its vehicle administration in acute treatment. The evaluation of an hyperalgesic response was measured with mechanical and thermal withdrawal thresholds. Diosmin administrated at dose of 316.2 mg/kg, produced a significant inhibition of the withdrawal thresholds in CCI model in both responses. Animals receiving pre-treatment of naloxone (1 mg/kg, i.p.) reduced the antinociceptive response of diosmin in both tests. Our data showed that systemic administration of diosmin decreased the CCI-induced hyperalgesia mediated by an opioid mechanism suggesting that diosmin is a potential useful flavonoid for the therapy of neuropathic pain.

Abstract: Introduction: Sepsis is a clinical condition associated with high morbidity and mortality in patients in intensive care units. The most frequent complication of sepsis is sepsis-associated encephalopathy (SAE), characterized by decline of mental processes, impaired attention, delirium and coma. Several factors contribute to this condition such as generation of proinflammatory cytokines, blood brain barrier (BBB) permeability, oxidative stress and molecules could amplifying this responses. CD40 molecule expressed in microglia active and your ligand CD40L can exert this function in different diseases that involve neuroinflammatory process. Therefore, for all the points raised so far, the objective to propose an investigation if the dyad CD40/CD40L fosters neuroinflammation and cognitive impairment in sepsis animal model. Materials and Methodos: Male Wistar rats were subjected to cecal ligation and puncture (CLP) to induce sepsis. The animals were killed 12, 24 and 48hours after CLP surgery and removed the hippocampus to evaluate the CD40 and CD40L levels by western blotting. In another experiment, Wistar rats received antibody anti-CD40 intracerebroventricularly and were divided in sham (control), CLP, CLP + anti-CD40 100mg/kg and killed 24 hours after surgery to cytokine determination (IL-1β, TNF-α and IL-6) and BBB permeability. Ten days after sepsis, in another experiment, the animals were submitted to the habituation to the open field and aversive memory to the step-down inhibitory avoidance task. Data were evaluated by ANOVA and Tukey post hoc test. Man Whitney test was utilized for behavioral analysis with all significant at $p<0.05$. Results: We observed in the hippocampus an increase of CD40 and CD40L in 12 and 24 hours after CLP. The use of anti-CD40 reverted the increase of BBB permeability and levels of IL-1β, IL-6 and TNF-α in the hippocampus 24 hours after CLP. The anti-CD40 additionally reverted the cognitive impairment. Conclusion: The results observed in this study reinforce the role of CD40-CD40L in the neuroinflammatory response and cognitive impairment verified in SAE

Title: Protective role of high mobility group box 1-toll-like receptor 2 axis on ischemia-induced oligodendrocyte death

Authors: *J. CHOI[1], B. G. KIM[2,4,3];
[1]Brain Dis. Res. Ctr., Inst. For Med. Sciences, Ajou Univ. Sch. of Med., Woncheon-Dong, Yongtong-Gu, Suwon, Korea, Republic of; [2]Dept. of Brain Sci. and Neurol., [3]Dept. of Biomed. Sci., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [4]Neurosci. Grad. Program, Ajou Univ. Grad. Sch. of Med., Suwon, Korea, Republic of

Abstract: Ischemic white matter injury is commonly encountered in clinical practices resulting in various neurologic disabilities ranging from sensorimotor dysfunctions to severe cognitive impairments. Demyelination with oligodendrocyte (OL) loss is a prominent histopathological feature of ischemic white matter injury. Therefore, protection of OLs from ischemic insults would be an important therapeutic strategy to overcome neurologic disabilities caused by ischemic white matter injury. Previously, we found that Toll-like receptor 2 (TLR2) expressed in OL lineage cells provides cell-autonomous protective effects. It has been shown that certain endogenous ligands can activate TLR2 in sterile pathological conditions. Among them, high mobility group box 1 (HMGB1), well known danger associated molecular pattern protein, is released from dying cells and elicit inflammation and/or promote tissue repair. In the present study, we identified HMGB1 as an endogenous TLR2 ligand to promote protective effect in ischemia-induced OL death. After oxygen-glucose deprivation (OGD), OLs released HMGB1 into bathing media as early as 5 minutes after OGD completion. Conditioned media collected from cultured OLs exposed to OGD exhibited protective activity against OGD-induced OL death in a TLR2-dependent manner. Immunodepletion of HMGB1 from the conditioned media abolished the protective activity. In addition, application of glycyrrhizin, a specific HMGB1 inhibitor, resulted in the aggravation of OGD-induced OL death, suggesting that HMGB1 released from OLs may exert endogenous protective effects on OLs through binding to TLR2.

Furthermore, exogenous recombinant HMGB1 application after OGD in OL culture also reduced OGD-induced OLs death. In primary microglia culture, HMGB1 application increased the expression of insulin-like growth factor 1 (IGF-1) a well-known OL survival factor, in a TLR2-dependent manner, suggesting a dual mode of OL protection by HMGB1. We confirmed the protective effects of HMGB1 in a endothelin-1-induced focal white matter stroke model. Animals with glycyrrhizin co-injection showed worsening neurobehavioral parameters measured by corner test and pole test compared to those with vehicle co-injection. Preliminary data also revealed the expansion of demyelinating lesion by glycyrrhizin. These results suggest that HMGB1 may act as an endogenous TLR2 ligand mediating protective effects on OLs after ischemic insult. Further studies on HMGB1-TLR2 signaling axis may reveal a novel therapeutic target to treat ischemic white matter injury.

Title: Spatiotemporal profile of blood monocyte subsets accumulation in the post-ischemic brain

Authors: *L. GARCIA-BONILLA, G. FARACO, J. MOORE, D. BREA, G. RACCHUMI, C. IADECOLA, J. ANRATHER;
Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Inflammation is a key component of ischemic stroke pathophysiology, participating both in tissue injury and repair (Nat Med 17:796, 2011). A key feature of post-ischemic inflammation is the infiltration of blood monocytes. There are two main monocytes subsets in the mouse blood: $CCR2^{+}/CX3CR1^{-}/Ly6C^{hi}$ "inflammatory" monocytes involved in acute inflammation, and $CCR2^{-}/CX3CR1^{+}/Ly6C^{lo}$ "patrolling" monocytes, which may play a role in repair processes (Immunity 19:71, 2003; J Exp Med 204:3037, 2007). CCR2 mediates the trafficking of $Ly6C^{hi}$ cells, while CX3CR1 of $Ly6C^{lo}$ cells. We hypothesize that inflammatory

monocytes are present in the early phase after ischemia, whereas patrolling monocytes infiltrate the brain at later times. To this end, lethally irradiated C57BL/6 mice (7 weeks old) were transplanted with $CX3CR1^{GFP/+}CCR2^{RFP/+}$ bone marrow. The restricted expression of GFP in hematogenous CX3CR1 cells allows differentiating infiltrating $CX3CR1^{GFP/+}$ monocytes from CNS-resident ($CX3CR1^{+}$) microglia. Five weeks after transplant, the chimeric mice underwent transient middle cerebral artery occlusion (MCAO) and were sacrificed 1, 2, 3, 5, 7, 14 or 28 days later (n=3-4/group). $CX3CR1^{GFP/+}$ and $CCR2^{RFP/+}$ fluorescent cells were mapped in serial sections using anatomical reconstruction and semi-automated cell counting**.** The number of $CCR2^{+}$ inflammatory monocytes in the ischemic brain peaked 3 days after MCAO ($3.8\pm0.9x10^5$ vs. $0.2\pm0.1x10^5$ cells in sham mice; $p<0.05$; mean±SE), returning toward baseline at day 7 ($0.8\pm0.2x10^5$) and 28 ($0.9\pm0.2x10^5$). $CCR2^{+}$ cells were observed mainly in the infarct core. On the other hand, $CX3CR1^{+}$ cells increased slightly at day 1 ($1\pm0.1x10^5$), 3 ($1.4\pm0.3x10^5$), 5 ($3.2\pm0.5x10^5$; $p<0.05$), and 7 ($1.8\pm0.3x10^5$, $p<0.05$) from sham ($0.6\pm0.1x10^5$), and peaked 14 days after MCAO ($7.1\pm0.8x10^5$, $p<0.05$). At day 28, $CX3CR1^{+}$ cells were still increased ($6.4\pm1.2x10^5$, $p<0.05$). $CX3CR1^{GFP/+}$ cells exhibited 3 distinct phenotypes: macrophage-like cells (amoeboid with retracted processes), microglial-like cells (with ramified processes) and perivascular cells (elongated shape). GLUT-1, PDGFRα, NeuN, and GFAP co-staining 28 days after MCAO revealed that $CX3CR1^{+}$ cells are phenotypically distinct from endothelial cells, pericytes, neurons or astrocytes. The data suggest that $CCR2^{+}$ monocytes are rapidly recruited to the injured brain, whereas $CX3CR1^{+}$ monocytes populate the infarct at later times. Although assessing the role of these monocytes subsets will require additional studies, it is conceivable that $CCR2^{+}$ cells are involved in the acute phase of the damage, while $CXCR1^{+}$ cells play a role in post-ischemic repair processes.

Title: Acute and chronic exposure to ozone produce lipid peroxidation in rat hippocampus

Authors: *M. L. MENDOZA-MAGANA, J. J. RAMIREZ-VAZQUEZ, M. A. RAMIREZ-HERRERA, J. C. FRIAS-MARQUEZ, A. A. RAMIREZ-MENDOZA, G. CAMARGO-HERNANDEZ;
Dept Physiol, Univ. Guadalajara Ctr. Univ. Ciencias Salud, Guadalajara Jalisco, Mexico

Abstract: Air pollution is a worldwide problem especially in large cities, where ozone (O3) and other toxic compounds constitute the smog. The concentration of such compounds increases due to the combustion of fossil fuels and industrial activity. Exposure to O3 is a risk factor to develop neurodegenerative diseases because of its high oxidizing power. The olfactory mucosa is the direct entryway to the CNS and the respiratory system constitutes the indirect route to the nervous system through blood stream. We evaluated the effect of an acute and chronic exposure O3 in cellular lipids of the hippocampus in young Wistar rats. The experimental group was placed in an acrylic exposure chamber with an artificial atmosphere containing O3 (0.7 ppm) and the control group was exposed to environmental air using the same chamber. The exposure acute (15 days) and chronic (60 days) was performed daily during 4 hours. Malondialdehyde (MDA) and 4 hydroxyalkenal (HAE) concentration of in hippocampus homogenates were analyzed. Lipid peroxidation was determined by a colorimetric assay as indicated by the manufacturer (Oxford Biomedical Research) and spectrophotometrically determined at 586 nm. Data were analyzed by ANOVA test and Bonferroni as post-hoc test. MDA/HAE concentration in the control group was 5.60 ± 1.85 and 5.95 ± 2.33 μM of protein in acute and chronic exposure respectively. MDA/HAE concentration in the O3 exposed group was 14.89 ± 1.52 and 21.15 ± 9.55 μM of protein in acute and chronic exposure respectively. Lipid peroxidation, as well as other assays to evaluate oxidative damage, are required to establish the oxidative status in experimental exposure to O3 as air contaminant. Neurodegenerative diseases usually bear the oxidative damage as part of their physiopathological hallmarks, but oxidative damage could play a more crucial role as initiator that triggers a cascade of events that may lead to the development of diverse diseases. It contributes to the maintenance of chronic inflammation in degenerative diseases.

Title: Distribution of ß-hydroxybutyrate (bhb) in cd-1 mice after experimental stroke

Authors: *K. A. KOCH, J. KONIETZKA, D. BERRESSEM, G. ECKERT, J. KLEIN; Pharmakologisches Inst. für Naturwissenschaftler, Goethe Univ. Frankfurt Am Main, Frankfurt Am Main, Germany

Abstract: Stroke is a major medical emergency and the second most frequent cause of death in the world. While drug treatment of stroke remains unsatisfactory, dietary approaches to stroke prevention and regeneration, such as ketogenic diet, have recently attracted much interest. (R)-3-Hydroxybutyrate (BHB) is the most important ketone body and is a precursor of acetyl-CoA which can be used as an energy source for the citric acid cycle in the brain. In the present study, we have used a common experimental stroke model, middle cerebral artery occlusion (MCAO), in mice to investigate the levels of BHB before and after brain ischemia. In female CD-1 mice, ischemia was induced in the left hemisphere with the MCAO method. After 90 min of ischemia, mice were sacrificed, blood was withdrawn, and liver and brain tissue were harvested and extracted for BHB measurements. After derivatisation with BSTFA/TMCS, the extracts were measured by GC-MS. We found that ischemia induced a 13-fold increase of BHB levels in the left (stroked) hemisphere when compared with sham-operated animals (control group: 105 ± 13,6 µM calculated for brain water; stroke group: 1385 ± 280 µM; mean ± S.E., N=6). In the right (healthy) hemisphere, an 11-fold increase was observed (control group: 99,3 ± 9,1 µM; stroked group: 1121 ± 237 µM). Liver homogenates showed the following results: control group, 258 ± 19 µM; stroked group, 3.688 ± 481 µM (calculated for intracellular water). Plasma levels of BHB showed the same tendency: control group, 61,4 ± 17 µM; stroked group: 924 ± 231 µM. Our data show massive increases of BHB levels in three compartments induced by ischemia in female CD-1 mice. The data demonstrate a strong production of ketone bodies by the liver which are accompanied by massive increases of BHB in plasma and in both hemispheres of the brain. Our current work focuses on the elucidation of the underlying interaction between brain and regulation of liver metabolism.

Title: Recombinant NAMPT exerts neuroprotective effects against cerebral ischemia

Authors: *X. R. CHEN[1,2], Z. JING[1,2], A. STETLER[1], Y. LUO[3], X. JI[3], S. H. GRAHAM[1,2], G. CAO[1,2,3];

Abstract: The protective effects of Nicotinamide phosphoribosyltransferase (NAMPT) have been observed across multiple systems, including brain injury, using both transgenic overexpression and viral delivery of the NAMPT transgene. To assess the more clinically relevant delivery of NAMPT as a recombinant protein, we investigated the impact of recombinant NAMPT on brain ischemia/reperfusion injury. METHODS: Recombinant NAMPT preparations were generated from either bacterial E. coli (PT-E.coli) or mammalian 293T cells (PT-293T). Transient focal cerebral ischemia was induced in male C57BL/6 mice by 60 min occlusion of the middle cerebral artery (MCAO) followed by 72 h reperfusion. Three different administration paradigms were used: 1) a single dose administered i.p. delivered at 1 h, 3h and 5h after stroke, 2) a single dose administered i.c.v. at 1 h after stroke, and 3) three doses of i.c.v administration (12 h prior to, right before and 12 h after MCAO). Body weight was monitored over 3 d post-surgery, and neurological dysfunction and brain infarct volume were assessed at 72 h post-stroke. Corner test and Rotarod test were also included. RESULTS: Intraperitoneal administration of either PT-E.coli or PT-293T reduced brain infarct size in a dose-dependent manner. PT-293T markedly reduced brain damage when administered within 3 h after transient ischemia and exhibited a larger therapeutic window compared to PT-E.coli. Reduction of ischemic brain injury was correlated with reduced functional impairment in mice. A single dose of PT-293T i.c.v injection exerted better neuroprotective effect compared to i.c.v. administration of PT-E.coli in the mouse model of ischemic stroke. In the paradigm which delivered recombinant proteins three times (i.c.v.) within the same animal, PT-293T also exerted significant neuroprotective effects. CONCLUSIONS: Recombinant delivery of NAMPT provides significant protection against ischemic brain injury. We have found that PT-293T appears to exert better ischemic neuroprotection compared to PT-E.coli. Taken together, these

results provide validation of recombinant NAMPT delivery as potential neuroprotective strategy for stroke.

Title: 2-Arachidonoylglycerol protects the retina from AMPA excitotoxicity *in vivo* via the activation of CB1 receptor. Involvement of the PI3K/Akt signaling pathway

Authors: *D. KOKONA[1], A. ZIMMER[2], K. THERMOS[1];
[1]Univ. of Crete, Heraklion, Greece; [2]Inst. of Mol. Psychiatry, Univ. of Bonn, Bonn, Germany

Abstract: Retinal ischemia leads to excitotoxicity and neurodegeneration that result in loss of visual acuity and blindness. It is prominent in retinal diseases such as diabetic retinopathy and glaucoma. Even today there are no efficacious treatments available for the treatment of neurodegenerative eye disease. New neuroprotective therapeutic targets are essential to protect retinal neurons and prevent blindness. Cannabinoids have been shown to protect the CNS, including the retina, from ischemic insults. An endocannabinoid system, which includes the endocannabinoids [2-arachidonoylglycerol (2-AG) and anandamide] and the cannabinoid receptors (CB1 and CB2), is present in the retina. In the present study we examined the ability of the endocannabinoid 2-AG to afford neuroprotection in the retina in an *in vivo* model of AMPA excitotoxicity, and the mechanisms involved in the neuroprotection. Sprague Dawley rats were intravitreally injected with PBS or AMPA (42nmol/eye). In previous work in our laboratory we detected the loss of retinal amacrine (cholinergic and nitric oxide synthetase containing) and horizontal cells, twenty four hours after the AMPA administration, but no loss of photoreceptors, rod bipolar or ganglion cells. Using bNOS immunoreactivity we examined the effect of 2-AG (10-8, 10-7, 10-6 M) in reversing retinal cell loss. We also used CB1 (AM251, 10-6 M) and CB2 (AM630, 10-6 M) antagonists, and JWH015 (CB2 agonist, 10-8, 10-7, 10-6 M) to elucidate the involvement of each receptor in the neuroprotection. In addition, wild type, CB1-/- and CB2-/-

C57BL/6 mice were also intravitreally administered with AMPA(21nmol/eye) or AMPA + 2-AG (10-7 M) or vehicle to validate the role of CB1 and CB2 receptors in the neuroprotection. In addition, Akt2-/- C57BL/6 mice were employed to investigate the involvement of the PI3K/Akt2 downstream signaling pathway, in the neuroprotection afforded by 2-AG. The results suggest that the endocannabinoid 2-AG protects the retina from AMPA excitotoxicity *in vivo* via a mechanism involving the CB1 receptor and the activation of the PI3K/Akt2 signalling pathway. The AMPA excitotoxicity model is useful in determining the early effects of ischemia. The pharmacologic profile of 2-AG renders it a promising therapeutic agent in retinal disease whose pathophysiology involves ischemic and excitotoxic insults. Ongoing studies are investigating other a) receptors involved in the neuroprotective effects of 2-AG, such as the TRPV receptor, and b) cannabinoids, as well as the inhibitors of the metabolic enzymes of the endocannabinoids, as possible targets of retinal therapeutics.

Title: A single, intravenous injection of minocycline prior to aortic occlusion is sufficient to reduce severe hind-limb motor impairment, attenuate spinal astrogliosis, and preserve neuronal cytoarchitecture in rats

Authors: E. JAFFREY[1,2], *A. SIDERIS[2], B. PISKOUN[2], T. J. J. BLANCK[3], B. DRENGER[5], E. RECIO-PINTO[4];

Abstract: The incidence of paraplegia following surgery or endovascular stenting of the thoracic aorta remains unacceptably high, despite advances in anesthetic and surgical management. Reducing the current paralysis rate is achieved by interventions which are mostly physical in nature. There is a need to find or develop pharmacological compounds administered

prophylactically and aimed at further lowering the patient risk of spinal cord ischemia. Minocycline is a tetracycline derivative, and has been used for many years in humans at low doses. There is mounting pre-clinical evidence for a new use of this old drug. Minocycline appears to be neuroprotective in several animal models of cerebral ischemia, stroke and inflammation; however, these effects are uncertain. Here, we used a model of spinal cord ischemia in which the thoracic aorta was occluded with a 2F Fogarty Catheter for 18 minutes under isoflurane anesthesia. A high intravenous dose, 10mg/kg, of minocycline hydrochloride was administered 30 minutes prior to aortic occlusion in a group of rats. Hindlimb motor function was evaluated using a modified Tarlov scale at 3 hours, 24 hours and 48 hours after reperfusion in naïve, sham, and drug-treated sham and injured animals. The occlusion time, under isoflurane anesthesia, produced severe hindlimb paralysis (Tarlov grade< 1) in 80% of rats acutely after reperfusion, and paralysis was maintained for 24 hrs and 48 hrs in 75% and 60% of animals, respectively. Interestingly, the single minocycline injection effectively mitigated severe hindlimb motor impairment (Tarlov grade ≥ 2) in 80% of animals at 3hrs after injury, and in 100% of the animals at 24 and 48 hours after reperfusion. Spinal cord tissue was collected 48 hours after reperfusion, and processed for histological staining (H&E and GFAP+). Quantification of GFAP+ areas indicated that relative to controls, ischemia induced significant astrogliosis in white matter ($p<0.0001$) and in gray matter ($p<0.0001$) of thoracolumbar spinal cord sections-areas caudal to the occlusion. Minocylcine significantly reduced astrogliosis in these areas (white matter, $p<0.05$; gray matter $p<0.0001$). Our data indicate that in addition to its reported inhibitory effects on microglia, minocycline may modulate the glial response to injury via inhibition of reactive astrocytosis. Minocycline also protected against neuronal damage as evidenced by an increased percentage of intact spinal cord tissue and decreased vacuolation in gray matter. Together, our data indicate that a single, high dose of minocycline administered prophylactically may be helpful in alleviating severe behavioral deficits in a model of spinal cord ischemia in rats.

Title: Dodecafluoropentane emulsion extends the time for effective tPA stroke therapy

Authors: *R. D. SKINNER[1], C. ARTHUR[2], A. T. BROWN[2], J. LOWERY[3], W. C. CULP[2]; [1]Dept. Neurobiol & Dev Sci. and Ctr. Translational Neurosci., [2]Dept. Radiology, [3]Dept. Lab. Animal Med., Univ. Arkansas Med. Sci., LITTLE ROCK, AR

Abstract: Nanometer-size bubbles of the perfluorocarbon Dodecafluoropentane in emulsion (DDFPe) carry large quantities of oxygen and can protect the penumbra in animal stroke models up to 24 hours. Currently the treatment of choice for ischemic stroke is the clot-lysing drug tissue Plasminogen Activator (tPA). However, due to contraindications, most commonly delays of >3 hrs (FDA) or >4.5 hrs (common use) post stroke, less than 5% of stroke patients receive IV tPA therapy. We tested the time constraint for stroke treatment using DDFPe to extend the time window for application of tPA. One hour IV delivery of DDFPe is clinically practical since, in the MagFast stroke trial, 73% of patients received IV drugs in <1 hr of onset and 97% in <2 hrs. The rabbit model was chosen because tPA transitioned into clinical care from rabbit testing. Many more patients will meet tPA criteria if DDFPe can be given early in the field. Thus, as in the phrase "Time Is Brain", effective extension of time to successful tPA treatment or other revascularization saves brain. Aim: To test the penumbra protecting ability of DDFPe to safely extend the time of tPA thrombolysis to 9 hrs after stroke, double or triple the current standard. Methods. IACUC approval was obtained. Under isoflorane anesthesia New Zealand rabbits (4-5 kg, N=23) received selective angiography followed by injection of a 4 mm blood clot in the internal carotid artery for flow directed middle cerebral artery occlusion. Angiography was repeated. Rabbits were recovered and randomly assigned to tPA (n=8), and DDFPe+tPA (n=7) groups. Standard 1 hr treatment of IV tPA (0.9 mg/kg) was given starting 9 hrs post stroke. In one group DDFPe (0.3 ml/kg of 2% emulsion) dosing began at 1 hr and continued at 90 min intervals for 6 doses; others received saline injections. Historic controls without therapy were compared (n=8). At 24 hrs Neurological Assessment Scores (NAS, 0-10) were determined. Then the brain was removed, sectioned, and stained with triphenyltetrazolium chloride. The area of stroke was measured in each section and a percent Stroke Volume (%SV) of the brain was computed. Results at 24 hrs: For NAS values, DDFPe+tPA was improved vs. controls, p=0.013, and also vs. the tPA alone group, p=0.032. The tPA only and controls were not different, p=.89. For %SV the combination treatment DDFPe+tPA was more effective, mean 0.80, vs. tPA only, mean 2.24, (p=0.0045). Conclusion. With reperfusion the combination of DDFPe+tPA therapy was more effective than tPA alone in preserving functioning brain tissue after stroke as determined by NAS and also %SV. Thus, DDFPe therapy significantly extends the time at which administration of tPA is effective by 2-3 times.

Title: Hsp70 inhibits dynamin expression: A new mechanism of protection in cerebral ischemia?

Authors: *N. KIM[1], J. KIM[1], J. LEE[2], M. A. YENARI[1];
[1]Neurol., UCSF, San Francisco, CA; [2]Anat. and BK 21 Project for Med. Sci., Yonsei Univ., Seoul, Korea, Republic of

Abstract: The 70 kD heat shock protein (Hsp70) has been shown to protect brain cells from apoptosis in animal and cell-culture models of stroke. The anti-apoptotic mechanism of Hsp70 is still not completely understood, particularly in the central nervous system. In a previous study, our lab found that Hsp70 overexpressing transgenic (Tg) mice were protected from experimental stroke compared to wild type mice. One protein particularly suppressed in the Hsp70 Tg brains was dynamin. Dynamin is best known for its role in endocytic mechanisms but has also been shown to translocate Fas protein to the cell surface where it can be bound by FasL. Once activated, the Fas receptor triggers one of several extrinsic apoptosis pathways leading to caspase-dependent cell death. Our study investigates the relationship between dynamin-Fas signaling and Hsp70's anti-apoptotic role in stroke. We subjected groups of wildtype, Hsp70 transgenic (Tg), and Hsp70 knockout (Ko) mice to cerebral ischemia using distal MCAO (dMCAO). Brains were assessed for dynamin, membrane Fas, and caspase-8 expression 3d following dMCAO as well as for infarct size and neurological behavior 14d post dMCAO. We found that dynamin is upregulated by ischemia and colocalizes primarily to neurons. In addition, Hsp70 overexpression protects the brain following dMCAO as evidenced by decreased infarct volume (n=6/group, $P<0.05$), improved neurobehavioral outcomes ($P<0.05$), and decreased brain

dynamin, membrane Fas, and caspase-8 expression relative to wildtype and KO groups. Neuron cultures treated with a dynamin antagonist showed reduced cell death following oxygen glucose deprivation (OGD, $P<0.01$). We locally administered the same dynamin antagonist in a mouse model of stroke (n=7/group) and saw improved neurobehavioral outcomes. Our results indicate dynamin as a potential target for treating cerebral ischemia. Furthermore, these findings identify a novel mechanism underlying Hsp70's neuroprotective, anti-apoptotic effects and may offer significant implications toward new therapeutic strategies for stroke.

Title: Cerium oxide nanoparticles improve survival and motor function in a *Drosophila* model of stroke

Authors: J. A. BATES, B. LOCKLER, *K. S. HOCKEY, C. A. SHOLAR, J. COOK, A. S. FREY, M. J. BILLINGS, B. A. RZIGALINSKI;
Pharmacol., Virginia Coll of Osteo. Med., Blacksburg, VA

Abstract: After stroke, return of circulation and oxygenation is known to produce abundant free radicals that impart damage to brain tissue and associated functional deficits. Based on the antioxidant activity of cerium oxide nanoparticles (CeONP) and their neuroprotective effects in other models of neurodegenerative disease, we reasoned that CeONP may be useful in treatment of neuronal deficits associated with stroke. In our prior tissue culture studies of mixed brain cells exposed to anoxia, CeONP protected neurons from cell death and maintained near-normal basal and agonist-stimulated intracellular free calcium levels. Therefore we hypothesized that CeONP would improve survival and functional outcome in a *Drosophila* model of stroke. Male and female Oregon R *Drosophila* were separated and collected upon eclosure, and fed standard fly mix or mix containing 1-200 micromolar CeONP (average particle size 10 nm) for 22 days, until approximately early mid-life in the fly. On day 23, flies were placed in empty vials and secured in a gas tent. All oxygen in the tent was evacuated and replaced with nitrogen, simulating anoxia

and stroke. Flies were kept under anoxic conditions for 2 ½ hrs, followed by return to their respective food groups in the normoxic environment. Survival was counted daily until all flies perished. Motor function was periodically assessed by measurement of negative geotaxis, which is the ability of a fly to climb to 3 different heights in response to a stimulus. Flies exposed to anoxia exhibited a significantly increased death rate as compared to controls, which was improved in groups treated with CeONP. Greater protective effects were observed for longevity in females, as compared to males. Motor function was also decreased in flies exposed to anoxia, and was significantly depressed at 6, 14, and 36 days after anoxia. However in flies fed CeONP, depression of motor function was significantly less, and had returned to levels consistent with unstroked controls by 14 days post-anoxia. Similar results were observed in flies treated with CeONP after exposure to anoxia (no pretreatment). These results demonstrate that CeONP improve survival and motor function after anoxia in *Drosophila*, suggesting that this nanopharmaceutical has potential for treatment or prevention of the neurological deficits associated with stroke.

Title: PELP1 - a major scaffold protein for efficient non-genomic estrogen signaling in the brain

Authors: ***R. D. THAKKAR**[1], Q.-G. ZHANG[1], Y. DONG[1], H. TANG[1], R. VADLAMUDI[2], D. BRANN[1];
[1]Dept. of Neurosci. and Regenerative Med., Georgia Regents Univ., Augusta, GA; [2]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: 17β-Estradiol (E2) has been suggested to be neuroprotective against a variety of neurological disorders, although the mechanisms underlying its action are not completely understood. In order to enhance understanding in this area, our lab previously cloned a novel estrogen receptor (ER) co-regulator protein named PELP1 (proline-, glutamic acid-, and leucine-

rich protein-1) that may help mediate E2 non-genomic and genomic signaling. The purpose of the present study was to examine whether PELP1 functions as a key scaffold protein to connect ER-α with the PI3K kinase (p85) subunit, and thereby facilitate activation of the downstream pro-survival factor, Akt. To test this possibility, we employed a co-immunopreciptation approach (Duolink) that allows detection of two interacting proteins *in situ*. Using this approach, PELP1 was shown to interact with p85 and ER-α in the hippocampal CA1 region of sham, placebo- and E2-treated ovariectomized female mice 30 minutes following global cerebral ischemia. Intriguingly, E2 caused a robust increase in PELP1 interaction with p85 and ER-α, an effect that correlated with E2 induction of Akt activation and neuroprotection. As a whole, the findings suggest that PELP1 may function as an important scaffold protein to mediate E2-induced Akt pro-survival signaling in the hippocampus.

Title: Neuroprotective effects of cilostazol through the multi-mechanisms in mice permanent focal ischemia

Authors: *H. SHICHINOHE[1], T. YAMAUCHI[1], H. SAITO[1], T. ABUMIYA[1], K. HOUKIN[1], S. KURODA[2];
[1]Hokkaido Univ., Sapporo, Japan; [2]Dept. of Neurosurg., Univ. of Toyama, Toyama, Japan

Abstract: Background and Purpose: It has been reported that Cilostazol, which is phosphodiesterase (PDE) 3 inhibitor clinically used as an antiplatelet drug, could ameliorate ischemic brain injury, but the mechanisms were not clarified. We aimed to investigate how

Cilostazol affected mice permanent focal ischemia model. Methods: Male Balb/c mice were subjected to permanent middle cerebral artery (MCA) occlusion. They were treated with Cilostazol (10- mg/kg or 20- mg/kg) or vehicle 30 min and 24 h post-ischemia. Infarct volume was assessed by 2,3,5-triphenyltetrazolium chloride (TTC) method after 48 h (n=8 in each group). In histological analysis, the animals were sacrificed 6 h or 24 h post-ischemia (n=5 in each group), and then the immunohistochemistry was performed to the brain sections. Results: We showed that the treatment with Cilostazol salvaged the tissue damage in the infarct rim in a dose-dependent manner, and 20- mg/kg Cilostazol significantly reduced infarct volume to 70.1±24.4% of the control ($P<0.05$). Immunoreaction for 8-Hydroxydeoxyguanosine (OHdG), an oxidative stress marker, showed the neuronal damage by oxidative stress in peri-infarct, and the treatment with Cilostazol reduced the ratio of the damaged neurons 6 h post-ischemia (65.8±33.5% in vehicle-treated animals, 21.3±9.9% in Cilostazol-treated ones, $P<0.05$). Double staining for 8-OHdG and von Willebrand factor also showed that Cilostazol attenuated oxidative stress on the endothelial cells in peri-infarct 24 h post-ischemia, significantly ($P<0.01$). On the other hand, the immunostaining for phosphorylated cAMP response element binding protein (pCREB) showed that Cilostazol increased the ratio of the pCREB-positive neurons in peri-infarct 24 h post-ischemia significantly (74.5±8.0% in vehicle-treated animals, 93.6±2.9% in Cilostazol-treated ones, $P<0.01$). Conclusions: These findings suggested that Cilostazol could have multi-mechanisms to ameliorate tissue damage due to permanent focal cerebral ischemia. Thus, one is to attenuate oxidative stress on neurnons and endothelial cells in the infarct rim, and another is to protect neural damage with anti-apoptotic effect through the pathway of Akt/pCREB.

Title: Vitexin protects brain against ischemia/reperfusion injury via modulating mitogen-activated protein kinase and apoptosis signaling in mice

Authors: *G. ZHANG, L. DONG, Y. WANG, Q. JIANG, Y. ZHEN;
Dept. of Pharmacol., Anhui Med. Univ., Anhui, China

Abstract: The injury from ischemic stroke and subsequent reperfusion is a major cause of permanent disability and death in the adult worldwide. Past decades have witnessed a tremendous advance in understanding of the pathophysiology of cerebral ischemia/reperfusion (I/R) injury, however therapeutic options for acute cerebral I/R injury are still limited. Vitexin (apigenin-8-C-β-D-glucopyranoside) is a flavonoid compound present in dried leaves of hawthorn (crataegus pinnatifida). Previously we found that vitexin protects the heart against I/R injury via modulating mitogen-activated protein kinase (MAPK, including ERK, JNK and p38) and apoptosis signaling pathways. Recent study revealed that vitexin has a neuroprotective effect in primary cortical neuron culture. Whether this protective effect applies to cerebral I/R injury remains unclear. In the present study, we examined the potential neuroprotective effect of vitexin against cerebral I/R injury and the underlying mechanisms. Focal cerebral I/R model in male Kunming mice was induced by occluding the middle cerebral artery occlusion (MCAO) for 2 h followed by reperfusion for 22 h. Vitexin (3.25, 7.50, and 15.00 mg/kg) was administered via tail vein at the beginning of the reperfusion. Twenty-four hours after I/R, vitexin at 7.50 mg/kg or 15.00 mg/kg significantly reduced neurological deficits, cerebral infarct volume and histopathological damages to cerebral I/R injury. Western Blot analyses revealed that vitexin markedly upregulated p-ERK1/2 and downregulated p-JNK and p-p38. Meanwhile, vitexin increased cortical Bcl-2 expression and suppressed the overexpression of Bax in I/R injured mice. Our data indicate that vitexin protects the brain against cerebral I/R injury, and this effect may likely occur via modulating MAPK signaling and preventing cellular apoptosis. To our knowledge, we report for the first time the therapeutic application of vitexin against cerebral I/R injury which may pave a new way for developing a novel drug candidate against cerebral I/R injury in stroke patients.

Title: L-carnitine enhances axonal plasticity and improves white matter lesions after chronic hypoperfusion in rat brain

Authors: *Y. UENO[1], M. KOIKE[2], Y. SHIMADA[3], H. SHIMURA[4], K. HIRA[3], Y. UCHIYAMA[2], N. HATTORI[3], T. URABE[4];

Abstract: Chronic cerebral hypoperfusion causes white matter lesions with oxidative stress and cognitive impairment, and in turn induces limited regeneration of oligodendrocytes. However, the biological mechanisms that regulate axonal plasticity under chronic cerebral hypoperfusion have not been fully investigated. Here, we investigated whether L-carnitine, an anti-oxidant agent, enhances axonal plasticity and oligodendrocyte expression, and explored the signalling pathways that mediate axonal plasticity in a rat chronic hypoperfusion model. Adult male Wistar rats subjected to ligation of the bilateral common carotid arteries were treated with or without L-carnitine. Immunohistochemical and western blot analyses, and behavioural tests were performed after ligation of the bilateral common carotid arteries. L-carnitine-treated rats exhibited significantly reduced escape latency at 28 days after operation in the Morris water maze task. L-carnitine increased levels of phosphorylated high-molecular weight neurofilament (pNFH), concurrent with reduction of phosphorylated phosphatase tensin homolog deleted on chromosome 10 (PTEN), and increases of phosphorylated Akt and mammalian target of rapamycin (mTOR), as well as reduction of semaphorin 3A at 28 days after chronic hypoperfusion. Axonal phosphorylated Akt and mTOR protein were present in pNFH+ axons at 28 days in the L-carnitine-treated rats. In contrast, axons at 28 days in the vehicle-treated rats exhibited many fewer axonal phosphorylated Akt and mTOR proteins. L-carnitine reduced lipid peroxidation and oxidative DNA damage, and enhanced oligodendrocyte marker expression and myelin sheath thickness after chronic hypoperfusion. Additionally, L-carnitine facilitated myelination of phosphorylated NFH+ axons by myelin basic protein+ oligodendrocytes at 28 days after LBCCA. Collectively, these findings demonstrate that L-carnitine regulates the PTEN/Akt/mTOR signalling pathway and semaphorin 3A, and enhances axonal plasticity while concurrently ameliorating oxidative stress and increasing oligodendrocyte myelination of axons, thereby improving white matter lesions and cognitive impairment in a rat chronic hypoperfusion model.

Title: Neuronal expression of GPR3 in rodent brain is associated with cell survival

Authors: *S. TANAKA, T. MIYAGI, I. HIDE, T. SHIRAFUJI, N. SAKAI;
Dept. of Mol. and Pharmacol. Neurosci., Hiroshima Univ. Sch. of Biomed. Sci., Hiroshima, Japan

Abstract: G-protein coupled receptor (GPR) 3 belongs to a member of constitutively active Gs-coupled receptors that activate 3'-5'-cyclic adenosine monophosphate (cAMP) and is highly expressed in the brain. Previously, we have reported that the expression of GPR3 in cerebellar granular neurons (CGNs) enhances neurite outgrowth (Tanaka et al., JBC 2007) and modulates proliferation of cerebellar granule cell precursors (Tanaka et al., 2009 PLoS One); however, the physiological functions of GPR3 remain to be fully elucidated. In the present study, we investigated the survival functions of GPR3 in rodent brain. CGNs from GPR3-knockout mice demonstrated lower survival than did CGNs from wild-type or GPR3-heterozygous mice under normal culture conditions. To further investigate GPR3 function in developing cerebellar granule neurons, cerebellar sections from wild-type and GPR3 -/- pups, aged postnatal day 7, day 14, and day 21, were stained with a cleaved caspase-3 antibody. The number of caspase-3-positive cells was significantly increased in the internal granular cell layer of the cerebellum in P7, P14 and P21 GPR3 -/- mice compared with that in P7 wild-type mice. Next, we introduced a transient middle cerebral artery occlusion (tMCAO) model in wild-type and GPR3-knockout mice to determine whether GPR3 expression modulates neuronal survival after brain ischemia. After tMCAO, GPR3-knockout mice exhibited a significantly larger infarct area than did wild-type mice. Furthermore, GPR3 -/- mice indicated larger neuronal loss in the cortex and the striatum in

the ischemic hemisphere by Nissl staining, twenty-four hours after ischemia .These results indicate that intrinsic GPR3 expression is involved in neuronal survival both *in vitro* and *in vivo*.

Title: Black rice extract ameliorates bilateral common carotid artery occlusion-induced memory impairment in mice

Authors: S.-N. HWANG[1,2], J.-C. KIM[1,2], *S. YOON[3,4], M. I. H. BHUIYAN[1,2], J. KIM[1,2], S. KIM[1,2];

Abstract: Black rice is likely to be beneficial because of its nutritional facts. It has been reported that black rice contains various bioactive compounds including anthocyanin to exhibit antioxidant activities. In addition, it has been demonstrated that black rice extract significantly reduces atherogenic progression. Until now, the effect of black rice extract on memory performance has not been elucidated. Thus, the present study was carried out to demonstrate effects of chronic treatment with the extract of black rice on bilateral common carotid artery occlusion (BCCAO)-induced memory impairment in C57BL/6 mice. Black rice extract (300 mg/kg) was orally administered once a day for 21 days. BCCAO with 23-minute occlusion time was adopted at 8th day following initial administration of the extract. From 7 days after BCCAO, Morris water maze test was performed to evaluate working and reference memory performance in mice. BCCAO profoundly resulted in impairments of both working and reference memory. The administration of black rice extract significantly ameliorated BCCAO-induced memory impairments. Additionally, black rice extract seems to have significant protective effects against BCCAO-induced hippocampal neuronal death in the CA1 area. Taken together, our results

suggest that black rice contains some ingredients which may ameliorate brain ischemia-induced memory impairments.

Title: The effects of anti-oxidants on experimental cerebral ischemia in the rat

Authors: J. PARK[1,2], J. KIM[1], S.-T. LEE[3], K.-M. LEE[3], K. PARK[1], W. LEE[1], *J. LEE[1,2]; [1]Anat., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]BK21 Plus Project for Med. Science, and Brain Res. Inst., Seoul, Korea, Republic of; [3]Neurol., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Dehydroascorbic acid (DHA), oxidized form of ascorbic acid, is able to enter the blood-brain barrier(BBB) system. Glutathione(GSH), a natural tripeptide of glutamate, cystein, and glysine, also plays an important role in reducing oxidative stress by detoxifying reactive oxygen species(ROS) and can serve as a substrate for various peroxidases. Melatonin (N-acetyl-5-methoxytryptamine, MEL) is an endogenously produced indoleamine secreted by the pineal gland and the secretion is suppressed by light. Melatonin is a highly effective antioxidant and plays a pivotal role in reducing the free radical, and has anti-inflammatory effect. The relation of DHA and GSH is known as boosting their generation through redox cycle. Previous studies focused on the effect of antioxidants treated before ischemic injury. In this study, it is hypothesized that single or combinational treatment of antioxidants after cerebral ischemia reduce the brain infarct size. Each antioxidant was prepared as following; DHA(100mg/kg/mL), GSH(500mg/kg/mL), MEL(10mg/kg/mL) in a sodium bicarbonate/acetate buffer, pH 5.5. All rats of 6 groups(NC, EC, DHA 100mg/kg/mL, GSH 500mg/kg/mL, MEL 10mg/kg/mL, DHA 100mg/kg/mL+GSH 500mg/kg/mL+MEL 10mg/kg/mL) were subjected to ischemic condition

for 90 min. Treatments of each prepared antioxidants were administered at the start of reperfusion. All Rats were sacrificed to confirm the volume of brain infarct 1 day after ischemic injury. Unlike our expectation, it was shown that the combinational treatment of antioxidants did not have protective effects on focal cerebral ischemia, but the infarct sizes were significantly reduced in DHA or GSH treatment groups. These results show the potential of antioxidant as therapeutic drug candidate in cerebral ischemia.

Title: The glial neuropeptide ODN worsens excitotoxic and ischemic cell death *in vivo*

Authors: *R. LAMTAHRI[1,2], B. LEFRANC[1], D. VAUDRY[1], J. LEPRINCE[1], J. CHUQUET[2]; [1]INSERM U982, Mont Saint Aignan, France; [2]Univ. of Rouen, INSERM U982, Rouen, France

Abstract: ODN is a biologically active fragment corresponding to the amino-acid residues 33-50 of diazepam binding inhibitor (DBI). This neuropeptide, is synthesized by astrocytes and is known to be involved in various neurobiological processes such as neurogenesis, central glucose sensing and calcium dynamics in astrocytes. We have recently shown that ODN protects cultured astrocytes and neurons from a lethal oxidative stress. The objective of the present work was to test, *in vivo*, the neuroprotective potential of ODN in stroke and in NMDA-induced brain damage. Focal cerebral ischemia was induced in mice by the transient occlusion of the middle cerebral artery (MCA) for 60 min. On average, both groups underwent a similar reduction of blood flow in the MCA territory as measured by laser-doppler flowmetry (control 40.30.6% *vs* treated 45.70.5%, respectively). ODN (1 µg/3 l) or its vehicle solution was injected in the ipsilateral ventricle 20 min before the onset of ischemia. For NMDA induced brain damage, mice received a mix of NMDA (20 nmol) and ODN (1 µg in 0.5 l) or its vehicle solution into the right striatum. In both model, the volume of the lesion was quantified 48 h later. In cerebral ischemia, administration of ODN resulted in an increase of the infarction volume (51%; $P<0.05$) accompanied by an increase in the brain edema volume (42%; $P<0.05$) although ODN is not toxic *per se*. For the excitotoxic lesion model, the co-administration of ODN and

NMDA also resulted in an increase in the lesion volume (87%; $P<0.05$). Our measurement of physiological parameters shows that this deleterious effect of ODN cannot be explained by a hyperthermic, a cerebrovascular or a cardiovascular effect induced by central ODN administration. Therefore, the neuroprotective potential of ODN seen *in vitro* seems overtaken *in vivo* by an exacerbation of excitotoxic processes likely to be caused by it's inverse agonist effect on the GABA-A receptor.

Title: Intranasal salvinorin A reduces cerebral ischemia/reperfusion injury in mouse middle cerebral artery occlusion model

Authors: C. CHEN[1], C. XI[1], J. MA[1], T. ABEL[2], *R. LIU[1];
[1]Dept. of Anesthesiol. and Critical Care, [2]Dept. of Biol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Aims: In this study, we investigated the effect of intranasal administration of SA in focal cerebral ischemic injury and the related mechanisms. **Methods:** The middle cerebral artery occlusion (MCAO) model was established using C57/BL6 male adult mice. The 120 minutes occlusion of MCA was induced by silicon-coated suture followed by 24 hr reperfusion. SA of different doses was administered intranasally after 120 min ischemia and when reperfusion was established. Norbinaltorphimine (2.5mg/kg, i.p.), a KOR antagonist, was given prior to administration of SA for an additional group given 50 ug/kg of SA. After 24 hr reperfusion, neurobehavioral outcome was investigated, infarct volume and Evans blue extravasations were determined. Nissl staining was used for the evaluation of neuronal morphological changes. Immunohistochemistry and western blot were performed to detect the activated caspase-3, eNOS, iNOS, IL-10 and TNF-alpha to investigate the apoptotic and inflammatory changes. **Results:** SA reduced infarct volume (as indicated in figure 1 using tetrazolium chloride staining) and improved neurological deficits dose dependently. Meanwhile,SA at the dose of 50ug/kg

protected the vascular integrity shown through the Evans blue extravasations. Immunohistochemistry and western blot analysis demonstrated that SA decreased the expression of cleaved casepase-3, iNOS, IL-10 and TNF-alpha in the penumbra areas, but increased the expression of eNOS. All these effects were blocked by Norbinaltorphimine. **Conclusions:** Salvinorin A alleviated ischemic brain injury by activation of KOR and eNOS, inhibition of iNOS, caspase-3 and inflammation factors such as IL-10 and TNF-alpha, suggesting that SA is neuroprotective. **Figure 1:** Tetrazolium chloride staining shows that intranasal salvinorin A (SA) reduced infarct volume (white area) dose dependently. Sham, control group without ischemia, MCAO, middle cerebral artery occlusion group; SA12.5; SA25; or SA50 represent middle cerebral artery occlusion with 12.5 ug/kg, 25 ug/kg, or 50 ug/kg (SA).

Title: Effect of mannitol on neurogenesis in a model of ischemic stroke

Authors: ***Y. CRUZ**[1], J. KIM[1], V. GÁLVEZ[1], E. GARCÍA-VENCES[1,2], A. IBARRA[1]; [1]facultad de ciencias de la salud, Univ. Anáhuac, México, Mexico; [2]INMEGEN, México, Mexico

Abstract: Stroke is a neurological disorder caused by the occlusion of cerebral arteries. The occlusion results in diminished cerebral blood flow triggering a series of events such as excitotoxicity, apoptosis and inflammation that eventually leads to neuronal death. Mannitol is used in the treatment of many neurological conditions. This molecule functions as an osmotic agent and therefore diminishes edema; it also is capable of neutralizing free radicals and reducing tissue damage. Studies have shown that mannitol facilitates the entry of neurotrophic factors into the brain and increases the efficacy of migration and mitotic activity of many cell types. Thus, we investigated if mannitol is capable of promoting neurogenesis in a rodent model of middle cerebral artery occlusion (MCAO). Two experiments were carried out. The first evaluated neurogenesis in the acute phase (7 days post-MCAo) and the second during the chronic phase of stroke (2 months post-MCAo). The neurological deficit was evaluated weekly. Neurogenesis was evidenced using immunofluorescence techniques utilizing the following markers: BrdU (bromodeoxyuridine) which incorporates into the cell during the proliferative stage and DCX (doublecortin) which stains microtubules expressed by young neurons during their migration progress. Neurogenesis was analyzed at the subventricular zone, hippocampal dentate gyrus, and cerebral cortex. The results showed that mannitol promotes a speedier neurological recovery and a marked tendency to increase neurogenesis in the analyzed regions ipsilateral to the lesion, in both the acute and chronic post-MCAo phases. Keywords: cerebral ischemia, stroke, neurogenesis, and mannitol.

Title: The sphingosine 1-phosphate receptor agonist FTY720 (Fingolimod) provides neuroprotection against experimental stroke in aged rodents

Authors: *M. A. YENARI[1], M. KAWABORI[2], Z. ZHENG[2], J. S. KARLINER[3];
[1]Neurol, Univ. California, San Francisco and San Francisco Veterans Affairs Med. Ctr., San Francisco, CA; [2]Neurol., [3]Cardiol., SF VAMC and UCSF, San Francisco, CA

Abstract: The sphingosine-1-phosphate (S1P) receptor agonist FTY720 (fingolimod) has anti-inflammatory properties, and is indicated for use in advanced multiple sclerosis. Recent studies now show that it decreases reperfusion injury in heart, liver, and kidney. There is accumulating evidence that FTY720 is also effective against experimental ischemic brain injury through multiple immunomodulatory actions, such as limiting lymphocyte production, trafficking, and apoptosis. S1P acts through several sphingosine kinases (SK), and prior work has suggested that it may act largely through SK2 in the brain, and SK2 and SK1 in the heart. However, it is still unknown whether FTY720 can alleviate ischemic injury in aged animals and under conditions of permanent middle cerebral artery occlusion (MCAO), or whether it acts through SK1. In this study, male sphingosine kinase 1 knockout (SK1-KO) and wildtype (WT) mice (C57/BL6 background) between 52-61 weeks of age were subjected to permanent distal MCAO. FTY720 (1 mg/kg IP) was given at the time of MCAO. Lesion size, behavioral indices and markers for inflammation were studied. Lesion size and behavior were no different between WT and SK1-KO mice; however, both WT and SK1-KO mice given FTY720 showed significant improvement in motor function and reduction of infarct size (WT; 28% reduction, KO; 48% reduction vs vehicle treated controls) at day 1. Apoptotic cells were significantly decreased in both treated groups compare to non-treated groups, but there was no difference in microglial activation in any of the groups. These data suggest that activation of sphingosine 1-phosphate receptor by FTY720 is neuroprotective, and is not dependent on SK1. The mechanism is also independent of any microglial activation, but does protect against permanent MCAO (brain ischemia without reperfusion) in older mice.

Title: Effect of low dose of recombinant human erythropoietin (rhEpo) administered intranasally on MAPK-mediated signaling regulating the transition of G1 / S on brain ischemia/reperfusion injury in adult rats

Authors: *R. CASTAÑEDA ARELLANO, A. FERIA-VELASCO, M. UREÑA GUERRERO, M. RIVERA-CERVANTES;
Univ. de Guadalajara, Zapopan, Mexico

Abstract: The erythropoietin in the nervous system is a neuroprotective potential factor for cerebral ischemic damage due to binding specific erythropoietin-receptor and that this interaction is associated at survival-mechanisms through signaling pathways that lead to the pro-apoptotic-neuronal regulation. Especially when high doses are administered of recombinant human erythropoietin (rhEpo) increases both endogenous Epo and its receptor expression that stimulates the survival and cellular proliferation. The purpose of this work was to assess whether a rhEpo-low dose (500UI/Kg) intranasal administered induces cell survival through MAPK-pathway that regulates G1/S phase transition and could exert a neuroprotective effect. Results shown using a low dose of rhEpo led to decrease the neuronal loss and neurodegenerative pattern caused by ischemia both in CA1 and dentate gyrus of hippocampus. This protective mechanism was mainly by increased MEK1-ERK1/2-Elk-1-c-Jun pathway and decreased p38-pathway expression leading to regulation of cell cycle effectors such as p16 and retinoblastoma. It is proposed as a major survival pathway that determines the neuronal fate of re-entry to cell cycle and consequently apoptosis.

Title: Glucosamine neuroprotection in a rat model of cerebral ischemia: Molecular mechanisms at play

Authors: *J. RENGIFO[1], A. VERA[1,3], C. F. CARDOZO[1], M. J. CRUZ[1], L. I. MOSQUERA[1], E. VIVEROS[1], C. A. ARANGO[2];
[1]Facultad de Ciencias Naturales, [2]Facultad de Ciencias de la Salud, Univ. Icesi, Cali, Colombia; [3]Univ. de Caldas, Manizales, Colombia

Abstract: A growing number of studies demonstrate that supplementation of glucosamine (which increases protein O-GlcNacylation levels) has cytoprotective effects in multiple organ systems. More than 3,000 nuclear and cytoplasmic proteins are now known to be transiently modified by the O-linked attachment of the monosaccharide b-N-acetylglucosamine (O-GlcNAc) to their serine and/or threonine residues and, like phosphorylation, O-GlcNAcylation has proven to be a highly dynamic and ubiquitous protein modification. Indeed, for many proteins it has been demonstrated that phosphorylation and O-GlcNAcylation are reciprocal modifications that regulate protein function. In multiple forms of cellular stress, including ischemic stress, it has been demonstrated that an acute increase of O-GlcNAc levels is an endogenous response to stress and that strategies that augment O-GlcNAc levels are pro-survival, whereas those that reduce O-GlcNAc levels are deleterious. Results from our group, and others, show that glucosamine administration reduces the size of the infarct in the rat Middle Cerebral Artery Occlusion (MCAO) model. Here we evaluate the participation of several proteins in the neuroprotection generated by glucosamine; MAP-2 and Tau, cytoskeleton associated proteins, and Akt, GSK-3b and Bcl-2, proteins implicated in the regulation of apoptosis. Using western blotting and fluorescent inmunohistochemistry we studied the protein levels of expression, phosphorylation and O-GlcNAcylation in the cerebral cortex, hippocampus and substantia nigra of the rat brain. There was no significant difference in the expression levels of these proteins in the ischemic rat brain with or without glucosamine treatment. But for some of these proteins, our results indicate that glucosamine supplementation in ischemia reduces protein phosphorylation at some residues, indicating that an O-GlcNAcylation/phosphorylation interplay is likely to be an important regulator of the glucosamine generated neuroprotection.

Title: Mechanisms of neuroinflammation in rat model of subarachnoid hemorrhage

Authors: *C. TOSUN[1], C. HONG[2], D. KURLAND[2], V. GERZANICH[2], M. SIMARD[2]; [1]Univ. of Maryland In Baltimore, BALTIMORE, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Subarachnoid hemorrhage (SAH) is a life-threatening condition and affects 27,000 people annually in the United States. The mortality rate approaches 30% acutely in hospitalized patients with SAH and survivors exhibit long-term neurological deficits. Recently, our laboratory has provided evidence that the sulfonylurea receptor type 1 (Sur1) and transient receptor potential channel member 4 (Trpm4) is transiently upregulated and co-associate to form the Sur1-Trpm4 channel in humans and rats following SAH. Previous work has implicated that opening of this channel is responsible for tissue swelling, cell death and formation of hemorrhagic transformation in animal models of CNS injury. Activation of TLR4 signaling pathways also upregulate the Sur1/Trpm4 channel and can play a major role in fine tuning the activities of inflammatory cells. Here, we tested whether pharmacologically blocking the Sur1/Trpm4 channel with glibenclamide would reduce SAH-induced neuroinflammation. 50ul of fresh non-heparinized autologous tail blood was injected bilaterally into the subarachnoid space of the entorhinal cortex. 48 hour after the injection of blood sections were labelled for markers of neuroinflammation. Vehicle treated rats had significantly higher numbers of microglia labelled with Iba-1 in the entorhinal cortex when compared to shams. Glibenclamide treatment following SAH significantly reduced the number of microglia, and were not different from shams. Vehicle treated rats had prominent astrogliosis in the entorhinal cortex marked by GFAP, and treatment with glibenclamide was sufficient to reduce the activation of astrocytes. Similarly, the number of neutrophils in the same area was increased in vehicle treatment, whereas glibenclamide treated rats had significantly fewer neutrophils. In contrast, the number of Iba-1 positive microglia was higher in glibenclamide treated rats when compared to vehicles in the hippocampus. The dynamic balance between M1/M2 microglial phenotypes has been shown to be critical following CNS injury and can be either responsible for a cytotoxic response or critical in reconstitution/repair and immunosuppression. Labeling with specific microglial markers revealed that the prominent phenotype of microglia in the hippocampus is M2 in glibenclamide treated rats, while the majority of microglia is M1 in vehicle treated rats 48 hours after SAH. Taken together, specifically blocking the SUR1-Trpm4 channel following SAH is sufficient to reduce neuroinflammation in the entorhinal cortex. Glibenclamide can switch the microglial phenotype in the hippocampus and can be critical in repair mechanisms.

Sch., Nanjing, Jiangsu, China; [4]Ctr. of Cerebrovascular Dis. Research, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Stroke is a devastating neurological disorder and one of the leading causes of death and serious disability. After cerebral ischemia, revascularization in the ischemic boundary zone provides nutritive blood flow as well as various growth factors to promote the survival and activity of neurons and neural progenitor cells. Enhancement of angiogenesis and the resulting improvement of cerebral microcirculationare key restorative mechanisms and represent an important therapeutic strategy for ischemic stroke. In the present study, we tested the hypothesis that post-stroke angiogenesis would be enhanced by omega-3 polyunsaturated fatty acids (n-3 PUFAs), a major component of dietary fish oil. To this end, we found that transgenic *fat-1* mice that overproducen-3 PUFAs exhibited long-term behavioral and histological protection against transient focal cerebral ischemia (tFCI). Importantly, *fat-1* transgenic mice also exhibited robust improvements in revascularization and angiogenesis compared to wild type littermates, suggesting a potential role for n-3 fatty acids in post-stroke cerebrovascular remodeling. Mechanistically, n-3 PUFAs induced upregulation of angiopoietin 2 (Ang 2) in astrocytes after tFCI and stimulated extracellular Ang 2 release from cultured astrocytes after oxygen and glucose deprivation. Ang 2 facilitated endothelial proliferation and barrier formation *in vitro* by potentiating the effects of VEGF on phospholipase Cγ1 and Src signaling. Consistent with these

findings, blockade of Src activity in post-stroke *fat-1* mice impaired n-3 PUFA-induced angiogenesis and exacerbated long-term neurological outcomes. Taken together, ourfindings strongly suggest that n-3 PUFA supplementation is a potential angiogenic treatment capable of augmenting brain repair and improving long-term functional recovery after cerebral ischemia.
Key words: angiogenesis, angiopoietin 2, astrocyte, neuroprotection, omega-3 polyunsaturated fatty acids, stroke, VEGF

Title: Resveratrol increases phosphorylated AMPK in cerebral ischemia

Authors: N. PINEDA-RAMIREZ[1], A. ORTIZ-PLATA[1], J. PEDRAZA-CHAVERRI[2], *P. AGUILERA[1], M. ESPINOZA-ROJO[3];
[1]Patologia Vascular Cerebral, Inst. Nacional de Neurologia y Neurocirugia, Mexico Distrito Federal, Mexico; [2]Dept. de Biología, Facultad de Química, Univ. Nacional Autónoma de México, DF, Mexico; [3]Lab. de Biología Mol. y Genómica, Univ. Autónoma de Guerrero, Chilpancingo, Mexico

Abstract: Cerebral Ischemia results from occlusion of a major cerebral artery and involves a sequence of molecular events that can induce either cell death or cell survival through diverse mechanisms. Decrease of cerebral blood flow restricts the delivery of substrates predominantly oxygen and glucose with consequent decline in the metabolism of energy. Interestingly, neuronal cell death can be prevented by modulating the energetic state of the cell. Antioxidants such as resveratrol (RSV) exert a neuroprotective effect in rats subjected to ischemia by increasing mitochondrial function through mechanisms closely associated with glucose metabolism and activation of ATP generating pathways in which AMP-activated kinase (AMPK) is involved. Objective: We investigated whether treatment with RSV regulates AMPK phosphorylation

following an ischemic cerebral event. Methods: Male Wistar rats (250 to 350g) were subjected to transient middle cerebral artery occlusion (MCAO) for 2 h followed by reperfusion (R). A dose of RSV (1mg/kg; i.v.) diluted in 50% ethanol, was given at the beginning of R. The rats were sacrificed at different times of R (0, 15, 30, 60 and 120 min). The AMPK and the phosphorylated AMPK (pAMPK) levels were evaluated by Western Blotting. Rat primary neuronal culture (from E18 embryos) was used to assed the mitochondrial membrane potential ($\Delta\Psi m$) using the fluorescent probe JC- 1 (3 μM). Results: MCAO does not change total AMPK but increased pAMPK levels. R induced an increase on pAMPK level after 15 min (93%) that peaks after 120 min (145%) of R. RSV increased pAMPK in control group (74.6 %). RSV also induced an increased after MCAO and R. The peak of pAMPK induced by RSV was observed after 15 minutes of R (203.3%). Significant changes were observed in the $\Delta\Psi m$ after treatment with RSV. Discussion: pAMPK levels were increased after MCAO and remained elevated up to 120 min of R. RSV induced an additional increase on pAMPK levels in MCAO groups. This transient effect of RSV was observed after short times of R. It is possible that the RSV mechanism of action might be related to AMPK activation since this enzyme modulates the energetic state of cell which is relevant to survival after ischemia

Title: Cortical microcirculation in a mouse model of subarachnoid hemorrhage

Authors: ***K. SCHUELLER**, N. PLESNILA;
ISD, Munich, Germany

Abstract: Subarachnoid hemorrhage (SAH) is a subtype of stroke, which leads to a mortality of 21% in patients within the first day after the bleeding (Pobereskin, 2001). Recently the term of early brain injury has been established to describe the cerebral pathophysiology following SAH. It may be caused by elevated intracranial pressure, inflammatory processes and cerebral ischemia. After SAH pearl- string- like constrictions of pial arterioles, called microvasospasms, were detected in humans (Uhl et al., 2003) as well as in mice (Friedrich et al., 2011). The effect

of these microvasospasms on blood flow dynamics in parenchymal vessels has not been investigated. The aim of the current study was to test whether microvasospasms lead to microcirculatory dysfunction and thereby induce cerebral ischemia after SAH. The deep cerebral microcirculation was measured 3 h after the hemorrhage by 2 photon microscopy. SAH surgery was performed by endovascular Circle of Willis perforation as described previously (Feiler et al., 2010). Cerebral vessels were visualized by fluorescent plasma dyes and scanned for different parameters. Physiologic parameters were monitored during the procedure and did not differ between the SAH and SHAM surgery group. Regional cerebral blood flow was reduced significantly after SAH, indicating that cerebral ischemia develops early after the bleeding. The overall arteriolar vessel diameter as well as the blood flow velocity were significantly reduced compared to the baseline condition. Additionally the volume of perfused microvessels in deep cerebral tissue diminished significantly after SAH which indicates parenchymal perfusion deficits. In line with this finding the number of sticking leukocytes increases in deep microvessels after SAH. With this *in vivo* 2 photon microscopy study we show that microvasospasms lead to ischemia in the cerebral cortex of mice. Spastic vessels reduce cerebral blood flow and cause perfusion deficits as well as leukocyte plugging. Taken together our findings demonstrating severe dysfunction of cerebral microvessels could serve as an explanation for the ischemic brain damage observed after SAH. Thus restoration of microcirculatory flow could be a novel therapeutic target after SAH.

Title: Adenosine a2b agonist inhibits hemorrhagic transformation induced by tpa after cerebral ischemia

Authors: *Q. LI[1,2], C.-F. CHANG[2], X. HAN[2], R. KOEHLER[2], Y. ZHAI[1], J. WANG[2];
[1]Dept. of Neurology,Shanghai Ninth People's Hosp., Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China; [2]Dept. of Anesthesiol. and Critical Care Medicine,, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Thrombolysis with tissue plasminogen activator (t-PA) is currently the only pharmacologic treatment approved for patients with ischemic stroke. However, some researchers believe that tPA is associated with hemorrhagic transformation and aggravates brain damage after reperfusion. Therefore, it would be beneficial to identify a drug that could be administered with tPA to reduce the risk of hemorrhage. The aim of this study was to explore whether adenosine A2b agonists reduce the risk of hemorrhage after tPA use for ischemic stroke. Male Sprague-Dawley rats (anesthetized with 2% isoflurane in 30% oxygen and 70% air) were subjected to transient middle cerebral artery occlusion by endovascular occlusion of the left middle cerebral artery. At 1.5 hours after ischemia onset, we administered Bay 60-6583, a selective A2b agonist (1 mg/kg via intravenous [i.v.] injection) combined with an intravenous perfusion of tPA (10 mg/kg, i.v.). The suture was withdrawn after drug treatment at 2 hours after ischemia onset. At 24 hours after reperfusion, we used Western blotting to assess expression of the tight junction proteins claudin-5, zonula occludens-1 (ZO-1), and matrix metalloproteinase-9 (MMP-9). Blood-brain barrier (BBB) permeability, as demonstrated by albumin extravasation, was evaluated by Western blotting and immunohistochemistry. We evaluated hemorrhagic transformation in the rats with the intraparenchymal brain hemoglobin assay and used a battery of tests to evaluate neurologic deficits. Administration of tPA after ischemia led to an increase in hemorrhagic transformation and BBB permeability. This effect was associated with an increase in MMP-2/9 activity, which led to aggravation of the post-ischemic degradation of ZO-1 and claudin-5. tPA also aggravated ischemia-induced neurologic deficits. Combining Bay 60-6583 administration with tPA preserved the expression of ZO-1 and claudin-5, reduced hemorrhagic transformation and BBB permeability, and improved neurologic function. Our results show that A2b adenosine receptor activation is an important pathway by which tPA-induced damage to the BBB can be inhibited after cerebral ischemia. Thus, using A2b agonists as adjuvants to tPA could be a promising strategy for decreasing the risk of hemorrhagic transformation during treatment of ischemic stroke.

Title: tPA interacts with the ER stress response to protect neurones during cerebral ischaemia

Authors: M. LOUESSARD, D. VIVIEN, C. ALI, *B. D. ROUSSEL;
Cyceron, INSERM U919, Caen, France

Abstract: Stroke is the third biggest killer and the leading cause of acquired disability in adults. The only drug approved to treat ischaemic stroke is tissue plasminogen activator (tPA). However, tPA exerts multiple and antagonistic effects within the brain parenchyma. In experimental models of ischaemia it has been shown that the endoplasmic reticulum stress (ER stress) pathway is activated and it has been suggested that it may modulate positively or negatively neuronal fate, depending on its duration. To date, the potential influence of tPA on ER stress has never been addressed in appropriate models. The aim of the study was to decipher the potential link between tPA and ER stress during stroke, and its implications in ischaemia-induced cell death. We used primary cultures of neurones under oxygen and glucose deprivation (OGD) in the presence or not of tPA to characterize the ER stress response. We measured by western blots the phosphorylation level of the eukaryotic initiation factor 2 alpha (eIF2 alpha) and by qPCR the expression levels of CHOP, GADD34 and Bip, which are ER stress response markers. Neuronal death was quantified by measuring lactate dehydrogenase release . As expected, OGD induced an ER stress response, as evidenced by the phosphorylation of eIF2 alpha, and the increased expression of CHOP, GADD34 and Bip. The ER stress response decreased in the presence of tPA, suggesting that tPA acts as an ER stress inhibitor during OGD. Moreover, OGD-induced neuronal death also decreased in the presence of tPA. Guanabenz an inhibitor of ER stress also protected neurones against OGD and no additive effect was observed with it. This suggests a direct role of tPA on OGD-induced neuronal death via an inhibition of the ER stress response. We report here for the first time a direct modulation of the ER stress response by tPA, showing beneficial effects on OGD-induced cell death. We need to understand the mechanisms of action of tPA on the ER stress response, to propose a strategy of neuroprotection in an *in vivo* model of stroke. Indeed we suggest a new neuro-trophic pathway for the tPA.

Title: Neuroprotection by inhibition of p53 after asphyxic cardiac arrest involves autophagic and apoptotic mechanisms in rat hippocampus

Authors: *D. CUI[1,2], H. SHANG[4,3], W. NI[1], Y. XU[1], X. ZHANG[1], W. JIANG[1], U. BHALALA[2];
[1]Anesthesiol., Shanghai Sixth People's Hosp., Shanghai, China; [2]Anesthesiol. and Critical Care Med., [3]Dept. of Neurosurg., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Dept. of Neurosurg., Shanghai Ruijin Hosp. Affiliated with Med. Sch. of Shanghai Jiaotong Univ., Shanghai, China

Abstract: Objective: This study focuses on the contributions of the p53 signaling pathway and the molecular mechanism of autophagy activation and cell death in hippocampus following cerebral ischemia-reperfusion (I/R) triggered by asphyxic cardiac arrest(CA) . Materials and Methods: Male Sprague-Dawley rats weighing between 300 and 350 g were implanted with a cannula aimed at the left cerebroventricle for subsequent i.c.v. administration of PFT, BFA or 3-MA. Rats were intubated orotracheally with a 14-gauge cannula. After a 10-min equilibration period following surgery, asphyxia was induced by stopping mechanical ventilation and clamping the tracheal tubes at the end of expiration. After 8-min asphyxia, CPR was initiated by administering an i.v. bolus injection of epinephrine (0.02 mg/kg) and 5% (w/v) sodium bicarbonate (1mmol/kg), followed by mechanical ventilation and thoracic compressions. Main Results : Morphological and biochemical results showed activation of autophagy in hippocampal cells as evident by the increased formation of the autophagosome, the expression of active lysosomal cathepsin B and D and the microtubule-associated protein light chain 3 (LC3), and the conversion of LC3-I to LC3-II. CA upregulated the expression of tumor suppressor protein 53 (p53) and its target genes, including Bax, p53-upregulated modulator of apoptosis (Puma), and

damage-regulated autophagy modulator (DRAM). CA-induced elevations in pro-apoptotic proteins Bax and Puma and autophagic proteins LC3-II and DRAM were significantly reduced by the p53 specific inhibitor pifithrin-α (PFT). PFT also reduced hippocampal neuronal damage caused by CA. Similarly, the autophagy inhibitor 3-methyladenine (3-MA) and the lysosomal inhibitor bafilomycin A1 (BFA) significantly inhibited hippocampal neuronal damage. These results indicate that p53 exerts effects on both autophagy and apoptosis signaling pathways and that autophagy plays a significant role in the process of hippocampal neuronal cell death induced by cerebral I/R following asphyxic CA. Conclusions: Our data indicate that in addition to necrosis, cell death induced by CA contains both autophagy and apoptosis. Activation of autophagy preceded the apoptotic process and is mediated, at least partially, by p53. Autophagy contributes to CA-induced hippocampal neuronal death. Further clarification of beneficial and detrimental roles of autophagy in CA will shed new light on elucidating pathogenesis of cerebral ischemic diseases involving protein misfolding.

Title: Do allografts of rat umbilical cord blood cells decrease infarct size to the same extent as human umbilical cord blood cell xenografts after middle cerebral artery occlusion in the rat?

Authors: *A. E. WILLING, J. D. NEWCOMB, S. GARBUZOVA-DAVIS, P. R. SANBERG; Ctr. Excellence Aging & Brain Repair, Neurosurg., Univ. South Florida, TAMPA, FL

Abstract: A single systemic injection of human umbilical cord blood (HUCB) cells delivered at the 48 hours post-stroke decreases infarct volume 80% and improves behavioral recovery after middle cerebral artery occlusion (MCAO). These improvements are associated with a reduction in both local inflammation in the brain and inhibition of the systemic immune response to the stroke. Our main hypothesis is that the mononuclear cell (MNC) fraction of the umbilical cord blood (UCB) decrease infarct size and improve stroke outcome by decreasing the

immune/inflammatory responses after stroke. Further, these cells will produce these effects regardless of whether they transplanted within species (rat (R) UCB cells into rat; allograft) or across species (HUCB into rat; xenograft). In order to address this hypothesis, we examined 1) the cellular composition of the MNC fraction of RUCB and HUCB cells compared to adult R MNCs and H MNCs; and 2) whether RUCB cells will decrease infarct size even more than xenografted HUCB cells. In the first study, samples of RUCB, HUCB, adult rat and human MNC underwent flow cytometric analysis to determine the distribution of T cells, B cells, monocytes and stem cells within the MNC fraction. HUCB cells had significantly more naïve T cells ($p < 0.001$) and significantly fewer cytotoxic T cells ($p < 0.05$) and stem cells ($p < 0.001$) than RUCB. When the RUCB and HUCB MNCs were injected intravenously 48 hours after MCAO and infarct size measured two weeks later, the smallest infarcts were present after HUCB administration, while infarcts in the RUCB group were similar to MCAO only group. These differences in the percentage of naïve T cells, cytotoxic and stem cells between RUCB and HUCB may have contributed to the differential effects of the allografted RUCB and the xenografted HUCB cells on infarct size. Alternatively, differences in immune functional capacity of the allografted and xenografted cells may have contributed to the observed results.

Title: The origin of self-renewing stem cells in the cortex after stroke

Authors: *M. FAIZ[1], N. SACHEWSKY[2], R. DESAI[1], C. MORSHEAD[2], A. NAGY[1]; [1]Lunenfeld-Tanenbaum Res. Inst., Mount Sinai Hosp., Toronto, ON, Canada; [2]Univ. of Toronto, The Donnelly Ctr., Toronto, ON, Canada

Abstract: Under physiological conditions, adult neural stem cells (NSCs) in the SVZ give rise to neuroblasts that migrate to the olfactory bulb and give rise to new neurons. Brain injury elicits a response from NSCs and causes a deviation in the migration of progenitor cells to sites of damage. In response to damage, resident astrocytes also respond and contribute to the process of ongoing gliosis. Recently, it has been suggested that reactive astrocytes have a potential for self-renewal and multipotency and show neurosphere formation *in vitro*. However, both endogenous stem cells from the SVZ or de-differentiated reactive astrocytes have so far been limited in their potential to regenerate the brain. In order to increase the availability of cells present at the site of injury, recent effort has been focused on using the power of cellular reprogramming to convert astrocyte to NSC or neurons. Here, we investigate the origin of cortical-derived stem cells following a mild cortical stroke. Lineage tracing using inducible Nestin-CreER^{T2};tdtomato^{fl} mice showed that cortical-neurospheres are derived from SVZ precursor cells that migrate to the lesion site early after an insult. A small population of stem cells persists at later time points post stroke, while the majority of cells rapidly differentiate and give rise to a subpopulation of reactive astrocytes (derived from SVZ cells) that contributes to the ongoing gliosis. Lastly, we show that forced expression of transcription factor, Ascl1 can efficiently reprogram SVZ-derived reactive astrocytes to neurons, a novel way to boost endogenous neurogenesis.

Title: Glutamate metabolism by inducible glutamate oxaloacetate transaminase protects stroke-affected brain

Authors: *S. KHANNA, S. GNYAWALI, J. WEIST, S. ROY, C. K. SEN, C. L. RINK; Surgery, Ohio State Univ., COLUMBUS, OH

Abstract: Glutamate serves multi-faceted (patho)physiological functions in the CNS as the most abundant excitatory neurotransmitter and under pathological conditions (i.e. ischemic stroke) as potent neurotoxin. The current work stems from our key observation demonstrating that induction of glutamate oxaloacetate transaminase (iGOT), a glutamate metabolizing enzyme in the brain, can attenuate stroke-induced injury. We have recently reported that by correcting the hypoxia component of stroke injury by supplementing oxygen (OH, oxygenated hypoxia) during stroke GOT level were significantly increased and glutamate levels were markedly reduced in stroke-affected brain. We hypothesize that under OH extracellular glutamate is taken up directly by neural cells and metabolized through a truncated TCA cycle. NMR spectroscopy was employed for *in vitro* and *in vivo* experiments to assess glutamate metabolism. For *in vitro* studies, primary cortical neuronal cells were incubated with [U13C]Glu for 4h under control and OH conditions. Under control conditions, greater proportion of [U13C] glutamate was metabolized and re-synthesized to [1,2,3-13C]Glu. In OH, less [U13C] was re-synthesized and [U13C]Aspartate was emerged as new metabolite supporting metabolism of glutamate via truncated TCA cycle. Next, 9.4T NMR spectroscopy was performed to assess spatial resolution of Glu and ATP distribution during stroke in mouse brain penumbra. Glutamate concentration was lower in penumbra stroke hemisphere of mouse receiving 100% inhaled oxygen. On the other hand, stroke-related loss of high energy phosphates were rescued by 100% inhaled oxygen. In this work we have identified that increased GOT in brain attenuates stroke injury by metabolizing extracellular glutamate via a truncated TCA cycle.

Abstract: Disruption of the blood brain barrier (BBB) is an antecedent event to intracerebral hemorrhage (ICH) in ischemic stroke. Interestingly, our previous studies showed that BBB disruption occurred within the thrombolytic time window of acute cerebral ischemia and tight junction protein occludin was damaged. However, the mechanism of this acute BBB disruption remains less well known. In the present study, we sought to determine whether hypoxia-inducible factor 1α (HIF-1α) and vascular endothelial growth factor (VEGF) play a role in ischemia induced BBB damage within the thrombolytic time window. Rats were subjected to 2 hrs filament occlusion of the middle cerebral artery (MCAO), followed by 10 min reperfusion. Successful MCAO was confirmed by 2,3,5-triphenyltetrazolium chloride (TTC) staining. Evans blue was injected to observe BBB damage, and HIF-1α and VEGF was detected by western blot and Immunohistochemistry. Extravasation of Evans blue was seen in brain sections after 2 hrs MCAO, with the tracer leakage limited to subcortical regions and the piriform cortex, indicating BBB damage, the expression of VEGF and HIF1α markedly increased at where the BBB was damaged, the tight junction protein occludin was degraded. Pretreatment with YC-1 (2 mg/kg, intra-vein, 30 min and 24 h before MCAO) significantly decreased VEGF expression, prevented the degradation of occludin and alleviated BBB damage. Taken together, early acute cerebral ischemic lead to HIF1α activate VEGF, which eventually leads to disruption of tight junction proteins BBB disruption. These findings may illustrate the effect of HIF1α and VEGF in early ischemic BBB injury, and may provide new ideas and strategies to extend the time window of thrombolysis, reduce cerebral hemorrhage caused by thrombolytic.

Abstract: Nicotinamide phosphoribosyltransferase (NAMPT) has been implicated in neuroprotection against ischemic brain injury, but the mechanism underlying its protective effect remains largely unknown. To further examine the protective effect of NAMPT against ischemic stroke and its potential mechanism of action, we generated a novel NAMPT transgenic mouse line. Transgenic mice and wild-type littermates were subjected to transient occlusion of the middle cerebral artery (MCAO) for 60 min. NAMPT overexpression significantly reduced infarct volume and improved long-term neurological outcomes compared to littermates. Interestingly, NAMPT transgenic overexpression significantly increased the area of myelin expression following ischemia compared to wild-type ischemic littermates, indicating that NAMPT protects against white matter injury. These data suggest a novel role for NAMPT in the protection of white matter following ischemic injury.

Title: Proinflammatory role of Receptor Interacting Protein-3 (RIP3) in Ischemia induced neuronal cell death

Authors: *D. C. GILLIS, S. KIM, J. LI;
Vet. Integrative Biosci., Texas A&M Univ., College Station, TX

Abstract: Pro-inflammatory role of Receptor Interacting Protein-3 (RIP3) in Ischemia induced neuronal cell death D. Christopher Gillis, Sunja Kim, Jianrong Li Department of Veterinary Integrative Biosciences, Texas A&M University, College Station, TX 77843 Ischemic tissue damage to the developing brain leads to death of the CNS resident cells and adverse long-term neurological deficits. Recent revelation that certain necrotic cell death is regulated by the Receptor Interacting Protein-3 (RIP3) suggests that programmed necrotic cell death mechanism may contribute to ischemic brain injury. As RIP3 is also implicated in promoting pro-inflammatory responses, we investigated the role of RIP3 in ischemia-induced neuronal damage as well as inflammation-induced potentiation of the neuronal damage. When we stimulated organotypical hippocampal slices with lLipopolysaccharide (LPS), a TLR4 ligand, we found that $RIP3^{-/-}$ slices exhibited decreased production of proinflammatory cytokines and chemokines such as IL-1β, IL-6, CCL2, CCL3, and CCL5 as compared to wild type $RIP3^{+/+}$ slices. LPS pretreatment markedly exacerbated Oxygen Glucose Deprivation (OGD)-induced CA1 neuronal death in wild type hippocampal slices, but to a much less extent in $RIP3^{-/-}$ slice cultures. These results demonstrate that pro-inflammatory microglial activation perpetuates neuronal damage after OGD by activating the RIP3 pathway. To determine the role RIP3 plays *in vivo*, we used a mouse neonatal hypoxia-ischemia model (HI), which involves permanent ligation of the right common carotid artery followed by exposure to a low oxygen environment. This experimental model revealed a potential role for microglia in ischemic brain injury. Further analysis of respective brain samples from $RIP3^{-/-}$ versus $RIP3^{+/+}$ mice is ongoing, and preliminary results show differences in neuronal populations. Finally, we seek to examine the developing brain of from $RIP3^{-/-}$ versus $RIP3^{+/+}$ mice after systemic pro-inflammatory challenge using LPS.

Title: Hyperoxia activates microglia but reduces apoptosis in the neonatal rat brain

Authors: *Y. PANG[1], L.-T. TIEN[2], X. DAI[3], J. SHEN[1], Z. ZHU[1], A. BHATT[1], L.-W. FAN[1]; [1]Univ. Mississippi Med. Ctr., Jackson, MS; [2]Med., Fu Jen Catholic Univ., New Taipei City, Taiwan; [3]Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Oxygen supplement is routinely used to care for premature infants due to their lung immaturity. High oxygen levels (hyperoxia) are well known to cause damage to retina in premature infants by generating excessive reactive oxidative species. Recent clinical data suggest that hyperoxia is associated with long-term adverse neurological outcomes in premature infants; however, the underlying mechanisms remain elusive. The aims of this study were to test: 1. whether hyperoxia exposure affects programmed neuronal death, which is an important developmental program in controlling neuronal numbers; and 2. whether hyperoxia exposure affects glial development. Rat pups at postnatal P4 were exposed to 85% oxygen for 48 h. On P6, brain sections were prepared for TUNEL and immunohistochemical studies. Our results showed there were extensive TUNEL+ cells in the control P6 rat brain, which were mostly abundant in the deep subcortical nuclei such as the basal ganglia, thalamus, and nucleus accumbens. Hyperoxia exposure significantly reduced the number of TUNEL+ as well as caspase-3+ cells in all these brain regions. In contrast, hyperoxia exposure markedly activated microglia in the periventricular region, indicated by increased amoeboid microglia labeled with Iba1 antibody. Hyperoxia also enhanced the immunoreactivity of Rip, a marker for immature oligodendrocytes. Our data suggest neonatal exposure to hyperoxia may lead to aberrant early neurodevelopmental programs, resulting in adverse neurological outcomes.

Title: Computational modeling of cytokine signaling in microglia

Authors: *W. D. ANDERSON, H. MAKADIA, J. SCHWABER, R. VADIGEPALLI; Thomas Jefferson Univ., PHILADELPHIA, PA

Abstract: Neuroinflammation due to glial activation has been linked to many CNS diseases, including Alzheimer's disease, epilepsy, neuropathic pain, and neurogenic hypertension. While etiologies vary, correlation between neuroinflammation and disease suggests that CNS inflammation may underlie the genesis and/or perpetuation of many pathological states. Because precision in the mechanistic understanding of how intercellular cytokine interactions coordinate the inflammatory milieu is limited in statistical analyses of expression data, we employed a dynamic modeling approach that permits the assessment of system control mechanisms using robustness analyses and targeted perturbations. We developed a microglial cytokine interaction network model to assess potential novel mechanisms of glial activation by employing Delay Differential Equations. The model has six nodes, 12 activating connections (e.g., TNFα promotes TGFß production), and 12 inhibitory connections (e.g., TGFß inhibits TNFα production), all of which were validated based on available literature. A model fit to cytokine data from LPS-stimulated cultured microglia demonstrated that the model captures the dynamics of experimentally observed cytokine production. Variance-based parametric sensitivity analysis suggested that that TNFα is highly sensitive to negative feedback from TGFß and IL-10. Consistent with experimental data, the model showed tolerance in the TNFα response to repeated doses of LPS. While both TGFß and IL-10 inhibit TNFα via feedback, IL-10 knockout (KO) enhanced TNFα tolerance whereas TGFß KO hyper-sensitized the TNFα response to repeated LPS stimuli. The contrasting effects of TGFß versus IL-10 occurred because the IL-10 KO enhanced the initial TNFα peak response, which resulted in subsequent TGFß activation and robust negative feedback, thereby rendering TNFα unresponsive to a second dose of LPS. Thus, IL-10 decreased tolerance by restraining the influence TNFα on TGFß. The mechanism of TNFα tolerance to LPS involved TGFß up-regulation following the initial LPS dose, consistent with data. Simulations examining adaptation of the TNFα response to LPS suggested that TGFß controls adaptation by modulating the steady-state response to LPS, with negligible effect on the peak TNFα response. In contrast, IL-10 primarily controlled the TNFα peak amplitude following LPS, without an effect on adaptation. In summary, our model simulations and analysis results predict that TGFß and IL-10 have prominent and contrasting roles in regulating microglia activation, suggesting potential for targeted therapeutic interventions against neuroinflammation.

Title: Idebenone stimulates mitochondrial respiration and attenuates nitric oxide production by activated microglial cells

Authors: *E. A. BORDT[1,2], P. STUDLACK[1], M. HANSCOM[1], S. X. GE[1,2], B. M. POLSTER[1,2];

Abstract: Microglia, the innate immune cells of the brain, survey their environment and maintain a healthy milieu through clearance of debris. Microglia enter an activated state following brain injury and release various proinflammatory factors such as nitric oxide and reactive oxygen species, which in excess are toxic. Using the Seahorse XF24 Extracellular Flux Analyzer to measure cellular oxygen consumption, we found that respiration was impaired following activation of rat HAPI microglial cells with lipopolysaccharide (LPS) and interferon-γ (IFN-γ). We tested the hypothesis that the cell permeable short chain Coenzyme Q analogue idebenone will bypass respiratory inhibition following microglial activation and reduce the release of proinflammatory mediators. Co-treatment of HAPI microglial cells with idebenone (20-40 μM) resulted in a marked decrease in the release of nitric oxide in response to LPS plus IFN-γ. In addition, idebenone partially rescued the respiration of activated cells when added 8-18 hours post LPS/IFN-γ treatment. Because idebenone is thought to shuttle reducing equivalents from cytoplasmic NAD(P)H to complex III of the electron transport chain, we tested the effect of electron transport chain inhibitors on the ability of idebenone to impair activation-induced nitric oxide production. The complex III inhibitor antimycin A but not the complex I inhibitor rotenone attenuated the ability of idebenone to diminish the LPS plus IFN-γ-induced release of nitric oxide without themselves altering nitric oxide release, consistent with the possibility that idebenone influences microglial activation by restoring mitochondrial electron transport. Overall, our results indicate that idebenone attenuates proinflammatory microglial nitric oxide

production, possibly through a mitochondrial mechanism. The safety of idebenone in humans is already well established. Our findings suggest that idebenone may be clinically useful for a number of additional neurodegenerative disorders with a neuroinflammatory component.

Title: Liver X receptor-dependent inhibition of microglial inducible nitiric oxide synthase

Authors: *U. OH, J. MCVOY;
Neurol., Virginia Commonwealth Univ. Sch. of Med., Richmond, VA

Abstract: The nuclear receptor liver X receptor (LXR) exerts transcriptional control over reverse cholesterol transport and inflammatory response in cells of the myeloid lineage, suggesting that LXR may be a potential target in a number of chronic neuroinflammatory and neurodegenerative diseases where persistent microglial activation has been implicated in the pathogenesis. Questions regarding endogenous LXR activation in the central nervous system (CNS), mechanism of transcriptional repression and the response to LXR agonist in the setting of established CNS inflammation remain. The effect of LXR activation on microglia and CNS inflammation was studied using a synthetic LXR agonist in cultured microglia, microglial cell line and experimental allergic encephalomyelitis (EAE), an animal model of CNS inflammation. LXR activation inhibited iNOS expression and the production of nitric oxide in lipopolysaccharide (LPS)-stimulated microglia. Inhibition of microglial response to interferon-γ was less reliable. LXR-dependent iNOS repression was associated with inhibition of histone 4 acetylation and of NF-kappaB p50 binding at the iNOS promoter. The addition of histone deacetylase inhibitor or HDAC3 siRNA partially reversed the LXR-dependent inhibition of nitric oxide production, suggesting that the histone deacetylase activity is mechanistically important for LXR-dependent transcriptional repression. Analysis of CNS gene expression in EAE showed that LXR and LXR-dependent genes expressions were downregulated in the setting of CNS

inflammation. Nevertheless, administration of LXR agonist GW3965 during the effector phase of EAE improved clinical disease and reversed the diminished LXR-dependent gene expression with respect to the genes involved in reverse cholesterol transport. However, the gene expression of iNOS and other inflammatory genes were not significantly inhibited by LXR activation in the CNS. In conclusion, LXR activation exerts transcriptional repression of iNOS in LPS-stimulated microglia, in part through associated HDAC activity, but endogenous CNS LXR activity was downregulated in the setting of EAE. The administration of LXR agonist reversed the downregulation of reverse cholesterol transport, but suppression of inflammatory genes in the CNS was less reliable.

Title: The role of macrophage scavenger receptor A (SR-A) in macrophage polarisation

Authors: *A. D. GREENHALGH[1], A. KRONER[2], S. DAVID[2];
[1]McGill Univ., Montreal, QC, Canada; [2]Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Uncontrolled inflammation after central nervous system (CNS) injury and disease can result in excessive tissue damage. Timely resolution of inflammation relies on the phagocytic removal of dead and damaged cells and their components. Macrophages of both microglial and monocytic origin perform this role in the CNS by clearing material through a myriad of cell surface receptors. The class A macrophage scavenger receptor (MSR-A) is the prototypic member of a family of membrane receptors collectively termed scavenger receptors. Receptors of this group recognise modified lipoproteins and apoptotic cells and are expressed on both peripheral macrophages and microglial cells. Here we investigate the influence of the SR-A in macrophage polarization. Preliminary results using mice lacking SR-A show that two receptors involved in the pro-inflammatory response; the co-stimulatory signalling receptor CD86 and the Fc receptor CD16, are more highly expressed is bone marrow-derived macrophage (BMDM)

cultures treated with LPS, compared to BMDMs from wild type (WT) controls. Conversely, enzymes involved in suppressing inflammation; Arginase-1 and sphingosine kinase, are down regulated in SR-A null BMDMs which phagocytose myelin, compared to WT controls. These results suggest that signalling at the SR-A has an anti-inflammatory effect and further studies are under way to assess its role in the context of CNS injury.

Title: The role of Galectin-3 in α-synuclein-induced microglial activation

Authors: *A. BOZA-SERRANO[1], J. REYES[2], N. REY[3], H. LEFFLER[2], L. BOUSSET[4], U. NILSSON[5], P. BRUNDIN[3], J. VENERO RECIO[6], M. BURGUILLOS[7], T. DEIERBORG[2]; [1]Exptl. Neuroinflam. Lab., [2]Lund Univ., Lund, Sweden; [3]Van Andel Inst., Grand Rapids, MI; [4]Lab. d'Enzymologie et Biochimie Structurales, Gif-sur-Yvette, France; [5]Ctr. for Analysis and Synthesis, Lund, Sweden; [6]Univ. de Sevilla, Sevilla, Spain; [7]Karolinka Institutet, Stockholm, Sweden

Abstract: Abstract Background: Parkinson's disease (PD) is the most prevalent neurodegenerative motor disorder. The neuropathology is characterized by intraneuronal protein aggregates of α-synuclein and progressive degeneration of substantia nigra dopaminergic neurons. It is believed that neuroinflammation contributes to the neurodegenerative process. Previous studies have shown that extracellular α-synuclein aggregates activate microglial cells and induce inflammation. The signaling pathways involved in α-synuclein-mediated microglia activation are poorly understood. Galectin-3 is a member of a carbohydrate-binding protein family. It is involved in inflammation in different tissues and is expressed in the brain. Therefore, we investigated whether galectin-3 is involved in the microglia activation triggered by α-

synuclein. **Results:** We cultured microglial (BV2) cells and induced cell activation by addition of exogenous α-synuclein monomers and aggregates to the culture medium. This caused a significant increase in the levels of proinflammatory mediators including the inducible Nitric Oxide Synthetase (iNOS), interleukin 1 Beta (IL-1β) and Interleukin-12 (IL-12). We then reduced the levels of galectin-3 expression using siRNA or pharmacologically inhibited galectin-3 activity using bis-(3-deoxy-3-(3-fluorophenyl-1*H*-1,2,3-triazol-1-yl)-β-D-galactopyranosyl)-sulfane. Both these approaches led to a significant reduction in the observed inflammatory response induced by α-synuclein. We confirmed these findings using primary microglial cells obtained from galectin-3 null mutant mice. Finally, we performed injections of α-synuclein in the olfactory bulb of wild type mice and observed that some of the α-synuclein was taken up by activated microglia that were immunopositive for galectin-3. **Conclusions:** We show that α-synuclein aggregates induce microglial activation and demonstrate for the first time that galectin-3 plays a significant role in microglia-induced activation by α-synuclein. These results suggest that genetic down-regulation or pharmacological inhibition of galectin-3 might constitute a novel therapeutic target in α-synucleinopathies that includes PD. **Keywords:** Microglia, Galectin-3, Neuroinflammation, α-synuclein, Parkinson's Disease

Title: Sema3A-Plexin-A1 interaction is crucial for Toll-like receptor-mediated microglial activation in the development of lipopolysaccharide-induced encephalopathy

Authors: *T. ITO[1], K. YOSHIDA[2], T. NEGISHI[2], K. YUKAWA[2];
[1]Physiol., Meijo Univ., Nagoya / Aichi, Japan; [2]Meijo, Nagoya, Japan

Abstract: Recent studies have suggested that semaphorins, a family of repulsive axon guidance molecules, may exert a crucial role in maintaining brain homeostasis by controlling microglial activity. Sema3A secreted in higher amounts from injured neurons is suggested to attenuate excessive inflammatory responses by inducing microglial apoptosis through its interaction with Plexin-A1 receptors on activated microglia. To disclose the *in vivo* role of Plexin-A1-mediated signaling in lipopolysaccharide (LPS)-induced injury in mouse brain, we examined the neuroinflammatory changes initiated by LPS administration to the cerebral ventricles of both wild-type (WT) and Plexin-A1-deficient (-/-) mice. WT mice administered LPS displayed significantly higher expression of COX-2, IL-1β, TNF-α, and iNOS in the hippocampus, and significantly greater ventricular enlargement and intracerebral infiltration of leukocytes, as compared with the saline-treated mice. In contrast, Plexin-A1-/- mice administered LPS did not show significantly increased COX-2, IL-1β, TNF-α, and iNOS in the hippocampus as compared with the saline-treated mice. Plexin-A1-/- mice administered LPS did not exhibit significant increases in ventricle size or infiltration of leukocytes into the brain, as compared with the saline-treated mice. In WT, but not in Plexin-A1-/- primary microglia treated with LPS, Sema3A induced significantly more NO generation than in the immunoglobulin G control. Further studies with BV-2 microglial cells demonstrated the crucial role of Sema3A-Plexin-A1 signaling through ERK activation for the Toll-like receptor-induced NO production in activated microglia. These results reveal the crucial role of the Sema3A-Plexin-A1 interaction in the Toll-like receptor 4-mediated signaling of the LPS-induced activation of microglia. Thus, our results reveal the essential role of Plexin-A1-mediated signaling in the development of LPS-induced neuroinflammation in mice, suggesting the possible application of microglial control of the semaphorin-plexin signaling system to the treatment of LPS-induced encephalopathy and other psychiatric diseases associated with neuroinflammation.

Title: IFNAR1 signaling regulates the microglial phenotype in response to peripheral LPS challenge

Authors: *J. M. TAYLOR, K. M. BRODY, P. J. CRACK;
Dept of Pharmacol., Univ. of Melbourne, Melbourne, Australia

Abstract: Neuroinflammation has been proposed to contribute to the neuronal cell damage following injury, infection or disease. We hypothesise that type-1 interferon (IFN) signalling is a key mediator of the neuroinflammatory response. Mice lacking the type-1 IFN receptor (IFNAR1) (n=6) were given a single intraperitoneal (i.p) injection of lipopolysaccharide (LPS) (2mg/kg). A temporal analysis of the early neuroinflammatory changes was undertaken by QPCR, western analysis and immunohistochemistry. QPCR confirmed increased expression of IFN-[[Unsupported Character - Symbol Font ]] and the downstream mediator, IRF7 in wildtype mice at 6 and 24 hours post-LPS injection (compared to sham levels), a response that was decreased in the IFNAR1-/- brains. Increased Iba-1 immunoreactive microglial cells were identified in the substantia nigra of both wildtype and IFNAR-1-/- mice at 6 and 24 hours post-LPS injection. Significantly, at both time-points the microglial number and activation was reduced in the IFNAR1-/- brains compared to wildtype mice. Upon activation, microglia can polarise to form two differing phenotypes; M1 (damaging) or M2 (neuroprotective). QPCR identified reduced expression of both M1 (iNOS and CD32) and M2 (Arg-1, YM1, CD206 and TGF-[[Unsupported Character - Symbol Font ]]) microglial markers in the IFNAR1-/- brains at 6 hours post-LPS suggesting an altered neuroinflammatory phenotype. This study confirms type-1 IFN signaling plays a role in regulating the cellular environment involved in the neuroinflammatory response. This modulation has implications in both acute and chronic neuropathologies where neuroinflammation may be a critical event in perpetuating the neuronal cell death.

Sch. of Ribeirão Preto, Sao Paulo, Brazil

Abstract: We previously demonstrated that the antibacterial drug doxycycline confers neuroprotection in a Parkinson disease mouse model by restraining glial cell activation (Lazzarini et al, Glia, 2013). In the present study, we wished to explore further the potential of doxycycline against neuroinflammation, using microglial cell-enriched cultures prepared from post-natal (P1) mouse brain. More specifically, we evaluated the impact that a 4 hour pretreatment with doxycycline exerts on microglial cells exposed for the next 24 hours to the bacterial inflammogen LPS (1 ng/ml). Our results show that the calcium-binding protein Iba-1 used as a marker of microglial cell activation, was detectable in 80% Mac-1+ cells after LPS treatment and that this number dropped to 20% with an optimal concentration of doxycycline, i.e., 200μM. Coherent with this result, doxycycline diminished the release of two pro-inflammatory cytokines, TNF-α and IL-1β and that of nitric oxide, a gaseous mediator of neuroinflammatory responses. Finally, doxycycline was also found highly effective in a situation where microglial cells were exposed to 10 ng/ml LPS, i.e., a concentration of the inflammogen required to adequately stimulate the production reactive oxygen species in microglial cells. Taken together our results suggest that doxycycline could operate as an efficient protective agent through a repressive effect on microglial cells.

Abstract: Microglia are heterogeneous population of brain immune cells important for homeostatic and inflammatory processes. We have previously shown that RNA editing by deaminase APOBEC1 in the transcriptome of bone marrow derived mouse macrophages leads to the generation of populations that are heterogeneous, and functionally diverse, enabling rapid population adaptation to different environmental settings. Here we demonstrate that APOBEC1 catalyzes editing both *in vivo* and *in vitro* in immune cells derived from the CNS. Among the edited transcripts in BV2 microglia cell line are genes particularly relevant for the development of neurodegenerative diseases, such App and adam10, as well as inflammatory genes, cd36, b2m, Lamp1 and Lamp2. Using brain immune cells of monocytic lineage isolated from the olfactory bulbs of vesicular-stomatitis virus (VSV) infected mice, and sorted based on the expression of CD45int/CD11b+/CD11c- and CD45int/CD11b+/CD11c+, we confirmed that APOBEC1 is also functional *in vivo*. Moreover, immuno-histochemical analysis of the APOBEC1 KO mice brains showed signs of demyelination and neurodegeneration, suggesting an important role for this RNA editing enzyme in the mechanisms of homeostasis in the CNS. The extent of APOBEC1 mediated editing in the CNS and the consequences for the inflammatory response (both acute and chronic) will be discussed, especially in the context of diseases of the aging brain.

Title: IL-1 signaling exacerbates brain injury following seizurogenic exposure to the nerve agent soman (GD) in mice

Authors: *T. F. BOWENS[1,2], M. A. GUIGNET[2], J. F. IRWIN[2], K. LAITIPAYA[2], M. D. WEGNER[3], E. A. JOHNSON[2];
[1]Uniformed Services Univ. of the Hlth. Sci., Abingdon, MD; [2]Pharmacol., [3]Comparative Pathology, USAMRICD, Gunpowder, MD

Abstract: Exposure to organophosphorus compounds can initiate status epilepticus (SE), which can lead to severe progressive neuropathology and behavioral impairment for survivors of exposure to chemical warfare nerve agents (CWNAs). While treatments are available to ameliorate SE, the therapeutic window for control is relatively short, with no approved treatments available to address the neurodegenerative process. Following exposure, brain damage resulting from SE activates microglia and astrocytes to upregulate inflammatory cytokines, including the pro-inflammatory cytokine interleukin-1 (IL-1). This proinflammatory environment creates a positive feedback loop that potentiates neurodegeneration, which can potentially damage healthy neuronal tissue. Inhibition of neuroinflammation reduces acute neurodegeneration in various CNS injury models and may also be beneficial following CWNA exposure. A soman (GD) model was developed using wild-type and IL-1 signaling knockout mouse strains (i.e., IL-1R and IL-1Ra) to validate IL-1 signaling as a viable neuroprotective target. Results showed significant neuroprotection in various brain regions in strains that had impaired IL-1 signaling. In addition, the IL-1 signaling inhibitor anakinra produced post-exposure neuroprotection and replicated results seen in the knockout mice. These results show that inhibition of IL-1 signaling can afford neuroprotection after GD exposure. Therefore, research into neuroprotective strategies is important to improve brain pathology and potentially improve behavioral outcomes.

Title: Cell-type-specific inflammatory-induced changes in dorsal horn synaptic transmission

Authors: P. BELAN[1], V. KROTOV[1], O. KOPACH[2], *N. V. VOITENKO[2];
[1]Lab. of Mol. Biophysics, [2]Lab. of Sensory Signaling, Bogomoletz Inst. of Physiol., Kiev, Ukraine

Abstract: Persistent peripheral inflammation alters trafficking of AMPA receptors (AMPARs) at the synapses between primary afferents and dorsal horn neurons that contributes to the inflammatory pain maintenance. However, how this alteration changes the synaptic activity within the dorsal horn circuitry and synaptic AMPARs, particularly, in different neuronal populations still remain unknown. Here we found that Complete Freund's Adjuvant (CFA) - induced peripheral inflammation prominently augmented excitatory synaptic drive to the lamina II dorsal horn neurons characterized by intrinsic adapting firing properties and apparently decreased that to the tonic firing lamina II neurons, proving thus different roles of these types of dorsal horn interneurons in pain processing. Persistent peripheral inflammation differentially changed excitatory and inhibitory synaptic drives in these neuronal populations, shifting a balance between excitation and inhibition of lamina II neurons within the dorsal horn circuitry towards excitation in the adapting firing but towards inhibition in the tonic firing neurons. Peripheral inflammation differentially adjusted AMPAR pool at the synapses of the adaptingfiring and tonic firing lamina II neurons, assuming different mechanisms for trafficking of synaptic AMPARs in these neuronal populations during persistent inflammatory conditions. Our results thus reveal differential, neuron-type specific rearrangements in synaptic drive within the dorsal horn circuitry and in the synaptic AMPAR pool in different types of lamina II neurons that may contribute to the inflammatory pain maintenance.

Abstract: Exacerbated cytokine release and dysfunctional brain-peripheral immune communications are important features of several inflammatory and autoimmune disorders. Dysregulated peripheral immune responses and cytokine production activate brain immune responses and deteriorate neuronal function. Peripheral cytokine release is controlled by neural mechanisms and brain cholinergic signaling plays an important role in this regulation. Using qPCR, we aimed to provide insight into alterations in gene expression of cytokines, microglia and astrocyte markers, and cholinergic system constituents in the brain (cortex, brainstem, cerebellum, hippocampus, hypothalamus, thalamus, and striatum), during lethal murine endotoxemia. In addition, serum cytokines, gross brain cell morphology and microglia morphology were evaluated. Significant increases in serum IL-1β, IL-6 and other cytokine levels 4h following LPS (8 mg/kg, i.p.) injection highlighted the magnitude of the systemic inflammatory response, which did not however result in gross morphological alterations in the brain (H&E staining). Brain *Il1b* and *Il6* mRNA expression were differentially increased in endotoxemic mice: the highest magnitude of *Il1b* mRNA expression upregulation was determined in cortex (144-fold), and the lowest in cerebellum (29-fold); the highest *Il6* mRNA expression was observed in cerebellum (173-fold), and the lowest in striatum (29-fold). *Gfap* mRNA expression was upregulated in cortex, cerebellum, brainstem, hippocampus and thalamus. Surprisingly, *Iba1* mRNA expression was decreased in some brain regions, in parallel with microglia activation, indicated by Iba1 immunostaining. Brain cholinergic system alterations were revealed by: *Chat* mRNA expression downregulation in striatum; *Ache* mRNA expression downregulation in cortex and upregulation in hippocampus; and *Chrm1* (M1 muscarinic acetylcholine receptor) mRNA expression downregulation in cortex and brainstem of endotoxemic mice. No *Chat* or *Chrm1* mRNA expression was detected in cerebellum. These

results identify region-specific *Il1b* and *Il6* mRNA expression upregulation during lethal, endotoxin-induced inflammation. Our results also indicate that trends in alterations of microglia marker gene expression and protein staining do not necessarily correlate. We also reveal specific alterations in the brain cholinergic system in these settings. These findings contribute to better understanding the bidirectional brain-periphery communication during inflammatory conditions, which may have therapeutic implications. This study was funded in part by NIH/NIGMS.

Title: Neuroinflammation and neuroprotection following acute soman-induced seizure in mice

Authors: ***J. F. IRWIN**[1], M. A. GUIGNET[2], K. LAITIPAYA[2], T. F. BOWENS[2], M. D. WEGNER[3], E. A. JOHNSON[2];
[2]Pharmacol., [3]Comparative Pathology, [1]USAMRICD, Edgewood, MD

Abstract: Severe neuropathology and behavioral impairment are a result of prolonged status epilepticus (SE) caused by organophosphorus compounds such as soman (GD). GD, a potent acetylcholinesterase inhibitor, causes prominent cell death in the hippocampus, thalamus and piriform cortex, leading to the activation of the neuroinflammatory cascade. Neuroinflammation can exacerbate tissue injury or promote healing, depending on the intricate interaction of multiple cells, inflammatory factors and receptors as the injury progresses, a fact that has complicated the development of effective neuroprotective therapies for CNS injury models such as SE. TNF signaling, a prominent proinflammatory pathway activated in response to injury, can worsen tissue damage. Therefore, this study investigated the temporal and regional upregulation of TNFα in the brain and the effects of the TNF signaling pathway on the acute development of tissue injury up to 24 hours after GD-induced seizure onset. A wild-type mouse model was

developed for GD exposure that maximized SE-induced brain damage. Various background-matched TNF pathway knockout mouse strains were used to identify their effects on acute neurodegeneration, mortality, seizure onset and other physiological variables following GD exposure. Results indicate that the loss of normal TNFR signaling does confer neuroprotection on various brain regions and can alter seizure onset times and mortality rates. These results along with neuroinflammation profiles from the mouse model guided the selection of pathway-specific drugs for testing. These studies describe a rational and relatively rapid therapeutic strategy for the development of effective post-exposure GD neuroprotectants and show that neuroprotection is possible following GD exposure with a longer therapeutic window than is afforded by conventional treatments.

Title: Characterization of inflammatory response after mouse spinal cord injury

Authors: *I. FRANCOS-QUIJORNA[1], R. LOPEZ-VALES[2];
[1]Univ. Autonoma De Barcelona, Bellaterra, Spain; [2]Univ. Autonoma De Barcelona, Barcelona, Spain

Abstract: Inflammatory response plays an essential role to protect the body after injury. Inflammation, however, must be a highly regulated response, otherwise, it may lead to tissue damage and/or to chronic inflammation, as observed after spinal cord injury (SCI). Despite the contribution of inflammation to SCI, the recruitment of the different immune cell populations and the expression at the protein levels of cytokines and chemokines in the mouse contused spinal cord has not been fully characterized. Understanding the factors that impede the clearance of immune cells after SCI is likely to be critical for the development of new therapeutic

strategies. Herein we assessed the changes in the main inflammatory cell types and cytokine/chemokine expression in the mouse contused spinal cord. Our results show that neutrophils are the earliest inflammatory cells to invade the injured spinal cord. They peak at 24 hours post-injury and decline progressively up to day 28. Microglial cells peak at day 7 post-injury and slowly decline up to day 28. Microglia, however, is the most abundant immune cell in the contused spinal cord from day 3. The infiltration of monocytes peaks in the contused spinal cord at day 3, and decreases in numbers up to day 14. Few lymphocytes are present within the injured spinal cord for the first week. Strikingly, there is a great influx of lymphocytes into the contused spinal cord at day 21, and their proportion remain elevated up to day 28. The increase of lymphocytes at later stages of spinal cord injury is mainly due to the recruitment of B cells, and to minor degree, to the invasion of CD4 and CD8 T cells. Regarding cytokine/chemokine expression, our results reveal that all these pro-inflammatory mediators are up-regulated within the first 24 hours, peaking between 6 and 12 hours post-injury. IL6 and G-CSF are the most abundant cytokines at this early phase, and could play a key role in triggering the activation of glial cells and the recruitment of granulocytes. Beyond 24 hours, most of the cytokines were undetectable, except for some of them, such as M-CSF, IL-1α and IL9, that remain elevated until 28 days. Interestingly, the expression of M-CSF peaks at day 3 post-injury, suggesting its importance in monocyte and microglia expansion in the contused spinal cord. Contrary to most cytokines, the expression of chemokines remains at high levels for the first 3-7 days, and some of them, such as CXCL9, CXCL10 and eotaxin, are overexpressed up to day 28. In conclusion, our data suggest that the lasting up-regulation of some cytokines and chemokines in the injured spinal cord might be responsible, in part, in the failure of immune cell clearance.

Title: Microglial activation in cardiovascular autonomic centers of diet-induced obese mice

Authors: *L. J. CHAAR, A. COELHO, W. T. FESTUCCIA, V. R. ANTUNES;
Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Obesity-associated sympathetic overactivity to different organs could be the linking factor between excessive fat accumulation and hypertension. Moreover, it has been shown that the hypothalamic inflammation induced by high fat diet can alter the neurotransmission of brain autonomic centers leading to hypertension. Here we screened the hypothalamus and brainstem of diet-induced obese mice for inflammatory factors that could be involved in changes in the mean arterial pressure (MAP). Ethical Committee for Animal Research of ICB-USP, #026, p.126; V.02. Male mice C57BL6 were submitted to high fat (HF; 60% kcal lipids) or control (C) diet for 8 weeks and body weight (BW), GTT, and plasma levels of leptin, insulin, triglycerides (TG) and free fatty acids (FFA) were measured. Femoral catheterization was performed to MAP recordings and spectral analysis in conscious freely moving mice. Hypothalamic and brainstem mRNA of inflammatory factors was quantified by qPCR. Immunoperoxidase for microglia followed by squeletonization were also performed. HF diet increased BW gain (31%), fasting plasma levels of glucose (C: 177±8 vs HF: 200±6 mg/dL); leptin (C: 8±3 vs HF: 17±5 ug/ml), insulin (C: 43±7 vs HF: 672±127 pmol/L), TG (C: 1.0±0.4 vs HF: 2.2±0.6 mmol/L), FFA (C: 0.2±0.1 vs HF: 0.7±0.2 nmol/L), and induced severe glucose intolerance (AUC, C: 23265 vs HF: 37633 u.a.). HF diet led to two different hemodynamic phenotypes: obese hypertensive (OH: 123±2 mmHg, n=2) and obese resistant to hypertension (OR: 106±4 mmHg, n=5) when compared to C (110±6 mmHg, n=5). OH mice had higher LF/HF (P=0.05) than C and OR. HF-diet elicited an increase of mRNA levels of CD86 in the brainstem (+30%, n=9) and CCL5 in the hypothalamus (+47%, n=10) when compared to C diet. Moreover, HF diet induced IBA+ cells accumulation at the caudal portion of the nucleus of the solitary tract (NTS) without changes at any specific hypothalamic nuclei. Taking together, our data indicate that HF induced obesity affected MAP and increased mRNA levels of CD86, a co-stimulatory molecule involved in microglia activation, and CCL5, a chemokine known to recruit leukocytes to inflammatory sites, respectively in the brainstem and hypothalamus. Further studies are required however to determine whether changes in gene expression are related to alterations in MAP.

Title: Neuroinflammation and neuroprotection following acute soman-induced seizure in mice

Authors: ***E. A. JOHNSON**[1], M. A. GUIGNET[1], J. F. IRWIN[1], K. LAITIPAYA[1], T. F. BOWENS[1], M. D. WEGNER[2];
[1]Pharmacol., [2]Comparative Pathology, US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Exposure to organophosphorus compounds such as soman (GD) can initiate status epilepticus (SE) that can lead to progressive brain damage and behavioral impairment. GD, a potent acetylcholinesterase inhibitor and chemical warfare nerve agent (CWNA), causes prolonged SE activity and cell death in the hippocampus, thalamus and piriform cortex. Current treatments can ameliorate GD-induced SE, though treatment effectiveness diminishes rapidly following exposure. Therefore, neuroprotective strategies that can be used at later time points are needed to reduce neurodegeneration and improve cognitive outcomes. One strategy involves modulation of the neuroinflammatory response, a prominent feature in CWNA-induced brain injury. Specific inhibition of this response can reduce acute neurodegeneration in various CNS injury models. This study focused on one class of neuroinflammatory factors, the C-C chemokine family (*i.e.* CCL2 and CCL3), to investigate whether inhibition of this pathway would be a viable neuroprotective strategy. C-C chemokines were significantly upregulated in multiple brain regions following seizurogenic GD exposure in wild-type (wt) mice. Multiple background-matched C-C signaling knockout mouse strains were also exposed and showed significant changes in neuropathology, mortality, seizure onset and other relevant physiological responses compared to wt mice. These results along with data from other KO strains can help guide the selection of pathway-specific drugs for neuroprotection testing. These studies describe a rational and relatively rapid therapeutic strategy for the development of effective neuroprotectants and show that neuroprotection is possible with a longer therapeutic window than conventional treatments after GD exposure.

Title: Toll-like receptor 4 regulates prooxidant-mediated release of prostaglanding E2 and resovin in macrophages

Authors: *Y. ZHANG, O. J. IGWE;
Univ. of Missouri-Kansas City, Kansas City, MO

Abstract: **Background:** Oxidative stress can lead to inflammation, which is a mediating factor in many human diseases. Toll-like receptor 4 (TLR4) has been shown to be essential in mediating inflammatory responses induced by prooxidants via-a-vis oxidative stress. However, the mechanism(s) involved in are not clear**. Objective:** This study examines the mechanism by which oxidant stress can initiate, propagate and maintain the inflammatory process through TLR4 activation. **Methods:** SIN-1 and potassium peroxychromate (PPC) were used as prooxidant sources and a TLR4-specific agonist LPS-EK was used as the positive control. The TLR4 signaling pathway inhibitor, CLI-095, was used to block TLR4 signaling. RAW-Blue cells were used to determine the activation of TLR4-coupled NF-κB pathway by measuring the levels of secreted embryonic alkaline phosphatase (SEAP) release with QUANTI-Blue assay. We also used primary murine peritoneal macrophages (PM) isolated from mice expressing TLR4 (TLR4-WT) and mice with complete deletion of TLR4 (TLR4-KO). Accumulation of intracellular reactive oxygen species (ROS) in the primary culture was quantified by immunofluorescence (IF). We used ELISA to measure the contents of prostaglandin E2 (PGE2) and resolvin D1 (RsD1) released into the media following treatments with prooxidants and LPS-EK. **Results:** We found that pro-oxidants and LPS-EK evoked increased level of SEAP from Raw-Blue cells, which was abolished by CLI-095. This suggests that enhanced SEAP release was specifically due to TLR4 activation. Compared with PM derived from TLR4-WT mice, intracellular ROS accumulation was significantly lower in PM derived from TLR4-KO mice upon treatments with prooxidants or LPS-EK. In addition, prooxidants and LPS-EK enhanced PGE2 and RsD1 release in PM derived from TLR4-WT but had no effect in PM derived from TLR4-KO. Furthermore, the ratio of PGE2 to RsD1 was increased by prooxidants and LPS-EK. **Conclusion:** Taken together, our data indicate that prooxidants induced NF-κB activation through TLR4 stimulation. Therefore, oxidant stress can serve as an initiator of inflammatory process. This can lead to an imbalance between pro-inflammatory mediator PGE2 and pro-resolution mediator RsD1 maintaining diseases.

Title: IL37 exerts anti-inflammatory effects after spinal cord injury

Authors: *M. COLL[1], R. LOPEZ-VALES[1], I. FRANCOS-QUIJORNA[1], E. SANTOS-NOGUEIRA[1], P. BUFLER[2], C. DINARELLO[3];
[1]Univ. Autonoma De Barcelona, Bellaterra, Spain; [2]Dr. von Hauner Children's Hosp. Ludwig-Maximilians-University, Munich, Germany; [3]Univ. of Colorado, Denver, CO

Abstract: Inflammatory response plays an essential role in protecting the body after injury or invasion by microorganisms. Regardless of the tissue in which it occurs, inflammation is a highly regulated event that undergoes resolution in a timely fashion, otherwise, it may lead to tissue damage or even to the development of an inflammatory disease. After spinal cord injury (SCI) an inefficient control of the inflammatory response occurs, which contributes to tissue damage and functional impairments. This is particularly harmful in the central nervous system (CNS) due to its limited ability to replace the damaged neurons and promote axonal regeneration, leading to irreversible deficits. Therefore, targeting inflammation could be a valuable approach to promote neuroprotection and functional recovery in SCI. Interleukin 37 (IL37) is one of the eleven members of the IL-1 family. Contrary to most IL1 cytokines, IL37 exerts potent inhibition on innate immunity. Although the mouse homolog of IL37 has not been found yet, previous works demonstrate that mice overexpressing human IL37 (hIL37tg mice) undergo significant resistance against several inflammatory insults, such as shock response, colitis, hepatitis and psoriasis. However, there is no information on the role of IL-37 in CNS pathologies yet. To evaluate whether IL-37 exerts beneficial actions after CNS trauma, we performed a contusion lesion into the spinal cord of WT or hIL37tg mice. mRNA transcripts of IL-37 were almost undetectable in the uninjured spinal cord of hIL37tg mice. However, IL37 was significantly up-regulated in the spinal cord of hIL37tg mice from 12h to 28 days post-injury, the latest time point examined. IL37 reduced the protein levels of several pro-inflammatory cytokines and chemokines in the spinal cord at 24 hours post-injury, such as IL6, KC, RANTES, G-CSF, among others, but did not alter the expression of the anti-inflammatory cytokines IL5 and IL10. Moreover, IL37

dampened the recruitment of neutrophils and monocytes in the contused spinal cord. In line with the anti-inflammatory actions of IL37, we found that IL37tg displayed reduced locomotor deficits and spinal cord tissue damage. Our data demonstrate for the first time that IL37 acts a suppressor of the inflammatory response in the CNS and leads to beneficial effects after spinal cord trauma.

Title: The transcription factor C/EBPδ regulates human brain pericyte inflammatory responses

Authors: J. RUSTENHOVEN[1], T. PARK[1], D. JANSSON[1], R. OLDFIELD[2], P. S. BERGIN[3], E. W. MEE[3], R. L. M. FAULL[1], *M. DRAGUNOW[1];
[1]Univ. of Auckland, Auckland, New Zealand; [2]Lab. Plus, Auckland, New Zealand; [3]Auckland City Hosp., Auckland, New Zealand

Abstract: Neuroinflammation contributes to the development and progression of epilepsy, traumatic brain injuries, stroke and many neurodegenerative diseases. Transcription factors are critical regulators of brain inflammation through modulating inflammatory gene expression. Induction of the transcription factor C/EBPδ has been observed in the brain of Alzheimer's disease and amyotrophic lateral sclerosis patients; with both diseases having a significant inflammatory component. Previous studies utilising rodent microglia and astrocytes have suggested a pro-inflammatory role for C/EBPδ through induction of COX-2, IL-6 and iNOS expression. Whilst these glial cells are essential in regulating the brains immune response, recent evidence suggests that pericytes, a cell type lining the brain vasculature, can also contribute to brain inflammation. Utilising human brain tissue, our lab has previously established *in vitro* cell cultures of primary brain pericytes. We sought to investigate the function of C/EBPδ induction in

the human brain pericyte inflammatory response. Naive pericytes display low C/EBPδ expression which is significantly induced by a diverse range of immunogenic stimuli (IFNγ, IL-1β, LPS and TNFα) as determined by immunocytochemistry and RT-qPCR. Nuclear C/EBPδ induction was observed as early as four hours after inflammatory treatments and remained elevated for up to three days. In order to examine the function of C/EBPδ induction in pericytes, RNAi was employed to attenuate the IL-1β induced expression of this transcription factor. Interestingly, following siRNA mediated knock-down of C/EBPδ induction, the expression of several pro-inflammatory genes (MCP-1, ICAM-1 and IL-8) was enhanced whilst others (IL-6 and COX-2) were reduced, as determined by immunocytochemistry and RT-qPCR. C/EBPδ induction in pericytes therefore appears to confer a specific inflammatory phenotype which is neither exclusively pro/anti-inflammatory. Whilst the C/EBPδ induced expression of IL-6 and COX-2 may produce a pro-inflammatory response, these mediators have also been shown to attenuate inflammation in certain contexts. Furthermore, MCP-1, ICAM-1 and IL-8 act to recruit peripheral immune cells across the vasculature into the brain. Induction of C/EBPδ in pericytes following an immunogenic challenge may therefore act to limit peripheral immune infiltration highlighting a possible anti-inflammatory role for this transcription factor in brain pericytes.

Title: Redox control of neuroinflammation by post-translational activation of glutamate cysteine ligase

Authors: *P. BHUYAN, L.-P. LIANG, M. PATEL;
Univ. of Colorado Denver, Aurora, CO

Abstract: Neuroinflammation and oxidative stress are hallmarks of several neurodegenerative diseases such as Parkinson's disease. However, whether and how the redox processes control neuroinflammation is relatively unknown. We determined the impact of modulating the

glutathione (GSH) redox status on markers of neuroinflammation *in vitro*. Cellular GSH levels were elevated by a novel approach i.e. post-translational activation of glutamate cysteine ligase (GCL), the rate limiting enzyme in GSH biosynthesis. A series of thiol-containing compounds were examined for their ability to increase intracellular GSH levels in a murine microglial cell line (BV2). The most potent compound to significantly increase intracellular GSH levels was identified as 2,3-dimercapto-1-propanol (DMP). DMP increased GCL activity and decreased LPS-induced production of pro-inflammatory cytokines (TNF-α, IL-1β, IL-6 and KC/GRO) in BV2 cells in a concentration-dependent manner. DMP's ability to elevate GSH levels and attenuate LPS induced pro-inflammatory cytokine production was inhibited by buthionine sulfoximide, an inhibitor of GSH biothynethsis suggesting a post-translational mechanism of GCL activation by DMP. Finally, we determined if DMP increased GSH levels and attenuated neuronal damage in a rat dopaminergic N27 cell line. DMP treatment in N27 cells increased GCL activity and GSH levels similar to the magnitude observed in BV2 cells. Furthermore, DMP inhibited paraquat- induced cell death in N27 cells. The data demonstrate that elevation of intracellular GSH levels by post-translational activation of GCL inhibits production of pro-inflammatory cytokines and exerts neuroprotection. This suggests the feasibility of modulating neuroinflammation via redox processes. Elevation of GSH via post-translational activation of GCL may be an attractive approach to target inflammation in age-related neurodegenerative diseases in which adaptive responses may be impaired.

Title: Neuroprotection by long-chain fatty acids in trauma: the control of neuroinflammation

Authors: S. CUZZOCREA[1], I. PATERNITI[1], D. IMPELLIZZERI[1], R. DI PAOLA[1], M. CAMPOLO[1], M. CORDARO[1], R. SIRACUSA[1], E. ESPOSITO[1], *P. L. CANONICO[2]; [1]Dept. of Biol. and Envrn. Sci., Univ. of Messina, Messina, Italy; [2]Univ. Piemonte Orientale, Novara, Italy

Abstract: Ethanolamides of long-chain fatty acids are a class of endogenous lipid mediators generally referred to as N-acylethanolamines (NAEs). NAEs include anti-inflammatory and

analgesic palmitoylethanolamide (PEA) and the endocannabinoid anandamide. It has recently been demonstrated that PEA exerts neuroprotection in central nervous system (CNS) pathologies such after spinal cord injury (SCI) and traumatic brain injury (TBI), disorders that are associated with a high morbidity and mortality and with no specific therapeutic treatments. In recent studies, we have demonstrated that treatment with PEA significantly reduced inflammatory secondary events associated with SCI and TBI. Since oxidative stress is considered to play an important role in neuroinflammatory disorders, in the present work we studied a new composite, a formulation including PEA and the antioxidant compound luteolin (Lut), subjected to an ultramicronization process, co-ultraPEALut. We investigated the effect of co-ultraPEALut in both an *ex vivo* organotypic spinal cord culture model and an *in vivo* model of SCI as well as in *in vivo* Controlled cortical impact (CCI) model of TBI. For the organotypic cultures, spinal cords were prepared from mice at postnatal day 6 and were cut into transverse slices of 400 μm thickness. After 7 days of culturing, the slices were mechanically injured and the co-ultraPEALut was applied at different concentrations 1 hour before damage. For *in vivo* model of SCI, SCI was induced through spinal cord compression at four-level T5 to T8 and co-ultraPEALut (1 mg/kg ip) was administered at 1 and 6 hours after SCI. At 24 hours after SCI, mice were sacrificed and the spinal cords were collected for further evaluation. Moreover, we performed the CCI model in mice where a craniotomy was made and a cortical contusion was produced on the exposed cortex and the impact tip was advanced farther to produce injury of moderate severity. Pretreatment with co-ultraPEALut significantly reduced COX-2 and iNOS expression, restored nNOS expression and protected cells by cell death (MTT assay) in spinal cord organotypic cultures. Moreover, we demonstrated *in vivo* that co-ultraPEALut 1 mg/kg reduced the severity of trauma induced by compression to the spinal cord and improved the motor activity evaluated at 10 days post-injury; also in TBI coultraPEALut-treated mice had lower infarct volumes and better outcomes in neurological and behavioral tests. The present study demonstrates that coultraPEALut association possess neuroprotective effects on modulating SCI and TBI-asscoiated neuroinflammation and could be a therapeutic target in traumatic diseases.

Title: Oxidative stress and increased inflammatory response is associated with APP over-expression in astrocytes acutely exposed *in vitro* to MMA III

Authors: *C. ESCUDERO-LOURDES[1], I. ROJAS-BARAJAS[1], E. E. URESTI-RIVERA[1], M. TORRES-RAMOS[2];
[1]Inmunotoxicología, Univ. Autonoma De San Luis Potosi, San Luis Potosi, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico, DF., Mexico

Abstract: Human exposure to inorganic arsenic (iAs), has been associated with an increased risk for Alzheimer's disease (AD) development, however the associated mechanisms have not been fully described. AD's neuropathological features include extracellular neuritic amyloid plaques (AP) formed by Aβ peptides derived from precursor amyloid protein (APP) excised by the consecutive action of β and γ secretases. Intracellular neurofibrillary tangles (NFT) which are composed of hyperphosphorylated Tau protein are also characteristic in AD brain tissue. Interestingly, APP over-expression and an increase in p-Tau have been previously demonstrated after *in vitro* or experimental exposure to arsenite. As it is known, neuroinflammation involving the induction of oxidative stress, underlines AD as well as other neurological diseases development. Importantly, iAs and its methylated metabolites (MMAIII/V, DMAIII/V) are known to induce oxidative stress and inflammatory responses in different cells and experimental models. Therefore As-induced toxicity in the brain, could involve its ability to induce neuroinflammation once it crosses the brain blood barrier (BBB) through the glucose transporter 1 (GLUT-1). Previously, we showed an important increase in ROS production soon after brain microvascular endothelial cells were exposed to 25, 50 and 100 nM of the monomethylated metabolite of arsenic (MMAIII) in an *in vitro* BBB model. In this work, we determined the effect of MMAIII on rat astrocyte from primary cultures. Toxicity assays based on lactate dehydrogenase (LDH) release showed no toxic effect in astrocytes exposed up to 1μM MMAIII; however exposure to 50 nM and higher led to astrocytes reactivation in terms of morphologic changes that are commonly correlated with a surrounding inflammatory milieu, as is observed in cells stimulated with LPS. Other set of cells were exposed to 50 to 250 nM MMAIII for 24 h and assayed for reactive oxygen species (ROS) production and for cytokines gene expression by RT-PCR. Results showed a significant increase in ROS production after 4 h in cells exposed to all MMAIII concentrations. Consistently, genes codifying for pro-inflammatory cytokines MIF, IL1-β and TNF-α were over-expressed up to 7.76, 19.1 and 9 times correspondingly, after 4h exposure to 50 and 250nM MMAIII, when compared with not exposed astrocytes. In these cells APP gene expression increased 2.3 times in cells exposed to 250nM MMAIII in correlation with inflammatory cytokines over-expression. These results suggest that arsenic-induced inflammation could importantly accounts for neurodegeneration and AD development in exposed populations.

Title: Roles for nicotinic acetylcholine receptors in modulation of inflammation and immunity

Authors: *R. J. LUKAS[1], A. SIMARD[2], B. J. MORLEY[3], Q. LIU[1], L. LUCERO[1], P. WHITEAKER[1], F.-D. SHI[1];
[1]Barrow Neurol Inst., Phoenix, AZ; [2]Univ. of Moncton, Moncton, NB, Canada; [3]Boys Town Natl. Res. Hosp., Omaha, NE

Abstract: Following on earlier suggestions for roles of nicotinic acetylcholine receptors (nAChR) in the immune system, our initial studies with the late Dom Deluca characterized nAChR subunit gene expression in the mouse and human immune systems using thymic organ culture models and demonstrated effects of nicotinic ligands on T cell development and differentiation. That work suggested that nicotine induces T cell anergy and inhibits T cell differentiation, contributing to general immunosuppressive effects. Subsequent work using experimental autoimmune encephalomyelitis (EAE) in mice as a model for multiple sclerosis (MS) has led to identification of roles for different nAChR subtypes in different stages in disease progression and recovery. This is consistent with refined evaluation of nAChR subunit

expression, always validated by other studies, in different immune cell types in the periphery or infiltrating into the brain, such as T cells, B cells, dendritic cells, peripheral macrophages, and brain microglia. Overall, nicotine exposure at behaviorally-relevant concentrations protects against EAE, delaying disease onset, attenuating the magnitude of disease signs, and facilitating recovery. Studies using combinations of nAChR subunit knockout, pharmacological approaches and adoptive transfer techniques indicate or suggest hypotheses: (1) that disease exacerbating effects are mediated by peripheral nAChR containing α9 subunits (α9*-nAChR) and attenuated by α9 subunit knockout or nicotine's antagonism of α9*-nAChR, (2) that α7-nAChR, probably expressed by brain cell types, play neuroprotective roles that become particularly evident in the absence of α9*-nAChR, and (3) that β2*-nAChR are involved in recovery from EAE, perhaps by facilitating oligodendroglial precursor cell maturation leading to remyelination. Effects on indices of inflammation and immune responsiveness and evidence from studies using reduced preparations correlate well with more gross measures of disease status. Collectively, these studies suggest exciting and novel therapeutic strategies to reduce disease-exacerbating or to enhance disease-ameliorating inflammatory and/or immune processes. Such strategies have the potential to improve treatment of maladies such as MS, lupus and arthritis, and even could be deployed in treatment of stroke, brain cancer or neurodegenerative diseases.

Title: Anti-neuroinflammatory effects of paeonol in microglial cells

Authors: *C. LIN[1], C.-F. TSAI[4], Y.-S. LIU[2], D.-Y. LU[3];
[1]Physiol., [2]Grad. Inst. of Basic Med. Sci., [3]Grad. Inst. of Neural and Cognitive Sci., China Med. Univ., Taichung, Taiwan; [4]Biotech., Asia Univ., Taichung, Taiwan

Abstract: Accumulating evidence suggests that inflammatory processes in the central nervous system mediated by microglial activation play important roles in several neurodegenerative

disorders. Therefore, development of methods for microglial inhibition is considered an important strategy in the search for neuroprotective agents. Paeonol is a major phenolic component of Moutan Cortex, widely used as a nutrient supplement in the Chinese medicine. In this study, we investigated the effects of paeonol on cultured microglia cells stimulated by inflammagens. Paeonol significantly inhibited the release of nitric oxide (NO) and the expressions of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2). Treatment with paeonol also reduced reactive oxygen species production and inhibited an ATP-induced increase cell migratory activity in the microglia. Furthermore, the inhibitory effects of neuroiflammation by paeonol were found to be regulated by phosphorylated adenosine monophosphate-activated protein kinase-α (AMPK-α) and GSK 3β. Administration with AMPK or GSK 3 inhibitors both reverses the inhibitory effect of neuroiflammation by paeonol in microglial cells. Furthermore, paeonol also showed significant anti-neuroinflammatory effects and improvement in the Rotarod performance in mice model as well. The present study is the first to report a novel inhibitory role of paeonol on neuroinflammation and presents a new candidate agent for the development of therapies for inflammation-related neurodegenerative diseases.

Title: Inhibitors of the mitochondrial fission GTPase Drp1 attenuate proinflammatory microglial activation by an unknown mechanism

Authors: ***B. M. POLSTER**[1], E. A. BORDT[1], B. A. ROELOFS[2];
[1]Anesthesiol, Univ. Maryland Sch. of Med., BALTIMORE, MD; [2]Ctr. for Biomed. Engin. and Technol. and Dept of Biochem. and Mol. Biol., Univ. Maryland Sch. of Med., Baltimore, MD

Abstract: Microglia, the innate immune cells of the central nervous system, shift from a surveying to an activated, proinflammatory state following brain injury. Using the bacterial endotoxin lipopolysaccharide (LPS) and the proinflammatory cytokine interferon-gamma (IFN-gamma) to induce the activation of rat HAPI microglial cells *in vitro*, we found that mitochondria fragmented into small donut shapes after approximately four hours of treatment and failed to recover normal morphology by 18 hours. We hypothesized that mitochondrial fission promotes microglial activation in rat HAPI cells and primary rat cortical microglia. Mdivi-1 and dynasore, putative inhibitors of the mitochondrial fission GTPase Drp1, partially and dose-dependently (37.5-75 micromolar) attenuated production of nitric oxide by activated HAPI or primary microglia while completely blocking the secretion of tumor necrosis factor-alpha (TNF-alpha) at the same concentrations. However, we were unable to demonstrate inhibition of the activation-induced fragmentation of mitochondria by mdivi-1. Using the Seahorse Extracellular Flux Analyzer to measure cellular oxygen consumption, we found that mdivi-1 but not dynasore partially impaired HAPI microglial respiration. The ability of mdivi-1 to inhibit respiration was unlikely related to its ability to impede markers of activation because partial complex I inhibition by the drug rotenone failed to mimic the effect of mdivi-1. Dynasore was previously suggested to inhibit internalization of the LPS receptor toll-like receptor 4 and effects of Drp1 inhibitors on microglial activation steps independent of mitochondrial fragmentation are under investigation. Overall, results indicate that two small molecule inhibitors of the mitochondrial fission GTPase Drp1 impair microglial activation by an unknown mechanism. Interestingly, inhibition of TNF-alpha secretion was more effective than that of nitric oxide production, suggesting that nitric oxide may be upstream of TNF-alpha or that production of the two proinflammatory mediators is regulated independently.

Title: Enhanced expression of glycoprotein non-metastatic melanoma B in macrophages and microglia in inflamed rat brain

Authors: J.-J. HUANG, *S. YOKOYAMA;
Res. Ctr. for Child Mental Develop., Kanazawa Univ., Kanazawa, Japan

Abstract: The glycoprotein non-metastatic melanoma B (Gpnmb), which possesses a type-I transmembrane protein-like structure, has been identified in various types of normal cells including melanocytes, osteoclasts, osteoblasts, and dendritic cells in blood, as well as in various carcinoma cells. Several studies have described that Gpnmb is abundantly expressed in highly invasive glioblastomas, implying its involvement in tumor progression and metastasis. We have demonstrated in the central nervous system (CNS) of rats that Gpnmb is produced by macrophages and microglia in normal neural tissues (Huang et al., Brain and Behavior 2, 85-96, 2012). We have also reported that Gpnmb is present in normal rat sciatic nerve and up-regulated after axotomy (Yokoyama and Yanagida, Soc. Neurosci. Abstr., 438.21, 2012; Yokoyama, Soc. Neurosci. Abstr., 813.15, 2013). In this study, we further examined whether inflammatory stimulation had any effects on Gpnmb expression in the CNS. Bacterial endotoxin lipopolysaccharide (LPS) from Escherichia coli serotype O127:B8 was dissolved in sterile phosphate-buffered saline (PBS; pH 7.4) and injected intraperitoneally at a dose of 0.1 mg/kg of body weight. After injection of LPS, we observed that Gpnmb-immunoreactive (IR) in the area postrema, which is one of the circumventricular organs, was prominent compared with that in rats injected with PBS. This change became obvious 8 hours after the LPS injection and was more widespread after 24 hours. The Gpnmb-IR cells were positive for the macrophage/microglia marker OX42, and frequently observed in the vicinity of vessels. The Gpnmb-IR in these cells was localized to cytoplasmic vesicles. Furthermore, an intraperitoneal LPS injection increased the number of Gpnmb and OX42 double-positive cells in the area postrema, indicating infiltration of blood-borne macrophages through this region. These results suggest that Gpnmb, which is expressed in microglia and macrophages in inflamed brain, plays an important role in the regulation of immune/inflammatory responses.

Title: Hmox1 and EP2 signaling regulate IL-13 - induced death of activated microglia: A potential pathway for resolution of inflammation

Authors: Y. FU[1], *M.-S. YANG[1], K.-J. MIN[2], T. GANESH[1], N. LELUTIU[1], E. JOE[2], R. DINGLEDINE[1];
[1]Emory Univ., Atlanta, GA; [2]Ajou Univ., Suwon, Korea, Republic of

Abstract: Acute inflammation protects the body from foreign invasions but chronic inflammation can be harmful, so understanding the mechanisms by which inflammation is aborted is an important question. Microglia, the brain's resident innate immune cells that mediate neuroinflammation in response to injurious events, can be activated by an endogenous Toll-like receptor 4 (TLR4) ligand, high-mobility group box protein B1 (HMGB1). HMGB1 was recently found to be released by injured neurons, causing long-lasting microglia activation. We examined the control of microglial death *in vitro* by pathways that are engaged during inflammation. We elicited microglia activation *in vitro* by lipopolysaccharide (LPS, 10-100ng/ml) or HMGB1 (100ng/ml) at 2h, judged by induction of mRNA encoding COX2 and TNFα. We confirmed that interleukin-13 (IL-13, 20ng/ml), an anti-inflammatory cytokine, caused death of LPS - activated microglia by 6 days. We also found that IL-13 upregulated cyclooxygenase (COX2) expression and downregulated Heme Oxygenase 1 (Hmox1) expression at both mRNA and protein levels between 6h and 72h after exposure. Tricarbonyldichlororuthenium (II) dimmer used as a source of CO (CO-releasing molecule, CORM, 10μM), a product of Hmox1, reduced IL-13 induced COX2 expression at protein level. CORM also reduced IL-13 induced microglia death by 18.9%, and a Hmox1 inducer, cobalt protoporphyrin IX (CoPP, 2.5μM), reduced IL-13 induced microglia death by 26%. Moreover, a novel antagonist for the EP2 receptor of prostaglandin E2 (PGE2) reduced IL-13 induced microglia death by 75%, suggesting a role for both Hmox1 and EP2 in regulating microglia death. Taken together, these results suggest that Hmox1 and EP2 signaling regulate IL-13 induced death of activated microglia *in vitro*. We propose that timely induction of microglia death by regulating IL-13 or EP2 signaling may be a potential way to control the degree of microglia activation and reduce chronic inflammation.

Title: WWL70 attenuates inflammatory response by blocking prostaglandin production in microglial cells

Authors: *M. TANAKA[1], J. WEN[1], S. MORAN[2], Y. ZHANG[1];
[2]BIC, [1]USUHS, Bethesda, MD

Abstract: Modulation of the endocannabinoid (eCB) system has been shown to play a therapeutic role in several pathological settings. Recently several studies have indicated that inhibition of eCB hydrolysis leads to enhancement of eCB signaling and reduction of inflammatory eicosanoid production. We previously reported that WWL70, an inhibitor of a 2-arachidonyl glycerol (2-AG) hydrolase α,β-hydrolase domain 6 (ABHD6), suppresses neuroinflammation and ameliorated neuronal injury in the animal models of traumatic brain injury and multiple sclerosis. In this study we investigated the anti-inflammatory mechanism of WWL70 *in vitro* using microglial cells. WWL70 was found to efficiently inhibit the accumulation of prostaglandins in LPS-activated microglia. Consistent with the recent view that 2-AG is a major substrate for arachidonic acid (AA) in the brain, addition of 2-AG dramatically increased the production of prostaglandins, which was also significantly inhibited by WWL70. However, the production of prostaglandin facilitated by AA was also significantly reduced by WWL70, suggesting alternative inhibitory effect(s) on the metabolic pathway from AA to prostaglandins, which is mediated mainly by cyclooxygenase 2 (COX2) and prostaglandin synthase (PGES). In addition, when cells were treated with a newly developed and a selective inhibitor for ABHD6, KT182, or knocked down of ABHD6 using siRNA, there was no reduction on prostaglandin production observed. Currently we are investigating whether WWL70 can directly inhibit the enzyme activities of COX2 or PGES. In terms of prostaglandin production, the effect of WWL70 was not reversed by the CB receptor antagonists, suggesting that WWL70 attenuates prostaglandin biosynthesis independently on CB receptor activation. Thus, it is likely that the anti-inflammatory and neuroprotective effects of WWL70 *in vivo* might be due to its inhibition on prostaglandin biosynthesis in microglia cell. The role of ABHD6 in the control of neuroinflammation and neurodegeneration needs to be further investigated.

Title: Anti-inflammatory effects of ketamine on microglia activation

Authors: *T. KHAYRULLINA[1], M. H. SCHMIDT[1], R. G. W. STAAL[1], N. PLATH[2], T. MÖLLER[1];
[1]Lundbeck Res. USA, Paramus, NJ; [2]Lundbeck Res. USA, Valby, Denmark

Abstract: Ketamine is a NMDA receptor antagonist that has been used as an anesthetic, antinociceptive and anti-depressive agent. Recently, much interest has focused on ketamine's non NMDA-related characteristics, for instance its anti-inflammatory properties. It has been reported that ketamine may reduce TLR4 stimulated microglial cytokine release, suggesting that ketamine may work by reducing neuroinflammation in a paradigm of bacterial endotoxin induced microglial activation. The goal of our study was to determine whether ketamine affects other microglial functions downstream of TLR4 activation. First, we set out to replicate previous reports showing that ketamine inhibits the TLR4 stimulated release of pro-inflammatory cytokines. Rat primary microglia were stimulated with control standard endotoxin (CSE), a purified form of LPS that activates TLR4 signaling. When administered prior to CSE (3EU/ml), ketamine significantly reduced the amount of the pro-inflammatory cytokines IL-1b, IL-6 and TNFa as well as nitric oxide. Ketamine was tested from 3-100uM, with minimally effective doses 10-30uM, suggesting a possibly non-NMDAR mediated mechanism. Ketamine did not show any cytotoxicity at the doses tested. Next we investigated the effects of ketamine on CD68, a marker of phagocytosis which is upregulated upon TLR4 activation in microglia. Ketamine produced a dose-dependent decrease of the CSE-induced CD68 levels. Together these data suggest that ketamine inhibits several parameters of microglial responses downstream of TLR4 activation, albeit at very high doses. To test whether ketamine regulates microglial activation pathways other than TLR4, we stimulated microglia with IFNg a known inducer of microglial MHC II expression. Treatment of microglia with IFNg significantly increased cell surface expression of MHCII over non-stimulated cells. Ketamine did not affect MHCII expression on microglia in conditions with or without IFNg. Ketamine also did not affect IFNg-induced TNFa and IL-6 levels. The data suggest that the anti-inflammatory effects of ketamine are not likely to intersect with the IFNg signaling pathway. In summary, our data suggests that ketamine at the doses tested can suppress TLR4 mediated, but not IFNg induced microglial activation. It is of

note that the ketamine concentrations used in our *in vitro* studies are in the high uM range. Additional studies are necessary to investigate whether these concentrations are reached in the CNS at clinically relevant ketamine doses and indeed affect microglia physiology.

Title: Role of P2X7 in a model of neuroinflammation associated with microglial activation: Ex-vivo and in-vivo correlates

Authors: P. ACTON[1], C. COTTO[1], W. ECKERT[2], J. Y. MA[2], B. LORD[2], P. BONAVENTURE[2], A. WICKENDEN[2], P. KING[1], B. SAVALL[2], N. CARRUTHERS[2], M. LETAVIC[2], T. LOVENBERG[2], *A. BHATTACHARYA[2];
[1]Discovery Sci. Imaging, Janssen Pharmaceut. Companies of Johnson & Johnson, SPRING HOUSE, PA; [2]Neurosci., Janssen Pharmaceut. Companies of Johnson & Johnson, SAN DIEGO, CA

Abstract: ATP-gated ion channel P2X7, expressed predominantly in the CNS glial cells, is activated during various CNS disorders that involve neuroinflammation associated with microglial activation. Microglial activation is assessed by studying pro-inflammatory cytokine burden such as IL-1b, up-regulation of markers for microglia (CD68) & astrocytes (GFAP) and the translocator protein TSPO. It is plausible ATP released during episodes of CNS disorders associated with glial activation (epilepsy, MS, AD, ALS, brain injury, mood disorders) may reach high concentrations to activate P2X7 leading to the release of IL-1b, which in turn may activate the microglial activation cascade. The aim of this study was to understand the role of P2X7 in such a process. Kainic acid was chosen as the stimulus to induce microglial activation in rats. In a dose response study, we observed robust changes in morphology of glial cells (astrocytes and microglia), neurodegeneration and TSPO up-regulation 7 days post a single administration of 8 mg/kg (ip) dose of kainic acid, indicating increased glial tone. In an effort to understand the in-vivo time course of microglial activation, rats were subject to PET scan of TSPO, using [F-18]PBR06 at various time points post kainic acid challenge. Robust PET uptake

was observed 5 days after kainic acid challenge and was maintained to 7 days (last time point studies). We then dosed rats with an orally bioavailable, high-affinity, CNS permeable P2X7 selective antagonist to test the effect on kainic acid-induced neuroinflammation on both ex-vivo (immunohistochemistry, TSPO autoradiography) and in-vivo (TSPO PET scan) endpoints. The P2X7 antagonist (10 mg/kg, oral dose; qd for 8 days), significantly attenuated the PET signal; it also produced reversal of kainic acid induced structural changes in the ventricle as assessed by MRI. To our surprise we failed to generate similar robust efficacy on the ex-vivo endpoints of neuroinflammation, primarily due to the inherent variability in the signals. The TSPO PET data is encouraging and suggestive of a critical role of P2X7 in modulating microglial activation that may have therapeutic benefits.

Title: Chronically reactive microglia in peroxisomal multifunctional protein 2 deficiency lose surveillance markers, upregulate mTOR driven pathways but are not neurotoxic

Authors: *M. BAES[1], S. VERHEIJDEN[1], L. BECKERS[1], A. CASAZZA[2,3], O. BUTOVSKY[4], M. MAZZONE[2,3];
[1]Pharmaceut. and Pharmacol. Sci., [2]Oncology, KU Leuven, Leuven, Belgium; [3]Vesalius Res. Ctr., VIB, Leuven, Belgium; [4]Neurol., Harvard Med. Sch., Boston, MA

Abstract: The functional diversity and molecular adaptations of reactive amoeboid microglia in the chronically inflamed central nervous system (CNS) is poorly documented. We previously showed that mice lacking multifunctional protein 2 (MFP2), a pivotal enzyme in peroxisomal β-oxidation, persistently accumulate reactive myeloid cells in the gray matter of the CNS. Here, we defined the signature of Mfp2-/- microglia by *ex vivo* FACS, microarray and immunohistochemical analysis. We found that the increased numbers of myeloid cells derive from proliferation of resident microglia and not from monocyte recruitment. Transcriptome analysis on freshly isolated microglia from Mfp2-/- brain revealed downregulation of many markers that define the unique signature of microglia in homeostatic conditions. Mfp2-/- microglia are immunologically activated but they do not show signs of neurotoxicity nor of phagocytotic activity. In agreement, neurons are conserved in Mfp2-/- brain but they release their inhibitory control on microglia as Cx3cl1 and CD200 are down regulated. Although the initiating signals remain unknown, we show that this reactive phenotype of microglia is governed by mammalian target of rapamycin (mTOR) activation leading to metabolic adaptations compatible with proliferation and growth. In conclusion, our data underscore that chronic activation of microglia not necessarily leads to overt neurotoxicity although we cannot exclude that loss of their surveillance functions contributes to CNS disease progression.

Title: Studying anti-inflammatory signaling by alpha7 nicotinic receptors in heterologous expression systems

Authors: *R. H. LORING, B. GARG, A. KULKARNI, G. THAKUR;
Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Significant literature (e.g. Wang et al., *Nat. Med.* 10: 216, 2004; Saeed et al., *J. Exp. Med.* 201: 1113, 2005, Dowling et al., *Mol. Med.* 13: 576, 2007) suggests that alpha7 nicotinic receptors (a7 nAChRs) play anti-inflammatory roles in innate immune function on macrophages and leukocytes, in part by blocking the transcription factor, nuclear factor kappa-light chain-enhancer of B cells (NFkB). We tested whether a7 nAChRs directly interact with NFkB signaling in a heterologous expression system in the rat pituitary cell line GH3. Wild type GH3 cells do not bind alpha-bungarotoxin (aBT) or show evidence of rat a7 nAChRs by either PCR or Western blots with Abcam polyclonal antibody Ab23832 (Ab832). 1-40 ng/ml rat tumor necrosis factor alpha (TNF) causes up to a 30 fold increase in secreted alkaline phosphatase (SEAP) in GH3 cells transfected with a plasmid consisting of an NFkB promoter driving SEAP (NFkB-SEAP). However, GH3 cells transfected with rat a7 nAChRs show significant aBT binding, and the presence of a7 is confirmed by both PCR and Western blots with Ab832. Nicotine had no significant effect on GH3 cells transfected with both a7 and NFkB-SEAP, but selective a7 drugs such as the agonist PNU282987 (PNU) or the active enantiomer of the allosteric agonist 4BP-TQS (GAT107) blocked TNF-stimulated SEAP secretion over the concentration range of 50-300 microM. However, PNU and GAT107 both block TNF-stimulated SEAP in GH3 cells transfected with NFkB-SEAP alone, suggesting that these compounds have direct effects on NFkB signaling or SEAP secretion. These data suggest that components are lacking in GH3 cells to allow a7 nAChR interactions with NFkB signaling. To see if the a7 anti-inflammatory effects are cell type dependent, we are also investigating a7 nAChR anti-inflammatory signaling in mouse J774A1 and RAW264.7 macrophage cell lines when stimulated with lipopolysaccharide. In addition, these results suggest that the direct effects of high concentrations of PNU or GAT107 on NFkB signaling or SEAP secretion complicate the use of these drugs to study anti-inflammatory effects mediated through a7 nAChRs.

Title: HFE H67D polymorphism is associated with reduced severity of cerebral malaria and increases survival with Plasmodium berghei ANKA

Authors: *J. R. CONNOR[1], D. F. LEITNER[1], M. LANDMESSER[2], E. NEELY[1], J. A. STOUTE[2];
[1]Neurosurg., Penn State Col. of Med., Hershey, PA; [2]Med., Penn State Univ. Col. of Med., Hershey, PA

Abstract: Cerebral malaria (CM) occurs in about 5 million individuals a year with Plasmodium falciparum. CM results in myelin damage, axon injury, blood brain barrier breakdown, and long term neurological deficits in survivors. Iron deficiency commonly occurs with CM, but iron supplementation is a controversial issue in these patients. It is thought that iron loading may increase parasitemia and severity of infection. In this study, we evaluated whether an animal model with genetic iron overload (H67D HFE) had increased severity of infection which would lead to reduced survival. We tested this with the animal model for CM using Plasmodium berghei ANKA. We found that H67D mice had lower parasitemia on day 6 post infection (p.i.) and survived longer than infected WT mice. We monitored hematological parameters throughout the infection. Hematocrit (Hct), hemoglobin (Hgb), and mean corpuscular volume (MCV) were elevated in H67D mice pre-infection. However, Hct, Hgb, and red blood cells (RBCs) decreased in infected H67D mice compared to uninfected H67D until day 14 p.i. These parameters decreased to WT levels from day 7-10 p.i. MCV began to increase from day 12-14 p.i., which indicates an increase in reticulocytes that replaced lost RBCs. We have previously found that Semaphorin4A (Sema4A) induces apoptosis of oligodendrocytes. In this model of CM, Sema4A was increased in the brain of infected WT mice but there was a smaller increase in H67D infected mice. The 33% of surviving H67D mice had the lowest level of Sema4A. We also evaluated iron management proteins in whole brain and myelin. In whole brain, Hft and Tim2 (T cell immunoglobulin and mucin domain containing 2), the receptor for Sema4A, were higher in H67D mice pre-infection and both decreased after infection. However, Hft remained increased in infected H67D when compared to infected WT. Transferrin receptor (TfR) in whole brain was decreased in H67D mice pre-infection compared to WT and remained decreased after infection compared to infected WT, while TfR decreased in WT mice after infection compared to uninfected WT. TfR in the myelin fraction was decreased in H67D mice pre-infection but was no longer significantly different after infection. One treatment option that has been considered for CM is erythropoietin (Epo) which becomes elevated following anemia that is a consequence of malaria. Epo not only promotes erythropoiesis, but also has anti-apoptotic and immunomodulatory effects. We evaluated plasma Epo and found that it was elevated in H67D surviving mice. These data suggest that elevated Epo may be at least partially responsible for the improved outcome in H67D mice and suggests a mechanism that involves lower brain Sema4A.

Medico Nacional Siglo XXI, Hosp. de Pediatria,, Mexico, City, Mexico

Abstract: **Introduction:** After spinal cord injury (SCI), many known auto-destructive mechanisms that are harmful for the patient take place, reducing the probability of neuronal regeneration. The expression of inflammatory genes modulates these mechanisms, hence, proinflammatory genes lead to an inflammatory response, oxidative stress and apoptosis induction, which ends with axonal demyelination and degeneration. Diverse studies are investigating a possible strategy to modulate this auto-destructive response and to promote neuroprotection. A novel approach, is the immunization with modified neural peptides such as A91 and Cop-1 derived from the 87-99 immunogenic sequence of myelin basic protein (MBP); this sequences are recognized by T-lymphocytes, causing its activation and deviation to a Th2 phenotype, which leads to expression of antiinflammatory genes; this phenomena is known as protective auto-reactivity (PA). **Objective:** Analyze the effect of A91 and Cop-1 on CASP-3, TGF-β, IL-12 and IL-6 gene expression in rats with moderate and severe SCI. **Methods:** Gene expression analysis was performed in Fischer 344 rats with SCI by contusion (moderate or severe), immunized 1 hour after the lesion with A91 and Cop-1, using as control the immunization with OVA (ovalbumin) and PBS (phosphate buffer saline) as vehicle. Seven days

post-lesion, was performed the total RNA extraction from the injured spinal cord using the method TRIzol-isopropanol (Invitrogen); RNA integrity was checked by electrophoresis and spectrophotometry. The following step was cDNA synthesis using Thermoscript Plus Reverse Transcription protocol (Invitrogen) to perform subsequently q-PCR with SYBRGreen protocol (Roche). **Results:** The results after the moderate injury showed a pattern of neuroprotection by decreasing the expression of CASP-3 and IL-6 in the immunized groups with A91 and Cop-1 compared with PBS and OVA ($P< 0.05$; Kruskal Wallis); increasing the expression of TGF-β only in Cop-1 group ($P=0.216$ Kruskal Wallis). The contrary pattern was observed in severe injury where the immunization with any antigen caused an increased expression of CASP-3, IL-12 y TGF-β compared with PBS ($P<0.05$). **Conclusions:** Immunization with A91 or Cop-1 decreases the expression of certain proinflammatory genes having their own mechanism of neuroprotection, being possible to correlate this with the reduction of lipid peroxidation and apoptosis in previous studies of our investigation group.

Title: Proinflammatory cytokines alter signalling in human brain pericytes

Authors: *D. JANSSON[1], J. RUSTENHOVEN[1], R. L. OLDFIELD[3], P. S. BERGIN[4], E. W. MEE[4], R. L. M. FAULL[2], M. DRAGUNOW[1];

Abstract: Brain inflammation is thought to be a contributing factor in brain pathologies such as epilepsy, stroke, Parkinson's disease, motor neurone disease, Huntington's disease and

Alzheimer's disease. Previous studies of brain inflammation have focused on principal immune cells such as microglia and astrocytes. While these cell types play an important role in inflammatory pathways, new research suggests that microvascular brain pericytes, which play a vital role in blood-brain barrier (BBB) maintenance and permeability, are also key participants of immune signalling in the central nervous system. We have established an *in vitro* cell culture system of α-smooth muscle actin, platelet-derived growth factor receptor-β (PDGFRβ), and NG2 positive primary pericytes derived from adult human brain tissue. We have previously shown that these cells may play an active role in the pro-inflammatory response by inducing changes in chemokine, cytokine and cell receptor expression at the gene and protein level. Studies have revealed that PDGFRβ is necessary for pericyte survival, as PDGFRβ knock-out animal models show loss of brain pericytes. Depletion of pericytes surrounding the brain vasculature is associated with impaired BBB function and therefore increased permeability to potentially toxic molecules and cells. Indeed, BBB breakdown and pericyte loss is a common feature of several neuroinflammatory diseases. However, whether changes in PDGFRβ expression are a cause or a consequence of pericyte dysfunction in neurodegeneration remains to be determined. We investigated the effects of pro-inflammatory pathways on PDGFRβ expression and regulation in primary adult human brain pericytes. We show that when pericytes have been pre-treated with low levels of chronic pro-inflammatory cytokines there is a change in both ligand stimulated and basal PDGFRβ expression, internalization and hence activation compared to controls. Further investigation will give insight into mechanisms and potential therapeutic interventions to prevent pericyte cell loss and therefore BBB breakdown and the neurotoxicity that ensues.

Title: Chronic alcohol consumption in combination with energy drinks causes an inflammatory response and neurodegeneration in rat

Authors: *A. D. DIAZ[1], D. CORDERO[1], S. TREVINO[1], V. TOXQUI[1], M. GONZALEZ-CORONEL[1], L. AGUILAR[1], G. CARMONA[2], J. MORENO-RODRIGUEZ[2], P. AGUILAR-ALONSO[3], G. FLORES[4], J. GUEVARA[5];
[1]Pharm., [2]Química Gen., [3]Bioquímica, Facultad De Ciencias Quimicas, BUAP, Puebla, Mexico; [4]Neuropsiquiatría, Inst. de Fisiologia, BUAP, Puebla, Mexico; [5]Bioquimica, Facultad de Medicina, UNAM, Mexíco DF., Mexico

Abstract: Energy drinks (ED), possess high concentration of caffeine and taurine, which often consumed in combination with ethanol, due to the popular belief that caffeine and taurine may counteract some of the intoxicating effects of ethanol. However, scientific research suggests that chronic use of these psychoactive substances in combination with alcohol trigger an inflammatory response mediated by pro-inflammatory cytokines (IL-1β and TNF-α) and iNOS both in the central and peripheral system modifying the behaviour of individuals and causing cell death (apoptosis). Currently, the mechanism of toxicity caused by the ED-ethanol interaction in the brain, are not well known. In the present study we evaluated the effects of chronic alcohol consumption in combination with energy drinks on the inflammatory response and neurodegeneration in rat. We used male Long Evans rats (200-250g). Were formed, 4 experimental groups (n=10 per group): 1) control (water); 2) Ethanol (40%); 3) ED (Red-bull) and 4) Ethanol + ED. Animals were orally administered for 2 months, in the course of treatment was evaluated, motor activity in closed field (day 0, 30 and 60). After treatment, the animals were sacrificed; the brains were removed for immunohistochemistry and fluorescence immunoassay (ELISA) to identify markers of inflammation (GFAP, IL-1β, TNF-α, iNOS, nitric oxide) and neurodegeneration (caspase-3 and -9, synaptophysin) in the temporal cortex and hippocampus, respectively. The results showed a progressive deterioration in motor activity during the administration of ethanol + ED. Biochemical and histological studies revealed that chronic ethanol + ED caused an increase in reactive gliosis, IL-1β, TNF-α, iNOS and nitric oxide, in the temporal cortex and hippocampus, respectively, also show immunoreactivity positive for caspase-3 and 9, and a decreases synaptophysin in temporal cortex and hippocampus. The results suggest that chronic consumption of alcohol in combination, cause an inflammatory response, which induces neurodegeneration in hippocampus and cerebral cortex, which affects the motor behaviour of the rats. Therefore, it is necessary to show caution in the consumption of these drinks combined with ethanol, so it is necessary to report urgently on the risks it is exposed to the health of consumers of these substances, especially young people.

Title: PKCδ mediates lipopolysaccharide-induced inflammatory response in astrocytes

Authors: N. SINGH, V. LAWANA, H. JIN, *V. ANANTHARAM, A. KANTHASAMY, A. KANTHASAMY;
Biomed Sci, Iowa Ctr. for Advanced Neurotoxicology, Iowa State Univ., Ames, IA

Abstract: Parkinson's disease(PD) is a progressive neurodegenerative disease that is characterized by the progressive loss of dopaminergic neurons in the substantia nigra. Accumulating evidence suggest that both oxidative stress and inflammation are co-contributors in the LPS-induced progressive and delayed loss of nigrostriatal dopaminergic neurons in neuro-inflammation models of PD. We have previously showed that TNFα-induced dopaminergic neuronal injury may be mediated via activation of PKC delta(PKCδ)-dependent cell signaling events; however the exact contribution of astroglial PKCδ in the induction of an inflammatory response remains elusive. It is well known that excessive microglial activation exerts toxic effects on bystander neurons, particularly nigrostriatal dopaminergic neurons. Besides microglia, astrocytes also expresses Toll like receptors (TLRs) and several kinases, including ERK, JNK, p38 mitogen activated protein kinase (MAPK), and several isoforms of PKC including PKCδ. In this study we examined the role of PKC delta in regulating bacterial endotoxin, LPS-induced pro-inflammatory mediator generation in mouse astrocytes obtained from WT and PKCδ knock out (KO) astrocytes.Here we show that PKCδ regulates the induction of proinflammatory response in murine astrocytes.Upon treatment of WT astrocytes with LPS, a pronounced induction in the mRNA expression levels of pro inflammatory cytokine and chemokines such as TNFα, IL1β, IL-12, COX-2, MMP 9, MCP-1 and CXCL10/IP10 were evidenced; however PKCδ KO astrocytes displayed a blunted inflammatory response thereby supporting a role for PKCδ in the induction of proinflammatory gene expression in activated astroglia. More importantly, the expression levels of NADPH oxidase (NOX 1) and iNOS, were significantly down regulated in LPS- treated PKCδ KO astrocytes as compared to drug treated wild type controls. In a similar fashion, LPS-induced phosphorylation of ERK1/2 and p38 MAPK, as well as NFκB transactivation were attenuated in PKCδ KO astrocytes as compared with wild type controls. Our finding identifies PKCδ as a major regulator of pro-inflammatory response and

suggest that PKCδ contributes to the induction of proinflammatory mediators, presumably via induction of ROS generation and activation of MAPK in activated astrocytes.

Title: Systemic lipopolysaccharide administration alters cortical neuromodulation by increasing monoamine-oxidase A and acetylcholinesterase activities

Authors: ***L. K. BEKAR**, M. ZHI, G. SAWICKI, M. E. LOEWEN;
Pharmacol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Lipopolysaccharide (LPS)-mediated sickness behavior is known to be a result of increased inflammatory cytokines in the brain. Although effects of cytokines on various neural pathways are known, further exploration of the mechanisms underlying cytokine induced behavioral changes is needed. Several studies have demonstrated cytokine-mediated increases in brain excitation by loss of GABAA-mediated inhibition through receptor internalization or inactivation. Given that inflammatory signaling pathways, reactive oxygen species and stress are also known to increase monoamine oxidase-A (MAO-A) and acetylcholinesterase (ACh-E) activity, we assessed the impact of systemic LPS on neuromodulator-mediated shaping of a simple cortical network. Extracellular field recordings of evoked excitatory post-synaptic potentials in adult mouse somatosensory cortical slices were used to evaluate effects of a single systemic LPS challenge on neuromodulator function one week later. Neuromodulators were administered transiently as a bolus (100 µl) to the bath perfusate immediately upstream of the recording site to mimic phasic release of neuromodulators and enable assessment of response temporal dynamics. LPS-mediated neuroinflammation resulted in loss of both spontaneous and evoked inhibition as well as alterations in the temporal dynamics of neuromodulator effects on a paired-pulse paradigm. The effects on neuromodulator temporal dynamics was sensitive to the MAO-A antagonist clorgyline (for norepinephrine and serotonin) and the ACh-E inhibitor

donepezil (for acetylcholine), suggesting inflammatory-mediated increases in MAO-A and ACh-E as the potential source of altered neuromodulation in LPS-treated animals. The results show that systemic LPS treatment leads to longer-term loss of cortical inhibition and decrease in neuromodulator action as a result of increased MAO-A and ACh-E activity. Given the significant role of neuromodulators in behavioral state and cognitive processes, it is likely that an inflammatory-mediated change in neuromodulator action plays a role in LPS-induced sickness behavior and could help define the link between infection and depression.

Title: Chemokine CCL3 inhibition of long-term potentiation in rat hippocampal slices

Authors: ***G. TU**[1,2], J. ZHANG[2], H. LIU[2], J. LIU[2], H. XIONG[2];
[1]Unmc, Omaha, NE; [2]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Chemokine (C-C motif) ligand 3 (CCL3, also known as MIP-1α) is produced by many types of cells and its cognate receptor has been detected in neurons in several brain regions including the hippocampus, suggesting CCL3 play a role in the central nervous system (CNS), in addition to its well established role in the immune system. Studies have shown that elevated CNS levels of CCL3 are associated with several neurological disorders. However, how elevated levels of CCL3 cause neurological disorders is not well understood. In this study, we investigated the effects of CCL3 on synaptic transmission and plasticity in the CA1 region of hippocampal slices prepared from 15-30d old male Sprague Dawley rats. Bath application of CCL3 produced a significant reduction in field excitatory postsynaptic potentials (fEPSP) and long-term potentiation (LTP), a well-known synaptic mechanism for learning and memory. The CCL3-mediated reduction of fEPSP and LTP was attenuated by Maraviroc, a specific CCR5 blocker. Addition of picrotoxin, a $GABA_A$ receptor antagonist, to the bath did not alter the CCL3-

mediated reduction on fEPSP and LTP, indicating that CCL3-associated reduction was not a consequence of activation of GABAergic interneurons. These results demonstrated that CCL3 alters synaptic transmission and plasticity via CCR5 which may have implications for pathogenesis of neurological disorders.

Title: Tumor necrosis factor-related apoptosis inducing ligand/glucocorticoid-induced TNF receptor ligand redundancy in neurodegenerative processes

Authors: G. DI BENEDETTO[1,2], N. RONSISVALLE[1], *P. GUARNERI[3], R. BERNARDINI[1], G. CANTARELLA[1];
[1]Clin. and Mol. Biomedicine, Univ. Catania Sch. of Med., Catania, Italy; [2]Li-Sa Lab, dept Exp Med, Med. Physiopathol Endocrinol Nutr, Univ. of Roma "La Sapienza", Roma, Italy; [3]IBIM-CNR, Palermo, Italy

Abstract: Tumour Necrosis Factor-Related Apoptosis-Inducing Ligand (TRAIL), a proapoptotic/proinflammatory cytokine of the TNF superfamily abundantly expressed by injuried neurons, has been proven to be a potent mediator of neurotoxicity related to various noxious stimuli, eventually setting into motion the apoptotic machinery in neuronal cells. Evidence shows that neutralization of the TRAIL death pathway in human neuronal cells is eventually associated with partial abrogation amyloid beta-related neurotoxicity. Similarly to TRAIL, the cytokine Glucocorticoid-induced TNF receptor ligand (GITRL) is able to transduce apoptotic signals. In spite of an array of reports suggesting redundant, additive effects between TRAIL and an array of cytokines, scanty data are, so far, available about a TRAIL/GITRL crosstalk. Here, we investigated possible interactions between TRAIL and the GITRL system in an *in vitro* model of neurodegeneration, using the human cortical neuronal cell line HCN-2. To accomplish this task, HCN-2 cells were treated with TRAIL in different experimental conditions. Real-time PCR analysis of cell lysates showed that HCN-2 cells did not express GITRL mRNA constitutively, whereas the latter was potently induced by treatment of cultured cells with TRAIL. In addition, HCN-2 cells did not express the GITRL receptor GITR mRNA, neither in

control cultures, nor after treatment with TRAIL. Real-time PCR data were corroborated by western blot analysis, showing similar pattern of the correspondent proteins at the level of protein expression. The MTT cell viability assay showed that TRAIL, when combined with GITRL, was able to exert additive toxic, lethal effects on HCN-2 cells. A counterproof to the latter data was provided in experiments performed using a GITRL neutralizing antibody, resulting in significantly attenuated TRAIL-mediated neurotoxicity in HCN-2 cells. Results suggest that TRAIL/GITRL redundancy during neurodegenerative processes implies reciprocal potentiation of detrimental effects of both cytokines on neurons, eventually leading to larger cell damage and death. Finally, characterization of novel molecular targets within the TRAIL/GITRL interplay may represent a platform for innovative treatment of neurodegenerative diseases.

Abstract: Human auto-antibodies specific for NMDAR have been implicated in anti-NMDAR encephalitis and dementia. Anti-NMDAR encephalitis is one of the most commonly identified causes of encephalitis and results in psychosis, altered consciousness, seizures, dyskinesias, and autonomic dysfunction. IgG antibodies in this syndrome are thought to bind to the extracellular

amino-terminal domain (ATD) of the NMDAR's GluN1 subunit, resulting in transient stabilization of the receptor's open conformation followed by NMDAR hypofunction due to receptor cross-linking and internalization. In dementia, IgA antibodies to the NMDAR have been described that are distinct from the IgG antibodies seen in encephalitis. The pathophysiological significance of these antibodies is unclear, and comparison of antibodies that bind the same receptor, but with different pathophysiological effects, will enable detailed structure/function studies. Limited amounts of anti-NMDAR antibodies can be obtained from individual patients, and these supplies are not pure. Thus, it has been impossible to establish definitively if anti-NMDAR antibodies are disease-causing. Furthermore, the polyclonal nature of serum and CSF antibodies makes diagnostic testing and detailed structure:function studies difficult. We have characterized the binding and activity of patient-derived, polyclonal anti-NMDAR antibodies and correlated these activities with anti-NMDAR monoclonal antibodies (mAbs) cloned from patients. Using a cell-free assay that employs a construct that preserves the native GluN1-ATD conformation, we have shown that the receptor's ATD alone is sufficient for IgG binding in anti-NMDAR encephalitis. We created a novel, whole cell ELISA (WCE) by expressing this domain in 293T cells. We collected B-cells from patients with anti-NMDAR encephalitis, and cloned 4 distinct mAbs immunoreactive with the GluN1-ATD WCE. The antibodies are affinity-matured, suggesting that they arose through T-cell dependent processes. We are characterizing the binding and activity of these mAbs using cultured neurons and transfected HEK cells. Studying anti-NMDAR polyclonal IgA antibodies from dementia patients, we have observed that these antibodies have different epitope-binding specificities than the IgG antibodies in anti-NMDAR encephalitis. Deletion of the ATD does not fully eliminate antibody binding, and that the C-terminal domain may play an important role. Furthermore, within GluN1 transfected HEK cells, IgA-dementia and IgG-encephalitis anti-NMDAR antibodies recognize distinct GluN1 pools, indicating a role for GluN1 post-translational processing in antibody recognition.

Title: Fluoropalmitoylethanolamine biodistribution and its potential as a PET tracer

Authors: *S. J. GATLEY[1], M. PANDEY[2], R. I. DUCLOS[1], T. R. DEGRADO[2];
[1]Pharmaceut. Sci., Northeastern Univ., BOSTON, MA; [2]Mol. Imaging Res., Mayo Clin., Rochester, MN

Abstract: N-Acylethanolamines are found widely as lipid signaling messengers in both plants and animals. Palmitoylethanolamine (PEA) is available as a nutraceutical claimed to be a "natural painkiller", and as an antipruritic cream. Its status has recently been reviewed (PMID:23964161). It is reported to have anti-inflammatory, pain reducing, anti-convulsant and neuroprotective actions. Though structurally related to the endocannabinoid, N-arachidonoylethanolamine (anandamide), PEA is believed to act by means of non-cannabinoid mechanisms, including as an agonist at peroxisome proliferator-activated receptors. It is a substrate for hydrolytic enzymes including fatty acid amide hydrolase (FAAH) and N-acylethanolamine-hydrolyzing acid amidase (NAAA). We previously presented (Abstract#: 404.19, 2012) a brief description of the synthesis of omega-fluoropalmitoylethanolamine (N[16-fluorohexadecanoyl] ethanolamine; FHEA) labeled with Fluorine-18 and also some data on its distribution and metabolism in mouse brain. We showed that FHEA enters the brain and that radioactive lipids but no remaining labeled FHEA were present one hour after intravenous administration. In subsequent work we have evaluated the biodistribution of FHEA and its brain metabolism in animals given URB597, a specific inhibitor of FAAH. In controls, tissue concentrations were in the order: liver > kidney > lung > heart > fat > spleen > whole brain > muscle > bone > blood > skin > testis, and ranged from 15% injected activity/g to 1% injected activity/g. URB597 did not significantly alter tissue concentrations, except in bone. In contrast to the lack of effect on total tissue F-18, URB597 did alter the pattern of labeled lipids in brain tissue seen after Folch extraction and radio thin layer chromatography of the chloroform fraction. In controls euthanized at 5 min, phosphatidyl choline (PC) was the most abundant lipid species (40%), while unmetabolized FHEA represented 10% of the F-18. After URB597, PC and FHEA represented 20% and 50%, respectively. Mean levels of all other neutral and phospholipid species detected were also lower after URB597, consistent with reduced supply of labeled fluoropalmitate from FHEA, due to inhibition of FAAH. The failure of URB597 to change net tissue F-18 levels at 30 min is disappointing in terms of the potential of FHEA as a PET tracer for FAAH. Once FHEA has entered the brain, it is retained and does not clear quickly enough to reveal a signal from label trapped by incorporation into lipid pools. Understanding the reasons

for this retention is important for the goal of developing a FAAH radiotracer based on metabolic trapping.

Title: Neonatal stress alters inflammatory responses in the adult mouse brain

Authors: G. ODEBODE[1], L. NAIDU[2], *C. F. HOHMANN[1];
[1]Biol., Morgan State Univ., BALTIMORE, MD; [2]Biol., Morgan State Univ., Baltimore, MD

Abstract: Early life stress and trauma are risk factors for mental health disorders including schizophrenia, depression and Autism Spectrum Disorder (ASD). Neuroinflammation and increased production of pro-inflammatory cytokines have also been observed in these disorders. Here, we investigate, if early postnatal stress exposure can alter inflammatory responses in the brain and serum of Balb/CByJ mice. Pups were separated from the dam for one hour/day between postnatal days (PND) 2 and PND 7 and simultaneously exposed to cold and hot temperatures on alternating days. Stressed (STR) pups were compared to litter mate controls (LMC) that remained with the dam and age matched controls (AMC) in separate litters. In experiment one, cortices of 8 male and female STR, LMC and AMC each, were harvested on PND 90 and processed for ELISA (ebioscience) detection of cytokines; trunk blood was collected for serum corticosterone measurements. In a second experiment 21 STR, 19 LMC and 18 AMC mice of both sexes were injected, as adults, with LPS (5ug/250 microl.) or saline (0.9%) and sacrificed 2 hours later for collection of brain tissue and blood/serum for cytokine measurements. Baseline cytokine levels in the cortex of non-injected STR, LMC and AMC mice did not differ significantly. Similarly, baseline serum levels of corticosterone were not significantly altered in the STR or LMC groups. However, following LPS injections, production of IL-6 and TNF-alpha was significantly elevated in STR and LMC compared to AMC mice. Serum levels of IL-6 were significantly increased in STR and LMC mice whereas serum levels of TNF-alpha decreased compared to AMC. Thus, early life adverse conditions predispose for an

altered neuroinflammatory and cytokine responses later in life, in Balb/CByJ mice. While increased serum levels of IL-6 were consistent with prior observations, decreased serum TNF-alpha, after LPS injections, was unexpected. In addition, comparison of experiments 1 & 2 revealed higher production of both TNF-alpha and IL-6 in saline injected STR mice, compared to non-injected mice, suggesting, that injection-stress may be sufficient to trigger cytokine production selectively in the STR mice. These data suggest, that increased inflammatory responses, seen in mental health disorders, may have been programmed by early life experience. Supported by S06GM051971.

Title: Enhancement of glutamate clearance via cortical glial glutamate transport (GLT-1) induced resiliency to stress

Authors: M. BANASR, A. LEPACK, J. MALDONADO-AVILES, C. KISELYCZNYK, V. DURIC, J. ZHANG, S. WILBER, K. TANAKA, R. DILEONE, R. DUMAN, *G. SANACORA; Dept Psychiatry, Yale Univ., NEW HAVEN, CT

Abstract: Glial pathology and impaired glial mediated glutamate uptake are implicated in the pathophysiology of several neuropsychiatric and substance abuse disorders. We previously demonstrated stress-induced effects on GLT-1 (EAAT2 in humans), the primary glutamate transporter, that are associated with decreased rates of glutamate/glutamine cycling in rodent models. In these studies we sought to examine if pharmacological and genetic manipulations of GLT-1 function and expression could modulate stress responsiveness in similar rodent models. Regional microinjections of dihydrokainate (DHK) were applied to frontal cortex to examine the effect of pharmacological blockade of GLT-1 function on stress response. We used transgenic

mice (GLT1+/- mice) along with a targeted viral GLT-1 overexpression to examine the effects of genetically determined GLT-1 expression on stress-response. Three weeks after surgery and infusion and exposure to chronic unpredictable stress (CUS), animals were tested for anhedonia-like or anxiety-like behaviors. Mice with impaired GLT-1 function, either secondary to local micro-infusion of DHK into the infra/pre-limbic regions or heterozygous GLT-1 knockout, exhibited an exacerbated response to CUS on sucrose consumption and other behavioral assays. Viral overexpression of GLT-1 had little effect on baseline measures but significantly attenuated the effects of stress on the behavior of both heterozygous GLT-1 knockout mice and wild type littermates. We also demonstrated that two drugs, riluzole and ceftriaxone known to increase GLT-1 expression, have antidepressant-like effects in chronically stressed animals and that increased cortical GLT-1 activity is necessary for antidepressant action of these drugs. Indeed, we showed, using transgenic mice (GLT1+/- mice) and PFC infusion of DHK (dihydrokainate, GLT-1 inhibitor) in rats, impaired response to both riluzole and ceftriaxone in GLT1+/- mice and blockade of the behavioral effects of these drugs in rats infused with DHK in the mPFC. Together our results demonstrate that impairment of glutamate uptake can exacerbate the deleterious effects of stress, but enhancement of glutamate clearance by astrocytes in the PFC is sufficient to induce resiliency to stress and can be targeted for antidepressant development.

Title: Conventional antidepressant drugs and DNMT inhibitors effects on stress-induced behavior and DNA methylation changes in mice submitted to forced swimming test

Authors: *S. S. JOCA[1], A. J. SALES[2];
[1]Physics-Chemistry/Pharmacology, FCFRP-USP, Ribeirao Preto-SP, Brazil; [2]Pharmacol., Sch. of Med. of Ribeirão Preto, USP, Ribeirao Preto-SP, Brazil

Abstract: DNA methylation is an epigenetic mechanism that is thought to play an important role in the neurobiology of depression. While stress increases DNA methylation and decreases the expression of genes involved in neuronal plasticity, DNA methyltransferases inhibitors (DNMTi) increase gene expression and induce antidepressant-like effects in preclinical models. As an attempt to furhter explore the involvement of DNA methylation in stress-induced behavioral changes, we investigated in the present work if DNMTi administration would have synergistic effect with conventional antidepressant drugs in behavioral and DNA methylation changes in mice submitted to the forced swimming test (FST). Therefore, mice received systemic injections of DNMTi, 5-aza-2'-deoxycytidine (5-AzaD, 0.1 and 0.2mg/Kg) and RG108 (0.1, 0.2 and 0.4mg/kg), or antidepressants, desipramine (DES, 2.5, 5 and 10mg/Kg) and fluoxetine (FLX, 5, 10, 20 and 30mg/Kg) and were submitted to FST or to the open field test (OFT). Additional groups received a combination of subeffective doses of 5-AzaD or RG108 with subeffective doses of DES or FLX. Subeffective doses of RG108 (0.1mg/Kg) or 5-AzaD (0.1mg/Kg) followed by DES (2.5mg/Kg) or FLX (10mg/Kg) induced significant antidepressant-like effects (one-way ANOVA, p0,05; n=8-9). Effective doses of RG108 (0.2 mg/Kg), 5-AzaD (0.2 mg/Kg), DES (10 mg/Kg) and FLX (20 mg/Kg) induced antidepressant-like effects ($F_{4,35}=4,715$, $p<0,05$) associated to similar changes in DNA methylation levels in the hippocampus (HPC) and prefrontal cortex (PFC). FST induced increase and decrease in DNA methylation in the HPC and PFC, respectively, and these effects were attenuated by antidepressants and DNMTi (HPC: $F_{5,37}=6,527$, $p<0,05$; PFC: $F_{5,40}=28,67$, $p<0,05$). These results suggest DNMTi potentiate the behavioral effect of antidepressant drugs and that antidepressants, as well as DNMTi, are able to modulate stress-induced changes in DNA methylation in brain regions closely related to the neurobiology of depression.

Title: Deletion of fibroblastic growth factor receptor 1 from NG2 cells exerts anxiolytic properties

Authors: *A. BECKER, A. LEPACK, X.-Y. LI, R. DUMAN;
Dept. of Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: Major depression is the most debilitating mood disorder in the United States and is often comorbid with anxiety disorders. Reciprocally, antidepressants of the SSRI type are also effective for treating anxiety disorders. In search of new treatment strategies for depression and anxiety disorders, accumulating evidence indicates modulation of the fibroblastic growth factor (FGF) signaling as a promising novel treatment approach. The potent neurotrophic activity of FGFs has been implicated in proliferation control, specification and survival of progenitor cells, axon guidance and regulation of synaptic plasticity, mechanisms that are disturbed in depression and potentially contribute to anxiety disorders. Recent findings from our lab show that FGF-2/FGF receptor signaling is sufficient and necessary for the behavioral, as well as gliogenic, actions of antidepressants. We have now investigated the behavioral and molecular consequences of selective FGF receptor 1 (FGFR1) ablation on NG2 positive cells in the context of depression-like symptoms and anxiety. Knockout mice were generated by breeding of NG2-Cre mice with homozygous FGFR1 floxed mice. Adult NG2-FGFR-/- mice did not differ from non-ablated littermates (NG2-FGFR+/+) in bodyweight, water and sucrose consumption, or in the amount of locomotor activity. However, NG2-FGFR-/- mice displayed decreased anxious behavior in animal models of anxiety, including increased exploration in the center of an open-field arena, more time spent in the open arms of an elevated plus maze, and decreased latency to feed in the novelty suppressed feeding paradigm. This finding is consistent with a function of FGFs as modulators of emotional behaviors, albeit opposite to predicted results. In line with the reported

correlation of anxiolytic behavior with increasing levels of FGF2, NG2-FGFR-/- mice showed a significant increase in hippocampal FGF2 which could explain this discrepancy. We are currently investigating further molecular consequences of the specific FGFR1 knockdown in NG2 positive cells, as understanding of the mechanisms involved in the regulation of anxiety by FGFR1 and their role on NG2 positive cells would open a new avenue for the treatment of anxiety disorders in humans.

Title: Molecular and behavioral characterization of optogenetic stimulation of infralimbic prefrontal cortex circuitry

Authors: *A. M. THOMAS;
Yale Sch. of Med., New Haven, CT

Abstract: Ketamine is an antidepressant that promises to be more effective and faster-acting than any of the currently available depression pharmacotherapies, but its clinical use is limited by side effects. It is thus important to understand how ketamine acts in the brain in order to develop new therapies that utilize its mechanism of action. One key area of study is the circuitry underlying ketamine's effects. Ketamine is known to increase glutamate release in the rodent medial prefrontal cortex (mPFC) as well as mammalian target of rapamycin (mTOR) signaling, both of which are critical to its antidepressant action. In humans, the prefrontal brain area thought to correspond most closely to the rodent mPFC is the anterior cingulate cortex, and functional brain imaging has shown differences in its activity in depressed patients compared to controls. We hypothesized that we could reproduce ketamine's antidepressant effects by inducing glutamatergic activity in the mPFC. To test this, we used a rAAV2/CaMKIIα-

ChR2(H134R)-EYFP construct injected into the infralimbic prefrontal cortex (IL-PFC) of male rats. A single, one-hour laser stimulation of excitatory neurons in this area produces an antidepressant effect lasting up to 2 weeks, as measured by the forced-swim test (FST) and novelty-suppressed feeding test (NSFT), which are measures of depression and anxiety, respectively. Using the same optogenetic manipulations, we have sought to characterize the circuitry underlying this effect. Three brain areas in particular, the dorsal raphe (dR), lateral habenula (lHb), and nucleus accumbens (NAc), have been found to have robust connections to the IL-PFC and to be involved in the development of depressive features in rodents. The relevance of these brain areas to the observed antidepressant effect of IL-PFC stimulation will be assessed by optogenetically stimulating axon terminals from the IL-PFC in these three regions after injection of the viral channelrhodopsin construct into the IL-PFC. Molecular studies are being conducted to characterize changes in activity in these regions and determine which cell types are the target of these projections.

Title: Neonatal exposure to clomipramine is a behavioral rat model of Obsessive Compulsive Disorder offering face validity as well as predictive validity for the GABA agonist diazepam, the serotonin uptake inhibitor fluoxetine, and the norepinephrine uptake inhibitor desipramine

Authors: *D. S. KREISS, S. E. FRANK, K. M. CRAIG, H. S. MULDER, A. L. HYDE, L. S. LAIKS;
Psychology and Neurosci. Dept, Colgate Univ., Hamilton, NY

Abstract: Obsessive Compulsive Disorder (OCD) - a psychiatric disorder affecting 2-3% of the population - is characterized by persistent, anxiety producing thoughts often accompanied by overwhelming urges to perform repetitive ritualistic behaviors. Current pharmacological treatments for OCD are only effective in 40-60% of patients and have an 8-10 week delayed

onset. Animal models with both face and predictive validity are imperative in the field of OCD so that better treatment avenues can be explored. The current study aimed to further validate a novel rodent model of OCD: neonatal exposure to clomipramine. Male Sprague-Dawley rats were administered clomipramine (15 mg/kg x 2) during neonatal Days 9-16 (= neoClom). Hole-board head dipping and behaviors in a marble arena (including marble burying and a novel marble checking behavior) were assessed at adulthood. At postnatal Days 208-228, neoClom rats (n=14) buried significantly more marbles than neoSaline controls, but did not differ in other observed behaviors. Our 2013 studies demonstrated that at postnatal Days 70-72, a group of 26 neoClom rats significantly buried more marbles, checked more marbles, had increased repetitive head dips, and spent more time in closed arms of the Elevated Plus Maze -> suggesting that younger behavioral testing and a larger group of neoClom rats facilitate observation of more robust differences. The effects of acute diazepam (1, 8 mg/kg) upon the current group of neoClom rats (n=14) differed significantly from neoSalines. The GABA agonist diazepam did not alter behaviors of neoClom rats. However in the NeoSalines, the low dose of diazepam significantly increased exploratory behaviors while the high dose significantly decreased behaviors. These results are congruent with the ineffectiveness of diazepam at alleviating symptoms of OCD patients and the typical behavioral alterations induced by GABA agonists in humans without OCD. In 2013, our lab demonstrated that 14-day repeated administration of fluoxetine (10 mg/kg) normalized marble and hole-board behaviors of the neoCloms, whereas repeated administration with desipramine (5 mg/kg) and saline had no effect. The ability of repeated fluoxetine and the inabilities of acute diazepam and repeated desipramine to normalize the altered behaviors of the experimental neoClom rats mirror the clinical efficacy of these agents in the treatment of OCD. These data confirm the face validity of the neoClom model of OCD and, for the first time, demonstrate the predictive validity of the model. The neoClomipramine model offers a unique permanent, multi-symptom behavioral profile of OCD that distinguishes it from models of anxiety and depression.

Title: S6 Kinase 1 signaling in prefrontal cortex controls depressive behavior

Authors: *J. M. DWYER, J. MALDONADO-AVILES, A. E. LEPACK, R. J. DILEONE, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Major Depressive Disorder (MDD) affects nearly one fifth of the population and is the second leading cause of disability worldwide. Although the precise molecular mechanisms underlying MDD remain largely unknown, our lab has recently demonstrated an important role for the mechanistic target of rapamycin complex 1 (mTORC1)/S6 Kinase 1 pathway in mediating stress-related behavior and rapid antidepressant responses. The mTORC1/S6K1 pathway is a critical regulator of protein synthesis, cell growth and cytoskeletal rearrangement. In the present series of experiments, we asked whether direct modulation of this pathway is sufficient to control depressive behavior. To address this question, we used an AAV2 viral-mediated approach to deliver either a constitutively-active or a kinase-inactive S6K1 mutant (Dr. John Blenis) to the rat mPFC to determine if modulation of S6K1 signaling is sufficient to control depressive behavior. Bilateral infusion of the active S6K1 mutant in the mPFC reduced immobility times in the forced swim test (40% reduction compared to control; $P < 0.002$), indicative of a robust antidepressant response. These effects are not due to differences in locomotor activity as control- and S6K1 mutant-infused rats did not differ. The observed antidepressant-like effect is specific to the mPFC as infusion of the active S6K1 mutant into the dorsal striatum did not produce an antidepressant effect. Conversely, rats infused with kinase-inactive S6K1 demonstrated increased immobility time, indicative of pro-depressive behavior (39% increase compared to control; $P<0.05$). In a separate set of experiments, infusion of active S6K1 into the mPFC rendered rats resilient to the behavioral deficits produced by chronic stress ($P<0.05$), whereas kinase-inactive S6K1 mimicked the effects of chronic stress in naïve rats ($P<0.05$). Studies are currently underway to assess alterations in neuronal morphology following enhancement or suppression of S6K1 activity. Preliminary data in primary cortical cultures demonstrate a significant increase in neuronal complexity due to activation of S6K1. Together, these data suggest that aberrant protein synthesis through S6K1 contributes to the pathology of MDD, and further studies of the molecular events involved may lead to much needed advancements in antidepressant therapy.

Title: Generation of Pet1210-Cre transgenic mouse line reveals non-serotonergic expression domains of Pet1 both in CNS and periphery

Authors: *M. PASQUALETTI[1,2], B. PELOSI[1], S. MIGLIARINI[1], G. PACINI[1];
[1]Biology, Cell and Developmental Unit, Univ. of Pisa, Pisa, Italy; [2]Ctr. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy

Abstract: Neurons producing serotonin (5-hydroxytryptamine, 5-HT) constitute one of the most widely distributed neuronal networks in the mammalian central nervous system (CNS) and exhibit a profuse innervation throughout the CNS already at early stages of development. Serotonergic neuron specification is controlled by a combination of secreted molecules and transcription factors such as Shh, Fgf4/8, Nkx2.2, Lmx1b and Pet1. In the mouse, Pet1 mRNA expression appears between 10 and 11 days post coitum (dpc) in serotonergic post-mitotic precursors and persists in serotonergic neurons up to adulthood, where it promotes the expression of genes defining the mature serotonergic phenotype such as tryptophan hydroxylase 2 (Tph2) and serotonin transporter (SERT). Hence, the generation of genetic tools based on Pet1 specific expression represents a valuable approach to study the development and function of the serotonergic system. We have generated a Pet1210-Cre transgenic mouse line in which the Cre recombinase is expressed under the control of a 210 kb fragment from the Pet1 genetic locus to ensure a reliable and faithful control of somatic recombination in Pet1 cell lineage. Besides Cre-mediated recombination accurately occurred in the serotonergic system as expected, Pet1210-Cre transgenic mouse line allowed us to identify novel, so far uncharacterized, Pet1 expression domains. Indeed, we showed that in the raphe Pet1 is expressed also in a non-serotonergic neuronal population intermingled with Tph2-expressing cells and mostly localized in the B8 and B9 nuclei. Moreover, we detected Cre-mediated recombination also in the developing pancreas and in the ureteric bud derivatives of the kidney, where it reflected a specific Pet1 expression.

Thus, Pet1210-Cre transgenic mouse line faithfully drives Cre-mediated recombination in all Pet1 expression domains representing a valuable tool to genetically manipulate serotonergic and non-serotonergic Pet1 cell lineages.

Title: The serotonin 5HT2 antagonist mianserin, but not the serotonin agonist 5HT2 mCPP (meta-chlorophenylpiperazine), shows predictive validity in the behavioral rat model of Obsessive Compulsive Disorder induced via neonatal exposure to clomipramine

Authors: *A. L. HYDE, H. S. MULDER, K. M. CRAIG, S. E. FRANK, L. J. KASPARSON, D. S. KREISS;
Psychology/Neuroscience, Colgate Univ., Hamilton, NY

Abstract: Obsessive Compulsive Disorder (OCD) - a psychiatric disorder affecting 2-3% of the population - is characterized by persistent, anxiety producing thoughts often accompanied by overwhelming urges to perform repetitive ritualistic behaviors. Current pharmacological treatments for OCD are only effective in 40-60% of patients and have an 8-10 week delayed onset. Animal models with both face and predictive validity are imperative in the field of OCD so that better treatment avenues can be explored. The current study aimed to further validate a novel rodent model of OCD: neonatal exposure to clomipramine. Male Sprague-Dawley rats were administered clomipramine (15 mg/kg x 2) during neonatal Days 9-16 (= neoClom). Hole-board head dipping and behaviors in a marble arena (including marble burying and a novel marble checking behavior) were assessed at adulthood. At postnatal Days 80-106, neoClom rats (n=14) buried significantly more marbles than neoSaline controls and trended towards poking more holes (p=0.06), but did not differ in other observed behaviors. Our 2013 studies demonstrated that at postnatal Days 70-72, a group of 26 neoClom rats significantly buried more marbles, checked more marbles, and had increased repetitive head dips -> suggesting that a

larger group of neoClom rats facilitates observation of more robust differences. Acute administration of mCPP (0.4, 0.8 mg/kg) to the current rats significantly decreased marbles checked in both neonatal groups, but did not alter other behaviors. These results are incongruent with the ability of mCPP to exacerbate symptoms in OCD patients, although the effects of alternative doses of mCPP upon neoCloms should be explored. In contrast to mCPP, the effects of acute mianserin (3 mg/kg) upon the current group of neoClom rats differed significantly from neoSalines. In the neoCloms, mianserin significantly decreased the total number of pokes, holes, and repeats - in comparison to vehicle injection. In neoSaline Controls, mianserin had no effect upon the behaviors. These results are congruent with the ability of serotonin 5-HT2 antagonists to alleviate symptoms in OCD patients. In combination, our 2013 and 2014 studies have shown that acute mianserin and repeated fluoxetine (10 mg/kg X 14 days) normalize the altered behaviors of experimental neoClom rats, whereas acute diazepam (1, 8 mg/kg) and repeated desipramine (5 mg/kg) do not. Our lab's data confirm the face validity of the neoClom model of OCD and demonstrate the predictive validity of the model. The neoClomipramine model offers a unique permanent, multi-symptom behavioral profile of OCD that distinguishes it from models of anxiety and depression.

Title: Ketamine stimulates mTORC1 and BDNF release in primary cortical cultures

Authors: *A. LEPACK, M. FUCHIKAMI, J. M. DWYER, A. TROG, M. BANASR, R. S. DUMAN;
Psychiatry, Yale, New Haven, CT

Abstract: Clinical and preclinical studies have shown that ketamine, a non-competitive NMDA receptor antagonist, produces rapid antidepressant actions in severely depressed patients. Preclinical studies demonstrate that the antidepressant actions of ketamine are dependent on glutamate-AMPA receptor activation, BDNF-mTORC1 signaling and synaptogenesis. While studies *in vivo* have answered many questions about the mechanisms underlying the effects of ketamine, we sought to establish an *in vitro* model to allow higher throughput testing of rapid antidepressant drugs and to assess specific mechanisms that are difficult to measure *in vivo*. In the present studies, we performed a comprehensive analysis in cortical neuronal cell cultures of ketamine as well as two other putative rapid acting antidepressants: scopolamine, an acetylcholine muscarinic receptor antagonist, and LY 341495, an $mGluR_{2/3}$ antagonist. We first assessed the dose and time course for ketamine stimulation of mTORC1 signaling. The results demonstrate that stimulation of ketamine (500 nM) produced rapid activation of mTORC1 signaling within 15 min and this effect lasted up to 1 hr. We have recently demonstrated that blockade of BDNF release within the mPFC blocks the behavioral effects of ketamine in the FST. In addition, the behavioral actions of ketamine are blocked in Val66Met knock-in mice, which have impaired activity dependent release of BDNF (Liu et al., 2012), suggest that the actions of ketamine require BDNF release. To test this hypothesis, we treated cells with ketamine (500 nM) for 15, 60 min and 6 hr. The results show that ketamine increased BDNF release (~50%) into the culture media within 15 min and that this effect was sustained up to 6 hr. We have also recently shown that the behavioral actions of ketamine are dependent on activation of AMPA receptors and L-type calcium channels. Pretreatment with either NBQX (50 uM), an AMPA receptor antagonist, or verapamil (10 uM), an L-type calcium channel antagonist, blocked ketamine-induced BDNF release. We have also determined doses that activate mTORC1 signaling for scopolamine and LY 341495. Studies are underway to assess if these compounds also increase BDNF release similar to ketamine and if this release is dependent on activation of AMPA receptors and L-type calcium channels. Future studies will also include analysis of dendritic branching and morphology of neurons following stimulation of each compound. Taken together, the current findings demonstrate that primary neuronal culture may provide an alternative platform for screening antidepressant drugs and determining mechanisms of action.

Title: Development of stem-cells therapy for depressive disorders combined with nanotechnology based CT imaging

Authors: *O. BETZER[1,2], A. SHWARTZ[3], M. MOTIEI[4], G. KAZIMIRSKY[3], I. GISPAN[3], C. BRODIE[3,5], R. POPOVTZER[4], G. YADID[2];

Abstract: Cell-based therapy using mesenchymal stem cells (MSCs) has emerged as a novel and successful approach for the treatment of various brain pathologies mainly due to their ability to migrate to sites of injury, secrete various vital soluble factors and promote neurogenesis. Depressive disorders are severe and debilitating medical illnesses affecting millions of individuals worldwide. Current psychotherapy & pharmacological agents address these disorders sub-optimally, causing patients to experience low remission rates and relapses and do not provide long term therapeutics, while DBS and ECT treatments are still under evaluation. In this study we have developed a novel MSC-based long term therapeutic application for treating these disorders, tested on the Flinders sensitive line (FSL) rat model. Another novel aspect of this research is the development of nanoparticle-based CT imaging technique for non-invasive longitudinal MSCs tracking. Tracking cells within deep brain structures is a key challenge, which cannot be thoroughly addressed using current techniques. This approach enabled us monitoring behavioral manifestation in parallel with longitudinal, real-time MSCs tracking by CT-based imaging. The results of this study demonstrate the therapeutic impact of MSCs on the depressive-like behavior displayed by the rat model. Cell's migration was traced up to one month post-transplantation, enabling sensitive detection and quantitative, longitudinal migration tracking of MSCs. Our data revealed that MSCs specifically navigated and homed to distinct depression-related brain regions. Furthermore we demonstrated that cell migration correlates with the therapeutic effect of MSCs on the depressive-like behavior displayed by the rat model (figure). Our new technique suggests future insight into the mechanisms underlying success, or failure of a potential cell therapy, which is currently poorly understood. .

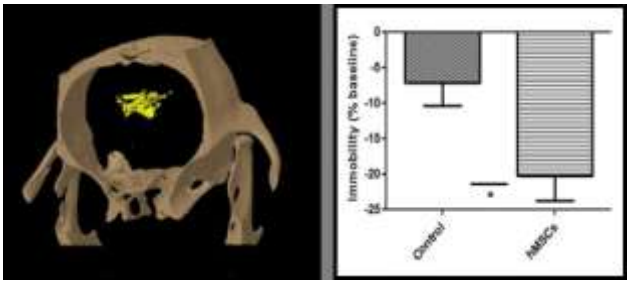

Figure: *In vivo* volume rendering CT scan one month post transplantation correlates with behavioral Fast swim test fold change differences after MSCs treatment.

Title: Differential serotonergic mechanisms of the noncompetitive NMDA receptor antagonists ketamine, memantine, MK-801 in the Differential Reinforcement-of-Low-Rate (DRL) 72 s procedure in rats

Authors: *J. H. PORTER, C. R. MERRITT, T. M. HILLHOUSE;
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The glutamatergic system has emerged as a therapeutic target for treatment of major depressive disorder (MDD). The noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine produces robust antidepressant effects in treatment-resistant patients. Other NMDA receptor antagonists such as memantine fail to produce reliable antidepressant effects in clinical research. The goals of the present experiment were to: 1) compare the antidepressant-like effect of the noncompetitive NMDA receptor antagonists ketamine, memantine, and MK-801 in the differential-reinforcement-of-low-rate (DRL) 72 s procedure with rats; 2) determine if the antidepressant-like and psychostimulant-like effects of ketamine and MK-801, respectively, in the DRL 72 s procedure are mediated by serotonin 5-HT2 receptors antagonism; 3) determine if the antidepressant-like effects of ketamine and memantine in the DRL 72 s procedure are mediated by inhibition of serotonin transporters. First, ketamine (5.6-10.0 mg/kg) and memantine (10.0 mg/kg) produced antidepressant-like effects in the DRL 72 s procedure; whereas, MK-801 (0.1-0.18 mg/kg) produced a psychostimulant-like effect. Second, the antidepressant-like effects of ketamine in the DRL 72 s procedure do not appear to be mediated by 5-HT2 receptors as co-administration of the 5-HT2 antagonist ritanserin (1.0 mg/kg) with a subeffective dose of ketamine (3.2 mg/kg) decreased responses, but failed to alter reinforcers or shift IRT distributions. Additionally, the 5-HT2 agonist quipazine failed to attenuate the antidepressant-like effects of ketamine in the DRL 72 s procedure. Conversely, the

psychostimulant-like effects of MK-801 in the DLR 72 s procedure are mediated, in part, by 5-HT2 receptors as 1.0 mg/kg ritanserin attenuated the increase in responses and leftward shift in IRT distributions produced by 0.18 mg/kg MK-801. Third, the antidepressant-like effects of ketamine in the DRL 72 s procedure do not appear to be mediated by inhibition of serotonin transporters as a subeffective dose of the SSRI fluoxetine (5.0 mg/kg) did not potentiate a subeffective dose of ketamine (3.2 mg/kg). In contrast, the antidepressant-like effects of memantine in the DRL 72 s procedure are mediated, in part, by inhibition of serotonin transporters as co-administration of subeffective doses of 5.0 mg/kg fluoxetine and 5.0 mg/kg memantine increased reinforcers and decreased responses, but failed to shift IRT distributions ($p = 0.58$). Taken together, these results indicate that the behavioral effects of these NMDA receptor antagonists are differentially mediated by serotonergic mechanisms.

Title: Discriminative stimulus properties of the noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine in rats

Authors: *B. L. JOSEPH, H. S. POPAL, T. M. HILLHOUSE, J. H. PORTER;
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine produces rapid and sustained antidepressant effects in treatment-resistant patients suffering from major depressive disorder. However, the abuse liability of ketamine is a concern. Drug discrimination procedures are used to evaluate the subjective effects of drugs, which may be associated with the abuse-related effects of drugs and with their therapeutic effects. Drug discrimination procedures also can be used to determine the underlying receptor mechanisms that mediate a drug's discriminative stimulus properties. In the present study, 17 male Sprague-Dawley rats were trained to discriminate 10.0 mg/kg ketamine from saline in a two-lever drug discrimination procedure for food reinforcement. Ketamine (7.5-20.0 mg/kg) produced full substitution for the training dose of 10.0 mg/kg ketamine, yielding an ED50 of 3.65 mg/kg. A time-course study found that the ketamine cue had a rapid onset, producing full substitution from

0-30 min injection times, but not at 60 and 100 min. The noncompetitive NMDA receptor antagonists MK-801 (0.1 mg/kg) and memantine (10.0 mg/kg) produced full substitution for the discriminative stimulus properties of 10.0 mg/kg ketamine, yielding ED50 values of 0.04 mg/kg and 2.83 mg/kg, respectively. The AMPA receptor antagonist NBQX (10.0 mg/kg) did not substitute for ketamine when administered alone and NBQX did not block or attenuate the discriminative stimulus properties of ketamine when administered in combination with 5.0 and 10.0 mg/kg ketamine. However, NBQX did produce a significant suppression of response rates when administered in combination with the 10.0 mg/kg dose of ketamine. The dopamine D2 agonist quinpirole (0.032-0.1 mg/kg) and selective serotonin reuptake inhibitor fluoxetine (2.5-20 mg/kg) did not substitute for the discriminative stimulus properties of ketamine, but both drugs produced rate suppression at the highest doses tested. These results suggest that the discriminative stimulus properties of ketamine are mediated by noncompetitive NMDA antagonism as only MK-801 and memantine produced full substitution for ketamine. Future studies will need to test selective ligands alone or in combination with ketamine to elucidate the underlying receptor mechanisms that mediate the discriminative stimulus properties of ketamine.

Title: Behavioral and neurobiological correlates for predicting resilience and susceptibility to social defeat

Authors: *Y. GROSSMAN[1], R. E. WALDMAN[2], G. PANDEY[3], W. G. JANSSEN[3], D. DUMITRIU[3];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Vassar Col., Poughkeepsie, NY; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Depression is a neuropsychological disorder that affects millions of people. There are currently no predictors for susceptibility to depression and a large proportion of afflicted individuals are resistant to available treatments. Therefore, the ability to predict selective psychosocial vulnerability and resilience to stress holds great promise in preventing this

debilitating disorder. Social defeat (SD) is a highly validated mouse model of depression. We used acute and chronic social defeat stress for elucidating the neurocircuitry involved in establishment and maintenance of divergent behavioral phenotypes. We developed non-invasive behavioral paradigms to serve as a proxy for cortical and limbic function, and found that performance on a prefrontal-dependent task prior to SD was correlated with resilience, while performance on a hippocampal-dependent task was correlated with susceptibility. Furthermore, using a classifier algorithm that considers performance on multiple behavioral tests, we were able to strengthen the absolute predictive power of our behavioral battery. To probe the neuroactivation correlate of the above findings, we analyzed cFos expression in various cortical and subcortical regions following SD and found that resilient animals have higher correlative activation between prefrontal and temporal regions while susceptible animals exhibit anti-correlative activation patterns within the same circuits. To investigate the synaptic mechanisms underlying these activation differences, we used a GFP virus to isolate amygdala-projecting prefrontal neurons that are active during the establishment of the behavioral response to SD. We found that in this select subpopulation of neurons, resilient animals have higher densities of mushroom spines compared to susceptible animals. Together, these results suggest that resilient animals have pre-existing higher prefronto-temporal connectivity that can be predicted via non-stressful behavioral tests.

Title: Effects of minocycline on preventing a second depressive-like episode following stressor exposure

Authors: *J. L. REMUS[1], D. JAMISON[2], J. JOHNSON[2];
[1]Biol. Sci., [2]Kent State Univ., Kent, OH

Abstract: The biological mechanisms that contribute to recurrent depression are not well understood. Our lab has recently developed a rodent model of recurrent depression. Here animals are exposed to chronic mild stress for 35 days during which we see a suppression of sucrose intake. Stressors are then removed for 20 days and animal's sucrose intake increases. Animals are re-exposed to the chronic mild stress paradigm over 15 days and we see a steeper (more rapid) decrease in sucrose intake during their second exposure than during their first. This suggests that animals are sensitized to stress following their first episode of chronic mild stress. In the current study, we evaluate the role of microglia activation in regards to preventing the sensitized behavioral response during reexposure to stress. Adult male fischer rats were exposed to our animal model of recurrent depression. During the recovery phase half of the animals receive minocycline in their drinking water. We expect to see that stressed animals that received minocycline will not show a sensitized response when re-exposed to the chronic mild stress paradigm.

Title: Depression and diabetes interplay: First steps towards identifying the common neural pathological mechanisms and treatment strategies in rodent models

Authors: *S. DUTHEIL, K. T. OTA, A. E. LEPACK, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Numerous reports show that high fat diet (HFD) and sedentary lifestyle increase the risk of developing obesity, cardiac disease, hypertension, type 2 diabetes and cognitive impairments. According to the World Health Organization, diabetes and depression will have the greatest health care burdens worldwide by 2025, and increasing evidence suggests that a

bidirectional relationship exists between these two disorders. However, the molecular and cellular pathways underlying the increased risk of developing both diabetes and depression remain unknown. In this regard, the current study seeks to identify potential common pathological mechanisms using a rat HFD-induced diabetes model, and to determine if HFD causes brain alterations that contribute to anxiety and depressive behaviors. The results show that rats fed a HFD during 16 weeks develop glucose intolerance, increased neuronal and peripheral corticosterone levels and enhanced brain inflammation in the hippocampus sustained by activation of genes involved in cytokine production. In addition, HFD induces anxiety-like behavior and cognitive deficits accompanied by alterations of p70S6 kinase, a downstream substrate of the mammalian target of rapamycin complex 1 (mTORC1) which plays a major role in the pathophysiology and treatment of stress-induced anxiety and depressive behaviors. Hence, our data show that a long-term diet rich in fat not only induces peripheral changes and metabolic stress, but also affects neuronal signaling pathways with increased inflammation in hippocampus, as well as anxiety and cognitive behavior in some ways similar to what is observed in chronic stress models. Studies are currently underway to determine if anti-inflammatory treatment strategies can reverse both behavioral and biochemical impairments induced by HFD. This study is a first step towards understanding the mechanisms linking diet-induced diabetes to depression. In the future, early interventions targeting the disrupted pathways could help to decrease the prevalence of mood disorders in diabetic patients and reciprocally, minimize the burden associated with these two conditions.

Title: The role of the gabaergic interneurons of the prefrontal cortex in the rapid-acting antidepressant effects of ketamine

Authors: *D. M. GERHARD[1], K. T. OTA[2], E. S. WOHLEB[2], B. B. LAND[2], R. J. DILEONE[2], R. S. DUMAN[2];
[1]Psychology, [2]Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: Major depressive disorder (MDD) is a growing public health concern with widespread effects on personal welfare, the economy and society. Selective serotonin reuptake inhibitors are the first-line treatment for MDD despite their weak efficacy and required long-term treatment plan. Recent efforts have focused on the therapeutic benefits of ketamine, an NMDA receptor antagonist that produces rapid and sustained antidepressant effects in patients that have failed to respond to other forms of treatment. Rodent models of depression have demonstrated that ketamine rapidly increases synaptic connections and glutamate release in the prefrontal cortex (PFC) shortly following acute treatment. Furthermore, optogenetic activation of the mPFC has an immediate antidepressant-like behavioral effect and unpublished data from our lab demonstrates that, like ketamine, these effects are long-lasting. However, a new hypothesis to emerge posits that the increased spiking of excitatory pyramidal neurons occurs via ketamine deactivation of inhibitory GABAergic interneurons that have direct connections with excitatory principal neurons. Microinfusion of muscimol, a $GABA_A$ agonist, into the infralimbic cortex (IL) of the mPFC blocks the effects of ketamine, giving insight into a potential route of action of ketamine through the GABAergic interneuron system of the mPFC. To examine the role of the GABAergic interneurons, we are using a GAD67-Cre transgenic mouse line in combination with optogenetic inhibition (floxed halorhodopsin virus) or stimulation (floxed channelrhodopsin virus). We hypothesize that optogenetic inhibition of GABA neurons will produce an antidepressant response and/or occlude the effects of ketamine, while optogenetic excitation will block the effects of systemic ketamine. In addition, we are developing an approach to examine the specific NMDA receptor subtype(s) on GABA neurons that mediates the antidepressant-like effects of ketamine. NR2B antagonists have been shown to produce antidepressant effects similar to ketamine in both rodent models and clinical trials. To address this question we are using the GAD-67 transgenic mouse line along with a virus to express floxed shRNA for NR2B. Behavioral, histological and immunohistochemical results are currently being collected for this experiment and will be discussed.

Title: Infralimbic and prelimbic contributions to anxiety-like behaviors in mice following developmental SSRI exposure

Authors: *M. K. CAFFREY[1], T. J. REBELLO[2], M. S. ANSORGE[1];
[1]Developmental Neurosci., Columbia Univ. and NYSPI, New York, NY; [2]Psychiatry, Columbia Univ., New York, NY

Abstract: Early-life serotonin (5-HT) signaling modulates brain development to impact adult behavior, but 5-HT sensitive periods, neural substrates, and behavioral consequences remain poorly understood. We have identified the period ranging from postnatal day 2-11 (P2-11) as 5-HT sensitive, with 5-HT transporter (5-HTT) blockade increasing anxiety-like behavior, and impairing fear extinction learning and memory in adult mice. Furthermore, P2-11 5-HTT blockade causes reduced excitability of infralimbic (IL) cortex pyramidal neurons that normally promote fear extinction, but increased excitability of prelimbic (PL) pyramidal neurons, which normally inhibit fear extinction. In order to test the effect of this altered medial prefrontal cortex (mPFC) balance on behavior, excitotoxic lesions of the IL and PL were performed, revealing that IL, but not PL lesions reproduce anxiety-related phenotypes. The relationship between IL, PL and anxiety/depressive-like behaviors was further explored using site-specific viral injections of activating cre-dependent hM3Dq DREADDs (designer receptors exclusively activated by designer drugs), which induce burst firing when activated by the otherwise inert drug CNO. This method allows for more precise probing of specific mPFC subregions to assess their contributions to affective alterations, without the confounding effects introduced by lesions. Together, our results suggest that increased 5-HT signaling during P2-11 alters adult mPFC function to increase anxiety and impair fear extinction, while also suggesting a dissociation between the roles of IL and PL in conditioned fear and unconditioned anxiety.

Title: Acute ketamine administration alters dendritic spines in rat medial prefrontal cortex

Authors: *C. H. DUMAN, R. TERWILLIGER, R. S. DUMAN;
Dept. of Psychiatry, Yale Univ., New Haven, CT

Abstract: Major depression is a significant cause of disability, suffering and economic burden worldwide. While the utility of currently available antidepressant drug treatments is limited by the length of time required for therapeutic effectiveness and by treatment resistance in a significant proportion of patients, recent studies have shown that the N-methyl-D-aspartate (NMDA) receptor antagonist ketamine can produce a rapid antidepressant response following acute treatment in humans and in animal models (1,4). The induction of synaptic spines after acute treatment is thought to be critical to the rapid antidepressant action of ketamine. This lab has documented increased synaptic protein levels and spine densities in rat prefrontal cortex following acute ketamine treatment, suggesting a synaptogenic action (3). The previous studies have focused on spines in dendritic fields of layer V pyramidal neurons, and the present study extends these findings and documents the effects of ketamine on dendritic spines of pyramidal neurons in layers II/II of rat prefrontal cortex. Pyramidal cells in fixed brain sections were intracellularly injected with Lucifer yellow under visual guidance following the method of Dumitriu et al., 2011 (2). Following dye filling, dendritic segments were imaged with confocal laser scanning microscopy and spine morphology was analyzed using NeuronStudio. Twenty four hours following acute, low-dose ketamine treatment, spine density was increased in apical dendrites of layer II/III pyramidal neurons in prefrontal cortex. This effect appears to be specific to the prelimbic region and was not apparent in neurons in the infralimbic cortex. We also found a region-specific increase in spine head diameters of layer II/III cells following ketamine treatment. These findings extend the evidence for cortical dendritic spines as important loci for structural and functional alterations associated with rapid antidepressant action. 1. Berman et al., 2000. Biol. Abstract: Adult women are twice as likely as men to develop major depression, although the precise molecular mechanisms underlying sexual dimorphism in depression susceptibility are unknown. We have developed a stress paradigm--subchronic variable stress (SCVS)--to mimic these sex differences in mice. Female mice subjected to SCVS exhibit depression-like behavior after 6 days of stress exposure, whereas male mice exhibit this behavior only after chronic stress exposure (21-28 days, but not 6 days, of SCVS). Thus, this model is a valid recapitulation of the sexual dimorphism characteristic of the human population. We profiled sex differences in gene expression and transcriptional regulation in the mouse nucleus accumbens (NAc), an essential structure in the processing of reward and motivation, using next generation mRNA and small RNA sequencing. Both types of sequencing were performed on the same NAc tissue from intact male and female mice subjected to SCVS. Bioinformatic analysis was used to determine differential mRNA and microRNA (miR) expression patterns, predict miR targets, and identify biological pathway enrichment. We find very little overlap in stress-regulated mRNA and miR profiles between male and female mice. miR target and pathway analyses revealed evidence for sex differences in regulation of molecular processes related to stress vulnerability in males and females. Our results demonstrate that male and female mice initiate fundamentally different transcriptional responses to stress. These transcriptional profiles correlate with behavioral susceptibility or resilience to stress. Our findings provide insight into the molecular underpinnings of enhanced female susceptibility to stress.

Title: The effects of Zoloft and Desyrel on crayfish behavior

Authors: G. M. PREZKOP, *R. F. WALDECK;
Biology/ Neurosci. Program, Univ. of Scranton, Scranton, PA

Abstract: Antidepressants are taken by millions of Americans. Among the most common antidepressants are selective serotonin reuptake inhibitors (SSRIs) such as Prozac, Zoloft, and Celexa. The effect of two antidepressants, Zoloft (an SSRI), and less common antidepressant, Desyrel (a serotonin antagonist and reuptake inhibitor-SARI), was tested on fight behavior in crayfish. Behavioral scores were obtained from fights to observe if there was an effect on the aggression of crayfish from pre-treatment to post-treatment and if one antidepressant was more effective than the other. Eleven female crayfish were used to collect behavioral data pre- and post-treatment with antidepressants. A modified behavioral scoring sheet (Mead, 2008) was used to score fighting (i.e. tail flip, retreat, boxing, etc.) and behavioral measurements were taken every ten seconds. Crayfish were given ventral injections over a period of ten days of the appropriate antidepressant and the control crayfish received saline injections. Doses given were 0.02 mL injections for each drug (Zoloft, Desyrel, and saline). Scores before treatment to after treatment showed a significant increase ($p=0.05$) in aggression of crayfish. The increase in aggression post-treatment can show that antidepressants have a risk of increasing aggression that can have an effect on humans currently taking these medications for treatment of depression symptoms. An increase in aggression in humans after taking these drugs can lead to not only an increase in aggression, but also thoughts or risk of suicide. These findings, through further research, can lead to a more effective drug for combating the symptoms of depression.

Title: Targeted knockdown of muscarinic acetylcholine receptors in the pre-frontal cortex to examine the rapid anti-depressant effects of scopolamine

Authors: *E. S. WOHLEB, K. T. OTA, A. NAVARRIA, A. E. LEPACK, J. M. DWYER, S. R. TAYLOR, M. R. PICCIOTTO, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Major depressive disorder (MDD) is a recurring psychiatric disorder that causes significant health and socioeconomic burdens. Although therapeutics to relieve depressive symptoms exist, they are limited in efficacy and many "treatment-resistant" patients receive no benefit from these drugs. Recent clinical reports revealed that the muscarinic acetylcholine receptor antagonist, scopolamine, caused rapid and persistent anti-depressant effects in individuals with MDD. Moreover, studies in our lab show that the anti-depressant behavioral effects of scopolamine were due to increased glutamate release, activation of mTOR signaling, and enhanced dendritic spine density in the medial pre-frontal cortex (mPFC). In fact, direct administration of scopolamine into the mPFC was sufficient to produce a rapid anti-depressant effect. These findings indicate that rapid anti-depressant effects caused by scopolamine are initiated through antagonism of muscarinic acetylcholine receptors in the mPFC. In addition, preliminary studies in the lab suggest that scopolamine exerts behavioral effects through blockade of M1-type muscarinic acetylcholine receptors (M1-AchR) in the mPFC. For instance, antagonists selective for M1-AchR activate mTOR signaling and promote anti-depressant effects comparable to scopolamine. This is pertinent because recent evidence suggests that M1-AchR are expressed primarily by glutamate-expressing (CamKII+) pyramidal neurons in the cortex. However, subsets of GABA-expressing (GAD67+) inhibitory neurons also express M1-AchR. We confirmed these results through immunohistology showing that M1-AchR co-localized with CamKII+ and GAD67+ neurons in the mPFC. Thus, the primary objective of these studies was to determine if the rapid anti-depressant effects of scopolamine can be modulated through

targeted knockdown of M1-AchR in CamKII+ or GAD67+ neurons in the mPFC. To examine the role of these different neuronal subsets we developed a viral construct that expresses a short-hairpin RNA targeting M1-AchR in a Cre-dependent manner. Using CamKII-Cre or GAD67-Cre mice we can effectively knockdown M1-AchR in these neuronal subsets. Further studies are aimed to examine the behavioral effects of M1-AchR knockdown in CamKII+ or GAD67+ neurons in the mPFC and will further define the cellular mechanisms underlying the rapid antidepressant actions of scopolamine. Supported by NIMH Grants MH045481 and MH093897, and the State of CT.

Title: Capturing the complexity of depression from mood through molecules: Bioinformatic integration of behavioral, physiological, proteomic, morphometric and intracellular signaling datasets in a female monkey model of depression

Authors: *S. L. WILLARD[1], K. E. BORGMANN-WINTER[1,2], P. M. SLEIMAN[3], H. Y. WANG[4], C. A. SHIVELY[5], C. G. HAHN[1];

Sch., New York, NY; [5]Dept. of Pathology/Comparative Med., Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Depressive disorders are complex trait disorders with vastly heterogeneous manifestation as well as multi-faceted origins. One approach to addressing this is modeling depression in non-human primates, which may bring us closer to capturing and understanding the complexity of depression. Thus, we examined a matched set of adult female monkeys characterized for behavioral depression (N=8/grp) and evaluated the relationships between molecular and cellular perturbations of synapses and morphological, behavioral and endocrinological phenotypes. Depressive behavior and social interactions were observed over four years, during which numerous physiological assessments were conducted, including HPA-axis and ovarian function. The hippocampus was dissected at necropsy, and several aspects of depression neurobiology were investigated, from the whole structure down to the molecules. Specifically, we reported alterations in regional and layer volume, neuronal and glial cell counts, and synaptosomal protein and gene expression. Recently, we found altered composition of the synaptic proteome as measured via LC-SRM/MS of 200+ proteins in fractionated synaptic microdomains. In addition, we observed attenuated NMDA and heightened TrkB signaling in postmortem hippocampal tissue dissections from behaviorally depressed monkeys using an *ex vivo* stimulation method. For the bioinformatic integration of datasets, we generated correlation matrices of the proteomic data and individual phenotypic endpoints. This was done for each synaptic microdomain assessed, and fraction-specific proteomic patterns were visualized in heat maps following cluster analysis with dendogram-reordering based on Euclidean distance functions. Numerous correlations were observed between the proteomic data and 1) the morphometric and volume analyses, 2) depression, 3) social status, and 4) physiological characteristics of the monkey model. Cluster analyses revealed that functional groups of proteins clustered separately with morphometry and depression, and these clusters varied among synaptic microdomains. Preliminary correlational analyses between NMDA and TrkB signaling data and hippocampal structural measures suggest a very high degree of association between most variables. The relationships that emerged from this mood-to-molecule bioinformatic approach were not apparent prior to this integration of data. These complex relationships as observed in a nonhuman primate model of depression will enable us to unravel the complexity of depression in ways that have not been done before.

Title: Effects of altered developmental monoamine signaling on adult aggressive behaviors

Authors: *D. MAHADEVIA[1], C. M. TEIXEIRA[1], Q. YU[2], D. SURI[1], M. ANSORGE[1]; [1]Psychiatry, Columbia Univ., New York, NY; [2]Ctr. for Human Genet. Res., Massachusetts Gen. Hosp., Boston, MA

Abstract: Early-life alterations in the strength of monoamine signaling can impact adult behavior. We have identified a peri-adolescent (P22-P41) sensitive time window during which altered dopamine (DA) and serotonin (5-HT) signaling affect the development of circuitries underlying adult aggression in mice. Monoamine oxidase A (MAOA) and DA transporter (DAT) blockade during peri-adolescence increases adult aggressive behavior, and 5-HT transporter (5-HTT) blockade during the same time period reduces adult aggression. To refine this sensitive period, we tested the consequence of monoaminergic interference during narrower time-windows and found that increased DA signaling during P32-P41 is sufficient to increase adult aggression. Initial insight into the underlying circuit-based mechanism was provided by our finding that levels of aggression following peri-adolescent blockade of DAT, 5-HTT or MAOA correlate positively with locomotor response to an amphetamine challenge in adulthood. These data suggest that DAergic function is permanently altered, which is congruent with findings implicating DA hyperactivity in pathological adult aggression. Together these data indicate that increased P32-P41 DAergic signaling permanently alters DAergic function to enhance adult aggressive behavior. To directly assess the causal role of DA function in aggression we used *in vivo* optogenetics. We found that ChR2-based activation of VTA but not SNc DAergic neurons increases aggressive behavior, supporting the hypothesis that altered mesolimbic/mesocortical DAergic function underlies altered aggression. To further dissect the DA-associated circuitry underlying adult aggression, we optogenetically probe VTA-target regions. Together our data provide insight into a monoamine-sensitive period that determines the developmental trajectory of aggression and behavioral sensitivity to psychostimulants, which might ultimately aid improving prevention and treatment approaches for neuropsychiatric disorders.

Title: BICC1 expression is elevated in depressed subjects and contributes to depressive behavior in rodents

Authors: *K. T. OTA[1], W. ANDRES[1], D. A. LEWIS[2], C. A. STOCKMEIER[3], R. S. DUMAN[1]; [1]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [3]Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Major depressive disorder (MDD) is a recurring psychiatric illness that affects up to 17% of the American population and can be severely debilitating by affecting sleep, work, social relationships, and appetite (Kessler et al., 2005). Studies to elucidate the pathophysiology of depression have recently included analysis of the genetic basis of MDD, focusing on single nucleotide polymorphisms (SNPs) that are associated with susceptibility to mood disorders. Consistent with this, a recent genome-wide association study (GWAS) identified two SNPs in the Bicaudal C homologue 1 (BICC1) gene showing suggestive significance for association in depressed patients compared to psychiatrically healthy controls (Lewis et al., 2010). BICC1 is an RNA-binding protein that plays a role in cytoskeletal organization and cell-to-cell communication (Mahone et al., 1995; Chicoine et al., 2007; Snee and Macdonald, 2009). Further, BICC1 can block Wnt signaling, a pathway implicated in the pathophysiology of depression (Voleti et al., 2011), via the uncoupling of disheveled-2 signaling from the canonical Wnt pathway (Maisonneuve et al., 2009). BICC1 is well-studied in the context of polycystic kidney disease (Guay-Woodford, 2003), but there have been few studies of BICC1 in brain. Here, we show that BICC1 mRNA is up regulated in the dorsolateral prefrontal cortex (dlPFC) and dentate gyrus (DG) of human postmortem MDD patients. We also show that BICC1 is increased in prefrontal cortex (PFC) and hippocampus in the rat chronic unpredictable stress (CUS) model of depression. Additionally, we show *in vivo* that a single acute anti-depressant

dose injection of ketamine leads to a rapid decrease of BICC1 mRNA, while *in vitro*, we show that this is likely due to activity-induced down-regulation of BICC1. Finally, we show that BICC1 knockdown in the hippocampus protects rats from CUS-induced anhedonia. Taken together, these findings identify a role for increased levels of BICC1 in the pathophysiology of depressive behavior.

Title: Antidepressant-like effects of ketamine in the Differential Reinforcement-of-Low-Rate (DRL) 72 sec operant procedure in mice

Authors: *M. A. FRIAR[1], T. M. HILLHOUSE[2], K. A. WEBSTER[2], J. H. PORTER[2]; [2]Psychology, [1]Virginia Commonwealth Univ., Richmond, VA

Abstract: Major depressive disorder (MDD) is the most common mood disorder in the United States affecting approximately 14% of Americans. Most preclinical procedures (e.g. forced swim test, chronic unpredictable stress, etc.) used for assessing antidepressant drugs utilize both rats and mice; however, the differential-reinforcement-of-low-rate (DRL) 72 sec operant procedure, which was established in the 1980s to selectively screen antidepressant drugs, has been used almost exclusively with rats. Recently, we reported that ketamine produces an antidepressant-like profile in the DRL 72 sec task with rats (Hillhouse & Porter 2014). However, the DRL 72 sec task has not been used in mice to evaluate the antidepressant-like effects of ketamine. In the DRL procedure animals are required to wait 72 sec between operant responses in order to receive a reinforcer. A drug demonstrates an antidepressant-like profile when the number of reinforcers is increased and the number of responses is decreased. The present study first established the DRL 72 sec task in 2 groups of C57BL/6 mice. In one group the response operandum was a nose

poke response and in a second group the response operandum was a lever press response (as used in DRL studies with rats). In the lever press group, ketamine (32 mg/kg), the tricyclic antidepressant imipramine (32 mg/kg), and the SSRI fluoxetine (32 mg/kg) significantly increased the number of reinforcers and decreased responses, producing an antidepressant-like profile similar to that previously reported in rats. In contrast, ketamine did not produce any significant changes in the number of reinforcers or responses in the nose poke group. While imipramine and fluoxetine at 32 mg/kg did significantly increase reinforcers in the nose poke group, there was no significant change in the number of responses. The higher affinity noncompetitive NMDA antagonist MK-801 (0.1 mg/kg) produced a significant decrease in the number of reinforcers and a significant increase in responses for lever press and nose poke - a psychostimulant-like profile that is consistent with DRL studies using rats. These results demonstrated that the DRL 72 sec operant schedule is a valid procedure for assessing antidepressant-like effects of drugs in mice, but only when a lever press response is used as the operandum. The antidepressant-like effects of ketamine may involve non-NMDA mechanisms as MK-801 did not produce an antidepressant-like profile.

Title: Mood stabilizers regulate cytokine levels but have no effect on memory impairment and BDNF reduction induced by maternal deprivation in rats

Authors: *M. MARTINS DE LIMA[1], R. M. C. PINHEIRO[1], B. C. D. PORTAL[1], S. B. BUSATO[1], L. FALAVIGNA[1], R. D. P. FERREIRA[1], A. C. PAZ[2], B. W. AGUIAR[2], F. P. KAPCZINSKI[2], N. SCHRÖDER[1];
[1]Pontifical Catholic Univ. of Rio Grande do Su, Porto Alegre, Brazil; [2]Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Exposure to stressful events early in life may increase the susceptibility to the onset of psychiatric disorders that often share cognitive impairments as a common component in adult life. Brain-derived neurotrophic factor (BDNF) levels have been shown to be decreased in the serum of patients with psychiatric disorders. On the other hand, inflammatory cytokines, such as interleukins (IL) and tumor necrosis factor-α (TNF-α), have been shown to be increased in the serum of these patients. Thus, the aim of the present study was to investigate the effects of maternal deprivation on cognition and on the levels of BDNF and IL-10, and TNF-α in the hippocampus and prefrontal cortex of adult rats. We also evaluated the potential ameliorating properties of valproic acid and topiramate (two anticonvulsants that also act as mood stabilizers) on memory impairment and BDNF and cytokines changes associated with maternal deprivation. The results indicated that, in addition to inducing memory impairment, maternal deprivation decreased hippocampal levels of BDNF and increased the levels of IL-10 in the hippocampus, and TNF-α in the hippocampus and in the cortex, in adult life. Neither valproic acid nor topiramate were able to ameliorate memory impairment or the reduction in BDNF levels induced by maternal separation. The highest dose of topiramate was able to reduce IL-10 in the hippocampus and TNF-α in the prefrontal cortex, while valproate only reduced IL-10 levels in the hippocampus. These findings may help to clarify the underlying mechanisms associated with alterations observed in adult life induced by early stressful events, and for the development of novel therapeutic strategies.

Title: Diffusion Tensor Imaging (DTI) in rats suggests that the posterior thalamus and prefrontal cortex are targets of Chronic Unpredictable Stress (CUS)

Authors: *C. L. KISELYCZNYK, M. BANASR, C. ABDALLAH, D. COMEN, F. HYDER, G. SANACORA;
Dept. of Psychiatry, Yale Univ., New Haven, CT

Abstract: In the investigation of stress-sensitive disorders such as depression, the rodent chronic unpredictable stress (CUS) model is useful in determining stress-induced molecular changes potentially underlying psychiatric disorders. CUS studies have uncovered stress-induced reductions in dendritic complexity and synaptic- and glial-related proteins in regions implicated in depression such as the prefrontal cortex (PFC). As changes in cellular morphology could reflect alterations in cell density and extracellular space that potentially affect water diffusion, measuring the ability of water to diffuse in these regions through Diffusion Tensor Imaging (DTI) is one potential method to observe stress-induced changes in both preclinical and clinical settings. Here we used DTI after CUS in rats to measure the functional anisotropy (FA) and average diffusion coefficient (ADC) throughout the brain. In a separate cohort of animals, we performed western blot analysis in the regions implicated by DTI to measure alterations in markers previously associated with CUS and stress, such as synaptic proteins, glial markers, and markers of the extracellular matrix. The most striking changes were observed in measurements of ADC, with stress-induced increases in water diffusion observed in the ventral medial prefrontal cortex (PFC), but also in the posterior thalamus, a region not typically associated with chronic stress. Subsequent western blot analysis of the thalamus replicated stress-induced alterations previously observed in the PFC, including reductions in the glial-related marker GFAP, and the synaptic marker PSD95, with a trend for reduction of GluR1. It is unclear if these stress-induced molecular changes are selective to regions indicated by our DTI findings and more work is needed to directly tie molecular changes to the alterations in ADC observed after stress. Ultimately, our current work demonstrates the use of DTI to discover new regions previously not known to be involved in chronic stress, and produces the novel finding that the posterior thalamus shows stress-induced alterations in glial- and synaptic-related proteins.

Title: Cortical GFAP astrocyte-specific ablation induces depressive-like and anxiety-like behaviors similar to chronic stressCortical GFAP astrocyte-specific ablation induces depressive-like and anxiety-like behaviors similar to chronic stress

Authors: *M. BANASR, M. XU, A. LEPACK, C. KISELYCZNYK, J. ZHANG, S. WILBER, G. SANACORA, C. PITTENGER, R. DUMAN;
Dept Psychiatry, Yale Univ., NEW HAVEN, CT

Abstract: Growing evidence implicates glial dysfunction in the pathophysiology of depression. Astrocyte number is reduced in the cortex of patients with major depression and in rodent models of depression. We previously reported that glial ablation in the medial prefrontal cortex (mPFC) using local infusion of a gliotoxin induces behavioral deficits similar to those produced by chronic stress in rat, including anhedonia, anxiety and helplessness. However, the contribution of glial subtypes in the development of depressive-like symptoms remains to be characterized. To address this question, we engineered targeted ablation of GFAP+ glial cells in the mPFC in mice. We used the cre/loxP system and a cre-activated virus to express the diphtheria toxin (DT) receptor (DTR) specifically in GFAP+ cells of the mPF, making these cells sensitive to DT. Three weeks after infusion of the virus (iDTR) into the mPFC, animals were injected with saline or DT at 3 different doses (0.1, 5, 20 ug/kg) i.p. once daily for 4 days. Sucrose consumption, which is reduced in depression rodent models, was measured on each day. GFAPcre+iDTR mice injected with 20ug/kg of DT showed a significant decrease in sucrose consumption on both days 2 and 3; GFAPcre+iDTR injected with 5 µg/kg DT also showed reduced sucrose consumption on day 3. Both groups still showed decreased sucrose consumption on D8 (4 days after the last injection of DT), but sucrose consumption levels returned to baseline by day 14. Similar effects were observed in the forced swim test: administration of DT (20ug/kg) to GFAPcre+iDTR mice showed significantly increased immobility on day 8, but not on day 14. GFAPcre+iDTR animals treated with DT also exhibited enhanced novelty-induced hypophagia test and a trend towards decreased time in the center in an open field, both of which are indicative of increased anxiety. We also demonstrated that GFAP cell ablation in striatum has no effect in these behavioral tests. Our results demonstrate that selective ablation of GFAP+ cells in the mPFC rapidly induces anhedonia-like and anxiety-like deficits that persist for at least 8 days. Our results suggest that the astrocytic loss observed in human depression is not just a consequence of depression but contributes to core symptoms. These studies also demonstrate the feasibility of our targeted ablation approach for the study of the contribution of specific glial (or neuronal) subtypes in PFC function.

Title: Differential sensitization of microglia and peripheral blood mononuclear cells following short-term and chronic unpredictable stress

Authors: *T. C. FRANKLIN, E. S. WOHLEB, R. S. DUMAN;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Exposure to acute and chronic stress has been shown to alter innate immune function leading to enhanced responses to subsequent stimuli. It has recently been demonstrated that sub-chronic and chronic unpredictable stress have contrasting effects on innate immune cells, specifically microglia, resulting in polar cell number and morphological changes. However, the sensitivity of innate immune cells to subsequent stimuli has not yet been investigated following short-term (3 d) and chronic (28 d) unpredictable stress (SUS and CUS, respectively). In this study, we identified stress induced alterations in the expression of inflammatory factors that may contribute to priming of peripheral blood mononuclear cells (PBMC) and microglial cells isolated from the prefrontal cortex (PFC) or hippocampus (HPC), two regions known to be susceptible to stress induced alterations. We demonstrate for the first time a differential effect of SUS and CUS on the function of PBMC and microglial cells following an immunological challenge. The mRNA expression level of several inflammatory factors including IL1b, TNFa, HMGB1, TLR2, TLR4 and RAGE were significantly increased in PBMC and PFC microglial cells following SUS compared to control. Moreover, LPS administration (100ug/kg i.p.) significantly enhanced the expression of these factors revealing a robust priming effect of SUS. In contrast, the mRNA levels of many of these factors in PBMC cells were significantly reduced

by CUS. LPS exposure did not increase the expression of these factors in PFC microglial cells suggesting an immunosuppressive effect of CUS. SUS and CUS did not significantly alter the expression of these genes in HPC microglial cells. Our data suggest that stress-induced sensitization of PBMC and microglial cells following unpredictable stress occur in a differential manner depending on the duration of the stress paradigm. Title: Methamphetamine produces increased neuropeptide gene expression by TET-dependent DNA methylation/hydroxymethylation events in the rat nucleus accumbens

Authors: *S. JAYANTHI[1], B. GONZALEZ[2], P. WONGPRAYOON[3], M. T. MCCOY[1], B. LADENHEIM[1], J. L. CADET[1];
[1]Mol. Neuropsychiatry Br., NIDA-IRP, BALTIMORE, MD; [2]Inst. de Investigaciones Farmacológicas, Buenos Aires, Argentina; [3]Res. Ctr. for Neurosci., Inst. of Mol. Biosciences, Mahidol Univ., Nakornpathom, Thailand

Abstract: Methamphetamine (METH) addiction is a relapsing neuropsychiatric disorder that is secondary, in part, to neuroadaptations within neurocircuitries that mediate stress responses. Our recent microarray and quantitative PCR (qPCR) analyses had revealed that an injection of METH (10mg/kg) upregulated several stress-related gene markers measured one month later using tissues from the rat nucleus accumbens. These genes included corticotropin-releasing hormone (*Crh/ Crf*), vasopressin (*Avp*) and cocaine-amphetamine regulated transcription factor (*Cart*). The long-lasting increases in *Crh*, *Cart*, and *Avp* mRNA expression had suggested that METH exposure might produce prolonged activation of the endogenous stress system via epigenetic modifications that have been identified as important mediators of long-lasting memories. For example, methylation of cytosine (5mC) bases in DNA is known to cause gene

silencing whereas reversible conversion of 5mC to its hydroxylated form, 5hmC, by the Ten-eleven translocation (Tet) family of enzymes can increase gene transcription. To assess if METH treatment could cause changes in DNA methylation, we used methylated DNA immunoprecipitation (MeDIP) followed by qPCR to measure DNA methylation at CpG sites around the TSSs of *Crh, Avp,* and *Car* genes. We found that METH significantly decreased cytosine methylation at CpG-rich sites near *Crh* and *Avp* TSSs but caused no significant changes near the *Cart* TSS. In addition, we used hydroxymethylated DNA immunoprecipitation (hMeDIP)-qPCR to test potential roles of DNA hydroxymethylation in METH-induced neuropeptide upregulation. There was significant increased DNA hydroxymethylation at the CpG-rich sequences located near *Crh, Avp,* and *Cart* TSSs. Because TET enzymes catalyze DNA hydroxymethylation, we conducted chromatin immunoprecipitation (ChIP) assay using TET1 and TET2 antibodies and found significant METH-induced increase in TET1 binding on the *Crh* promoter sequence. In contrast, we found no significant changes in TET1 recruitment on *Avp* and *Cart* promoter sequences. There were also no changes in TET2 binding on either *Crh*, *Avp* or *Cart* promoter sequences. Together, these results show a potential role of Tet1 in mediating METH-induced up-regulation of *Crh* mRNA expression in the nucleus accumbens. These observations hint to the possibility of using TET1 inhibitors to alleviate stress-induced neurobiological alterations in METH addicts. Title: Methamphetamine induces a rapid increase of intracellular Ca++ levels in neurons overexpressing GCaMP5

Authors: *Y. WANG[1], K.-J. WU[1], E. K. BAE[1], M.-J. HSU[1], C. T. RICHIE[2], B. K. HARVEY[2], S.-J. YU[1];

[1]Ctr. for Neuropsychiatric Res., Natl. Hlth. Res. Inst., Zhunan, Taiwan; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: In this study, methamphetamine (Meth) and glutamate (Glu) -mediated intracellular Ca++ (Ca++i) signals were examined in real time in primary cortical neurons overexpressing an intracellular Ca++ probe, GCaMP5, by AAV serotype 1. Binding of Ca++ to gCaMP increased green fluorescence intensity in cells. Both Meth and Glu induced a rapid increase in Ca++i, which was blocked by MK801, suggesting Meth enhanced Ca++i through Glu receptor in neurons. The Meth-mediated Ca++ signal was also blocked by Mg++, low Ca++, or the L-type Ca++ channel inhibitor nifedipine. The ryanodine receptor (RyR) inhibitor dantrolene did not alter the initial Ca++ influx but partially reduced the peak of Ca++i. These data suggest Meth enhanced Ca++ influx through membrane Ca++ channels, which then triggered release of Ca++ from the endoplasmic reticulum in the cytosol. AAV-GCaMP5 was also injected to the parietal cortex of adult rats. Administration of Meth enhanced fluorescence in the ipsilateral cortex. Using immunohistochemistry, Meth -induced green fluorescence was found in the NeuN containing cells in cortex, suggesting Meth increased Ca++ in neurons *in vivo*. In conclusion, we have used *in vitro* and *in vivo* techniques to demonstrate a rapid increase of Ca++i by Meth in cortical neurons through overexpression of GCaMP5. Since Meth induces behavioral responses and neurotoxicity through Ca++i, modulation of Ca++i may be useful to reduce Meth related reactions.

Title: Pentedrone leads to psychological dependence via dopaminergic system

Authors: J.-Y. HWANG, S.-H. KWON, S.-I. HONG, Y.-H. JUNG, S.-X. MA, J.-S. KIM, J.-Y. SEO, J.-H. LEE, S.-Y. LEE, *C.-G. JANG;

Abstract: Cathinone derivatives are new recreational drugs known to produce psychostimulant effects. Addictive potential of cathinone derivatives has not been widely studied. Here, we investigated the addictive potential of pentedrone, a kind of cathinone derivatives, in conditioned place preference (CPP). As a result, pentedrone 3 and 10 mg/kg showed significant increase of CPP in mice. Also, acute administration of pentedrone enhanced locomotor activity and apomorphine-induced climbing behavior in a dose-dependent manner. However, chronic administration of pentedrone did not induce behavioral sensitization. Furthermore, in order to confirm the involvement of dopamine in the addictive property of pentedrone, we also carried out RT-PCR and Western blot. We revealed that pentedrone decreased tyrosine hydroxylase mRNA level and increased dopamine transporter, D1 receptor, D2 receptor mRNA levels and phosphorylation of CREB in PC-12 cells. These data suggest that the psychological dependence induced by pentedrone may be due to the effect of pentedrone on the dopaminergic system.

Title: Decrease in dopamine neuron activity following acute amphetamine withdrawal is mediated by the BLA and reversed by ketamine

Authors: *P. BELUJON, A. A. GRACE;
Neurosci., Univ. Pittsburgh, Pittsburgh, PA

Abstract: The negative emotional state described after drug use often drives an individual to subsequent use, leading to abuse. For drugs such as amphetamine, the increase of dopamine (DA) release from neurons in the ventral tegmental area (VTA) facilitates reward-driven

behaviors and therefore is critical for their acute reinforcing actions. However, this positive affect is followed by a negative emotional state each time a drug is taken, including the first time. Anhedonia has been repetitively associated with dysfunction in the DA system; this negative state drives additional drug intake which we propose is due to a compensatory decrease in DA neuron activity. In the chronic mild stress and the learned helplessness models of depression, the decrease in DA activity can be reversed by prior inactivation of the basolateral amygdala (BLA), and prior injection of ketamine, respectively. Using *in vivo* extracellular single-unit recordings from identified DA neurons from the VTA in chloral hydrate-anaesthetized male rats, we found that an acute dose of amphetamine (2 mg/kg) had no effect on DA activity measured one hour after amphetamine injection; however there was a decrease specifically in tonic DA neuron activity 18 hours following an acute dose of amphetamine. This response partially reverses after 48 hours, meaning that the impact of acute amphetamine withdrawal on dopamine neuron activity is transient. Moreover, either ketamine administration or BLA inactivation one hour prior to recording circumvents the decrease in DA neuron tonic firing that we propose underlies this negative withdrawal state. These data suggest that the negative state, due to a DA deficit, could be reversed by ketamine administration, which would circumvent the seeking and taking of more drugs after a single use of amphetamine.

Title: Long-term effects of a single use of methamphetamine administration on the expression of histone deacetylases (HDACs) in the rat nucleus accumbens

Authors: *M. T. MCCOY, S. JAYANTHI, B. LADENHEIM, J. CADET;
Mol. Neuropsychiatry Res. Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: Methamphetamine (METH) is an illicit psychostimulant that is abused worldwide. The cellular and molecular mechanisms involved in the long-term effects of taking a single dose

of the drug are not known. In fact, this pattern of drug injection might be associated with plastic changes in the transcriptional machinery in the brain. These might occur via epigenetic alterations that might include changes in the expression of histone deacetylases (HDACs) that catalyze the removal of acetyl moieties from histones. To test this idea, rats were given a single injection of METH (10 mg/kg) or saline and the nucleus accumbens (NAc) was dissected one month later. HDAC expression was measured by quantitative PCR analysis. We found that the METH injection caused decreased mRNA levels of HDAC2, HDAC3, HDAC7, Sirt1, Sirt2, Sirt3, Sirt4, and Sirt7. These changes in HDAC expression may be responsible for the large-scale changes in gene expression observed in animals similarly treated and for METH-induced molecular neuroadaptations in the rat brain. Title: Egr3 regulates mitochondrial biogenesis genes in nucleus accumbens neuron subtypes in cocaine abuse

Authors: *R. CHANDRA[1], T. C. FRANCIS[1], A. AMGALAN[1], L. JENSEN[1], P. KONKALMATT[2], A. GANCARZ[3], S. A. GOLDEN[4], G. TURECKI[5], S. J. RUSSO[4], D. M. DIETZ[3], M. K. LOBO[1];

Univ. Inst. and McGill Univ., Montréal, QC, Canada

Abstract: Previous studies demonstrate that the two projection neuron subtypes in nucleus accumbens (NAc), the medium spiny neuron (MSN) subtypes have opposite rewarding and reinforcing roles in drugs abuse. The two MSN subtypes are differentiated based on their

enrichment of genes including dopamine 1 (D1) receptors or dopamine 2 (D2) receptors. To provide insight into the molecular mechanisms occurring in the D1-MSN vs. D2-MSN subtypes, after chronic cocaine exposure, we examine the early growth response 3 (Egr3), a transcription factor. Egr3 is a known target of BDNF and dopamine signaling, two critical signaling pathways in drug abuse. Using Cre-inducible Ribotag mice combined with D1-Cre and D2-Cre mouse lines, we are able to isolate ribosome-associated RNA from both MSN subtypes after 7 days of cocaine (20mg/kg, i.p.). We find that that Egr3 is increased in D1-MSNs and decreased in D2-MSNs in this condition. We used a Cre-inducible adenoassociated virus (AAV) to overexpress Egr3 in NAc MSN subtypes in D1-Cre and D2-Cre mice. We observe that Egr3 overexpression in D1-MSNs enhances behavioral responses in cocaine conditioned place preference and cocaine-induced locomotion while overexpression in D2-MSNs blunts these behaviors. We next investigated target genes of Egr3 and demonstrate, with chromatin immunoprecipitation (ChIP), that Egr3 binding is increased on promoters of mitochondrial biogenesis genes after chronic cocaine. We find many of these mitochondrial biogenesis genes upregulated in the NAc after chronic cocaine conditions including cocaine self-administration (10 days, 20mg/kg, i.v.) and in postmortem NAc of human cocaine dependent individuals. When we examine ribosome-associated RNA in MSN subtypes, we find that the increase in mitochondrial biogenesis genes occurs in D1-MSNs while these genes are decreased in D2-MSNs after chronic cocaine. We are currently exploring the role of peroxisome proliferator-activated receptor γ coactivator-1α (PGC-1α), an Egr3 regulated mitochondrial biogenesis transcriptional activator, in MSN subtypes in cocaine-mediated behaviors. Our studies implicate a novel role for Egr3 in mediating energy homeostasis, through mitochondrial biogenesis, in MSN subtypes in cocaine abuse.

Title: Cocaine-mediated epigenetic adaptations in the ventral pallidum

Authors: M. ENGELN[1], J. LENZ[1], R. CHANDRA[1], A. M. GANCARZ[2], T. FRANCIS[1], D. M. DIETZ[2], *M. LOBO[1];
[1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Dept. of Pharmacol. & Toxicology, State Univ. of New York at Buffalo, Buffalo, NY

Abstract: Cocaine exposure has profound effects on chromatin remodeling in the nucleus accumbens (NAc). However, there is no information about cocaine-induced epigenetic alterations in the ventral pallidum (VP), a target of both NAc projection medium spiny neuron (MSN) subtypes. In this study we investigate gene expression changes in chromatin remodeling enzymes in the VP in two models of chronic exposure to cocaine. First, we collected VP tissue in mice that received 7 days of cocaine (i.p., 20mg/kg) or in rats after 10 days of cocaine (i.v., 20mg/kg) self-administration. We performed quantitative RT-PCR on cDNA from VP for chromatin remodeling enzymes, including the histone-lysine N-methyltransferase Set domain (Setd) proteins and histone deacetylases (HDACs) to gain insight into cocaine-induced molecular adaptations in the VP. Both repeated cocaine exposure and cocaine self-administration induced alterations in Setd genes such as Setd2, Setd3, and Setd7 in the VP. Interestingly, in contrast to the NAc literature, HDAC5 expression was increased in the VP after both 7 days of cocaine exposure and 10 days of cocaine self-administration. Finally, we are exploring the effects of NAc MSN inputs on these molecular adaptations in the VP by using bidirectional optogenetic control of dopamine receptor 1 or 2 MSN subtypes. Using Cre-inducible viruses combined with D1-Cre and D2-Cre mice we can inhibit eNpHR3.0 expressing D1-MSNs with green (532nm) light or activate ChR2(H134) expressing D2-MSNs with blue (473nm) light to blunt cocaine-induced locomotion. Preliminary studies demonstrate that D1-MSN inhibition abolishes the cocaine-mediated induction of Setd2, Setd3 and Setd7 in the VP. Our findings explore the currently unknown molecular role of the VP in cocaine abuse and provide information on the NAc-VP circuit specific regulation of epigenetic markers in VP by cocaine.

Title: NrCAM regulating neural systems in addiction vulnerability

Authors: *H. ISHIGURO[1,2], K. TABATA[1], T. SAKURAI[3], M. GRUMET[4], E. ONAIVI[2], G. UHL[5], N. MOTOHASHI[1];
[1]Univ. of Yamanashi, Chuo, Yamanashi, Japan; [2]William Paterson Univ., Wayne, NJ; [3]Kyoto University, Med. Innovation Ctr., Kyoto, Japan; [4]W.M. Keck Ctr. for Collaborative Neuroscience, Rutgers Univ., Piscataway, NJ; [5]NIDA-IRP/NIH, Baltimore, MD

Abstract: We have previously shown that genetic variations associated with decreased NrCAM expression in brain is protective against addiction vulnerability in humans and that Nrcam knockout mice do not develop conditioned place preferences for illegal drugs or alcohol. In order to gain insight into NrCAM involvement in addiction vulnerability, which may involve specific neural circuits underlying behavioral characteristics relevant to addiction, we evaluated several behavioral phenotypes in Nrcam knockout mice. NrCAM works in substance abuse including alcoholism vulnerability, possibly through its effects on behavioral traits that may affect addiction vulnerability, including novelty seeking, obsessive compulsion and responses to aversive or anxiety-provoking stimuli. In order to prove glutamate and GABAergic homeostasis hypothesis of addiction specific neural circuits, we analyzed expression patterns of glutamatergic and GABAergic molecules regulated by Nrcam and methamphetamine (MAP) treatment in midbrain of Nrcam knockout mice, using micro-array gene expression analysis in comparison between wild and heterozygote genotypes, and between treatment with saline and MAP. Glutaminase appears to be reduced in low expression of NrCAM tissue in human and mouse. An inhibitor of the enzyme, PLG, treatment produced, at least, some of the phenotypes of mice shown in alcohol preference and in anxiety-like behavior. Further, metabotropic glutamate receptor 2 appears to be reduced in MAP treated Nrcam heterozygote mice, although any difference of its expression was found between genotypes with saline treatment. GABAergic molecules are also detected differences in their expression. Thus, NrCAM could affect addiction-related behaviors via at least partially modulation of some glutamatargic and GABAergic pathways and neural function in brain.

Title: Transcriptional changes induced by amphetamine addiction in the striatum of spontaneously hypertensive rats (SHR), an animal model of attention-deficit/hyperactivity disorder (ADHD)

Authors: *J. CHEONG[1], I. DELA PEÑA[1], J. DE LA PEÑA[1], I. DELA PEÑA[1], M. NOH[2]; [1]Dept Pharm., Sahmyook Univ., Seoul, Korea, Republic of; [2]Col. of Pharmacy, Seoul Natl. Univ., Natural Products Res. Inst., Seoul, Korea, Republic of

Abstract: Attention-deficit/hyperactivity disorder (ADHD), the most commonly diagnosed neurobehavioral disorder of childhood, is usually treated with psychostimulants (e.g. amphetamine). Little is known about the neuronal correlates associated with long-term amphetamine use or abuse in individuals with ADHD. Of all ADHD animal models, the spontaneously hypertensive rat (SHR) is the most validated and widely used. In this study, we evaluated striatal transcriptomes in amphetamine-addicted SHR. Addiction was induced by repeated amphetamine pretreatment (5 mg/kg, i.p. for 7 days [twice daily]). The striatum of rats which showed conditioned place preference to and self-administration of amphetamine were analyzed. Genome-wide transcriptional analysis revealed an mRNA increase in 55 genes (>1.65-fold increase) while 17 genes were downregulated (<0.6-fold) in the striatum of SHR in response to amphetamine reinforcement. These differentially expressed genes included transcription factor-encoding genes (e.g. Cebpb, Per2), genes associated with angiogenesis (e.g. Kdr, Klf5), cell adhesion (e.g. Col11a1, Ctgf), apoptosis (e.g. Nfkbia, Perp) and neuronal development (e.g. Egr2, Nr4a3). Therefore, amphetamine regulates the expression of several genes in the striatum of SHR. These transcripts may mediate amphetamine-induced behavioral outcomes and could serve as candidate genes for amphetamine-abuse alterations in the brains of individuals with ADHD.

Title: Mephedrone alters basal ganglia and limbic dynorphin systems

Authors: *A. E. FLECKENSTEIN[1], A. J. HOONAKKER[2,3], G. R. HANSON[2,3], C. L. GERMAN[2];
[1]Pharmacol. and Toxicology, Univ. of Utah, SALT LAKE CTY, UT; [2]Pharmacol. and Toxicology, [3]Sch. of Dent., Univ. of Utah, Salt Lake City, UT

Abstract: Mephedrone (4-methymethcathinone) is a synthetic cathinone designer drug that disrupts central nervous system (CNS) dopamine (DA) signaling. Numerous neuropeptide systems reciprocally interact with dopaminergic neurons to provide regulatory counterbalance and are likely dysregulated by mephedrone and aberrant DA activity. Endogenous opioid neuropeptides are highly concentrated within dopaminergic CNS regions and involved in facilitating the rewarding and aversive properties associated with drug consumption. Dynorphin, an opioid neuropeptide and kappa receptor agonist, signals within the basal ganglia and limbic systems to cause dysphoria and aversion to drug consumption, and is affected by numerous psychostimulants. This work evaluated how mephedrone altered basal ganglia and limbic system dynorphin content, and the potential role of DA signaling in these changes. Repeated mephedrone administrations (4 x 25 mg/kg/injection, 2-h intervals) increased dynorphin content within various regions of the striatum and globus pallidus, while decreasing dynorphin content within the frontal cortex. Pre-treatment with D1-like (SCH-23380) or D2-like (eticlopride) antagonists blocked mephedrone-induced changes in dynorphin content, indicating increased dynorphin is a due to excess DA signaling at these receptors. The potential consequences of mephedrone-induced dynorphin changes in behavior and drug consumption will be discussed.

Title: Methylphenidate-induced ultrasonic vocalizations in adolescent and adult rats

Authors: *A. BINETTE, A. ROOS, C. G. GONZALEZ, K. A. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: Methylphenidate (Ritalin) is a common treatment for children, adolescents and adults afflicted with Attention Deficit Hyperactivity Disorder (ADHD). There is growing concern about how methylphenidate affects the developing adolescent brain, and if there are any differences in response to the drug between adolescents and adults. The present study examined behavioral differences between adolescent and adult rats in response to methylphenidate. To assess behavior, ultrasonic vocalizations (USVs) of adolescent rats (30 days of age) and adult rats (60 days of age) were recorded following treatment with saline or methylphenidate (5 mg/kg). In addition, the animals were tested 10 and 20 days later. Based on previous work in our laboratory with other psychostimulants, it was hypothesized that methylphenidate would induce increases in complex 50 kHz USVs in rats and that methylphenidate-treated adult rats would emit a greater number of complex 50 kHz calls than methylphenidate-treated adolescent rats. Although we did not find any significant differences in the overall number of complex 50 kHz calls emitted between the methylphenidate-treated adolescent and adult groups, there were very interesting trends. Methylphenidate-treated adolescents showed a greater number of other 50 kHz and complex 50 kHz USVs during the first half the session. Later in the session these trends reversed, and adults showed greater methylphenidate-induced increases in complex 50 kHz and other 50 kHz USVs. As the adolescent rats increased in age, they transitioned to the adult pattern of response. Although the lack of statistical differences does not allow us to arrive at strong conclusions, the results point toward differences between adolescents and adults in response to methylphenidate. We are currently examining a higher dose of methylphenidate to determine if significant differences will emerge, and to explore the dose-dependency of these effects.

Title: Adolescents show a reduced behavioral response to methamphetamine and dextroamphetamine when compared to adults

Authors: *V. ESPINOZA, C. Y. HELLER, A. ROCHA, K. A. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: Methamphetamine (METH) and Dextroamphetamine (D-AMPH) are psychomotor stimulants and common drugs of abuse. According to the Monitoring the Future Survey, amphetamines are second to marijuana in use by 12th graders, and among the highest used in 8th and 10th graders; thus, they are very significantly abused by adolescents. This is important because there is significant evidence linking initiation of drug use during adolescence to the formation of drug addiction. Despite this, relatively little is known about the effects of METH and D-AMPH in adolescents when compared to adults. Research to date suggests that adolescents show a reduced response when compared to adults. In this study, the locomotor response to METH and D-AMPH was examined in adolescent (30 days of age at the start of the study) and adult (60 days of age at the start of the study) male Sprague Dawley rats. Animals were administered METH (0.3 mg/kg or 1.0 mg/kg s.c.) or D-AMPH (1.0 mg/kg s.c.) at three developmentally relevant time points. A Kinder Scientific Motor Monitor was used to assess locomotor behavior. METH and D-AMPH produced an increase in activity in adolescents and adults. The results show that adolescents and adults exhibit similar locomotor effects for these two types of amphetamines. Differences between adolescents and adults depended on the specific type of locomotor behavior examined. For example, adults showed a greater response when examining fine movements (indicative of stereotypy), but not when examining horizontal activity (indicative of forward locomotion). As the adolescents approached adulthood (60 days of age), differences diminished. These results show that adults are more sensitive to both drugs when compared to adolescents, but only for specific aspects of locomotor behavior. To the extent that the differences indicate a reduced subjective effect of the drugs in adolescence, the consequence may be an increased intake of the drugs. Further studies will explore other behaviors related to METH and D-AMPH in adolescents and adults.

Title: Methamphetamine-induced ultrasonic vocalizations differ in adolescent and adult rats

Authors: ***C. G. GONZALEZ**, T. TOWNER, F. LOPEZ, A. ROCHA, K. A. TRUJILLO; Dept. of Psychology, California State Univ. San Marcos, San Marcos, CA

Abstract: A growing body of work has demonstrated behavioral differences between adolescents and adults in response to drugs of abuse. It has also been suggested that rat ultrasonic vocalizations (USVs) may reflect emotional states, with 50 kHz frequency-modulated USVs associated with positive states (such as reward) and flat 22 kHz USVs associated with negative states (such as aversion). Previous studies have shown that psychomotor stimulants, including cocaine and amphetamine, elicit 50 kHz USVs in adult rats. However, relatively little is known about the response of adolescent rats, and whether they emit these calls to the same degree as adults in response to drugs of abuse. In addition, 14 call variations in the 50 kHz range have been reported (Wright et al. 2010). These calls remain poorly understood in the context of affective status, developmental period, or drugs of abuse. The purpose of this study was to explore these 14 calls in adolescents (30 days of age) and adults (60 days of age) after administration methamphetamine (METH, 1 mg/kg). 12 adults and 12 adolescent rats were given 15 minutes to habituate to a sound-attenuating recording chamber, injected with METH or saline, and placed back in the chamber for an additional 45 minutes of recording. As expected, METH administration dramatically increased the number of 50 kHz USVs in both adults and adolescents. A subtype known as complex 50 kHz USVs increased robustly in adults while only a moderate increase was seen in adolescents. Interestingly, age dependent differences in several other USV types were also noted. For example, adults emitted a significantly greater number of "step-up" calls, while a strong trend toward increased "step-down" calls was evident in adolescents; these patterns were not present in control animals. Taken together, the results

demonstrate age-related differences in response to METH administration. Further work establishing the salience of these calls will give us greater insight into rat models of affective states of drug abuse and addiction.

Title: The influence of methamphetamine on maternal behavior and development of the pups during the neonatal period

Authors: *M. MALINOVA, I. HREBICKOVA, E. MACUCHOVA, R. SLAMBEROVA; Dept. of Normal, Pathological and Clin. Physiol., Charles Univ. In Prague, Third Fac. of Med., Prague, Czech Republic

Abstract: Methamphetamine (MA) as a psychostimulant affects maternal behavior. During lactation period, MA can penetrate into the breast milk and influence the postnatal development of the pups. The present study examined the effect of MA on maternal behavior when MA is abused during 11 days after parturition and the differences in postnatal development of the pups when MA is injected to the pups directly or is received by breast milk of mother during postnatal days (PD) 1-11. The development of nervous system of the rat pups during PD 1-11 should correspond to the third trimester of humans. Maternal behavior was examined by observation test (PD 1-22) and retrieval test (PD 1-12). Development of the pups was observed in the following tests: righting reflex on surface (PD 1-12), negative geotaxis (PD 9), righting reflex on mid-air (PD 17), rotarod and beam-balance test (PD 23). The weight of the pups was examined for the whole testing period and the day of eyes opening was recorded. Mothers who received MA groomed their pups less than controls although MA-treated mothers nursed actively their pups

more than control dams. In retrieval test, MA-treated mothers showed increased latency to return all the pups into the nest relative to controls. Due to anorectic effect of MA, the weight gain of the pups was significantly lower during the injection period relative to saline-exposed. In addition, when receiving drug via the breast milk all pups weighted less than the pups who received the drug directly. Pups who received the drug directly were faster in righting reflex on surface in first 3 PDs compared to pups who received drug via the breast milk. Females who received MA via the breast milk were faster in righting in first 2 PD´s compared to control females. However, the gender did not affect the righting reflex. In the test of negative geotaxis, pups receiving the drug via the breast milk were slower in turning upward in comparison to pups who received the drug directly. Neither drug nor gender influenced the performance. MA caused the earlier eyes opening when the pups received drug via the breast milk compared to controls. No differences in eyes opening were observed when the drug was administered directly to the pups. At the end of lactation period, males who received MA via the breast milk were less able to balance on a beam compared to males who received MA directly. The performance of males was worst compared to performance of females on a beam. In addition, the neonatal treatment of MA improved the performance of rotarod test relative to saline-exposed pups. Thus it seems that MA exposure in neonatal period affects early and also late sensorimotor development of the pups.

Title: Gender differences in behavioral changes caused by early neonatal methamphetamine exposure and application of the same drug in adult rats

Authors: *I. HREBÍCKOVÁ, M. MALINOVA, E. MACUCHOVA, R. SLAMBEROVA; Dept. of Normal, Pathological and Clin. Physiol., Charles University, Third Fac. of Med., Prague 2, Czech Republic

Abstract: Methamphetamine (MA) is a street drug causing potent psychomotor activation. Our previous works demonstrated that effect of MA exposure on behavior of adult rats prenatally exposed to MA depends on their gender. The aim of the present study was to compare the response to acute application of MA in adult male and female rats neonatally exposed to the same drug. Rat mothers during lactation period or their pups were treated subcutaneously by a daily injection of MA (5 mg/kg) or saline (SAL) throughout early neonatal period (from PD 1 to 11), which is a period of brain development that corresponds to human third trimester of gravidity. Spontaneous locomotor activity and exploratory behavior of adult animals were tested in Laboras apparatus (Metris B.V., Netherlands) for 1 hour. Rats were injected with MA (1mg/kg) or SAL prior to testing. Our results demonstrated that acute administration of MA in all groups increased locomotion, distance traveled, rearing as well as the velocity. In the groups, where mothers were treated and the drug crossed to the fetus via the breast milk, the MA-induced increase in exploratory behavior was higer in SAL-exposed males than MA-exposed males. In contrast, in the groups of injected pups, exploratory behavior after acute MA was higer in rats neonatally exposed with MA than with SAL. In all groups females displayed more locomotion and more rearing, faster velocity and longer distances traveled than males regardless of neonatal treatment. The sex-induced differences decreased as the time from the MA application progressed. Thus, our results indicate that adult MA injection affect behavior of adult males in sex- and prenatal drug exposure-specific manner.

Title: What is the effect of acute methamphetamine exposure on anxiety-related behavior in female rats after prenatal treatment with the same drug?

Authors: *E. MACÚCHOVÁ, K. NOHEJLOVÁ, M. MALINOVÁ, I. HREBÍčKOVÁ, M. POMETLOVÁ, R. ŠLAMBEROVÁ;
Dept. of Normal, Pathologigal and Clin. Physiol., Charles Univ. In Prague/Third Fac. of Med., Prague, Czech Republic

Abstract: Methamphetamine (MA) is among the most widely used addictive drugs, which leads to long-lasting changes of the developing brain of the fetus, when taken by pregnant women. Anxiety, panic attacks and mania have been reported among psychostimulant users, especially after the first use. Furthermore, females differ in the effect of psychostimulant drugs when compared to males. The aim of the present study was to examine the effect of acute MA exposure (1 mg/kg) on the female rats' behavior in the test of the elevated plus-maze (EPM) after prenatal treatment with the same drug (MA, 5 mg/kg) or saline (SA). EPM is commonly used for evaluation of anxiolytic and anxiogenic drug effects, based on the natural aversion of rodents to height and open spaces. Four groups of animals were tested (accordingly to prenatal/acute treatment): SA/SA, MA/SA, SA/MA, MA/MA. The parameters analyzed were divided into three groups: anxiogenic behavior, anxiolytic behavior and motor activity. As far as the anxiogenic behavior is concerned, the groups did not differ in a frequency of closed arms entries. However, females treated with MA in adulthood (regardless of prenatal treatment) showed increased frequencies of other parameters of anxiogenic behavior (protected head dipping and stretched-attend postures). Females from MA/MA group had increased frequency of open arms entries. This finding might not be taken as anxiolytic, as females from this group also had a higher frequency of all arms entries, and a higher frequency of rearing, when compared to other groups. So this effect was more likely caused by the locomotor activating effect of acute MA treatment. Additionally, the frequency of sniffing and the duration of sniffing episodes were decreased in the group of MA/MA females. Furthermore, we suggest that the effect of MA treatment on anxiety of female rats might be related to hormonal changes within the estrous cycle. Title: Chronic treatment with mood stabilizer lithium inhibits amphetamine-increased risk-taking behaviour in rats

Authors: Z. ZHOU[1], Y. WANG[1], H. TAN[1], Y. SUN[1], Y. CHE[2], *J.-F. WANG[1];
[1]Dept. of Pharmacol. & Therapeutics, Fac. of Medicine, Univ. of Manitoba, Winnipeg, MB, Canada; [2]Med. Col. of Soochow Univ., Suzhou, China

Abstract: In humans frequent use of amphetamine causes symptoms that resemble psychotic mania such as hyperactivity, elevated energy, risk-taking, enhanced mood and racing thoughts. The drug lithium is commonly used to treat mania. In this study, we analyzed the effects of lithium on amphetamine-induced risk-taking behaviour in rats. Risk-taking behaviours were measured by elevated plus maze test. The number of stretch-attend postures, the open-arm duration and the open-arm entrance frequency were each recorded for 5 min. We found that treatment with amphetamine at 2 mg/kg for 10 and 14 days significantly increased the number of stretch-attend postures, the open-arm duration and the centre entrance frequency, but treatment with amphetamine for 1, 3 and 7 day has no effect on these behaviours. We also found that chronic treatment with lithium significantly inhibited amphetamine- increased open arm duration and entrance frequency. In addition, treatment with amphetamine for 14 days increased protein carbonylation in rat frontal cortex, and chronic treatment with lithium inhibited amphetamine treatment-increased protein carbonylation. These results suggest that repeated amphetamine treatment in rats displays risk-taking manic-like behaviors in rats, and this risk-taking behaviour can be inhibited by chronic lithium treatment. Our findings also indicate that the process of oxidative stress may be targeted by lithium for its anti-manic treatment.

Title: Acute food deprivation decreases the expression of methamphetamine-induced sensitization of motor activity in rats

Authors: *F. MIRANDA-HERRERA, J. C. JIMENEZ-MEJIA, M. BECERRA-DIAZ, I. BARRIENTOS-NORIEGA, J. A. MIRANDA-BARRIENTOS;
Univ. Nacional Autonoma De Mexico, Tlanepantla, Edo Mex, Mexico

Abstract: Addictive effects of psychostimulants such as cocaine, amphetamine (AMPH), and methamphetamine (METH) are associated with an increase in extracellular dopamine (DA) levels in the brain reward circuitry by facilitating the release of DA from presynaptic nerve terminals and/or inhibiting the reuptake. Cocaine inhibits the reuptake of DA by blocking the DA transporter (DAT). AMPH and METH facilitate the release of DA from presynaptic terminals by reversal the DAT function. DAT is, therefore, a critical regulator of DA levels. There is now evidence that insulin pathways in the brain reward circuitry play an important role in regulating the DAT activity. Some studies have reported that the hypoinsulinemia attenuates the DAT functions and, as a consequence, the psychostimulant-induced behaviors are also reduced. Galici et al. (2003) reported that the depletion of insulin by single injection of streptozotocin reduced AMPH self-administrations. In the present study we examined the effects of acute food deprivation, that it also reduces the insulin levels, on the METH-induced sensitization of motor activity in rats. In addition, in independent groups of rats, glucose and insulin levels were also examined. Male Wistar rats were divided in five groups (n=10) and treated with METH or saline during the days 3-7 (development phase). On day 10 (expression phase) rats were treated with METH or saline. On days 8-9, animals remained drug-free in their home cages. Groups M24M and M0M were treated with METH (1 mg/kg) during development and expression phase. Rats of group M24M were deprived of food 24 h before the expression phase. Groups S0M, S24S and S0S were treated with saline on the development phase. They were different because rats of group S0M were treated with METH (1 mg/kg) on the expression phase and rats of group S24S were deprived of food 24 h before the expression phase. The behavioral activity was recorded by 60 min on open-field cages and glucose levels were measured on days 7 and 10 before the experimental session. The glucose and insulin levels were also evaluated in independent groups of rats after 0 and 24 h of food deprivation. The results showed that repeated administration of METH induced a progressive increase in locomotor activity in rats on development phase. However, METH administration on the expression phase produced a decrease on locomotor activity after 24 h of food-deprivation on group M24M. The results also showed that as a result of food-deprivation it was observed a reduction in glucose and insulin levels. These results are in

line with previous studies and suggest that food-deprivation reduces some behavioral effects of the psychostimulants such as METH.

Title: Methamphetamine, alcohol and nicotine dependent subjects have different neural signatures on a discounting task

Authors: *W. F. HOFFMAN[1,2], D. SCHWARTZ[2], V. WILSON[3], B. TREMBLAY[4], L. DENNIS[2], S. MITCHELL[5];

Abstract: We evaluated 38 alcohol dependent (EtOH), 25 methamphetamine dependent (MA) and 25 control subjects (CS) on an imaging task that differentiated neural networks representing reward magnitude, delay and probability. Subjects (52 male) were asked to choose between an immediate, certain monetary reward and an alternative reward that varied in magnitude, time to receipt and probability. Each aspect of the stimulus was presented separately and in pseudorandom order. When all aspects of the alternative were presented, the subject was signaled to choose and was informed of trial outcome. A standardized measure of impulsivity was obtained for each subject (IMP). We used amplitude modulated regression (AMR) to model the response to each stimulus aspect. The groups were well matched demographically; the EtOH group was more impulsive than the CS. We identified regions of group contrast in the AMR

coefficients (Figure 1) that suggest a qualitative difference in the neural signatures between the groups (Figure 2). EtOH subjects activate posterior insula for longer delays and LMFG for shorter delays and more certain outcomes. Conversely, MA users activate ACC with increasing reward, but EtOH do not. The difference between EtOH and CS does not show variability across regions, but rather quantitative differences within regions. EtOH show steeper activation decrease to increasing delay and decreasing probability than CS. Groups addicted to EtOH or MA respond differently to cardinal characteristics of monetary rewards.

Abstract: Methamphetamine (MA) abuse and dependency are international problems. Studies have shown that neuronal inflammation and degeneration after long term use of MA.

Memantine, an Alzheimer's disease medication, has NMDA antagonist property and neuroprotective effects *in vitro* and *in vivo*. In this study, we evaluated whether co-administration or post-treatment of memantine (10-20 mg/kg, s.c.) would be effective to prevent or treat MA-induced rewarding and drug-seeking behavior in male ICR mice. A conditioned place preference test with 6 days of conditioning was used. We found that co-administration of memantine (10 or 20 mg/kg, s.c.) with MA (0.5 mg/kg, i.p.) significantly attenuated the MA-induced place-preference in mice. Post-treatment of memantine for 4 days after conditioning did not show statistical significant effect. The neurochemical and other addiction or inflammation related changes including dopamine turnover rate, striatal delta-Fos B level, plasma cytokines, etc. are under investigation.

Title: The effects of amphetamine exposure during adolescence on anxiety- and depression-like behavior in young adulthood

Authors: *S. KANG[1,2], A. P. SINGH[3,1], W. M. SOLER[3,1], M. WU[3,1], Z. P. DANIELS[3,1], R. GALVES[3,2,1], J. M. GULLEY[3,2,1];
[2]Neurosci. Program, [3]Dept. of Psychology, [1]Univ. of Illinois At Urbana Champaign, Champaign, IL

Abstract: We have previously demonstrated that repeated exposure to amphetamine (AMPH) during adolescence induces changes in dopamine D1 and D2 receptors in the medial prefrontal cortex (mPFC) that last into young adulthood. It is not clear whether this is the result of changes in the expression of these receptors or if AMPH also alters anxiety- and depression-like behaviors that have been previously shown to be sensitive to manipulations of dopamine receptor

function. To investigate this, we treated pair-housed male and female Sprague-Dawley rats with saline or 3 mg/kg AMPH (i.p.) every other day from postnatal day 27 to 45 (10 injections). One, 7 and 22 days after the last injection (i.e., on P46, P52 and P67), sucrose preference tests were performed to assess depression-like behavior. During each test, consumption of water and a 1% sucrose solution was measured for 48 hours. One day before the last sucrose preference test (P66), anxiety-like behavior was assessed by measuring activity in an open-field arena and in an elevated plus maze (EPM). On P68 or P69, rats were sacrificed and the mPFC and nucleus accumbens (NAC) were collected for subsequent western blot analysis of D1 and D2 protein levels. Our preliminary result suggested that AMPH exposure induced a decrease in sucrose preference for both sexes, especially during the first test session. However, there was no apparent effect of AMPH pre-exposure on anxiety-like behavior measured by EPM. The expression levels of dopamine receptors are currently being quantified, but findings from previous studies have led us to predict that AMPH exposure will likely induce a reduction of D1 and an increase of D2 receptor level in the mPFC and NAC. These preliminary results are consistent with our previous work suggesting AMPH exposure has a long lasting effect on the dopamine system in the mPFC and NAC. Future analysis will reveal whether the predicted changes in dopamine receptors levels are associated with disruptions in depression- and anxiety-like behavior.

Title: Acute methamphetamine induces reactive oxygen species in dopamine terminals of the nucleus accumbens

Authors: *S. C. STEFFENSEN[1], D. M. HEDGES[1], N. D. SCHILATY[1], E. Y. JANG[1], J. T. YORGASON[2], F. P. BELLINGER[3];
[1]Brigham Young Univ., Provo, UT; [2]Oregon Hlth. and Sci. Univ., Portland, OR; [3]Univ. of Hawaii, Honolulu, HI

Abstract: Methamphetamine (METH) is a powerful psychostimulant known to act on both the dopamine (DA) transporter (DAT) and the monoamine vesicular transporter (VMAT-2).

Ultimately, METH facilitates DA release by causing a reverse transport of the DAT while simultaneously blocking VMAT-2. Dopamine is subject to auto-oxidation and enzymatic degradation, resulting in formation of hydrogen peroxide (H2O2) and superoxide (O2-), reactive oxygen species (ROS). This induces significant oxidative stress for DA neurons. Using fast scan cyclic voltammetry (FSCV), we evaluated the role of ROS in acute METH enhancement of DA release. Using FSCV *in vivo*, IV administration of METH (1.0 mg/kg) markedly increased DA release in the nucleus accumbens (NAc) 340%. Similarly, superfusion of METH (0.1-100 μM) dramatically increased DA release in the NAc slice preparation (330% at 100 μM METH) *ex vivo*, but the effect was more transient than that found *in vivo*. Within 15 minutes of continuous superfusion, the evoked signal decreased back to baseline level, suggesting some desensitization. This effect was difficult to wash out - over an hour later a similar challenge dose of METH was unable to raise the signal more than 5%. Due to the inherent nature of METH to raise oxidative stress in DA neurons, we sought to determine if part of the DA enhancement by METH was due to ROS formation. We tested the effects of METH in the presence of glutathione (GSH). Glutathione (100 μM) decreased METH-induced DA release in the NAc approximately 50%. To determine if this effect of GSH was due to molecular antioxidant properties, we tested METH in the presence of 2 mM sodium ascorbate, which failed to alter METH enhancement of DA release. In addition, we have also tested TEMPOL, a SOD mimetic compound, both *in vivo* and *ex vivo*. In both experimental paradigms there was no significant decrease in METH's effect. These results indicate that GSH is able to decrease METH's effect likely through enzymatic processes. Taken together, these results indicate that acute METH elicits a significant cellular response in DA cells based on ROS formation. The enzymatic processes associated with ROS formation may prove to be a potential therapeutic target.

Title: The combined neurotoxic effects of 3,4-methylenedioxymethamphetmine (MDMA) and selected substituted methcathinones in a mouse model

Authors: *N. MINER, R. JOHNSON, A. ESHLEMAN, A. JANOWSKY;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The rise in popularity of substituted methcathinones (aka "Bath Salts") has increased the focus on the neurotoxic effects of these substances. Two of the more popular methcathinones, 3,4-methylenedioxymethcathinone (methylone or MDMC) and 3,4-methylenedioxypyrovalerone (MDPV) are similar in structure to MDMA, yet differ significantly pharmacologically. Many users, whether intentionally or unwittingly, are concomitantly ingesting these methcathinones along with the popular illicit drug MDMA. To examine potential neurotoxic effects of these drug combinations, we studied the effects on C57BL/6 mice of administering a single-day neurotoxic regimen (4 i.p. injections spaced 2 hours apart) of the drugs either by themselves: MDMA (15 mg/kg and 30 mg/kg), MDMC (20 mg/kg), MDPV (1 mg/kg), or in combination: MDMC with MDMA (20 and 15 mg/kg), MDPV with MDMA (1 and 15 mg/kg), in comparison to control animals receiving saline injections. Core temperature was continuously monitored during day of administration using telemetry and animals were euthanized either 2 or 7 days following the last injection. Dopamine (DA) levels were analyzed in the striatum *via* competitive ELISA and striatal glial fibrillary acidic protein (GFAP) expression was analyzed by sandwich ELISA. At 2 days following the last injection, striatal DA was significantly decreased only with the highest dose of MDMA, whereas GFAP levels were increased by both doses of MDMA. DA or GFAP levels were not significantly altered by either methcathinone administered alone or in combination with MDMA. There were also no significant changes from baseline in any groups for DA or GFAP, measured 7 days later, indicating these changes are transient. Mice in all treatment groups, with the exception of MDPV alone, developed varying degrees of acute hypothermia, followed by hyperthermia. These results indicate that, at the doses used here, the effects of MDMC and MDPV are not additive with the effects of MDMA on acute DA depletion, or on increased astrocyte activation in the striatum, but may potentially block astrogliosis caused by MDMA alone. Additionally, temperature responses to these drugs appear to be mediated by different mechanisms that are not correlated with DA and GFAP levels.

Title: Interactions between methamphetamine self-administration, early life stress, and MeCP2

Authors: *C. LEWIS, M. F. OLIVE;
Psychology, Arizona State Univ., Tempe, AZ

Abstract: Early life stress and epigenetic processes are known mediators of drug addiction, yet little is known how these two factors interact to contribute to the vulnerability to abuse various substances such as methamphetamine. The maternal separation (MS) paradigm is an animal model used to study the long-term effects of early life stress. Animals subjected to prolonged daily maternal separation during a critical period of neurological development display altered behavioral and neurological development as adults. We recently examined the effects of early life stress on methamphetamine self-administration in rats (Lewis et al., Frontiers in Psychiatry, 2013). Male rats subjected to MS conditions self-administered significantly more methamphetamine and acquired methamphetamine self-administration earlier than males without a history of MS. The effects of MS on multiple neural systems and behaviors are in part mediated by epigenetic regulation of target genes. Methyl-CpG-binding-protein 2 (MeCP2) is an epigenetic marker that binds to methylated DNA and attracts other regulatory complexes, and has previously been implicated in psychostimulant reward and reinforcement. In our study, methamphetamine self-administration was inversely related to levels of MeCP2 in the nucleus accumbens core (NAcc). In order to determine a causal role for MeCP2 levels in MS-induced increases in methamphetamine intake, we are currently conducting studies on the effects of virally mediated knockdown of MeCP2 expression in the NAcc using an AAV9-U6-shRNA virus. The effects of the active shRNA-expressing vs. control virus on methamphetamine self-administration, extinction, and drug primed reinstatement in male rats with and without a history of early life stress are being examined. These studies will hopefully provide a potential epigenetic basis for the ability of early life stress to increase vulnerability to drug intake, and thus offer insight into potential intervention strategies for individuals with a history of early life stress. This work was supported by DA025606.

Title: Passive exposure to cannabis smoke leads to signs of dependence in rats

Authors: *A. W. BRUIJNZEEL, X. QI, S. WALL, M. GOLD, M. FEBO, B. SETLOW; Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: Cannabis is the most widely used illicit drug in the US and cannabis use among young adults continues to rise. Previous studies have shown that chronic systemic administration of delta 9-tetrahydrocannabinol (THC), the main psychoactive component of cannabis smoke, or CB1 cannabinoid receptor agonists leads to the development of dependence. However, because smoking is the most popular route of THC self-administration it is critical to investigate the effects of cannabis smoke exposure. In previous work, we established a whole body tobacco smoke exposure protocol and showed that exposure leads to the development of nicotine dependence and an upregulation of nicotinic receptors. The goal of the current study was to investigate if exposure to cannabis smoke has behavioral effects and leads to the development of cannabis dependence, similar to what has been shown previously with THC administration. Cannabis cigarettes (5.8% THC) were obtained from NIDA and cannabis smoke was generated using an automated cigarette smoking machine. Adult rats (n=4) were exposed to cannabis smoke for 1 h per day, 5 days per week, for a total of three weeks in an exposure chamber. Control rats (n=4) were exposed to the smoking machine in the absence of smoke, for the duration of the exposure sessions. Blood samples were collected immediately after exposure and THC levels were determined using a THC ELISA kit. Exposure to cannabis during weeks 2 and 3 led to THC levels of 58.6 ± 1.8 and 59.4 ± 2.1 ng/ml, respectively. Similar THC levels have been detected in humans after smoking a cannabis cigarette. During week 2, the effect of cannabis smoke exposure on locomotor activity was investigated. Exposure to cannabis smoke led to a decrease in locomotor activity and rearing compared to control rats. Similar effects have been observed after THC administration in rats. When the rats were tested 3 days after cannabis smoke exposure there was no difference in locomotor activity or rearing between the two groups. At the end of weeks 2 and 3, the rats received the CB1 receptor antagonist SR 141716A (5 mg/kg, ip) and somatic withdrawal signs were recorded for 10 min. At both time points, the cannabis rats displayed about twice as many somatic withdrawal signs as the control rats. Finally, exposure to cannabis smoke led to a significant reduction in body weight gain during the 3-week exposure period. Taken together, the present data show that chronic exposure to cannabis smoke leads to an increase in serum THC levels, decreased activity levels, and early signs of cannabis dependence. This exposure model should be useful for separating the effects of THC from cannabis smoke and developing treatments for cannabis dependence.

Title: Species differences of cannabinoid receptor 2 genes and their roles in cocaine self-administration

Authors: ***Q.-R. LIU**, H.-Y. ZHANG, E. L. GARDNER, Z.-X. XI;
Behavior Neurosci. Res. Br., Intramural Res. Program, NIDA/ NIH, BALTIMORE, MD

Abstract: The discovery of functional neuronal cannabinoid receptor 2 (CB2R) expressed in brain suggests a potential new therapeutic target for neurological and psychiatric disorders. However, species differences in CB2R gene structures, protein sequences and brain expression patterns confound the pharmacological and behavioral interpretations in different animal models. The pharmacological effects of the CB2R-selective agonist JWH133 on cocaine self-administration were different between mice and rats. Systemic administration of JWH133 (10, 20 mg/kg) significantly and dose-dependently inhibited intravenous cocaine self-administration under both fixed-ratio (FR) and progressive-ratio (PR) reinforcements in mice, but had little effect on intravenous cocaine self-administration under FR reinforcements, but increased PR break-point for cocaine self-administration in rats. We analyzed the molecular differences of CB2R in different species. In comparison with human and rat CB2R, mouse CB2R contains a premature stop codon that truncates the C-terminal 13 amino acids. We previously found that mouse and human brains express CB2A and CB2B isoforms, with mRNA levels of CB2A higher than that of CB2B in their respective brain regions. In this study, we discovered novel rat-specific alternatively spliced isoforms of rCB2C and rCB2D that are produced by inter- and intra-exonal splicing events, respectively. The ultrasensitive RNAscope *in situ* hybridization found that CB2R mRNA was expressed in ventral subiculum of hippocampus of both rat and mouse. These findings suggest that an accelerated evolution of CB2R gene in terms of alternative spliced isoforms, brain expression patterns, and variations of the protein functional

domains might in part contribute to the behavioral differences of CB2R-selective ligand effects in different animal models.

Title: Evoked dopamine dynamics in nucleus accumbens core following acute versus chronic administration of the CB1/CB2 agonist, CP55,940

Authors: *S. LEE[1], G. V. REBEC[1,2], K. D. BUNNER[1,2];
[1]Program in Neurosci., [2]Dept. of Psychological and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Marijuana, like many drugs of abuse, increases dopamine transmission in the nucleus accumbens (NAc). This effect is believed to enhance goal-directed behavioral responses, including the motivation to obtain natural and drug rewards. Cannabinoid receptors (CB) play a key role in the marijuana-induced dopamine increase, and acute exposure to cannabinoids promotes NAc dopamine by activating dopamine neurons in the ventral tegmental area. The effect of prolonged cannabinoid exposure on NAc dopamine, however, is unclear. Moreover, a recent *in vitro* study indicated a possible interaction between cannabinoids and the dopamine transporter, suggesting a role for cannabinoids on dopamine uptake (Pandolfo et al., Eur. J. Pharmacol., 2011). Here, we examined extracellular dopamine dynamics in the NAc core, which is involved in goal-directed behavior, in response to acute as well as chronic administration of CP55,940, a CB1/CB2 receptor agonist. Fast scan cyclic voltammetry was used to measure dopamine overflow in the NAc core evoked by electrical stimulation of the median forebrain bundle in anesthetized, male Sprague-Dawley rats. Dopamine release was assessed immediately following one or seven daily injections of CP55,940 (0.2mg/kg, ip) or corresponding vehicle. Whereas a single injection of CP55,940 increased stimulation-evoked dopamine release, repeated

exposure failed to increase dopamine above the vehicle response. In fact, compared to vehicle, chronic CP55,940 lowered basal dopamine release. Our results show that although CB1 receptor activation increases NAc dopamine release, tolerance develops to this effect and may even lead to a decrease in dopamine transmission. Thus, altered dopamine signaling in the reward pathway by acute and chronic cannabinoid exposure may contribute to differential changes in motivational state.

Title: Development and validation of a device for the intrapulmonary delivery of cannabinoids and stimulants to rats

Authors: *M. A. TAFFE[1], S. M. AARDE[2], M. COLE[2];
[1]Cmte Neurobio. of Addictive Disorders, The Scripps Res. Inst., LA JOLLA, CA; [2]The Scripps Res. Inst., La Jolla, CA

Abstract: The recent popularization of non-combustible methods for intrapulmonary delivery of psychoactive drugs to humans (Vape, Volcano, e-cigarette, etc) has stimulated interest in the intrapulmonary administration models for rodent studies. We have designed a sealed rodent chamber, with a well regulated air flow, that is suitable for the controlled exposure of rats to psychoactive substances. Use of e-cigarette type delivery systems was found to afford excellent dosing control for this purpose. Studies were conducted in male rats to verify the *in vivo* efficacy of drug delivery. Implantable radiotelemetry methods were used to demonstrate that a 20 min exposure to Δ9-tetrahydrocannabinol (THC), or the CB1 receptor full agonist JWH-018, produces a robust hypothermia. The temperature nadir was reached within 40 min of exposure, was of comparable magnitude to that found after 30 mg/kg THC or 1.1 mg/kg JWH-018, i.p. and had resolved within 3 hours compared with a 6 hour time course following injection. Studies also

demonstrated that 30 min of intrapulmonary exposure to methamphetamine (MA) significantly increased home cage locomotor behavior for up to 2 hrs. A final study showed that a 30 min intrapulmonary exposure to MA reduced drug intake during the loading phase of intravenous self-administration of MA. Finally, it is shown that rats will nosepoke for the delivery of MA vapor. These studies show that an electronic cigarette type delivery system can be successfully used to model intrapulmonary drug delivery in rats. These techniques will be of increasing utility as recreational users continue to adopt "vaping" for the administration of psychtropic drugs.

Title: Chronic cocaine self-administration up-regulates cannabinoid CB_2 receptor expression in mice and rats

Authors: ***H. ZHANG**, Q.-R. LIU, G.-H. BI, E. L. GARDNER, Z.-X. XI;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Brain cannabinoid CB_2 receptors (CB_2Rs) have been recently reported to regulate nucleus accumbens dopamine (DA) release and intravenous cocaine self-administration (SA) in mice and rats, which appears to challenge a long-accepted view that CB_2Rs are expressed mainly in periphery, not in brain. It is well documented that CB_2Rs are up-regulated in microglia during neuroinflammation or several other CNS disorders, suggesting that brain CB_2Rs are inducible under certain pathological circumstances. However, little is known as to whether chronic drug use and abuse similarly alters brain CB_2 receptor expression. Here we report that chronic, but not acute, exposure to cocaine up-regulates brain CB_2 mRNA expression in both mice and rats. We first used quantitative real-time PCR (RT-PCR) assays to measure mouse brain CB_2 mRNA with two different Taqman probes that target the 5′ and 3′ regions of mouse CB_2 (mCB_2) gene, respectively. We found that chronic cocaine self-administration (0.5-1 mg/kg/infusion, 3

hrs/session/day with maximal 50 cocaine infusions/session, for 4~6 weeks) significantly up-regulated (4-5 fold) CB_2 mRNA expression in prefrontal cortex (PFC) and striatum of mice compared to oral sucrose self-administration (0.02 ml of 5% sucrose/infusion, 3 hrs/session/day with maximal 100 sucrose infusions/session, for 4~6 weeks) control mice or drug naïve mice. In contrast, a single injection (10, 20, 30 mg/kg, i.p.) or repeated injections of cocaine (15 mg/kg, i.p. for 7 daily injections) (i.e. locomotor sensitization dose regimen) failed to alter brain CB_2 mRNA expression. We then used *in situ* hybridization (ISH) assays with a mouse CB_2 RNAscope probe that targets the 3′ untranslated region (UTR) of the mCB_2 gene, and found similar mCB_2 mRNA up-regulation in cortical and striatal neurons. To further confirm this finding, we used the same RT-PCR and ISH assays to detect CB_2 mRNA expression in rat brains with one rat CB_2 (rCB_2)-specific Taqman probe and an rCB_2 RNAscope probe. We observed the same results - cocaine, but not sucrose, self-administration up-regulated CB_2 mRNA expression in both the PFC and striatum in rats. Taken together, these findings suggest that brain CB_2 receptors are inducible and responsive to chronic cocaine use and abuse. Thus, brain CB_2 receptors may constitute a new target in medication development for the treatment of drug addiction and possibly other CNS disorders.

Title: Selective activation of CB2Rs eliminates VTA dopamine neuronal bursting firing in rodents

Authors: *M. GAO[1], Z. XI[2], J. WU[1];
[1]Divisions of Neurol., Barrow Neurolog. Institute, St. Joseph's Hosp. and Med. Ctr., Phoenix, AZ; [2]Intramural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Recently, the "peripheral cannabinoid type 2 receptors (CB2Rs)" have been detected in various brain areas, suggesting that CB2Rs are also expressed in the central nervous system and they may participate in the modulation of neuronal functions under both physiological and pathological conditions. Our previous study demonstrated that the activation of central CB2Rs significantly reduced animal cocaine seeking behavior, which indicates an important role played by CB2Rs in mesolimbic circuit for drug addiction. It is well known that drug addictive behavioral is highly correlated with VTA dopamine (DA) neuronal firing activity, especially bursting firing. However, whether central CB2Rs modulate VTA DA neuronal bursting firing is unknown. We hypothesize that the selective activation of functional CB2Rs in the VTA eliminates VTA DA neuronal bursting firing through the enhanced small-conductance Ca2+-activated K+ channels (SK). In the present study, we test our hypothesis using *in vivo* and *in vitro* electrophysiological approaches. In anesthetized mice, we performed extracellular single unit recording and found that systemic injection of CB2Rs agonist (JWH 133, i.p., 10 mg/kg) moderately reduced VTA DA neuronal firing rate but dramatically reduced bursting firing fraction in WT, but not CB2R KO, mice. In WT mice, the JWH133-induced inhibition in DA neuronal firing can be prevented or reversed by injection of CB2Rs antagonist AM630 (i.p. 10 mg/kg), suggesting that systemic JWH133 alters VTA DA neuronal bursting firing through the activation of CB2Rs. In VTA DA neurons in slice, bath-applied JWH133 (1 μm) significantly enhanced the amplitude of apamin-sensitive after-hyperpolarization, suggesting that the altered SK conductance may underlie JWH133-induced reduction of neuronal bursting firing. To elucidate this possible mechanism, we induced DA neuronal bursting firing with NMDA (30 μM) in VTA slices both in rats and mice. We found that JWH133 significantly inhibited NMDA-induced bursting firing represented as a decrease in amplitude of the inter-burst hyperpolarization potential. Importantly, this inhibition can be blocked by either AM630, or a SK selective blocker NS8593. Furthermore, JWH133 also enhanced SK current amplitude in DA neurons of VTA slices. Taken together, our results suggest that the selective activation of VTA CB2Rs significantly eliminates the bursting firing of VTA DA neurons, which is mediated through enhanced amplitude of SK currents. Therefore, our findings provide directly experimental evidence to improve our understanding, for the first time, of how CB2Rs play a critical role in drug addiction and DA associated diseases.

Title: Cortical glutamatergic type 1 cannabinoid receptor protects against diet-induced obesity: Potential role of odor function in the motivation for food intake

Authors: I. RUIZ DE AZUA, A. APARISI REY, S. RUHLE, F. REMMERS, M. HAMANN, *K. MONORY, B. LUTZ;
Inst. of Physiological Chem., Univ. Med. Ctr. of the Johannes Gutenberg Univ., Mainz, Germany

Abstract: Palatable food can promote overfeeding, beyond energy homeostatic requirements, and is a major risk to develop obesity. In this context, the endocannabinoid system is a key regulator of appetite and energy balance through the modulation of type 1 cannabinoid (CB1) receptor activity in central and peripheral tissues. Previous studies have shown that mice with deficiency of the CB1 receptor in cortical glutamatergic neurons (Glu-CB1-KO mice) lacks the well-known endogenous orexigenic effect of cannabinoids in a hunger state, but Glu-CB1-KO mice did not show body weight differences on standard diet, when mice had "*ad libitum*" access to food. In the present study, we investigated Glu-CB1-KO mice in a diet-induced obesity model. Strikingly, when Glu-CB1-KO mice had free access to palatable food (34% high-fat enriched diet, HFD), the lack of CB1 receptor in these particular neurons was sufficient to protect against the deleterious effects of HFD. We also found a strong and significant reduction in food intake linked to lower body weight. Importantly, a fasting-re-feeding experiment was enough to reverse the body weight difference, suggesting that the reduction in food intake in Glu-CB1-KO mice was mainly responsible for the resistance to HFD treatment. It has recently been demonstrated that CB1 receptor promotes food intake in fasted mice by increasing odor detection (Soria-Gomez et al., 2014). The analysis of mRNA levels of CB1 in mutant mice under HFD pointed out that there were small reductions in most brain areas except for cortical olfactory areas (decrease around 75%), where the well-known centrifugal glutamatergic innervations of the olfactory bulb are located. Immunohistochemistry showed a strong reduction of CB1 receptor expression in internal layers of the olfactory bulb in Glu-CB1-KO mice. Therefore, we tested the olfactory function and found that Glu-CB1-WT mice had a significantly better exploratory performance as compared to Glu-CB1 KO mice after six weeks on HFD during an odor habituation test. Finally, "re-expression" of CB1 receptor locally in these olfactory cortical areas in Glu-CB1-KO mice, by AAV carrying a Cre-dependent CB1 receptor transgene (AAV-stop-CB1), was able to partially rescue the differences in terms of body weight, food intake, odor function and glucose metabolism between Glu-CB1-KO and -WT mice. In summary, these findings suggest that CB1 receptor in cortical glutamatergic neurons is particularly relevant to promote overconsumption, when mice have free access to palatable food, and uncover a new role of CB1 receptor in the olfactory system in the motivation for food intake and the emergence of diet-induced obesity.

Title: Involvement of cortico-striatal glutamatergic neurotransmission in the reinforcing effects of delta-9-tetrahydrocannabinol (THC)

Authors: ***M. SECCI**[1], Z. JUSTINOVA[1], P. MASCIA[1], H.-Q. WU[2], G. TANDA[1], R. SCHWARCZ[2], S. GOLDBERG[1];
[1]Preclinical Pharmacol., NIDA, IRP, NIH, DHHS, Baltimore, MD; [2]Maryland Psychiatric Res. Ctr., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Although it is not as addictive as cocaine or heroin, delta-9-tetrahydrocannabinol (THC, the active constituent of cannabis) produces DSM-defined dependence and it is used by increasingly large numbers of people. Gaining a better understanding of THC's effects could lead to improved treatments for cannabis dependence. Like all other addictive drugs, THC produces rewarding effects in the brain by increasing extracellular dopamine levels in the nucleus accumbens (NAc) shell and ventral tegmental area (VTA). However, the mechanism by which THC affects dopamine in these areas differs from other drugs and has yet to be fully elucidated. Our goal was to determine the effects of THC on the release of glutamate, which is the primary excitatory neurotransmitter in the brain and a key modulator of dopamine neurotransmission. Using in-vivo microdialysis in rats, we examined the effect of systemic injection of THC on glutamate levels in the NAc and VTA. We also studied the involvement of glutamatergic projections from the medial prefrontal cortex (mPFC) to the NAc shell on THC-induced dopamine release by using the GABA(B) receptor agonist baclofen. By giving local injections of baclofen (0.3 nmol/0.5 ul) into the mPFC, we also disrupted the release of glutamate by cells that project from the mPFC to the NAc shell, to determine whether this would affect THC-induced dopamine release. We found that systemic injection of THC (3 mg/kg i.p.) increased glutamate release in the NAc and VTA by 86.5% and 90%, respectively. This effect of THC was mediated by cannabinoid CB1 receptors, since it was blocked by pretreatment with the CB1 receptor

antagonist, rimonabant (1 mg/kg i.p.). Consistent with these glutamatergic effects of THC playing a role in THC reward, local injection of baclofen into the mPFC significantly blocked THC's ability to induce dopamine release in the NAc shell. As a result, this study shows for the first time that: 1) THC can increase glutamate levels in key brain reward areas; 2) that this increase is mediated by CB1 receptors; and 3) that THC-induced dopamine release in the NAc shell is modulated by glutamatergic projections from the mPFC. Thus, cortico-striatal neurotransmission seems to play an important role in the abuse-related effects of THC.

Title: Cannabinoid withdrawal and hypodopaminergia: A role for rostromedial tegmental neurons?

Authors: *A. MUNTONI[1], S. ARONI[2], C. SAGHEDDU[2], M. PISTIS[2,1];
[1]CNR Neurosci. Institute-Cagliari, Monserrato, Italy; [2]Dept. of Biomed. Sciences, Div. of Neurosci. and Clin. Pharmacol., Univ. of Cagliari, Monserrato, Italy

Abstract: The mesolimbic dopamine (DA) system, which arises from the ventral tegmental area (VTA), shows a decline in its spontaneous activity after chronic cannabinoid exposure and withdrawal, the critical phases of addiction. These changes in neuronal plasticity are thought to play a role into withdrawal-induced negative affective states that eventually lead to relapse into drug taking. The rostromedial tegmental nucleus (RMTg), a GABA structure located just posterior to the VTA, is a key site implicated in aversion processes. The RMTg provides a major inhibitory projection to the VTA and is a substrate for cannabinoid actions on DA cells. Indeed, acute administration of cannabinoids suppresses RMTg inputs to the VTA, thus contributing to cannabinoid-induced DA neuronal excitation. Here we sought to verify whether RMTg GABA projections to VTA neurons are causally involved in the hypodopaminergic state that characterizes cannabinoid withdrawal. To this aim, we took advantage of single unit extracellular

recordings from RMTg and VTA neurons in anesthetized male Sprague-Dawley rats. To induce Δ^9-tetrahydrocannabinol (Δ^9-THC) dependence, rats were chronically treated with Δ^9-THC (15 mg/kg, i.p.) twice daily for 6.5 days. Administration of the cannabinoid antagonist SR141716A (5 mg/kg, i.p.) precipitated an intense behavioral withdrawal syndrome, whereas abrupt Δ^9-THC suspension produced only milder signs of abstinence. Electrophysiological experiments confirmed that Δ^9-THC withdrawal produced a marked decrease in the firing rate and burst firing of VTA DA neurons. As expected, RMTg stimulation elicited a complete suppression of DA neuron discharge activity. In Δ^9-THC withdrawn rats the duration of RMTg-evoked inhibition was increased when compared with controls, suggesting an augmented GABA inhibitory input onto DA cells. Whether or not spontaneous activity of RMTg GABA neurons is altered in cannabinoid-withdrawn rats is currently under investigation. While preliminary, our results support the hypothesis that enhanced GABA inputs from the RMTg might contribute to the hypodopaminergia induced by cannabinoid withdrawal, and confirm that the RMTg takes part in the neuronal circuits underlying drug dependence and addiction.

Title: Effects of restraint stress on zebra finch vocal production: Evidence for social context-dependence

Authors: *T. L. HOLLAND[1], K. SODERSTROM[2];
[2]Pharmacol. and Toxicology, [1]East Carolina Univ., Greenville, NC

Abstract: Chronic cannabinoid treatment during the sensorimotor stage of zebra finch vocal development, but not during adulthood, has persistent effects on song patterns, suggesting interaction with processes responsible for late-postnatal brain development. Given accumulating evidence of an endogenous role for cannabinoid signaling in mediating physiological responses to stress, we have begun to investigate the extent to which cannabinoid-altered learning may be attributable to interaction with stress responses. Male zebra finches learn a complex song during a sensitive period of development with similarities to human language acquisition. During an early auditory phase, birds listen to and memorize the song pattern of an adult. During a

following sensorimotor learning phase, birds gradually improve songs through auditory feedback during sensorimotor practice. By adulthood, formation of a stable song pattern is achieved. Mature zebra finch song is stereotyped, but performance of the song may vary. The bird may add, skip, or repeat notes that are typically present in a motif, deviating from the typical stereotyped song pattern. We predicted that this type of note variability would be increased in stressed animals. To test this, songs were recorded before and after 30 minutes of restraint stress (isolation in a paper bag). Female-directed and undirected social context groups were included. Post-stress songs of the undirected social context group were more variable in song note composition than pre-stress songs. This difference was not seen in the female-directed social context group. As undirected song is established to involve activation of both vocal motor and anterior forebrain pathways (e.g. pre-motor HVC and anterior Area X and lMAN) and female-directed song involves activation of a more limited motor pathway (e.g. HVC) these results implicate involvement of the anterior forebrain pathway in mediating stress effects on vocal performance. Given evidence of a synergistic effect of cannabinoid treatment and stress on corticosterone levels, in future experiments we will test the hypothesis that corticosterone and cannabinoid pre-treatments will increase the magnitude of stress effects on song performance. These effects are predicted to only occur in undirected song social context. Results will provide insight into the role of stress on acute cannabinoid responses. Since cannabinoids have developmentally significant effects, future studies will evaluate effects of concurrent acute stress and cannabinoid treatment in developing zebra finches.

Biol., Baylor Col. of Med., Houston, TX

Abstract: G-protein-coupled CB1 cannabinoid receptors (CB1Rs) are highly expressed in the central nervous system (CNS), and together with the endocannabinoids, anandamide and 2-arachidonoylglycerol, modulate appetite, reward, pain, memory and motor activity. Cannabinoid receptor-interacting protein 1a (CRIP1a) is a novel regulatory protein that binds to the C-terminus of CB1Rs but not CB2Rs. Studies in cell models suggest that CRIP1a negatively regulates CB1R signaling. To determine effects of loss of CRIP1a function, we generated Cnrip1 genetic null mice. Cnrip1 knockout (KO) mice are viable, fertile and do not express CRIP1a mRNA or protein, as determined using both qPCR and Western immunoblot analysis, indicating a true null phenotype. No differences in CB1R expression levels were observed between CRIP1a KO and wild-type (WT) mice, as indicated by [3H]CP55,940 Bmax values, in any CNS regions examined so far. These animals were then characterized for novel behavioral phenotypes as well as alterations in CB1R-mediated G-protein activation, determined by agonist-stimulated [35S]GTPgammaS binding, in multiple regions of the CNS. Several CB1R-expressing CNS regions, including cerebellum, hippocampus, prefrontal cortex and spinal cord, did not display enhanced CB1R-stimulated G-protein activity between CRIP1a KO and WT mice. However, the amygdala and striatum of CRIP1a KO mice both exhibited significant enhancement of CB1-mediated G-protein activation compared to WT mice, as determined by concentration-effect curves using both the potent synthetic cannabinoid agonist CP55,940 and the putative endocannabinoid noladin ether. Importantly, behavioral analysis revealed that CRIP1a KO mice displayed significant anxiolytic-like phenotypes relative to WT mice in both the light:dark box and marble burying tests. Treatment-naïve CRIP1a KO mice also displayed slightly elevated tail-flick latencies, indicating a modest antinociceptive phenoptype, but were not different from WT mice in body temperature, spontaneous motor activity or rotarod performance. Moreover, no significant genotype differences were observed in antinociception, catalepsy, hypothermia or impairment of rotarod performance after acute administration of CP55,940, suggesting that CRIP1a selectively modulates anxiety-like behavior without enhancing CNS-mediated cannabinoid side effects. Our studies are the first to investigate the role of CRIP1a function in live animals, and suggest that CRIP1a could serve as a promising pharmacological target for future study and potential treatment of anxiety disorders.

Title: Regulation of 2-AG-mediated cannabinoid CB1 receptor signaling and adaptation by beta-arrestin2

Authors: *L. J. SIM-SELLEY[1], B. M. IGNATOWSKA-JANKOWSKA[1], I. B. ADAMS[1], A. TOMARCHIO[1], B. F. CRAVATT[2], C. K. ARNATT[1], Y. ZHANG[1], A. H. LICHTMAN[1], D. E. SELLEY[1];
[1]Virginia Commonweatlh Univ., RICHMOND, VA; [2]Scripps Res. Inst., La Jolla, CA

Abstract: Cannabinoids such as delta ^{9}-tetrahydrocannabinol (THC) and the endogenous cannabinoids (eCBs) 2-arachidonoylglycerol (2-AG) and anandamide (AEA) modulate neurotransmission in the central nervous system (CNS), primarily by activating cannabinoid CB_1 receptors (CB_1R). CB_1Rs are G-protein coupled receptors (GPCR) that activate mainly $G_{i/o}$-family proteins. Like other GPCRs, CB_1Rs are regulated by and can signal through beta-arrestins, such as beta-arrestin2 (Barr2). Accordingly, the relative ability of ligands to activate G-proteins versus recruit beta-arrestins determines their short and long-term signaling. Because THC and other CB_1 agonists have psychoactive side effects, a promising approach to regulate CB_1R activity for therapeutic benefit is the use of catabolic enzyme inhibitors to enhance eCB levels. In the present study, we compared the potency and efficacy of eCB ligands and THC to activate G-proteins in CB_1R-expressing CHO cells and N18TG2 neuroblastoma cells using [^{35}S]GTPgammaS binding, and to recruit Barr2 in CB_1-CHO cells using an enzyme complementation assay. We then examined the effects of repeated administration of THC or the monoacylglycerol lipase inhibitor JZL-184, which elevates 2-AG to a greater extent than other

eCBs, on the pharmacological actions of THC *in vivo* and on desensitization of CB_1R-mediated G-protein activation *in vitro*, in Barr2 knockout (KO) and wild-type (WT) mice. Results showed that 2-AG and AEA were essentially full agonists for G-protein activation in both cell lines, whereas 2-AG was more efficacious but had similar potency compared to AEA to recruit Barr2. Both eCBs recruited Barr2 with lower potency but much higher efficacy than THC. Repeated THC or JZL-184 administration produced tolerance to the hypothermic and thermal antinociceptive actions of THC in WT and Barr2 KO mice, but significant cross-tolerance was not observed to THC-induced catalepsy in repeated JZL-184-treated WT mice. Repeated THC produced tolerance to catalepsy in WT mice, which was reduced in Barr2 KO mice. CB_1R-mediated G-protein activation was partially desensitized by repeated treatment with THC or JZL-184 in multiple CNS regions, including spinal cord, cerebellum, hippocampus, caudate-putamen and nucleus accumbens. However, less CB_1R desensitization was detected in the caudate-putamen and nucleus accumbens of Barr2 compared to WT mice, and this difference was more robust with JZL-184 than THC. These results indicate that 2-AG is a high efficacy CB_1R ligand to both activate G-proteins and recruit Barr2, and that CB_1R desensitization and tolerance to motor effects are regulated by Barr2 in the striatum.

Title: Effects of adolescent nicotine exposure on cannabinoid-induced place preference in young adult rats

Authors: C. P. PLANT, M. STONE, A. D. HARDIN, *C. A. CRAWFORD;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Nicotine is one of the most commonly abused substances during adolescence and is associated with later illicit drug use. For example, cigarette smoking during adolescence is

highly associated with the increased use of marijuana in adulthood. The mechanisms underlying this relationship are unknown, but it may be the result of nicotine-induced changes to dopaminergic reward circuitry. Thus, the goal of the present study was to determine whether adolescent nicotine exposure alters the rewarding properties of the cannabinoid agonist, CP 55,940. To this end we exposed rats to nicotine during the adolescent period and later assessed CP 55,940-induced conditioned place preference (CPP) in adulthood. Male Sprague-Dawley rats were injected with nicotine (0.16, 0.32, or 0.64, sc) daily for 10 consecutive days beginning on postnatal day (PD) 31. On PD 60, nicotine-induced CPP was assessed using a 14-day biased CPP procedure, consisting of one preconditioning day, 10 conditioning days, one test day and two rest days. Rats were pre-exposed to CP 55,940 (0, 10, 20, or 30 µg/mg, ip) 30 minutes after the preconditioning session. The rats were pre-exposed to the same dose of CP 55,940 as they received in the conditioning phase. Repeated pairings of CP 55,940 with the non-preferred CPP compartment induced a preference for the drug paired room at the 20 µg/kg dose but not at 10 or 30 µg/kg. Adolescent exposure to nicotine altered CP 55,940-induced CPP in a dose dependent manner. Specifically, the high doses of nicotine (0.32 and 0.64 mg/kg) decreased preference for the drug paired room compared to saline treated control. These findings suggest that adolescent exposure to nicotine does not increase the rewarding nature of cannabinoid drugs.

Title: Randomly-methylated β-cyclodextrin used to solubilize Δ(9)-THC has effects on long-term potentiation in wildtype, CB1 and CB1:CB2 knockout mouse models

Authors: *M. SPEROW, H. ZANIEWSKI, L. G. KIRBY, M. E. ABOOD;
Ctr. for Substance Abuse Res., Temple Univ., Philadelphia, PA

Abstract: Δ(9)-tetrahydrocannabinol (Δ(9)-THC) is the principal psychoactive compound in marijuana and its actions in the brain are primarily mediated through CB1 receptors. Effects of Δ(9)-THC have been robustly demonstrated to cause deficits in long-term potentiation (LTP) of the hippocampus[1,2]. However studying this very hydrophobic compound in physiological systems is an ongoing technical challenge. Hazekamp and Verpoorte [3] demonstrated that randomly methylated β-cyclodextrin (RAMEB) can help maintain the aqueous solubility of Δ(9)-THC up to 8 weeks at 14 mg/ml. Starting with wild type littermates we attempted to replicate previous work showing the negative effect of Δ(9)-THC on hippocampal LTP. We then progressed to CB1 and CB1:CB2 knockout (KO) mice to elucidate the role of the different cannabinoid receptor subtypes. The RAMEB buffer was incorporated to increase solubility of the Δ(9)-THC in artificial cerebral spinal fluid as previously reported[4]. The CB1 KO mice showed a decrease in potentiation compared to wild type mice, an effect not seen in the CB1:CB2 double KO mice. However, unexpectedly, the RAMEB buffer had a genotype-specific effect on LTP, which was independent of Δ(9)-THC. RAMEB potentiated the LTP response in wild type mice, an effect that was attenuated by the addition of 8μM Δ(9)-THC. In CB1:CB2 double KO mice, the RAMEB buffer alone depressed the LTP below baseline. This effect was again mitigated by the addition of 8μM Δ(9)-THC. This interesting phenomenon highlights the importance of carefully examining the effects of vehicle controls, and suggests that RAMEB alone can alter LTP. 1. Nowicky AV., Teyler TJ. and Vardaris RM. Title: Dissecting the contribution of cannabinoid type-1 receptor activation to reward circuitry function

Authors: *B. TURNER[1,3], B. A. GRUETER[2,3];
[2]Anesthesiol., [1]Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Vanderbilt Brain Inst., Nashville, TN

Abstract: Forebrain excitatory inputs to the nucleus accumbens shell (NAcSh) are essential for encoding the salience of reward-associated cues and initiating goal directed behavior. In addition to its established role in addiction, past work has shown that NAcSh pharmacological manipulations, including infusion of the endocannabinoid (eCB) 2-arachidonyl glycerol, can induce voracious feeding in satiated animals suggesting that the NAcSh may be a key node in appetitive nutrient-independent feeding circuits. Given the prevalence of obesity and its high correlation with overconsumption of calorically dense and highly palatable foods, understanding the circuitry of brain regions that regulate hedonic feeding may be beneficial to treating or preventing obesity. Interestingly, recent epidemiological studies have noted that, paradoxically, use of cannabis sativa correlates with a lower body mass index and a reduced prevalence of diabetes despite its hyperphagic effects. Activation of cannabinoid type-1 receptors (CB1Rs) by the exogenous ligand THC specifically at glutamatergic terminals in the forebrain is required to induce hyperphagia. The strength of forebrain-NAc connectivity is known to be influenced by exposure to rewarding stimuli, including drugs of abuse, in an eCB dependent manner, and the strength of these inputs can influence response strength following repeated exposures. Additionally, CB1R signaling is necessary for the generation of psychostimulant-induced behavioral plasticicty. Despite its involvement in multiple aspects of motivated behavior, it remains to be shown how eCB signaling impacts the strength of region-specific afferents and their integration at NAcSh medium spiny neurons in different neural states. Therefore, we have investigated excitatory transmission within the NAcSh using *ex vivo* electrophysiology techniques following metabolic challenge and an amphetamine induced locomotor sensitization task using region specific CB1R knock out animals. We have found that prolonged consumption of a high fat diet (HFD) or acute fasting is sufficient to cause enhanced sensitivity to synaptically-induced long term depression (LTD) of excitatory transmission within the NAcSh. Additionally, knocking out CB1R expression on PFC afferents is sufficient to blunt amphetamine induced behavioral plasticity. These data suggest that CB1R signaling at glutamatergic inputs to the NAcSh is influenced by metabolic state and that CB1Rs may play a role in processing rewarding stimuli by selectively altering the strength of specific afferent fibers and potentially gating hedonic food intake.

Title: Investigation of parvalbumin expressing interneurons in the nucleus accumbens

Authors: *D. GHOSE[1,2], E. B. BISEN-HERSH[2], B. A. GRUETER[2,3];
[1]Dept. of Psychology, Vanderbilt Univ., Nashville, TN; [2]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN; [3]Vanderbilt Brain Inst., Nashville, TN

Abstract: The nucleus accumbens (NAc) is a key brain structure involved in integrating signals from external and internal stimuli ultimately gating emotional and motivational states. The projection neurons of the NAc, GABA-ergic medium spiny neurons (MSNs), comprise 90%-95% of the neuronal population. The rest, 5-10%, are interneurons (INs). Based on morphological, physiological and histochemical properties, recent studies have identified four main classes of NAc INs. Of these inter-neuronal sub-types, parvalbumin containing interneurons (PV-INs) and calretinin containing interneurons are GABA-ergic in nature while choline acetyltransferase (Chat) and nitric oxide synthase expressing interneurons are the main sources of acetylcholine and nitric oxide in the NAc. It is well established that NAc MSNs receive the majority of their excitatory glutamatergic inputs from Prefrontal Cortex (PFC), basolateral amygdala (BLA) and ventral subiculum (vSub) while the inhibitory drive onto the MSNs arises mainly from two sources: GABA-ergic INs that synapse onto proximal dendrites and cell bodies of the MSNs, and neighboring MSN collaterals that preferentially synapse onto the distal dendrites of MSNs. Inhibitory synapses onto or near the MSN cell body allows the GABAergic INs to exert a strong influence on MSN activity by mediating feed-forward inhibition despite comprising a small proportion of the total NAc neuronal population. Hence we hypothesize that it is the balance between excitation and inhibition that controls MSN output and in turn influences reward-related behaviors under both physiological and pathological conditions. The function of excitatory synapses onto the MSNs and its influence on reward-related behavior has been widely studied. In contrast, less is known regarding excitatory transmission onto INs and the role of inhibitory control on NAc function. PV-INs were tagged with D1tdTomato by crossing PV-cre mice with Ai9 mice. We performed targeted PV-IN and MSN whole-cell patch-clamp recordings of electrically evoked EPSCs and IPSCs. This allowed us to measure excitatory drive onto the PV-INs and excitatory and inhibitory drive onto MSNs. In addition, the

differential role of specific excitatory inputs onto the PV-INs was investigated utilizing optogenetics. The results of these studies afford a more thorough understanding of the microcircuitry of the NAc.

Title: NPY and CCK interneurons lacking GAD1 have distinct behavioral responses to cocaine

Authors: *E. B. BISEN-HERSH[1], D. GHOSE[1], K. GARBETT[2], K. MIRNICS[2,3,4], B. A. GRUETER[1,3,4,2];
[1]Anesthesiol., [2]Psychiatry, Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Vanderbilt Brain Inst., [4]Vanderbilt Kennedy Ctr. for Res. on Human Develop., Vanderbilt Univ., Nashville, TN

Abstract: There are many diverse GABA-ergic interneuron cell-types with distinct function and expression patterns in different brain regions. Mature interneurons can be distinguished by protein expression, electrical properties and laminar distribution. However, cell type specific effects of distinct interneuron populations on behavior remain largely unknown. As behavioral adaptations depend on intricate communication within neural circuits, disruption of GABA-ergic transmission within specific cell types has been implicated in many neuropsychiatric disorders. To date, much emphasis has been put on the influence of inter-regional circuit connectivity on reward-related behavior and adaptations in these connections continue to be elucidated at a rapid pace. In contrast, there remains a relative paucity of information about the changes in behavioral outcomes as a result of modifications in interneuron microcircuits: information that is critical for a thorough understanding of the circuit adaptations underlying addiction. The present study used transgenic mouse lines that silence glutamic acid decarboxylase 1 (GAD1) transcript in either cholecystokinin (CCK) or neuropeptide Y (NPY) interneuron populations by expressing miRNA for GAD1 driven by the CCK and NPY promoters. GAD1 produces the majority of GABA in the brain. Using these mouse lines, the consequences of GAD1 deficiency in two interneuronal cell types on reward-related behavior was examined. Baseline assessment of locomotor activity and

thigmotaxis was measured during a 60 min open field assay. Cocaine-induced locomotor sensitization was compared between NPY-miGAD1, CCK-miGAD1, and wildtype mice by administration of cocaine (20 mg/kg, i.p.). Additionally, conditioned place preference was used to assess the rewarding effects of cocaine following GAD1 deficiency in these mouse lines. Finally, we analyzed synaptic properties from NPY- and CCK-miGAD1 mice treated with cocaine or saline. NPY- and CCK-miGAD1 mice displayed differential responses to cocaine in these assays. In summary, the present study characterizes the adaptations to reward-related behavior in mice lacking GABA in either CCK or NPY expressing cells and demonstrates differential cocaine-induced adaptations in these mouse lines. These results suggest that GABAergic signaling from NPY and CCK cells may serve as important, but distinct, neuronal targets for cocaine to induce behavioral alterations related to addiction.

Title: Deconstructing nucleus accumbens circuit functions with cell type-specific NMDA receptor deletions

Authors: *M. JOFFE[1], B. A. GRUETER[2];
[1]Pharmacol., [2]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Dysregulation of the mesolimbic dopamine (DA) system is a hallmark of the pathophysiology of drug addiction and many other prevalent diseases. The nucleus accumbens (NAc), a region essential for the incentive and hedonic properties of drugs of abuse, is a primary site of these aberrant changes. At least 90% of the neurons in the NAc are GABAergic medium spiny neurons (MSNs). The MSNs, which provide the output of the NAc, can be divided into two classes anatomically and biochemically: direct pathway MSNs project primarily to the midbrain DA areas and express D1 DA receptors, while indirect pathway MSNs project to the ventral pallidum and express A2A adenosine receptors. MSNs are generally quiescent, resting at

relatively hyperpolarized membrane potentials. Excitatory drive is therefore essential to governing the output of the NAc and subsequent behavioral outcomes. The predominant excitatory afferents to the NAc are the prefrontal cortex, ventral subiculum of the hippocampus, and basolateral amygdala. Respectively, these regions are thought to support behaviors related to motivational significance, contextual memories, and emotional reactivity. While much remains to be understood about reward-related changes in NAc circuit dynamics, drug-induced modifications of excitatory signaling (i.e. synaptic plasticity) in the NAc have been suggested to underlie the maladaptive behaviors observed in addiction. At glutamatergic synapses, plasticity is mediated in large part through AMPA receptor trafficking. In turn, AMPA receptor surface expression is modulated bidirectionally by activity of the NMDA receptor, a tetrameric glutamate receptor generally composed of two obligatory GluN1 subunits, and two GluN2 or GluN3 subunits. Recent data suggests that changes in NMDA receptor stoichiometry and function occur in the NAc following *in vivo* cocaine exposure, and that these events may necessarily precede the persistent synaptic changes observed alongside addiction-like behaviors. We hypothesize that *in vivo* cocaine experience alters AMPA receptor function at specific NAc synapses, and that NMDA receptor activity is essential for these phenomena and related behavioral abnormalities. Here, we used a bacterial artificial chromosome (BAC) transgenic Cre-Lox approach to genetically delete NMDA receptors via the D1 or A2A promotor. Our findings suggest that circuit-specific NMDA receptor function is important for the expression of reward-related behaviors that require learning and memory processes. Furthermore, we believe that excitatory synaptic strength and plasticity are compelling cellular mediators of these phenomena.

Title: Incubation of methamphetamine craving after prolonged self-imposed abstinence in a contingency management alternative-reward procedure

Authors: ***D. CAPRIOLI**, M. VENNIRO, T. ZERIC, N. MARCHANT, Y. SHAHAM; Behavioral Neurosci., Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: We previously found that the rat's response to cues associated with methamphetamine progressively increases after forced abstinence from the drug (incubation of methamphetamine craving). Here, we determined whether incubation of methamphetamine craving would occur when abstinence is self-imposed (volitional), because of the availability alternative non-drug rewards, a condition that more closely mimics human abstinence. Methods: We trained non-food-deprived rats to lever-press for palatable food (6 days, 9 h/day; 5 pellets per reward delivery). We then trained them to lever-press for methamphetamine (12 days, 9 h/day 0.1 mg/kg/infusion). On abstinence day 1, we tested rats for cue-induced methamphetamine seeking in an extinction test and then assigned them to forced and volitional abstinence conditions. The forced-abstinence rats had no access to the drug- or food-paired levers for 20 days. The volitional-abstinence rats had access to the two levers during 20 daily mutually exclusive choices (10 min apart) between palatable food and methamphetamine. On day 21, we tested all rats for cue-induced methamphetamine seeking. Results: The rats reliably self-administered the palatable food and escalated methamphetamine self-administration over time. During the abstinence period, the volitional-abstinence group showed a strong preference (over 90%) for the palatable food over methamphetamine. The rats in both groups showed significantly higher cue-induced methamphetamine seeking on abstinence day 21 than on day 1. Conclusions: Availability of a non-drug reward during the abstinence period had no effect on incubation of methamphetamine craving. Our procedure may serve as an animal model of relapse after extended periods of contingency management in humans.

Title: Persistent and inflexible palatable food preference in rats with a history of limited and extended access methamphetamine self-administration

Authors: *M. VENNIRO, T. ZERIC, Y. SHAHAM, D. CAPRIOLI;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Background: In recent studies of Ahmed, Lenoir, and colleagues reported that when rats are given a mutually exclusive choice between cocaine and palatable foods, most of them prefer the food over cocaine. Here, we used a discrete choice procedure to assess drug versus food preference in rats with a history of limited (3 h/d) and extended access (6 or 9 h/d) methamphetamine self-administration. Methods: On different daily sessions, we trained non-food-deprived rats to lever-press for either methamphetamine (0.1-0.2 mg/kg/infusion) or palatable food (5 pellets per reward delivery) for several weeks. We then assessed preference during the training phase, after priming injections of methamphetamine (0.5 and 1.0 mg/kg), after food-pellet exposure in the home cage (a satiety manipulation) prior to choice testing, and after extended abstinence (21 days). We also assessed progressive-ratio responding for food and methamphetamine. Results: We found that independent of the daily drug access conditions and the abstinence period, the rats strongly preferred the palatable food, even when the food pellets were freely available in their home cage. Progressive ratio for methamphetamine, which increased over time, did not predict preference. Conclusions: Under our experimental conditions, most rats strongly and inflexibly prefer palatable food pellets over methamphetamine, confirming previous studies using discrete choice procedures with cocaine. We currently assess food-methamphetamine preference during extended training periods (2-3 months).

Title: The cfos-tetO-Cre transgenic rat system: A new tool to examine neuronal ensembles in learned behavior

Authors: *F. C. CRUZ[1], R. M. LEAO[1], Y. ZHANG[2], K. R. BABIN[1], C. T. RICHIE[3], J. M. PICKEL[4], Y. SHAHAM[1], B. K. HARVEY[3], B. T. HOPE[1];
[1]Natl. Inst. on Drug Abuse - NIDA, [2]OTTC - Natl. Inst. on Drug Abuse - NIDA, [3]OTTC- Natl. Inst. on Drug Abuse - NIDA, [4]NIMH transgenic core facility, NIH, Baltimore, MD

Abstract: Learned associations are thought to be encoded within specific patterns of sparsely distributed neurons called neuronal ensembles. However it has been difficult to manipulate and examine their unique properties because their only distinction is increased activation state during behavior. To address this problem, we developed bitransgenic rats that contain two transgenes: (1) the cfos-tetO::Cre recombinase transgene has a c-fos promoter that drives expression of Cre recombinase in strongly activated neurons, and (2) the EF1a-TetR transgene has an EF1a promoter that drives constitutive expression of a Tet repressor protein that binds to the tetO site in the cfos-tetO::Cre transgene to repress Cre transcription. Systemic injections of tetracycline remove TetR repression and open a short time window for Cre induction than can then invert and activate DIO (double-floxed inverse open reading frame) versions of virally expressed transgenes only in those neurons recently activated during behavior. We determined the dose response and time course for tetracycline-induced opening of the c-fos activation window in ventral medial prefrontal cortex (vmPFC). We injected adeno-associated virus (AAV) with a Cre-dependent EF1a::DIO-eYFP transgene into vmPFC to label activated neurons with YFP. One week later, we injected tetracycline (0-10 mg/kg, i.p) 2 hr prior to injection of cocaine (30 mg/kg, i.p.). We found strong YFP expression following only 2.5, 5 and 10 mg/kg tetracycline. We then injected 5 mg/kg tetracycline 0-24 hr before injecting cocaine and found YFP transgene expression only when tetracycline was injected 0.5-6 hours, but not 12 or 24 hours, before the cocaine injections. We are currently using the cfos-tetO-Cre transgenic rat system to study the role of neuronal ensembles and their unique alterations in context-induced reinstatement of cocaine seeking.

Title: Role of prefrontal cortical neuronal ensembles in appetitive (palatable food) operant extinction learning in rats

Authors: *B. L. WARREN, F. C. CRUZ, R. M. LEAO, K. R. BABIN, K. MCPHERSON, Y. SHAHAM, B. T. HOPE;
NIDA IRP/NIH, Baltimore, MD

Abstract: In operant tasks, animals can be trained to perform an operant response to receive a reward and then to extinguish the learned response when the reward is withheld. Memories encoding reinforced and non-reinforced (extinction) responding are thought to be distinct and are likely encoded by different patterns of sparsely distributed neurons called 'neuronal ensembles.' Here, we assess activation of infralimbic and prelimbic mPFC neuronal ensembles during an operant appetitive task. We trained food-restricted rats to lever press for palatable food pellets for 7 days (60 min/day). Rats in the Extinction group underwent 7 daily extinction sessions while rats the No Extinction group were not. On test day, we exposed half of the rats from each group to a 15 min extinction session and perfused them with paraformaldehyde 75 min after testing. The other rats from each group were not tested. We then assessed Fos (a marker of neuronal activity) expression in infralimbic and prelimbic mPFC. Non-reinforced responding during testing was higher in the No Extinction than in the Extinction group. Fos immunoreactivity in infralimbic mPFC of the Extinction group was higher than in the No Extinction groups; an opposite pattern of results was observed in prelimbic mPFC. Our data suggest anatomical double dissociation between mPFC neuronal ensembles encoding rewarded operant responding and extinguished operant responding.

Title: Role of histone deacetylase 5 in dorsal striatum in incubation of methamphetamine craving

Authors: *T. ZERIC[1], M. B. CARREIRA[2], H. CATES[3], P. KENNEDY[4], S. KAMBHAMPATI[1], J. M. BOSSERT[1], E. J. NESTLER[3], C. W. COWAN[2], Y. SHAHAM[1], X.

Abstract: Background: We previously reported that cue-induced methamphetamine seeking progressively increases after withdrawal from extended access methamphetamine self-administration (incubation of methamphetamine craving). Here we studied the role of striatal histone deacetylase 5 (HDAC5), recently implicated in cocaine behavioral effects, in incubation of methamphetamine craving. Methods: In Exp. 1, we trained rats to self-administer intravenous methamphetamine or saline (control) for 10 days (9 h/d) and then measured HDAC5 mRNA and protein levels in ventral and dorsal striatum on withdrawal days 2 and 35. In Exp. 2, we injected adeno-associated virus bilaterally into dorsal striatum to express either GFP (control) or a mutant form of HDAC5 (MUTANT-HDAC5, which strongly localizes to the nucleus). After training rats to self-administer methamphetamine, we tested cue-induced drug seeking in extinction tests on withdrawal day 2 and 35. We then assessed re-escalation of methamphetamine intake and responding on a progressive ratio reinforcement schedule. Results: We found that methamphetamine self-administration increased HDAC5 mRNA and protein in dorsal but not ventral striatum on withdrawal day 35 but not day 2. MUTANT-HDAC5 viral expression in dorsal striatum increased cue-induced extinction responding on day 35 but not day 2; dorsal striatum MUTANT-HDAC5 viral expression also increased re-escalation of methamphetamine self-administration after prolonged withdrawal and progressive ratio responding. Conclusions: Our results suggest a role for nuclear HDAC5 in the dorsal striatum in both incubation of methamphetamine craving and methamphetamine reward. We are currently examining the effect of inhibiting endogenous HDAC5 in dorsal striatum on incubation of methamphetamine craving.

Title: Unique molecular alterations in dorsal striatal neuronal ensembles selectively activated during context-induced reinstatement of methamphetamine seeking in rats

Authors: *F. J. RUBIO;
Behavioral Neurosci. Res. Branch, NIDA IRP, NIH, Baltimore, MD

Abstract: Background: Learned associations between environmental cues and drug taking promote relapse in drug addicts. Here we assessed molecular alterations induced specifically in Fos-expressing dorsal striatal neurons that were activated by the drug-associated context. Methods: We trained rats to self-administer methamphetamine in context A, extinguished drug-reinforced responding in a distinct context B and assessed context-induced reinstatement under extinction condition in context A. In Exp. 1 we examined the effects of injecting the GABA agonists muscimol+baclofen into dorsomedial and dorsolateral striatum on context-induced reinstatement. In Exp. 2, we used immunohistochemical detection of the neural activity marker Fos and the neuronal marker NeuN to determine the degree of neural activation in dorsal striatum. In Exp. 3, we isolated Fos-positive and Fos-negative dorsal striatal neurons using fluorescence-activated cell sorting (FACS) and assessed gene expression from the sorted neurons using gene-targeted pre-amplification and quantitative PCR; we also used quantitative *in situ* hybridization with RNAscope® to assess expression of Grin2a gene encoding NMDA subunit NR2A in Fos-positive neurons from dorsal striatum brain sections. Results: Reversible inactivation of dorsolateral but not dorsomedial striatum decreased context-induced reinstatement. Context-induced reinstatement increased the number of Fos-positive neurons 2-3 fold in dorsal striatum. qPCR data from FACS-isolated neurons indicated selective upregulation of immediate early genes, as well as the NMDA receptor subunit gene Grin2a, in Fos-positive, but not Fos-negative, neurons. The RNAscope® assay confirmed that Grin2a mRNA was preferentially increased in Fos-positive neurons in dorsolateral, but not dorsomedial, striatum. Conclusions: Results demonstrate a role of dorsolateral striatum in context-induced reinstatement of methamphetamine seeking and that this reinstatement is associated with unique molecular alterations in activated neuronal ensembles in this brain region.

Title: Incubation of methamphetamine craving is associated with selective increases of the epigenetic HDAC5 gene in FACS-sorted Fos-positive activated neurons in dorsal striatum

Authors: *X. LI[1], F. J. RUBIO[1], T. ZERIC[1], R. CIMBRO[2], Q.-R. LIU[1], B. T. HOPE[1], Y. SHAHAM[1];
[1]Behavioral Neurosci. Res. Br., Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Sch. of Medicine, Div. of Rheumatology, John Hopkins Univ., Baltimore, MD

Abstract: Background: We recently found that incubation of methamphetamine craving (time-dependent cue-induced methamphetamine seeking after withdrawal) is associated with increased (about 50%) histone deacetylase 5 (HDAC5) expressions in dorsal striatum homogenates. We also found that viral expression of nuclear HDAC5 in dorsal striatum enhanced this incubation (Zeric et al. SFN 2014). Here we used fluorescence-activated cell sorting (FACS) to examine whether incubation of methamphetamine craving is associated with increased HDAC5 gene expression in Fos-positive neurons selectively activated in dorsal striatum by methamphetamine-associated cues after prolonged withdrawal. Methods: We trained rats to self-administer intravenous methamphetamine for 10 days (9 h/d) and then either tested or not tested the rats between withdrawal days 30 to 50 for cue-induced methamphetamine seeking under extinction conditions. After extinction tests or no test, we used FACS to isolate dorsal striatum Fos-positive and Fos-negative neurons. We then measured mRNA expression of both immediate early genes (c-fos, Arc, Fosb, Egr1) and Hdac5 by gene-targeted pre-amplification and quantitative RT-PCR. Results: Cue-induced methamphetamine seeking during the late withdrawal extinction tests increased c-fos, Fosb (total), Arc and Egr1 mRNA expression in Fos-positive but not Fos-negative neurons. Moreover, Hdac5 mRNA expression was selectively increased (about 300%) in Fos-positive neurons of rats that underwent the extinction tests. Conclusions: Our results suggest that cue-selected activated neurons in rat dorsal striatum exhibit an HDAC5-regulated genetic profile that is distinct from that of non-activated neurons. Results also suggest that methamphetamine-induced neuroadaptations identified in brain homogenates likely underestimate the neuroadaptations induced in neurons activated by methamphetamine cues, which potentially play a role in drug relapse

Title: Role of ventral medial prefrontal cortex neuronal ensembles in context-induced reinstatement of cocaine seeking

Authors: *R. M. LEÃO, F. C. CRUZ, K. R. BABIN, J. M. BOSSERT, Y. SHAHAM, B. T. HOPE;
NIDA/NIH, BALTIMORE, MD

Abstract: In human addicts and rat models, cues associated with previous drug use can provoke relapse to drug seeking. Learned associations between cues, context and drug are thought to be encoded by specific patterns of sparsely distributed neurons called neuronal ensembles. We trained rats to lever-press for cocaine (0.5 and 1 mg/kg/infusion) for 10 days in Cocaine context A; lever-presses were paired with a tone-light compound cue . Next the rats underwent 12+ daily extinction sessions in Extinction context B. On test day, re-exposure to Cocaine context A, but not Extinction context B, reinstated cocaine seeking and increased expression of the neural activity marker Fos in 9.4% of ventral medial prefrontal cortex (vmPFC) neurons. To assess a causal role for these activated neurons in context-induced reinstatement, we trained cfos-lacZ transgenic rats that co-express β-galactosidase and Fos to self-administer cocaine in Cocaine context A and extinguish lever pressing in Extinction context B. On 'induction day', we exposed the rats to either Cocaine context A or a Novel context C (round bowl with bedding) for 30 min and injected the prodrug Daun02 or vehicle into vmPFC 60 min later. β-galactosidase catalyzes Daun02 into daunorubicin that lesions the activated neurons. On test day, three days later, reinstatement of cocaine seeking in context A and vmPFC neuronal activity were attenuated in rats previously injected with Daun02 after exposure to Cocaine context A, but not to Novel context C. We conclude that a small subset of vmPFC neurons form neuronal ensembles that encode learned associations between cocaine and the drug-associated context and play a role in context-induced reinstatement of cocaine seeking.

Title: Assessing dendritic spine plasticity in transgenic rat nucleus accumbens neuronal ensembles activated during amphetamine sensitization

Authors: *R. V. FALLON[1,2], F. C. CRUZ[2], B. T. HOPE[2];
[1]Cellular, Molecular, Developmental Biol. and Biophysics, Johns Hopkins Univ., Baltimore, MD; [2]Behavioral Neurosci. Br., NIDA IRP, Baltimore, MD

Abstract: We have previously shown that conditioned drug behaviors in rats are mediated by specific patterns of sparsely distributed neurons called neuronal ensembles. We are now developing a procedure for assessing morphological alterations of dendritic spines in Fos expressing neuronal ensembles after amphetamine sensitization. In our initial experiments, we injected rats with adeno-associated virus (AAV) that constitutively expresses a membrane-restricted version of GFP (memGFP) to label plasma membranes including dendritic spines. One week after low-titer AAV injections, rats were perfused and sections collected from the nucleus accumbens. We are currently using confocal microscopy to collect images for dendritic spine analysis. In future experiments, we will use our cfos-tetO-iCre transgenic rat system to induce memGFP exclusively in neuronal ensembles that were activated during context-specific amphetamine sensitization.

Title: Cellular mechanisms underlying cocaine-evoked plasticity in the lateral habenula

Authors: ***M. MAMELI**[1], S. LECCA[1], K. VALENTINOVA[1], L. MARION-POLL[1], J.-A. GIRAULT[1], S. MUSARDO[2], F. GARDONI[2], F. GEORGES[3], F. MEYE[1];
[1]Inserm UMR S839 Inst. Du Fer A Moulin, Paris, France; [2]Dept. of Pharmacol., University of Milano, Italy; [3]Bordeaux Neurosci. Inst., Inserm, France

Abstract: The lateral habenula (LHb) powerfully inhibits dopamine neurons through its projections to the rostromedial tegmental nucleus (RMTg), and has emerged as a key structure encoding aversive states. Addictive drugs, such as cocaine, functionally modify the habenulo-mesencephalic circuitry. However the underlying mechanisms remain so far elusive. We combined retrograde tracing, ex-vivo and *in vivo* electrophysiology to assess the influence of cocaine experience on excitatory transmission onto a subset of LHb neurons that specifically project their axons to the RMTg. We find that, in mice, cocaine exposure increases the amplitude of miniature excitatory postsynaptic currents (mEPSCs), but not their frequency, indicating an increased efficacy of glutamatergic synapses onto RMTg-projecting LHb neurons. The cocaine evoked plasticity requires dopamine 2 receptors activation as pretreatment *in vivo* with specific antagonists prevents the cocaine-induced synaptic adaptations. We next used a viral-based strategy that allows expressing a dominant-negative sequence that interferes with the activity dependent delivery of AMPA receptors at the membrane to test the postsynaptic requirements for the cocaine-evoked plasticity. Expression of the dominant negative in the LHb prevents the cocaine-evoked plasticity in RMTg-projecting neurons. Furthermore, we find that AMPA receptors exocytosis in the LHb depends on the phosphorylation of the serine 845 residue in the C terminal of GluA1 subunits, as in a mouse with a single mutation at the serine 845, cocaine does not produce synaptic plasticity. Using *in vivo* and *in vitro* electrophysiology we find that cocaine exposure increases the excitability of LHb neurons. Precluding AMPAR trafficking, not only blocked the synaptic adaptations but also the increased excitability. Altogether, drug-driven modifications in the LHb-to-RMTg pathway at the synaptic and cellular level may contribute to specific aspects of drug taking, highlighting the LHb as a potential hub controlling cocaine-evoked behavioral adaptations.

Title: Differential calcium signaling mediated by NMDA and AMPA receptors in individual dendritic spines of nucleus accumbens medium spiny neurons

Authors: *D. T. CHRISTIAN, C. A. BRIGGS, M. E. WOLF, G. E. STUTZMANN; Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Cue-induced cocaine seeking intensifies or incubates during withdrawal from extended-access cocaine self-administration and is mediated by GluA2-lacking, Ca2+-permeable AMPARs (CP-AMPARs) in the nucleus accumbens (NAc). A previous study from our lab (Ferrario et al. 2012) demonstrated that a smaller percentage of NAc medium spiny neuron (MSN) spines in "incubated rats" responded to glutamate uncaging, in the presence of CNQX, with NMDAR-mediated Ca2+ entry compared to saline controls. We speculated that unresponsive spines might be "new spines" that have accumulated CP-AMPARs but not NMDARs. The goal of this study is to assess Ca2+ entry into MSN dendritic spines via CP-AMPARs and/or NMDARs utilizing 2-photon microscopy, whole cell electrophysiology, and photo uncaging of NPEC-caged-(S)-AMPA and MNI-caged-NMDA compounds following withdrawal from saline or cocaine self-administration. In preliminary studies, the sequential photolysis of caged NMDA and caged AMPA allowed for the identification of different populations of dendritic spines based on their complement of NMDARs and CP-AMPARs (conclusions about the presence of GluA2-containing AMPARs cannot be drawn because they do not pass Ca2+). In both groups of rats, individual spines on MSNs in the NAc showed Ca2+ responses to: 1) caged AMPA but not caged NMDA, 2) caged NMDA but not AMPA, or 3) both caged AMPA and NMDA compounds. Our preliminary results suggest an increase in the percent

of spines responding to caged AMPA in the cocaine group. In addition, electrophysiological measures of somatic current following NPEC-AMPA but not MNI-NMDA application increased in cells from cocaine rats. These are some of the first experiments to utilize caged AMPA to characterize Ca2+ signaling in dendritic spines and the first to analyze cocaine-induced AMPAR plasticity in functional terms at the single spine level. **Support:** DA034943 (G.E.S), DA015835, DA009621, DA029099 (M.E.W) and postdoctoral NRSA DA36963 (D.T.C.).

Title: Role of protein translation in regulating surface and synaptic AMPA receptor levels in cultured nucleus accumbens neurons

Authors: *M. E. WOLF, C. T. WERNER, K. K. Y. WOO, J. LOWETH;
Neurosci., Rosalind Franklin Univ. of Med. and Sci., NORTH CHICAGO, IL

Abstract: Glutamatergic transmission in the nucleus accumbens (NAc) is critical for motivated behaviors including drug addiction. In an animal model of cocaine addiction called the "incubation" model, rats exhibit progressive intensification or incubation of cue-induced cocaine craving during withdrawal from extended access cocaine self-administration. We have shown that this cocaine regimen leads to the accumulation of Ca2+-permeable AMPA receptors (CP-AMPARs) in the NAc and that these high conductance AMPARs mediate the expression of incubated cue-induced cocaine craving after prolonged withdrawal (Conrad et al., 2008). Recently, it has been demonstrated that ongoing protein synthesis is required for the maintenance

of this adaptation. Thus, after NAc slices obtained from "incubated rats" were treated for 1 h with inhibitors of translation, NAc neurons in the slices no longer showed elevated CP-AMPAR levels (Scheyer et al., 2014). However, studying the role of protein synthesis in maintaining CP-AMPARs is difficult *in vivo*. Therefore, we are using a model system consisting of rat NAc neurons co-cultured with prefrontal cortex neurons from enhanced cyan fluorescent protein (CFP)-expressing mice. The cortical neurons restore excitatory input onto the NAc neurons but can be distinguished based on their fluorescence. NAc neurons in this co-culture system express high levels of CP-AMPARs, recapitulating the state of the NAc after incubation of cocaine craving (Sun et al., 2008). To determine the role of ongoing protein synthesis in regulating surface and synaptic levels of AMPARs in NAc neurons, we are examining surface expression, synaptic expression and turnover of the AMPAR subunits GluA1 and GluA2 after pharmacological inhibition of protein translation, as well as expression of proteins that regulate AMPAR levels, including Arc and Ube3A. These studies will better our understanding of mechanisms that shape excitatory transmission in the NAc, which has translational implications related to drug addiction and relapse.

Title: UPS activity in the nucleus accumbens: Parsing out effects of cocaine self-administration, withdrawal time, and memory retrieval

Authors: *C. T. WERNER, M. MILOVANOVIC, J. A. LOWETH, M. E. WOLF; Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: The ubiquitin-proteasome system (UPS), responsible for proteasomal-dependent protein degradation, has been implicated in synaptic reorganization associated with memory retrieval (Lee et al., 2008, Jarome et al., 2011), including drug reward memory retrieval after cocaine conditioned place preference (Ren et al., 2013). However, nothing is known about its role in memory retrieval after self-administration of cocaine or how the length of withdrawal from cocaine may influence the UPS. Here we examined UPS activity in the nucleus accumbens (NAc) of rats that self-administered cocaine for 6 h/day for 10 days, a regimen leading to withdrawal-dependent intensification ("incubation") of cue-induced seeking. Control rats self-administered saline. We used a ubiquitin, Lys-48 antibody to measure polyubiquitinated proteins bound for proteasomal degradation and a fluorescence assay to quantify catalytic (chymotrypsin- and trypsin-like) activities of the proteasome. First, we compared rats that received a cue-induced seeking test on withdrawal WD50-60 (memory retrieval groups) to rats that were killed after 55 days of withdrawal in their home cages (no retrieval). Responding in the active hole during the test delivers the drug-associated cue (light) but no cocaine. We expected the cocaine group to show elevated polyubiquitination after the test, since the NAc mediates the expression of incubated cue-induced seeking after prolonged withdrawal. To our surprise, we found significant increases in polyubiquitinated proteins in the NAc of the retrieval groups compared to the no retrieval groups, but no difference between cocaine and saline groups. This suggests that patterns of protein tagging for proteasomal degradation are affected by memory retrieval but are independent of prior drug treatment. We also quantified proteasome activity following retrieval. Consistent with our results on polyubiquitination, seeking tests conducted on WD50-60 were not associated with significant changes in proteasome activity in the NAc in rats that self-administered cocaine compared to saline. However, we did find changes in other brain regions examined, including the amygdala, dorsal striatum and medial prefrontal cortex. In contrast, we found that activity was significantly increased in the NAc, as well as the dorsal striatum and medial prefrontal cortex, in cocaine rats compared to saline rats that underwent a seeking test on WD1. We conclude that the relationship between UPS activity and memory retrieval is complex and dependent on training paradigm, brain region and the time elapsed since training.

Title: Development of mGluR-LTD in the nucleus accumbens during withdrawal from extended-access cocaine self-administration

Authors: *A. F. SCHEYER[1], M. E. WOLF[2], K. Y. TSENG[3];
[1]Neurosci., [2]Dept. of Neurosci., [3]Dept. of Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Prolonged withdrawal from extended-access cocaine self-administration (6 h/d, 10d) is associated with incubation of cocaine craving as well as several changes in medium spiny neurons (MSN) of the nucleus accumbens (NAc). These include accumulation of Ca2+-permeable AMPA receptors (CP-AMPAR) and a switch from group I metabotropic glutamate receptor (mGluR) 5- to mGluR1-mediated synaptic depression, typically after withdrawal day (WD) 40. More importantly, these adaptations are disrupted by protein-synthesis interference, indicating ongoing active processes required for their maintenance and therefore the maintenance of drug-seeking behavior. In order to better understand the mechanisms underlying the emergence of this novel form of plasticity, we conducted whole-cell patch-clamp recordings of NAc MSN at multiple time-points during withdrawal and examined the nature of mGluR-mediated synaptic depression through bath-application of the group I mGluR agonist, DHPG (50μM). In contrast to results obtained in saline controls or earlier in withdrawal from cocaine, DHPG application in slices obtained after WD15 induced a form of synaptic depression which persisted for >30min after washout of the drug (mGluR-LTD). This mGluR-LTD was maintained through WD45 and beyond. To determine if this mGluR-LTD was mediated by the removal of CP-AMPARs as indicated by previous work characterizing mGluR-mediated synaptic depression after prolonged withdrawal (>WD45), we used the rectification index in addition to the CP-AMPAR antagonist naspm (100μM) to quantify the contribution of CP-AMPAR transmission at numerous points during withdrawal. Surprisingly, we found that CP-AMPAR-mediated synaptic transmission in the NAc was significantly elevated only after WD25. Together, these results indicate that additional mechanisms underlie the development of mGluR-LTD at earlier withdrawal points. Ongoing studies will identify the mechanisms underlying the emergence of mGluR-LTD, thereby illuminating the processes that underpin the development of aberrant behaviors following prolonged withdrawal from extended-access cocaine self-administration.

Title: Effects of extended access cocaine self-administration on inhibitory neurotransmission in the nucleus accumbens

Authors: *A. PURGIANTO, J. J. MIAO, M. MILOVANOVIC, M. E. WOLF;
Dept. of Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Excitatory synaptic transmission in the nucleus accumbens (NAc) undergoes time-dependent changes during withdrawal from extended access cocaine self-administration in concert with the incubation of cue-induced cocaine craving. The goal of this project is to determine if incubation of cocaine craving is also accompanied by plasticity of inhibitory transmission in the NAc. While prior studies have found changes in both presynaptic and postsynaptic aspects of inhibitory transmission after different cocaine regimens, very little is known about whether these measures are affected during incubation. Three types of studies are underway to compare rats after prolonged withdrawal (>45 days) from extended access cocaine or saline self-administration. The first is an immunocytochemical study of parvalbumin expression, which provides an index of the activity of parvalbumin positive (PV+) interneurons. We found no differences in cell count, indicating there was no loss or de novo generation of PV+ interneurons. However, we did find an increase in PV immunoreactivity in the NAc of the cocaine group compared to the saline group. When we separated our data into 3 rostral to caudal levels, we found that the increase in PV immunoreactivity was specific to middle- and caudal NAc. The second study aims to measure GABAA receptor subunit expression at several different withdrawal time points (2, 25, and 48 days) using biotinylation and immunoblotting. We found significant decrease in surface expression of the GABAA α2 subunit after 48 days of withdrawal from cocaine. No changes were observed for α1 on any withdrawal day or for α4 on withdrawal day 2. Our first two studies described above suggest potential pre- and post-synaptic alterations in inhibitory neurotransmission. Our third study uses electrophysiological local field potential (LFP) recordings to obtain a measure of overall inhibitory tone in the NAc. We are currently

analyzing LFP in the NAc after stimulation of medial prefrontal cortex (mPFC). In this mPFC-NAc circuit, there seems to be no alteration in basal synaptic strength, as indicated by lack of change in the input/output (I/O) curve. However, our results after train stimulations showed loss of potentiation after 5Hz and 10Hz stimulation in the cocaine group. To determine whether this is due to changes in GABA transmission, we are repeating these studies after intra-NAc injection of picrotoxin, a GABAA receptor antagonist. We are also investigating changes in the basolateral amygdala-NAc circuit. These studies are the first to explore changes in inhibitory neurotransmission in the NAc that may contribute to the withdrawal-dependent incubation of cocaine craving.

Title: Altering group I mGluR tone selectively affects surface expression of GluA2-lacking AMPA receptors in cultured nucleus accumbens neurons

Authors: *J. A. LOWETH[1], J. M. REIMERS[2], M. E. WOLF[1];
[1]Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]UT Southwestern Med. Ctr., Dallas, TX

Abstract: After prolonged withdrawal from extended-access cocaine self-administration, Ca2+-permeable AMPA receptors (CP-AMPARs) accumulate in the nucleus accumbens (NAc) and mediate the withdrawal-dependent intensification ("incubation") of cue-induced cocaine craving. Using patch-clamp recordings in NAc slices from "incubated rats" (extended access-cocaine

self-administration and >40 days of withdrawal), we showed that acute bath application of the group I mGluR agonist DHPG rapidly removes CP-AMPARs from NAc synapses through an mGluR1-dependent mechanism and attenuates incubated craving. To study mechanisms underlying the interaction between mGluR1 and CP-AMPARs, we have taken advantage of the fact that Nac neurons co-cultured with prefrontal cortical (PFC) neurons contain a significant population of CP-AMPARs, making this a suitable *in vitro* model for NAc synapses in "incubated rats". To begin, we tested the effects of brief incubation with DHPG (50 μM, 10 min) on AMPAR surface expression in NAc neurons co-cultured with PFC neurons. Consistent with our findings in the incubation model, live cell labeling studies showed that DHPG significantly decreased GluA1 but not GluA2 surface expression, indicating that group I mGluR activation selectively internalizes GluA2-lacking, CP-AMPARs. Interestingly, in contrast to our findings in the incubation model, we found that incubation with either the mGluR1 antagonist LY 367385 (100 μM) or the mGluR5 antagonist MTEP (1 μM) prevented the DHPG-induced decrease in GluA1 surface expression, indicating that both receptor subtypes mediate DHPG-induced CP-AMPAR internalization in cultured NAc neurons. Additional studies focused on consequences of long-term changes in group I mGluR transmission. We found that 24 h of incubation with the mGluR1 antagonist LY 367385 (100 μM) leads to a significant increase in GluA1 surface area but no change in GluA2 levels. These studies are consistent with those in the incubation model showing that a decrease in mGluR1 tone during early withdrawal contributes to CP-AMPAR transmission in NAc synapses and incubation of cocaine craving. Studies are now underway to assess whether this effect is also produced in cultured NAc neurons following long-term inhibition of mGluR5-mediated transmission. By further characterizing group I mGluR-mediated regulation of AMPAR trafficking *in vitro*, these studies will provide insight into the mechanisms mediating enhanced AMPAR transmission and cue-induced cocaine seeking in the incubation model, as well as insight into mechanisms that mediate homeostatic adaptations in NAc synapses as a result of altered levels of glutamate transmission.

Title: Long-term behavioral effects after postnatal morphine exposure in a rat model

Authors: M. M. CRAIG, *D. BAJIC;
Dept Anesthesiol., Boston Children's Hosp., Boston, MA

Abstract: Prolonged morphine treatment in the developing brain is associated with a high incidence of opioid tolerance and dependence. This suggests that early postnatal opioid treatment runs the risk of significantly altering neural pathways. Our knowledge of the long-term consequences associated with prolonged post-natal opioid exposure is sparse. We hypothesized that prolonged morphine administration in a neonatal rat model of antinociceptive tolerance and dependence is associated with long-term behavioral changes in adulthood. Animals received either morphine (10 mg/kg; n=21) or equal volume of saline (n=17) subcutaneously twice daily for 13 ½ days (postnatal day (PD)1-14). Morphine treated animals underwent a weaning period of 10 days to prevent occurrence of any signs of withdrawal. Subsequently, all animals were tested in adulthood at PD55. The series of behavioral tests included: (1) Hot Plate test, (2) calibrated forceps test, (3) novel object test, (4) locomotor activity, and (5) forced swim test. These tests evaluated thermal and mechanical pain threshold, short-term memory, addiction potential, as well as anxiety/emotional processing, respectively. We combined data for male and female rats since no sex differences were found. Mean values were compared using t-test. Analysis revealed that thermal threshold (paw-withdrawal time (sec) ± SD) is increased in animals treated with morphine (12.4 s ± 3.0) in comparison to saline control (9.74 ± 2.77; p=0.015). No differences were found in adulthood between groups with respect to mechanical threshold, novel object recognition time, individual swim test activities (swimming, climbing, immobility), and total or individual locomotor activity (central, peripheral, rearing). Using a rat model of chronic postnatal morphine exposure, these novel results demonstrating selective long-term neuroplastic differences in sensory processing: thermal and not mechanical. Negative results are also important in implicating a lack of long-term alterations on memory, affective processing, and addictive behaviors.

Title: Changes in expression of brain-derived neurotrophic factor and calbindin following behavioral sensitization to apomorphine in rats

Authors: D. J. LUSTBERG[1], M. P. HIND[1], *D. A. WELDON[2];
[1]Neurosci. Program, Hamilton Col., Clinton, NY; [2]Psychology, Hamilton Col., CLINTON, NY

Abstract: Behavioral sensitization has been demonstrated in response to chronic treatment with a variety of pharmacological agents and is thought to share common mechanisms with the development of drug dependence. Evidence has been provided for changes in a number of neurochemicals in the nucleus accumbens, prefrontal cortex, and hippocampus as a result of drug-induced sensitization. In the present experiment, we examined the expression of brain-derived neurotrophic factor (BDNF) and calbindin-D28k (CB) following sensitization to the dopamine receptor agonist apomorphine. Administration of 2 mg/kg (SC) of apomorphine for 14 days induced behavioral sensitization in adult male Sprague-Dawley rats. Control animals received an equivalent volume of isotonic saline. On Days 1, 7, and 14, the locomotor behavior of the animals was recorded for 20 minutes in an open field test conducted 15 minutes following injections. Sensitization was shown by a progressive increase in distance traveled along the peripheral zone of the open field across the three testing days in the APO group, with no changes in the distance traveled by the SAL group. Tracking records showed that the APO rats restricted their routes to the periphery of the open field. SAL rats entered the center zone more frequently than APO rats on each testing day. More BDNF and CB immunoreactivity was found in the ventral tegmental area, striatum, and hippocampus in APO animals compared to those of SAL animals. These increases in BDNF expression with APO-induced sensitization are similar to those previously demonstrated in rats sensitized to cocaine and amphetamine. In addition, the increase in the number of CB immunoreactive cells suggests that dynamic induction of this calcium-binding protein may be involved in the neuroadaptations associated with sensitization to dopaminergic drugs.

Title: A kappa opioid receptor antagonist reverses stress-induced neuroplasticity and cocaine-seeking even well after the stressor

Authors: *A. M. POLTER[1], R. A. BISHOP[1], L. A. BRIAND[2], R. C. PIERCE[2], J. A. KAUER[1]; [1]Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI; [2]Psychiatry, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Stress can be an important precipitating factor that drives escalation or relapse of drug-seeking behavior, and dopaminergic neurons in the ventral tegmental area (VTA) are an important site of convergence of drugs and stress. We previously identified a long-term potentiation of GABAergic synapses onto these neurons (LTP_{GABA}). Nitric oxide release by the dopaminergic neuron activates guanylate cyclase in the presynaptic GABAergic terminals, resulting in accumulation of cGMP, activation of PKG, and persistently increased release of GABA. Multiple drugs of abuse and stress block or inhibit LTP_{GABA} (Nugent et al, Nature, 2007; Niehaus et al, Eur J Neurosci 2010), suggesting that this common mechanism may play a role in addiction and stress-related diseases. Our recent work shows that the block of LTP_{GABA} by stress is dependent on both glucocorticoid (GR, Niehaus et al 2010) and kappa opioid receptors (KOR, Graziane et al, Neuron, 2013). We set out to understand how long the block of LTP_{GABA} lasts after stress and what is required to maintain the block. To address this, we performed whole-cell patch clamp recordings in slices prepared at various time points after acute cold-water swim stress. Here, we show that the block of LTP_{GABA} by stress is long lasting, persisting for five days after stress (control: IPSC amplitude 143±10% of baseline; 5 days post stress 101±13% of baseline). Administration of a glucocorticoid antagonist one hour after stress rescues LTP_{GABA} (IPSC amplitude 141±11%of baseline), however, by 24 hours after stress blocking glucocorticoid receptors is no longer effective in rescuing LTP_{GABA} (IPSC amplitude 113±8% of baseline). Surprisingly, antagonism of KORs with nor-binaltorphimine is effective at recovering LTP_{GABA} even when administered days after the stressor. When norBNI (10 mg/kg, i.p.) is given 2 hours, 24 hours or even 4 days after stress, LTP_{GABA} can be induced in slices (2 hrs: IPSC amplitude 131±7% of baseline; 24 hrs: 138±14% of baseline; 4 days (130±9% of baseline). In parallel, administration of nor-BNI 2 hours after stress also prevents reinstatement of cocaine

self-administration (Lever presses in reinstatement session: vehicle 36±7; norBNI 5±2). Therefore, a single exposure to acute stress can cause days-long changes in the reward circuitry that can be reversed with a kappa opioid receptor antagonist even well after the stressor has occurred.

Title: Identifying striatal gene networks and pathways associated with cocaine dependence

Authors: ***D. C. MASH**[1], Z. JIANG[2], E. CAPOBIANCO[2], N. F. TSINOREMAS[2], D. S. DELUCA[3], K. ARDLIE[3], S. P. GARAMSZEGI[1], G. TURECKI[4];

Abstract: Multiple interacting genes and environmental factors underlie the risk of drug addiction. Drugs of abuse cause lasting change in ventral limbic brain areas that process reward, and addiction is a form of aberrant dopamine plasticity in the dorsal striatum that underlies drug craving and relapse. In this study, we used RNA-seq to quantify transcript changes and analyzed global gene expression in well-characterized cohorts to identify candidate gene markers that are regulated by cocaine abuse in striatal dopamine pathways. The dorsal caudate and the nucleus accumbens were sampled post-mortem from individuals who were chronic cocaine abusers (N=25) and from age-matched control subjects who died suddenly without a history of drug or alcohol abuse (N= 25). The RNA-seq read alignment and differential analysis were done using TopHat and Cufflinks packages. For the initial analysis, cutoffs were set as FDR < 5%, fold change >1.2 and RPKM > 1 for cases and control groups. The caudate nucleus had 383 up-regulated and 124 down-regulated genes that were differentially expressed ($p < 0.05$). Differentially expressed genes in the nucleus accumbens showed a strikingly different pattern

with only 34 genes up-regulated and 117 down-regulated in chronic cocaine abusers compared to drug-free control subjects. Gene network and pathway analysis by GeneGo demonstrated dysregulated neurophysiological processes in the dorsal caudate, including glutamate regulation of dopamine D1A receptor signaling, constitutive and regulated NMDA receptor trafficking, activity-dependent synaptic AMPA receptor delivery and PKA signal transduction. The most significant altered biological function genes in the nucleus accumbens were associated with growth factor function, developmental regulation of cytoskeleton proteins and oligodendrocyte precursor cell proliferation. Our study reveals human gene networks and canonical pathways associated with cocaine dependence. These data provide not only networks between genes, but also map significant pathways in the up- and down-regulated gene set in cocaine dependence for future development of novel therapeutic strategies.

Title: Cocaine-induced metaplasticity in the cerebellum: Effects on the cerebellar Perineuronal nets

Authors: *M. CARBO-GAS[1], D. VAZQUEZ-SANROMAN[1], K. LETO[2,3], C. SANCHIS-SEGURA[1], D. CARULLI[2,3], F. ROSSI[2,3], M. MIQUEL*[1];

Abstract: External factors might promote structural remodelling of brain circuitry by modulating the activity of regulatory molecules that restrict neuronal plasticity in order to stabilize circuits. These plasticity inhibitory mechanisms take place in a cartilage-like structure called Perineuronal net (PNN) consisting of several molecules of extracellular matrix. Deep nuclear cerebellar projection neurons, those receiving strong innervation from GABAergic Purkinje axons are enveloped by PNNs. Therefore, by reducing or over-expressing extracellular matrix components, drugs and environmental factors might be able to modify conditions for synaptic change in the outputs from the cerebellum. In the present research, we addressed three different studies exploring cocaine effects on PNNs of the large projection neurons in the medial cerebellar nucleus. First, we evaluated the effects of a repeated cocaine treatment followed by a one-week withdrawal period and then a new cocaine administration; second, we administered the same cocaine regimen but including a one-month drug free period. Third, chronic cocaine administration was evaluated in a conditioned-odour cue paradigm. To properly identify PNNs, we employed Wisteria floribunda agglutinin (WFA), and we immunolabelled medial nuclear neurons with antibodies recognizing SMI32 and. We sampled all the SMI32+ neurons per section and estimated the number of them being surrounded by WFA+. At the same time, we performed an analysis of WFA staining intensity. Each net was assigned to one of three categories of staining intensity, ranging from the lowest to the highest value of WFA intensity: faint= 0-33%, medium= 34-66%, strong= 67-100% of the maximum staining intensity We observed that short withdrawal after chronic cocaine administration results in an increase of the number of PNNs exhibiting strong WFA intensity in the deep medial nucleus. Conversely, when the withdrawal was extended up to a month, or cocaine was repeatedly associated with a cue there was an increase in the number of PNNs expressing faint WFA intensity. Nevertheless, cocaine-mediated regulation of the PNN expression in the medial nucleus appears to be an unconditioned effect of the drug, as it was unrelated to cocaine-induced conditioned preference. These results show for the first time that cocaine might alter PNNs expression, thereby, promoting or restricting structural remodelling of the synapsis.

Title: Long-term effects in rat resting state networks following postnatal morphine exposure

Authors: D. BAJIC[1], M. M. CRAIG[1], *D. BORSOOK[2], L. BECERRA[1];
[1]Anesthesiology, Perioperative and Pain Med., Boston Children's Hosp., Boston, MA; [2]Boston Children's Hosp., Waltham, MA

Abstract: Exposure to prolonged morphine treatment during development is associated with increased incidence of opioid tolerance, dependence, as well as long-term neurodevelopmental delay, neurocognitive and motor impairments. Currently, the long-term consequences of neonatal morphine treatment on functional brain networks are not known. We hypothesized that functional activity in resting state networks following chronic morphine administration in adulthood will differ depending on previous exposure to opioids in postnatal period. Rats received twice-daily injections of either morphine (10 mg/kg, n=12, MMA Group) or equal volume of saline (n=7, SMA Group) subcutaneously for 13 ½ days (postnatal day (PD) 1-14). Morphine group underwent a weaning period of 10 days to prevent withdrawal. In adulthood, both groups received an additional two weeks of morphine treatment (PD55-70) following which they underwent high field functional magnetic resonance imaging (fMRI). Following anesthesia with isoflurane (0.5-2%), rats underwent an anatomical scan (RARE : 256x256 in-plane resolution FOV:3 cm, 0.6 mm 40 slices, TR/TE=5.3/33ms), and a functional scan (EPI: 64x64 in-plane resolution, FOV: 3cm, 1mm slices, TR/TE=1s/21.5ms, 600 volumes) using a 7T Bruker Biospec MRI. Analysis was performed with fsl. Preprocessing steps included brain extraction, motion correction, high pass filtering-100 s and spatial smoothing 0.7 mm. We used independent component analysis (ICA) to determine total group components and subsequently used dual regression to determine differences in connectivity between the groups. A rat brain template from our lab was used for registration and group comparison. Group ICA results were compared to published RSN rat templates (Becerra et al. NeuroImage 2011) for network identification. We identified 6 published rat brain networks (Becerra et al. PLoS One 2011): default mode (DMN), sensorimotor (SMN), interoception (ICN), cerebellar, basal ganglia and autonomic networks. We observed significant differences in connectivity in DMN, SMN, and ICN. The DMN displayed increased connectivity with orbito frontal (OFC), anterior cingulate, primary sensory, nucleus accumbens (NAc) and periaqueductal gray. The SMN displayed increased connectivity with OFC, NAc, Caudate Putamen, hippocampus and thalamus. The ICN only displayed decreased connectivity with primary motor, septal nucleus, retrosplenial, and hippocampus. These results suggest exposure to morphine in neonates produced brain alterations in adulthood when re-exposed to morphine.

Title: Voluntary aerobic exercise normalizes methamphetamine-induced changes in frontocortical BDNF and striatal D2 transcription

Authors: *A. B. THOMPSON[1], A. STOLYAROVA[1], Z. YING[2], F. GÓMEZ-PINILLA[2], A. IZQUIERDO[1];
[1]Psychology, [2]Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Substance abuse is a complex, multifaceted disorder characterized by an inability to cease drug seeking/taking in spite of negative consequences and repeated attempts to discontinue use. Drug abusers show decreased cognitive flexibility and impulse control, two endophenotypes which are predictive of relapse after abstinence and continued drug seeking. These deficits in inhibitory control have been associated with decreased dopamine D2-like receptor availability in the striatum (Groman 2012). Aerobic exercise increases striatal dopamine D2 receptor availability in Parkinson's patients (Fisher 2013), suggesting that it may serve to normalize D2-like dysregulation in drug abusers. Exercise has already been successfully applied in a clinical setting as a therapy for methamphetamine abuse, with encouraging results (Mooney 2014). Aerobic exercise enhances cognitive flexibility in healthy human adults and promotes expression of neurotrophins such as BDNF (Masley 2009; Gómez-Pinilla 2013), which has been linked to improved learning rates in a strategy set-shifting task, a measure of cognitive flexibility (D'Amore 2013). In order to investigate the relationship between aerobic exercise and the addiction process, rats were allowed to voluntarily run on a wheel in their home cage following a 2-week escalating methamphetamine (mAMPH) treatment. Sedentary controls were housed in home cages without running wheels. Running behavior was recorded for 6 weeks, then rats were sacrificed to analyze changes in BDNF and D2 mRNA transcripts in the striatum and frontal cortex, regions that are associated with differential learning rates following mAMPH and exercise. Following an acute withdrawal period, mAMPH-treated rats ran significantly more than their saline-treated counterparts, and maintained this elevated running activity for the duration of the exercise period. This could indicate increased sensitivity to the rewarding effects of aerobic exercise. All BDNF and D2 transcription differences between saline-treated and mAMPH-treated rats were normalized by subsequent aerobic exercise. Interestingly, BDNF in the frontal

cortex and D2 in the striatum were altered in the same direction by mAMPH alone and by exercise alone, supporting the idea of a shared neurochemical mechanism. Future research will investigate the efficacy of exercise as a non-pharmacologic intervention for methamphetamine addiction, both by serving as a substitute for the addictive substance and by enhancing cognitive functioning, protecting against relapse.

Title: Neuroadaptation induced by acute or chronic ketamine: Long-term effects of ketamine self-administration on zif-268 expression in rats

Authors: *C. V. CHIAMULERA[1], M. VENNIRO[1], D. W. S. CHEUNG[2], A. MUTTI[1], L. PADOVANI[1], M. DI CHIO[1], G. FUMAGALLI[1], D. T. YEW[2];
[1]Univ. Verona, Verona, Italy; [2]Brain Res. Centre, Sch. of Biomed. Science, Fac. of Med., The Chinese Univ. of Hong Kong, Shatin, Hong Kong, Hong Kong

Abstract: Ketamine was shown to own reinforcing properties, i.e. to initiate and maintain self-administration (S/A). Recently, we showed that single ketamine injection induced neuroadaptive changes in addiction-related brain areas (Tedesco et al., 2013). The objective of this study was to assess the expression of zif-268 as a marker of neuroadaptation in rats exposed to ketamine S/A trying to discriminate from the acute effects. Rats were daily trained to self-administer IV ketamine S/A (group 12x30). As a control, 2 separate groups of rats were exposed respectively to a single ketamine 0.5 mg/kg IV (group 1x1) or vehicle (group 0x1). Ketamine S/A was acquired and maintained for an average of 36 days. At endpoint, the total ketamine intake was 191.2 ± 82.1 mg/kg IV, with an average of 6.4 mg/kg ± 2.7 mg/kg IV of daily intake (mean ± SD). Brains were perfused and processed for immunohistochemistry in prelimbic (PRL) and infralimbic (IL) cortex, nucleus accumbens core (NACC) and shell (NACS), ventral tegmental area (VTA), hippocampus CA1, CA2 and CA3, and basolateral amygdala (BLA). Semi-

quantitative zif-268 cell counting showed a significant main effect of ketamine IV in all the brain areas except for hippocampal CA3. Post-hoc Tukey's multiple comparisons, showed a significant effect in the 1x1 vs. 0x1 group in PRL, NACC, NACS. Group 12x30 showed a significant increase of zif-268 vs. 0x1 group in all brain regions except CA3. In NACC, NACS, VTA, CA1 and BLA, this effect was also significantly greater than that observed in 1x1 group. Zif-268 cell counts from each brain area were analysed with Pearson's multiple comparison in order to identify correlated changes. In the 12x30 group zif-268 levels significantly correlated between hippocampal CA areas and dopaminergic nerve terminals areas such as PRL, IL and NAC areas. In group 1x1, significant correlations were found within the mesocorticolimbic pathway, and between CA3 and NAC areas. Our study is the first to report zif-268 expression in rats exposed to ketamine S/A. The comparison to single ketamine injection showed a significant difference in pattern and intensity of zif-268 signal, suggesting discrimination between the reinforcing (group 12x30) and potentially antidepressant (group 1x1) effects of ketamine.

Title: Optogenetic self-stimulation of the infralimbic-accumbens pathway blunts the development of cocaine sensitization

Authors: A. J. ASP, *E. B. LARSON, M. C. HEARING, M. J. THOMAS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Discrete optogenetic manipulation of reward circuitry is reported to influence cocaine-mediated behavioral changes. For example, co-administration of cocaine and optogenetic stimulation of the afferents to the nucleus accumbens shell (NAcSh) enhances cocaine-induced psychomotor sensitization, while afferent inhibition during cocaine exposure attenuates sensitization (Britt et al. 2012). On the other hand, optogenetic activation of infralimbic cortex (IL)-NAcSh afferents during drug abstinence is reported to disrupt the expression of cocaine sensitization (Pascoli et al., 2012). One parameter that has not yet been well investigated as a potential source of variability in the influence of NAcSh optogenetic stimulation on cocaine-induced behavior is the temporal relationship between stimulation and drug exposure. We tested the idea that non-concurrent optogenetic activation of IL-NAcSh afferent and cocaine exposure would influence the development of cocaine sensitization. To do this, we used a spatial optogenetic self-stimulation task in which C57BL/6J mice expressing channelrhodopsin in IL cortex quickly learn to optically self-stimulate IL-NAcSh afferents (465 nm, 30 hz, 10 ms, 5 s max pulse train) upon entry into a visually unique "active quadrant." Spatial preference in this task was measured in daily sessions (30 min/day) for two weeks, during which preference for the treatment quadrant was robust and stable. Similarly, a separate group of mice expressing the inhibitory opsin, Archaerhodopsin, in the IL cortex with optical fibers in the NAcSh was tested in the same spatial optical self-stimulation task (525 nm, constant illumination in active quadrant). In this case, no preference for the treatment quadrant was observed. During the second week, each mouse completed a cocaine sensitization regimen (15 mg/kg i.p., 5 once-daily injections) administered 3-5 hours prior to the optogenetic stimulation. Interestingly, we find that non-concurrent optogenetic excitation of IL-NAcSh afferents attenuates the development of psychomotor sensitization while optogenetic inhibition of IL-NAcSh afferents increases cocaine-induced locomotion. We hypothesize that these two behavioral profiles result from differential NAcSh synaptic plasticity induced by repeated bouts of either optogenetic excitation or inhibition. These data fit an emerging model in which the timing of IL-NAcSh afferent stimulation relative to drug exposure is a fundamental factor in determining the direction of influence on cocaine-mediated behavior.

Title: Alpha2a-adrenergic receptors filter parabrachial inputs to the bed nucleus of the stria terminalis

Authors: *S. FLAVIN[1], R. MATTHEWS[2], D. G. WINDER[2];
[1]Mol. Physics and Biophysics, Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Vanderbilt Univ., Nashville, TN

Abstract: Addiction is a chronically relapsing disorder characterized by continued use of drugs despite negative consequences. Stress exposure increases an individual's risk of relapse. The bed nucleus of the stria terminalis (BNST) is a key player in rodent behavioral models of stress-induced reinstatement of drug-seeking behavior. The BNST receives a dense norepinephrine (NE) input and α_2-AR agonists locally administered into the BNST have been shown to attenuate stress-induced reinstatement behavior. α_{2A}-ARs have widespread expression in the BNST and heterosynaptically modulate glutamatergic signaling in this region. Yet, it is not clear what glutamate inputs are regulated. The parabrachial nucleus (PBN) relays important stress/arousal information from the brainstem to the BNST and thus may play a role in stress-induced reinstatement. The PBN is also interesting for its heavily somatic innervation of BNST neurons and little is known about the nature of PBN regulation of it's amygdalar targets. Thus, we used a combination of optogenetic and electrophysiological approaches to assess the PBN input to the BNST and to test the hypothesis that α_{2A}-ARs specifically filter excitatory transmission from this input to the BNST. To study excitatory inputs, an AAV-CaMKII-ChR2:YFP viral vector was microinjected into the PBN. 6-8 weeks following surgery, brain slices were prepared and the PBN afferents in the BNST were optogenetically activated to generate excitatory postsynaptic responses (oEPSCs/oEPSPs). Using current clamp analysis, we found that PBN stimulation leads to two major classes of postsynaptic actions in BNST neurons. In one class, a large EPSP followed by a burst of action potentials was observed, while in the other, substantial feed-forward inhibition was seen. We found these two types of responses to be differentially sensitive to the α_{2A}-AR selective agonist guanfacine. EPSPs recorded from the PBN-excited cells showing consistent decrease. IPSPs from PBN-inhibited cells showed more variable responses. Using voltage clamp analysis of the isolated PBN oEPSC, we found that guanfacine inhibited the PBN oEPSC in a manner that was subsequently reversed by the α_2-AR antagonist atipamezole. In

contrast, these drugs had no effect on oEPSCs from BLA. Moreover, we have found a line of Thy1-ChR2 mice in which ChR2 expression is not apparent in CGRP+ PBN inputs to the BNST. In these mice, we find that a low concentration of guanfacine transiently enhances optically evoked excitatory responses in BNST. In total, these data suggest that the PBN input plays an important role in regulating the responsiveness of BNST neurons, and that this role can be suppressed by α_{2A}-ARs.

Title: The FAAH inhibitor PF-04457845 has THC-like rewarding and reinstatement effects in squirrel monkeys and increases dopamine levels in the nucleus accumbens shell in rats

Authors: *Z. JUSTINOVA[1], P. MASCIA[1], M. E. SECCI[1], G. H. REDHI[1], D. PIOMELLI[2], S. R. GOLDBERG[1];
[1]Preclinical Pharmacol. Section, NIDA, IRP, NIH, DHHS, Baltimore, MD; [2]Dept. of Anat. and Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: FAAH inhibitors (like URB597), that increase brain levels of anandamide, OEA and PEA, show promise for treatment of several neuropsychiatric disorders, including drug dependence. The agonist substitution strategy has been effective for several substance use disorders, mainly nicotine and opioid dependence, and its therapeutic effectiveness is currently under investigation for cannabinoid dependence. We previously showed that the prototypical FAAH inhibitor URB597, unlike cannabinoid CB-1 receptor agonists like THC and anandamide, is not rewarding in squirrel monkeys (Justinova et al., 2008). Here we assessed a newer FAAH inhibitor PF-04457845, currently in clinical testing for treatment of cannabis withdrawal, for THC-like agonist effects. In squirrel monkeys trained to self-administer anandamide (FR10 schedule, 60-s timeout), PF-04457845 maintained higher numbers of self-administered injections

per session and higher rates of responding than vehicle at doses of 3 and 10 µg/kg/injection. The cannabinoid CB1 inverse agonist/antagonist rimonabant (0.3 mg/kg, i.m.) blocked self-administration of the peak dose of PF-04457845 (10 µg/kg/injection). In abstinent monkeys that had previously self-administered THC, PF-04457845 caused moderate reinstatement of drug-seeking behavior over a narrow dose range. In rats, PF-04457845, unlike URB597, significantly increased extracellular dopamine levels in the accumbens shell, but similarly to URB597 did not show THC-like subjective effects. It is clear now that FAAH inhibitors can produce a spectrum of outcomes ranging from no evidence of rewarding, reinstatement or dopaminergic effects (URB597) to significant self-administration, reinstatement and accumbal dopamine release (PF-04457845). FAAH inhibitors that produce THC-like actions may be useful for management of cannabis dependence via agonist substitution strategy.

Title: Self-administration of the sigma-receptor agonist, DTG, in experimentally naïve rats

Authors: T. HIRANITA[1], T. A. KOPAJTIC[2], C. MESANGEAU[3], C. R. MCCURDY[3], *J. L. KATZ[4];
[1]NIDA/IRP/NIH/DHHS,, Baltimore, MD; [2]NIDA/IRP/NIH/DHHS, Baltimore, MD; [3]Sch. of Pharmacy, Univ. of Mississippi, University, MS; [4]MDRB, DHHS/NIH/NIDA IRP, Biomed. Res. Ctr., BALTIMORE, MD

Abstract: Previous studies demonstrated the reinforcing effects of the sigma-receptor (σR) agonists [1,3-di-o-tolylguanidine (DTG), PRE-084, (+)-pentazocine] in rats with a history of stimulant self-administration (Hiranita et al., 2010; 2013). However, none of the selective σ1R

agonists [PRE-084, (+)-pentazocine] were self-administered in naïve rats or those with a history of food reinforcement (Hiranita et al., 2013). The present study assessed the reinforcing effects of the non-selective σ1/2R agonist DTG in experimentally naïve, male Sprague-Dawley rats using a drug self-administration procedure. In marked contrast to the selective σ1R agonists, response-dependent injections of DTG (1.0 mg/kg/inj) increased and maintained responding over 28 daily sessions. The self-administration of DTG was long lasting; a response for which subjects had no history of reinforcement was newly conditioned with DTG, extinguished when injections were discontinued, and reconditioned when DTG injections again followed responses. The self administration of DTG was insensitive to omission of the visual stimulus (VS) that accompanied injections. Further, there was no appreciable difference in dose-effect curves for DTG (0.1-3.2 mg/kg/inj) self-administration with and without the VS changes, indicating a primary role of DTG pharmacological effects in its self administration. Moreover, the acquisition of DTG (1.0 mg/kg/inj) self-administration (with VS changes) over 15 daily sessions was blocked by presession treatment (i.p.) with the non-selective σ1/2R antagonist BD 1008 (10 mg/kg), the selective σ1R antagonist CM 304 (3.2 mg/kg) and the selective σ2R antagonist CM 398 (1.0 mg/kg). Subsequently, acquisition of DTG self-administration was obtained within 15 daily sessions in these same subjects when saline replaced pre-session antagonist treatments. Finally, acquisition of food-reinforced responding was obtained within 15 daily sessions in separate groups of subjects pre-treated with each σR antagonist. In marked contrast to the findings with selective σ1R agonists, the present results suggest reinforcing effects mediated by σ2Rs in naïve subjects. However, that the selective σ1R antagonist CM 304 blocked acquisition of DTG self-administration suggests a cooperative interaction among σ2 and σ1R-mediated reinforcing effects. That cooperation is unidirectional as evidenced by the lack of antagonism of self-administration of selective σ1R agonists by the selective σ2R antagonist CM 398 (previous results). Supported by NIDA IRP (JLK) and grants R01 DA023205 (CRM) and P20 GM104932 (CRM).

Title: Role of orexin terminal regions during conditioned food seeking

Authors: *A. M. CASON[1], G. ASTON-JONES[2];
[1]Med. Univ. South Carolina, CHARLESTON, SC; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous studies in our laboratory demonstrated that signaling at the orexin 1 receptor (OxR1) is involved in operant responding for sucrose, and in cue-induced reinstatement of extinguished sucrose or saccharin seeking; however, the specific orexin circuitry involved in cue-induced food seeking remains unknown. The present study examined the involvement of the orexin system in cue-induced reinstatement of extinguished sucrose or saccharin seeking by examining Fos expression in orexin terminal regions implicated in hedonic feeding and activated by cues associated with food reward and after local microinfusions of the OxR1 antagonist SB-334867 (SB) or vehicle. Rats were trained to self-administer sucrose or saccharin (paired with a tone+light cue) and then extinguished as described previously (Cason and Aston-Jones, 2013). Reinstatement of extinguished food seeking was elicited by presentation of the previously paired tone+light cues. Prior to reinstatement testing, rats were given systemic injections of SB (30mg/kg) or vehicle (for Fos comparisons); or rats were given a bilateral microinfusion (0.3ul) of SB (1mM) or vehicle (artificial cerebrospinal fluid) into an orexin terminal region. Pretreatment with systemic SB decreased Fos expression in prelimbic (PL) and infralimbic (IL) cortices, medial amygdala (but not central or basolateral amygdala), and paraventricular nucleus of the thalamus (PVT) during cue-induced sucrose seeking, and in PL, but not IL, during cue-induced saccharin seeking. Furthermore, microinfusions of SB aimed at PL decreased cue-induced reinstatement to saccharin seeking. These results indicate that signaling at the OxR1 in PFC, PVT and MeA are involved in cue-driven seeking of palatable food rewards, and indicate that orexin increases motivation to seek palatable foods. Orexin may also act in other regions including the ventral tegmental area and nucleus accumbens to influence conditioned food seeking. Current experiments are underway to test this hypothesis.

Title: Behavioural response to a 5-HT_{1b} agonist following MDMA self-administration

Authors: D. ARONSEN, J. WEBSTER, N. BUKHOLT, N. ARNOTT-STEEL, *S. SCHENK; Victoria Univ. Wellington, Wellington, New Zealand

Abstract: A significant body of research has suggested a role of the serotonin 1B (5-HT_{1B}) receptor in drug reinforcement because of its ability to modulate dopamine (DA) neurotransmission. 5-HT_{1B} agonists increase DA release via activation of heteroreceptors localized on GABA and Glutamate afferents. Because MDMA preferentially stimulates the release of 5-HT, the possibility that repeated exposure might impact these receptors was investigated. The effect of MDMA self-administration on the behavioural responses to the 5-$HT_{1B/1A}$ agonist, RU 24969, was determined and compared to rats that had self-administered vehicle. Rats self-administered a total of 350 mg/kg of MDMA during 22-57 daily 2 hour sessions. The day following the last self-administration session, the effect of RU 24949 (0.3-3.0 mg/kg) on fluid consumption was measured. RU 24969 dose-dependently decreased fluid consumption in control rats. The dose-effect curve was shifted to the right in rats that had self-administered MDMA. These results suggest a desensitization of the 5-HT_{1B} receptor following MDMA self-administration.

Title: Motivation to self-administer methamphetamine in a behavioral-economics paradigm predicts the effect of oxytocin on relapse behavior

Authors: *B. M. COX[1], B. S. BENTZLEY[1], R. E. SEE[2], C. M. REICHEL[1], G. ASTON-JONES[1];
[1]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Fac. of Med., Univ. of Tabuk, Tabuk, Saudi Arabia

Abstract: Human and animal studies indicate that females differ in their motivation to use methamphetamine (meth), and have increased propensity to relapse. However, addiction pharmacotherapies have primarily only been tested in males, which may not accurately predict treatment outcomes in females. Evidence indicates that oxytocin, an endogenous peptide well known for its role in social behaviors, childbirth and lactation, is a promising addiction pharmacotherapy. We have shown that oxytocin differentially affects meth seeking in males vs. females on a progressive ratio (PR) test, but attenuates reinstatement of meth seeking similarly in the two sexes. To further examine oxytocin's relationship to motivation and relapse we used a within-session behavioral economic (BE) paradigm, that allows measurement of drug demand at high effort (motivation; α) normalized for intake at low effort (baseline consumption; Q0). This approach also allows us to assess individual variability in meth demand in relation to relapse behaviors, and in response to oxytocin administration. Male and female Sprague Dawley rats were trained to self-administer meth, followed by daily BE sessions. Rats were tested with oxytocin (1 mg/kg, IP) or saline during BE, and then the effects of oxytocin were tested on cue-induced or meth-primed reinstatement responding. Compared to males, females showed greater motivation to seek meth (lower α) and higher meth intake (higher Q0). In both sexes, α correlated with both cue-induced and meth-primed reinstatement. Oxytocin decreased motivation to seek meth in both sexes during BE and reinstatement, and baseline α predicted the efficacy of oxytocin to attenuate cued reinstatement (e.g., low α predicted a greater effect of oxytocin). Motivation (α) assessed during BE accurately predicted relapse of meth seeking and the ability of oxytocin to attenuate relapse. Overall, this novel paradigm will help to delineate sex differences observed in the motivation to seek meth and may predict the efficacy of pharmacotherapies to treat meth addiction.

Title: Pharmacological modulation of the reinforcement enhancing effects of toluene in intracranial self-stimulation

Authors: *M. E. TRACY, K. L. SHELTON;
Pharmacol. and Toxicology, Virginia Commonwealth Univ. Med. Ctr., Richmond, VA

Abstract: Inhalants are a diverse group of abused substances characterized by their route of administration. Despite widespread abuse, little is known about the mechanism underlying the reward-related effects of inhalants. Intracranial self-stimulation (ICSS) is one method by which these properties can be examined in rodents. In ICSS electrodes are surgically implanted into the medial forebrain bundle of C57BL6/J mice which are then trained to respond on a lever for direct electrical stimulation of the brain. Previously, we have demonstrated that brief exposure to toluene vapor significantly enhances responding for electrical brain stimulation. In the present study, we probed the contributions of the gamma amino butyric acid A receptor system (GABAA) to the reward related effects of toluene. In a group of 8 mice, the GABAA benzodiazepine site neutral antagonist flumazenil or the GABAA benzodiazepine-site negative modulator RO15-4513 were administered alone as well as prior to 3300 PPM toluene vapor exposure. When administered alone 1 or 3 mg/kg flumazenil did not affect ICSS compared to vehicle control. Similarly doses of 0.3 and 1 mg/kg RO15-4513 alone had no significant effect compared to vehicle control. A higher dose of 3 mg/kg RO15-4513 significantly decreased responding for ICSS relative to vehicle control. Preadministration of 1 or 3 mg/kg flumazenil had no effect on toluene vapor facilitated ICSS. However, both the 0.3 and 1 mg/kg RO15-4513 doses significantly decreased the facilitation of ICSS produced by 3300 ppm toluene vapor. These results suggest that the GABAA receptor system is involved in modulating the rewarding effects of toluene.

Title: Quantitative structure-activity relationships (QSAR) for abuse-related neurochemical and behavioral effects of para-substituted methcathinone derivatives in rats

Authors: ***J. S. BONANO**[1], M. L. BANKS[1], R. A. GLENNON[1], J. S. PARTILLA[2], M. H. BAUMANN[2], S. S. NEGUS[1];
[1]Virginia Commonwealth Univ., Richmond, VA; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Methcathinone (MCAT), the β-keto analog of methamphetamine, is a potent central nervous system stimulant and the parent compound to an emerging class of abused drugs that includes mephedrone and methylone (bath salts components). This study examined quantitative structure-activity relationships (QSARs) for MCAT and six para-substituted MCAT derivatives on two experimental endpoints: (1) *in vitro* potency to function as substrates for dopamine and serotonin transporters (DAT and SERT, respectively), and (2) *in vivo* modulation of intracranial self-stimulation (ICSS) in male Sprague Dawley rats. Correlation analysis was used to compare neurochemical and behavioral effects to each other, as well as to steric (Es), electronic (σ) and lipophilic (π) constants for the seven para substituents: -H (methcathinone), -F (flephedrone), -OCH3 (methedrone), -Cl, -Br, -CH3 (mephedrone), and -CF3. For *in vitro* neurochemical studies, drugs were tested in a rat-brain synaptosome preparation to assess potency of compounds to promote monoamine release through DAT or SERT. All seven compounds

functioned as substrates at DAT and SERT, and DAT vs. SERT selectivity varied across compounds (H>F>Cl>CH3>Br>OCH3>CF3). For *in vivo* behavioral studies of ICSS, rats were implanted with electrodes targeting the medial forebrain bundle and trained to respond under a fixed-ratio 1 schedule for varying frequencies of electrical brain stimulation (56-158 Hz). Brain stimulation maintained a frequency-dependent increase in response rates, and drug were evaluated for their effects on ICSS frequency-rate curves and on the total number of stimulations self-administered across all frequencies. All drugs dose-dependently altered ICSS, and selectivity to facilitate low ICSS rates vs. depress high ICSS rates varied across compounds (H>F>Br>Cl>OCH3> CH3>CF3). *In vitro* DAT selectivity correlated with *in vivo* potency to facilitate ICSS (R=0.92, p=0.003). In addition, the steric parameter (Es) of the para substituents correlated with both *in vitro* DAT selectivity (R=0.78, p=0.04) and *in vivo* facilitation of ICSS (R= 0.81, p=0.03). Together, these results suggest that DAT vs. SERT selectivity of MCAT derivatives is a key determinant of abuse-related facilitation of ICSS by these compounds, and that steric aspects of the para substituent of the MCAT scaffold are key determinants of DAT vs. SERT selectivity. Thus, MCAT derivatives containing para substituents with low steric bulk display DAT selectivity and have high abuse liability, while MCAT derivatives containing para substituents with greater steric bulk display SERT selectivity and have lower abuse liability.
