Title: Motor activity modulates slowly oscillating basal ganglia neurons in awake, dopamine depleted mice

Authors: *T. C. WHALEN¹, A. M. WILLARD², K. J. MASTRO³, J. E. RUBIN⁴, A. H. GITTIS²

²Biol. Sci., ¹Carnegie Mellon Univ., Pittsburgh, PA; ⁴Mathematics, ³Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Oscillatory activity in several frequency bands has long been a hallmark of dopamine depletion (DD) and implicated in motor control in the basal ganglia (BG). Previously, oscillations in the delta band (1-4 Hz) have been reported after DD in the anesthetized mouse BG, but were generally attributed to anesthesia-induced cortical slow wave activity permeating into deep brain regions. To explore the oscillatory properties of BG neurons in awake DD mice and observe how they are modulated by motor activity, we injected 6-hydroxydopamine into the medial forebrain bundle, then recorded from mice head-fixed to a wheel on which they could voluntarily walk or run. Using linear multielectrode probes, we recorded single units in the substantia nigra pars reticulata (SNr), external segment of the globus pallidus (GPe) and subthalamic nucleus (STN) of DD and healthy mice. Approximately 30% of all recorded units in each region displayed prominent delta oscillations in DD, whereas no units oscillated in healthy animals. Using short-time autocorrelation measures, we show that bouts of walking correlated with decreased delta band power in oscillating SNr and GPe units, but increased power in STN units. This study shows single unit slow oscillations in several regions of the awake, dopamine

depleted basal ganglia that are modulated by motor activity in a consistent way within a particular BG region. A deeper understanding of how firing patterns in the basal ganglia change after loss of dopamine innervation will help elucidate dopamine's functional role in shaping basal ganglia activity and motor output.

Abstract: Measurement of local field potentials (LFPs) is a classical physiological technique often used for general characterization of neural activity in brain circuits. LFPs can be used to characterize various physiological phenomena underlying changes in behavior, from spontaneously occurring oscillations to responses evoked by sensory or electrical stimulation. Electrical stimulation applied at various frequency protocols are known to result in long-term plasticity. Although this technique gives a good overview of circuit dynamics, it lacks specificity important for detailed analysis of plasticity mechanisms in specific neural pathways. This specificity is especially difficult to achieve with electrical-stimulation in vivo. In our studies we combined LFP recording with optogenetic afferent stimulation to overcome this problem, taking advantage of the unique precision of this latter technique. First, we compared electrically- and optically-evoked LFPs in the dorsal striatum in brain slices and anesthetized mice to characterize the basic properties using varying stimulus parameters. Next, we compared long-term plasticity changes evoked by low- and high-frequency protocols. Finally, assessed pharmacological effects on plasticity by application of well-characterized pharmacological agents such as AP5, NBQX, TTX, kynurenic acid, alcohol and more. Our results proved that LFPs can be evoked with channel-rhodopsin 2 (ChR2) expression and light stimulation. We also showed similarities and differences between electrically- and optically-evoked LFPs and their dependence on intensity of the stimulation current, stimulation parameters, and topographical organization of the recorded region. Furthermore, we revealed that pharmacological modulation of electrically-induced

plasticity affects electrical and optical LFPs to different extents. In all parts of our project we recorded LFPs evoked by stimulation with a tungsten electrode and recorded with a glass pipette or evoked by light stimulation and recorded with an optrode. Mice expressing ChR2 in cortex were generated by breeding Emx1-Cre mice with AiCOP4 conditional ChR2-expressing mice. We examined plasticity mechanisms specifically in cortico-striatal circuits because these circuits underlie action control and action learning. Furthermore, we focused on dorso-medial and dorso-lateral striatum that receive projections from the prefrontal cortex and motor cortex respectively. These pathways are especially interesting due to their engagement in alcohol-related behaviors.

Title: Resting-state fMRI analysis revealed human caudate topology along two principle axes: Medial-lateral and anterior-posterior

Authors: *J. F. O'RAWE, M. KHAN, H.-C. LEUNG Stony Brook Univ., Stony Brook, NY

Abstract: The striatum has been implicated in the gating of motor and cognitive behavior. In particular, the caudate has been implicated in goal-oriented learning and action selection. What computations it performs to produce this type of behavior are largely unknown. Understanding the organizational properties of this region is a critical step. While there is a relatively large animal literature in examining afferent and efferent projections of the caudate, the methodology is intrinsically limited. Neuroimaging methods, however, allow us to tackle some of these limitations via continuous sampling of the brain image space. Previous attempts have been made to utilize human brain imaging data to examine the organization of the caudate, though few have taken full advantage of the continuous nature of the data. We've developed a regression based approach of analyzing functional magnetic imaging (fMRI) data, allowing for the quantification of anatomical gradients in functional connectivity. We examined the caudate spatial topology in two databases of healthy participants: the Cambridge-Buckner subset of the 1000 Functional Connectomes database (n = 198, ages 18-30), and the NKI/Rockland database (n = 189, ages 4-85). Our results supported the previous literature by demonstrating stable gradients of connectivity patterns across the caudate's anterior-posterior (A-P) and medial-lateral (M-L) axis. However, we found that the differential connectivity along the M-L gradient is better described with respect to networks, with default mode network preferring the medial extent of the caudate, and the frontoparietal network preferring the lateral extent of the caudate. We replicated this

result across subsamples within the same and across different databases. Further, stable patterns of caudate topology was evident at the single subject level. Lastly, we examined the effects of aging and found that age predicts the integrity of the M-L organization within the head of the caudate, and that this relationship seems mediated by preferential connectivity from the nucleus accumbens (N.Acc) to the anterior caudate. The systems level differential organization in network connectivity along the M-L axis of the caudate suggests the potential integration of internally and externally oriented information. Further, it seems that connectivity decreases with age.

Title: Spine density in the nucelus accumbens is differentially changed after rat gambling task with different housing condition

Authors: M. KWAK, W. KIM, B. CHO, W. CAI, *J.-H. KIM Yonsei Univ. Coll Med., Seoul, Korea, Republic of

Abstract: Poor decision-making is closely related to symptoms of various psychiatric disorders. Rat gambling task (rGT) adopts the basic principle of Iowa Gambling Task, which is widely used to assess the decision-making process in humans. Dendritic spine is a key structure for structural plasticity in the brain, and its morphology dynamically changes through the learning process. Here we examined how housing condition and choice preference appeared in rGT contributes to morphological change of dendritic spines in the nucleus accumbens (NAc). Rats were housed as isolated or paired, and trained in a touch screen chamber to learn the relationships between 4 different light signals on the screen and accompanied reward outcomes or punishments set up with different schedules. Once they show a stabilized pattern of preference upon free choice, rats were separated as risk-averse or risk-seeking group according to their preference of choice. A control group of rats were housed in pair and never exposed to rGT training. When we visualized dendritic spines by GFP expression incorporated with adeno-associated virus in the NAc, and conducted quantitative analysis, we observed that rGT alone with pair-housing, whether it turned out to be risk-averse or risk-seeking, did not contribute to show any difference in spine density compared to control group. However, when combined with isolation-housing, rGT showed increased number of total and thin spine density only in risk-seeking compared to control groups. These results indicate that trait (risky choice preference) and environment (isolated housing)

inter-influence to contribute to morphological changes of dendritic spines in the NAc, and may suggest that these changes might underlie maladaptive decision making.

Title: Visualization of ERM proteins on dendritic spines in the rat nucleus accumbens

Authors: W. CAI, *W. KIM, M. KWAK, J.-H. KIM Yonsei Univ. Col. Med., Seoul, Korea, Republic of

Abstract: The ezrin-radixin-moesin (ERM) proteins are a family of widely distributed membrane-associated proteins. They have been implicated not only in cell-shape determination but also in signaling pathway. When a threonine residue at C-terminal regulatory domain is phosphorylated, they become activated and crosslink F-actin filaments to plasma membrane. Although it has previously shown that ERM proteins are expressed in neuronal cells in the brain, there are few studies directly visualizing their presence on dendritic spines in vivo. The present study aimed to explore the experimental methods to visually detect phosphorylated ERM proteins on dendritic spines of the medium spiny neurons in the rat NAcc. First, we used immersion weak fixation in aldehyde solution to achieve enhanced immunohistochemical staining of phosphorylated ERM proteins in the NAcc tissues. Second, we labeled medium spiny neurons with eGFP by using adeno-associated virus and examined the presence and distribution of phosphorylated ERM proteins on dendritic spine under confocal microscope. Phosphorylated ERM proteins were found located in dendritic shafts and extra-synaptic sites of dendritic spines. These results, first time directly to our knowledge, visually elucidated subcellular localization of phosphorylated ERM proteins in the NAcc medium spiny neurons, and suggest that we may be able to use these methods as a new tool to examine the functional significance of these proteins in the brain.

Title: Vestibular input modulates visuomotor feedback responses in reaching

Authors: *L. OOSTWOUD WIJDENES, W. P. MEDENDORP

Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Reaching movements are controlled continuously. This implies that information relevant to the task at hand is monitored throughout the movement and that the movement is adjusted if necessary. Visual and mechanical perturbations of the hand and the target elicit task-sensitive movement adjustments at very short latencies. Also vestibular perturbations to an otherwise unperturbed body and environment lead to hand movement adjustments. It is unknown if the vestibular system interacts with the online visuomotor control system for reaching movements. Here we asked if vestibular information modulates the gain (defined as the velocity of the hand to correct for perturbations) of visuomotor feedback responses.

Participants were seated on a vestibular sled that translated them forward or backward with a low or high acceleration profile (1.7 or 3.2 m/s^2 peak acceleration, bell-shaped velocity). During the passive full body translation, they were instructed to move their right index finger in the sagittal plane toward a body-fixed target, which jumped perpendicular to the main movement direction in half of the trials. The jump could occur 100, 200 or 350 ms after trial start. If vestibular information modulates the feedback response, the gain of the response to the early jumps should be higher for the fast than for the slow sled profile because the acceleration is higher at the moment of the jump. The gain of responses to the late jump should be equal for the slow and fast sled profile, as the imposed acceleration is equal at this time.

The first results are in line with our predictions. In response to the target jumps, movements were corrected at very short latencies (~150 ms). The gain of the corrections in response to the early jumps was larger for the high than the low acceleration; the gain was not different for late jumps. Importantly, response gains did not differ between forward and backward passive translation, suggesting that inertial forces on the arm in the main movement direction were not modulating the feedback responses. Critically, the distance of the finger relative to the target at the moment of the early jumps was the same for slow and fast sled profiles, ruling out that the gain effect was due to differences in hand position. These results therefore suggest that vestibular information is integrated in visuomotor feedback control at a very early stage.

Title: Unique oscillatory entrainment of spike timing after ischemic infarct in rat motor cortex is associated with behavioral outcomes

Authors: *M. D. MURPHY¹, A. R. PACK², C. L. DUNHAM³, S. BARBAY³, D. J. GUGGENMOS³, R. J. NUDO^{3,4}

¹Bioengineering Grad. Program, Univ. of Kansas, Lawrence, KS; ²Neurosci. Doctoral Program, Emory Univ., Atlanta, GA; ³Dept. of Physical Med. and Rehabiliation, ⁴Landon Ctr. on Aging, Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Following ischemic infarct in the cerebral cortex, spared neurons fire in noisy bursts that function as a signal for neurite growth. While this activity has been suggested to promote beneficial axonal reinnervation, it may also interfere with behavior by disrupting motor-related neural activity during critical post-infarct periods, when rehabilitation is optimal. Weak, periodic signals, such as neuronal subthreshold membrane voltage oscillations, may be amplified by noisy events via stochastic resonance (SR). In the distribution of inter-spike intervals (ISIs) for a given neuron, SR is evidenced by multiple peaks. Therefore, multi-peak ISI (MP-ISI) may indicate the presence of noisy processes that disrupt normal spike timing in behavior. We investigated whether MP-ISI is associated with behavioral outcomes in rats performing a pellet-retrieval task after an endothelin-1 (ET-1) ischemic infarct of primary motor cortex (M1). Extracellular activity was recorded using micro-wire arrays implanted in ipsilesional premotor cortex (PM) and contralesional M1. Spikes were sorted into clusters according to their waveform and location. ISIs were aggregated separately for spikes in epochs surrounding either unsuccessful or successful grasps. To test whether noisy spiking is associated with behavioral outcomes, we counted and classified the number of spike clusters with MP-ISI during one or both alignment epochs. Spike clusters demonstrated comparable average firing rates and burstiness for both healthy and lesioned rats. While more total spike clusters demonstrated MP-ISI in rats with ET-1 lesions (114 of 157 spike clusters with MP-ISI were from lesioned rats), there was a significant increase in the frequency of MP-ISI in lesioned rats during either only unsuccessful or only successful grasps (57 of 69 spike clusters) compared to spike clusters with MP-ISI in both grasp outcomes (57 of 88 spike clusters; G = 6.44, df = 2, $P[X^2 > G] < 0.05$). Qualitative differences in spike timing patterns indicate that the oscillations emphasized in MP-ISI are unique to

behavioral outcome. These results suggest that noisy spiking processes inherent to recovery from ischemic infarct potentially amplify spike timing entrainment to weak neural oscillations during behavior.

Title: Sensory prediction and sensory surprise in goal-directed movement

Authors: *G. JURAVLE^{1,2}, F. L. COLINO³, G. BINSTED⁴, A. FARNE⁵

¹Bron Cedex, France; ²Impact Team U1028, INSERM, Lyon Neurosci. Res. Ctr., Lyon, France; ³Sch. of Hlth. Exercise Sci., Univ. of Victoria, Victoria, BC, Canada; ⁴Univ. of British Columbia, Kelowna, BC, Canada; ⁵Lyon Neurosci. Res. Center, INSERM 1028, CNRS 5292, Ucbl1, Bron, France

Abstract: Goal-directed movement affects tactile perceptual processing. Specifically, touch is suppressed during action (see Juravle, Binsted, & Spence, 2016, for a recent review). Here, we set to investigate the reverse influence, that is, whether and how the visually-conveyed tactile qualities of an object to be grasped affect the kinematics of the executed movement. To achieve this purpose, each trial we presented our participants with a cylindrical object and instructed them to prepare to grasp it. Vision was then occluded for a variable delay during which the object could be replaced (or not), depending on the condition for the trial. The return of vision was the go signal for the movement. Participants reached for, grasped, and lifted the object off the table. We used two objects, a smooth cylinder and an irregularly carved one. Furthermore, because we were interested in how sensory priors might affect the movement profile, in two separate experiments (each with N = 16), we manipulated the probability of the object being the same or different at the time of the go signal (by blocks: 100%, 50%, and 80%). In an additional block (80% +), a third unexpected 'spiky' object was presented only twice. Results indicate that the visually-conveyed tactile attributes of an object consistently affect the transport component of the reach-to grasp movement, as a function of their predictability. These findings suggest that perception modulates movement in a reverse fashion to the documented tactile suppression. Taken together, our results point toward sensorimotor integration as a bidirectional process, with the motor prediction being adjusted online during the reaching movement based on available visual input and current sensory priors.

Title: Neuronal activity in motor cortex during coherent sequential reach

Authors: *T. WANG, Y. ZHANG, H. CUI Inst. of Neuroscience, CAS, Shanghai City, China

Abstract: While motor cortex has been found to exhibit heterogeneous and dynamic firing patterns related to various movement kinematics (i.e., direction, speed, and distances) during arm movement, sensory or cognitive factors (i.e., serial target presentation) also influence its activities. To examine temporal dynamics of directional selectivity during sequential arm movement, we recorded single-unit activity from the motor cortex while a monkey performed a coherent double reach instructed by memorized cues presented simultaneously. The monkey was seated in front of a touch screen. Trial began with a green circle displayed on the center of the screen, monkey was required to touch the green circle for 300 ms. Then, in 1/3 of trials (singlereach trials), another green circle was presented as a reaching goal for 400 ms (cue period) at one of six vertexes locations of a regular hexagon around the central green circle with side length 15 cm. After the cue was extinguished, the monkey had to keep his hand on the central green circle for a delay period of 600 ms before it was turned off (GO signal), and the monkey was then required to reach to the previously cued location to obtain a reward. In the remaining trials (double-reach trials), a green square and a green triangle were presented simultaneously, with the triangle placed at a location either 120° clockwise (1/3 of trials) or counter-clockwise (1/3 of trials) from the square. After the 600 ms delay, the monkey was required to reach the remembered square location first, and then to reach the remembered triangle location immediately, the monkey was rewarded only if he reached the both targets accurately in the correct order. All the 18 trial types (3×6 , three conditions by six directions) were pseudorandomly interleaved. Among 62 neurons recorded from one monkey to date, 30 of them showed significant directional tuning (one-way ANOVA, p<0.05) during pre-movement (200 ms before first movement onset) or peri-movement (-100-100 ms around first movement onset). While some neurons exhibited differential pre-movement activity for single-reach and double-reach trials with same first reach, most neurons showed similar preparatory activity before GO signal

in the double-reach trials but became tuned for the second reach before the first reach offset. These results suggested that movement preparation rather than execution is a predominant function of motor cortex.

Title: Neuronal activity in motor cortex during flexible manual interception

Authors: *Y. ZHANG, T. WANG, H. CUI

Inst. of Neuroscience, CAS, Shanghai City, China

Abstract: Although motor cortex traditionally was believed to contain 'upper motor neurons' driving muscle, converging recent evidence suggested that its heterogeneous activity carries information far beyond movement kinematics/kinetics, including large cognitive components and responses to visual and somatosensory inputs. To elucidate dynamic interplay between sensory inflow and motor outflow, we recorded single-neuron activity from motor cortex while macaque monkeys performed a flexible manual interception task. The monkey initiated a trial by positioning a hand at the center of a touch screen for 600ms. Then, a peripheral target (green circle) appeared and whirled along a circular annulus around the center, and the monkey was required to intercept it within 800 ms after the random delay (400 ± 100 ms). Once a peripheral location was touched, the target stopped, and if the angle between target and hand endpoint was less than 15°, the trial was a success and the endpoint was marked for feedback with a red circle (blue if missed). The moving target appeared at a random direction and moved with shuffled five speed conditions: 120° and 240°/s clockwise, 120° and 240°/s counter-clockwise, and 0°/s (control). The arm trajectory was sampled by an electromagnetic tracking system (Polhemus G4). In such a flexible stimulus-response contingency, interceptive reach was launched to the future interception zone rather than the instantaneous stimulus location. Under the incongruent incoming sensory stimuli and impending movements, most neurons we recorded to date exhibited invariant movement tuning for different target motion speeds, suggesting that the motor cortex plays an intimate role in forming motor programs based on sensory inputs and behavioral context.

Title: The functional organization of movement maps in New World titi monkeys

Authors: *M. K. BALDWIN¹, A. C. HALLEY², L. A. KRUBITZER³ ¹Ctr. for Neurosci., Univ. of California Davis, Davis, CA; ²Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; ³UC Davis, Davis, CA

Abstract: The current study is part of an ongoing project in the laboratory exploring and comparing the functional organization and dynamics of cortical motor areas in primates and their close relatives. Recent evidence from our lab using long-train (LT) intracortical microstimulation (ICMS) in macaques and tree shrews (one of the closest living relatives of primates) has shown that movements can be evoked not only from classical frontal and posterior parietal motor regions of the brain, but also from somatosensory cortex (Baldwin et al., 2016; Baldwin et al., 2017). Further, in tree shrews, we have discovered that evoked movements within somatosensory cortex are unaffected when motor cortex is reversibly inactivated (Baldwin et al., 2014). The current study explores the extent and organization of evoked movements using LT-ICMS, and how the different cortical fields from which movements can be evoked are functionally organized using reversible inactivation methods. Titi monkeys were chosen for these experiments because they share many common brain features with macaque monkeys; however, all motor and somatosensory cortical fields are located on the cortical surface and are therefore easily accessible for reversible inactivation using cortical cooling. Our main findings were that evoked movements could be elicited from frontal motor areas, posterior parietal cortex, as well as somatosensory cortical areas. Similar to findings in macaques and tree shrews, these movements were complex in nature involving multiple joints and body parts such as the shoulder + elbow + wrist, the hand + mouth, or the forelimb + hindlimb. Unlike macaques, we found few sites at which movements of single digits could be elicited; however, representations of forelimb movements were extensive. When motor cortex was inactivated by cooling, evoked movements in posterior parietal cortex were diminished, while those in somatosensory cortex were relatively unaffected. Our findings suggest that somatosensory cortex may not only provide feedback for

the execution of complex movements, but could itself be directly involved in the generation of these movements.

Title: Movement characteristics encoded by single neurons in the cuneate nucleus of an awake behaving rhesus macaque

Authors: *C. VERSTEEG¹, R. CHOWDHURY¹, T. TOMLINSON², J. M. ROSENOW⁴, L. E. MILLER^{2,5,6,3}

¹Biomed. Engin., ²Physiol., Northwestern Univ., Chicago, IL; ³Biomed. Engin., Northwestern Univ., Evanston, IL; ⁴Neurolog. Surgery, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; ⁵Physical Med. and Rehabil., Northwestern Univ. and Rehabil. Inst. of Chicago, Chicago, IL; ⁶Shirley Ryan AbilityLab, Chicago, IL

Abstract: Located in the dorsal brainstem, the cuneate nucleus (CN) is difficult to access with either acute or chronically implanted recording electrodes. As such, there have been few attempts to record CN single units, virtually none from awake animals. Transmission of afferent signals through CN in anesthetized preparations depends on a number of factors, including the history of afferent input and descending cortical inputs. Thus, the representation of somatosensation in CN during behavior is nearly unknown.

Despite these hurdles, we have successfully implanted multi-electrode arrays in rhesus monkeys. We trained the monkey in three types of tasks using a manipulandum to control a cursor on a screen. In the first, the monkey reached to random targets in the workspace. In the second, the monkey performed a classic center-out task, reaching from a center target to one of four outer targets. On some trials, while the monkey held the handle in the center target, motors in the manipulandum randomly applied a force to the monkey used isometric force on the handle to control the cursor, reaching once again to random targets. Although early implants recorded tens of neurons for ~4-6 weeks, in the most recent animal, we recorded ~20 neurons during a series of experiments spanning six months. Another animal had over 50 units, but with only one recording

session prior to failure. Receptive fields of these neurons were typically were on the proximal arm, with a mix of cutaneous and proprioceptive afferents.

95% of neurons modulated their firing rates significantly during the isometric task, with many well-tuned to the direction of applied force. Virtually the same proportion of neurons responded during the active component of the unloaded, center-out task, with 60% of neurons tuned to movement direction. During these active movements, some neurons appeared to modulate their firing rates 50-100 prior to movement onset, suggesting the influence of descending inputs. Three-quarters of neurons responded to the applied bumps, with approximately one-third having some directional tuning. We are able activate individual muscle receptors (muscle spindles and Golgi tendon organs) selectively through vibration and electrical stimulation. We intend to compare these patterns of activation to the modulation observed during the movement and isometric tasks. Furthermore, by using a combination of motion tracking and musculoskeletal modeling to extract muscle lengths and length changes, we will assess the tuning properties of these neurons in intrinsic, as well as Cartesian coordinates.

Title: Cortical EEG dynamics during reaching movement under the influence of the mirror illusion

Authors: *K. YAMANAKA Showa Women's Univ., Tokyo, Japan

Abstract: Mirror illusion can be used to induce systematic errors for reaching movement made with the unseen hand behind the mirror. However, it remains unclear the cortical mechanism during the reaching movement under the influence of the mirror illusion. The aim of this study is to investigate the cortical mechanism during the reaching movement under the influence of the mirror illusion. Nine right-handed female volunteers conducted reaching tasks under the influence of the mirror illusion. Participant initially placed right hand in front of, and the left hand behind, a mirror placed vertically in the mid-sagittal plane on the table. She asked to move the right hand to the directions toward or away from the mirror. After 10 s of exposure to the mirror reflection (mirror illusion condition) or to the mirror covered by an opaque sheet (control

condition), participant reached to unseen target situated 15 cm forward with their unseen left hand behind the mirror. We recorded the reaching trajectories made with the tip of index finger of the unseen left hand using by VICON motion capturing system. Surface electroencephalography (EEG) was recorded during the reaching movement in the mirror illusion and control conditions and analyzed by a traditional event-related potential (ERP) and a single-trial-based EEG power and phase dynamics. As a result, during an early stage of the reaching movement, horizontal errors were larger in the mirror illusion condition than in the control condition. These results suggest that, in the mirror illusion condition, participants plan and execute their left hand reaching movements to the direction away or toward from the mirror. Next, positive ERP deflections during reaching movement in the mirror illusion condition were larger than those in the control condition over sensorimotor site opposite to the reaching hand. Theta-band EEG power during reaching movement in the mirror illusion condition sustained longer than in the control condition, while theta-band EEG inter-trial phase-locking in the mirror illusion condition was stronger than those in the control condition. These results suggest that, in the mirror illusion condition, participants are difficult to control their left hand in the late stage of the reaching movement under the influence of the mirror illusion because they become more able to detect their visual-proprioceptive conflict in the late stage of the reaching movement.

Title: 3D assessment of upper limb proprioception

Authors: *J. D. KLEIN^{1,2,3}, B. WHITSELL^{1,4}, P. ARTEMIADIS^{1,4}, C. A. BUNEO^{1,5,3} ¹ASU, Tempe, AZ; ²Interdisciplinary Grad. Abstract: Proprioception is the sense of body position, movement, force and effort. Loss of proprioception can affect planning and control of limb and body movements, negatively impacting activities of daily living and quality of life. Assessments employing planar robots have shown that proprioceptive sensitivity directionally-dependent within the horizontal plane (Wilson et al, 2010). Little is known however about proprioceptive sensitivity when tested outside the horizontal plane. To investigate proprioceptive sensitivity in 3D we developed a novel experimental paradigm employing a 7-DoF anthropomorphic robot arm (LWR4+, KUKA Inc.), which enables reliable testing of arm proprioception along arbitrary paths in 3D space, including vertical motion. A participant's right arm was coupled to a trough held by the robot that stabilized the wrist and forearm, allowing for changes in configuration only at the elbow and shoulder. Sensitivity to imposed displacements of the endpoint of the arm were evaluated using a "same-different" task, where participant's hands were moved 1-4cm from a previously visited reference position. The proportion of trials where subjects responded "different" when the stimuli were different ("hit rate"), and where they responded "different" when the stimuli were the same, ("false alarm rate"), were used to calculate d', a measure of sensitivity derived from signal detection theory. Data have been obtained from 76 subjects, each of whom was tested in two directions (34 upward, 36 downward, 21 backward, 19 forward, 18 leftward, and 18 rightward). For all directions sensitivity (d') increased monotonically as the distance from the reference location increased. However, we also found differences in sensitivity between directions at some distances. For example, sensitivity was greater for rightward and leftward displacements than for downward and backward ones at 2cm and 3cm (permutation tests, p<0.05). Sensitivity was also greater for upward and forward displacements than for downward and backward ones at 3cm (permutation tests, p<0.05). These data confirm previous findings that the ability to estimate the position of the limb via proprioception is anisotropic across a 3d workspace, which has important implications for understanding the multisensory planning and control of reaching movements in 3D space.

Title: Segregated processing of reach depth and direction signals in the macaque area PE

Authors: M. DE VITIS^{1,2}, K. HADJIDIMITRAKIS^{1,3}, R. BREVEGLIERI¹, *A. BOSCO¹, C. GALLETTI¹, P. FATTORI¹

Abstract: The posterior parietal cortex (PPC) includes several anatomically and physiologically defined areas that combine visual and somatosensory information with motor commands to generate appropriate arm movements in the three-dimensional space. Over the years, the role of several PPC areas in the encoding of arm movements in different directions has been extensively studied, but few works have investigated the processing of reach depth and the relative influence of these two signals in the reach-related activity. Area PE (Brodmann's area 5), located in the rostral part of the PPC, is one of the key nodes of the reaching circuit of the medial PPC and has strong projections to the primary motor cortex. In the present study we examined the relative influence of depth and direction information on neurons of the medial part of area PE and characterized their temporal evolution over the course of a fixate-to-reach task in darkness towards targets placed at different depths and directions. The same task configuration was used in the studies of neighboring superior parietal lobule areas V6A and PEc (Hadjidimitrakis et al., 2014, 2015), thus allowing us to compare direction and depth processing between the three PPC areas. Single unit activity was recorded from two Macaca fascicularis (N= 120) and was quantified within four main epochs: target fixation, reaching preparation, execution, and target holding. We found reach-related cells in PE tuned by target depth (16%) and by direction (12%) and by both of these signals (6%, average percentages across task epochs), and these modulations were differently distributed across the task epochs. The tuning of activity by direction was strong at the beginning of the task, whereas the depth tuning mainly occurred during movement execution. Our study shows that different populations of cells code for reach depth and direction, thus arguing for a segregated processing of depth and direction information in PE. This finding is in contrast with evidence from V6A and PEc where high and intermediate, respectively, degree of convergence of depth and direction signals has been reported. Altogether the results from the three areas suggest a gradual parcellation of spatial information that occurs in a caudal-to-rostral fashion in medial PPC. This coding scheme parallels the increase of somatosensory and the simultaneous decrease of visual processing observed along the caudorostral axis of the medial PPC, and it also correlates with the reference frame transformations from extrinsic to intrinsic coordinates that occur in the same direction.

Title: Relationship between muscle synergies and physical performance in patients with hemiparesis

Authors: *T. KAWASE¹, A. NISHIMURA², A. NISHIMOTO², F. LIU², Y. KIM¹, H. KAMBARA¹, N. YOSHIMURA¹, Y. KOIKE¹

¹Tokyo Inst. of Technol., Kanagawa, Japan; ²Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Previous studies have suggested that damage to central nervous system may alter muscle synergies, coordinated activities of multiple muscles that organize modules for motor control. To investigate the alternation following the damage will facilitate more effective design of neurorehabilitation technologies. Most of the studies have focused on muscle synergies of the patients recruited during simple tasks, such as isometric force generation or reaching movements, and contributed significant insight into the research field. We have investigated how the muscle synergies were modulated during a peg transfer task in patients with hemiparesis toward the realization of effective neurorehabilitation systems covering complex movements. In the present study, we investigated relationship between the muscle synergies and physical performance, which was measured by Fugl-Meyer (FM) assessment, in patients with hemiparesis. Thirty-two patients with hemiparesis (FM upper arm score 15-64) picked a peg on 3×3 grid points on a board and placed it out of the board sequentially by using their affected arms. Fourteen able-bodied subjects also performed the same task. We estimated a set of muscle synergies for each subject by applying nonnegative matrix factorization to electromyographic signals measured during the task, and classified the synergies into 14 classes by using a hierarchical clustering method. We investigated which class of the synergies affected the FM upper arm scores by using lasso, which is a sparse regression method that can select relevant variables to the explanation, with binary variables that indicated the synergy was detected in the patient or not as explanatory variables and the FM upper arm score as response variables. The results of the regression showed that the FM upper arm scores could be explained moderately by using only variables for 3 classes of the synergies (correlation between measured and estimated FM upper arm scores 0.73). Two of the classes, which had concentrated activity on anterior deltoid or biceps, were assigned positive weights (i.e. increased the scores), and the

other one, which had co-contraction on shoulder muscles, was assigned a negative weight (i.e. decreased the scores). Post-hoc logistic regression with the FM upper arm score as an explanatory variable showed that probabilities of detection of the synergies in the patients significantly depended on the FM upper arm scores (p < 0.05).

These results suggested that the extracted muscle synergies had relationship with physical performance in the patients. The results may be useful for development of new neurorehabilitation technologies.

Title: Neurobehavioral effects of sensory loss and augmented feedback

Authors: *J. T. JOHNSON¹, L. A. WHEATON²

¹Applied Physiol., Georgia Inst. of Technol., Atlanta, GA; ²Applied Physiol., Georgia Tech., Atlanta, GA

Abstract: Motor planning and control are influenced by the availability and reliability of sensory feedback. When proprioceptive sensory feedback is deficient or unavailable, compensatory processes may increase function, but may come at the price of increased cognitive load or decreased quality of movement. It is unclear whether augmented feedback, such as vibrotactile feedback, can ameliorate the effects of these sensory changes. By assessing neural and behavioral activity during a well-characterized motor task with sensory reduction and augmentation, the role of augmented sensory feedback for motor control can be assessed. Electroencephalography (EEG) and kinematic data were gathered while persons (n=12) with sound limbs using a prosthetic limb simulator performed a repetitive reach and grasp task involving medium, small, and large discs. The participants were divided into two groups, one with full vision, and one with a barrier that occluded their vision during the reach and return phases of a reach-grasp- transport-return task. Subjects in both groups performed the task in two conditions, with or without vibrotactile feedback. We hypothesized that vibrotactile feedback would reduce visuomotor cortical network activation with accompanying improvements in efficiency of motor behavior. Neural results for the vibrotactile condition show decreased activation of the visuomotor cortical network in the full vision group, while the occluded group

showed decreased activation of the frontoparietal network. Kinematic results showed no significant effect of vibrotactile feedback on transport velocity. There was a significant effect on aperture, but only for the large disc. In conclusion, the effect of vibrotactile feedback supports our hypothesis regarding neural activity, yet kinematic results appear minimal. This may demonstrate the limitations of artificial sensory feedback for improving motor behavior independent of sensory adaptations following sensory loss.

Title: Involvement of the posterior parietal cortex in online control of reaching

Authors: *L. MIKULA^{1,2}, L. PISELLA¹, G. BLOHM³, A. Z. KHAN²

¹Equipe ImpAct, Ctr. de Recherche en Neurosciences de Lyon, Inserm U1028, CNRS UMR5292, Bron, France; ²Ecole d'optometrie, Univ. de Montreal, Montreal, QC, Canada; ³Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Optic ataxia is a consequence of brain damage to the posterior parietal cortex (PPC) resulting in errors during visually-guided arm movements. Because the PPC is known to be involved in multisensory integration processes, optic ataxia has been proposed to originate from a deficit of transforming sensory information into an accurate reaching movement. Optic ataxia patients are paradoxically more accurate when they point toward remembered targets indicating that they do not benefit from on-line motor control (lack of hand automatic pilot). Accurate reaching relies on a comparison between hand and target positions before and during movement execution. In the case of a visual target, this comparison can be cross-modal (when only proprioceptive information about the hand is available) or visual-to-visual (when visual information is also available for hand location). In order to investigate the role of the PPC in these hand-target comparisons at different phases of the movement we asked a patient with unilateral optic ataxia to reach to remembered peripheral positions of visual targets while maintaining fixation under three different conditions: without vision of the hand (noV), with vision of the hand only before the movement (startV) or during the entire reach (fullV). Six neurologically intact control participants also took part in this experiment. Overall, reaching errors of the patient were reduced by 38% in the fullV as compared to the noV condition. However, such an improvement was not found in the startV condition, suggesting that the optic

ataxia patient benefitted from hand visual information only at the end of the movement. This finding suggests that the optic ataxia patient can perform correct reach movements only when proximal visual-to-visual comparison is possible between hand and target locations. Together, these results indicate that the PPC is involved specifically when the visual target location has to be compared with hand location informed from proprioception or from internal models. In addition, visual information of the hand at start does not improve the ongoing dynamic prediction of hand location. This could also be due to inability to process visuo-visual comparisons at further distances due to impairments of visual localization in peripheral vision.

Title: What is the best methods to determine reaction times

Authors: *J. B. SMEETS, E. BRENNER

Human Movement Sci., Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Reaction times can be measured and analysed in many different ways. By comparing several options we show that the method that one chooses influences both the judged reaction time and, more importantly, conclusions about how the reaction time depends on the circumstances under study. We compared simple auditory reaction times in two conditions: one in which the response amplitude was constrained and one in which it was not. One might expect that adding constraints will increase reaction times. Indeed, when the reaction time was defined as the time that was needed to release a micro-switch (i.e. to raise the finger by 0.5 mm) it was longer when the amplitude was constrained than when it was not. However, constraining the amplitude of the response makes the response less vigorous, so determining the reaction time on the basis of a fixed displacement, even if it is a very small displacement, could make the reaction time appear to be shorter for a more vigorous response, even if the moment of movement onset is unaffected. We therefore analysed the data in various alternative ways. Reaction times determined in what appeared to be the most reliable ways were not systematically longer for the more constrained movements. The most reliable methods use extrapolation of the change in the average force that the finger exerts on the surface or of the change in the finger's average acceleration to estimate the reaction time.

Title: Reaching for water: A novel cortex dependent forelimb task for mice

Authors: *C. BONARDI, G. GALINANES, D. HUBER Fundamental Neurosci., Univ. of Geneva, Geneve, Switzerland

Abstract: Cutting edge genetic and optical tools to study neural circuits in the mouse only gain their full potential in combination with well-controlled behavioral paradigms. In rodent motor research, the "reach-to-grasp" behavior has proven to be a powerful paradigm because it closely resembles that of primates and it has been well characterized in the context of stroke and Parkinson's disease. However, the classical reaching for food pellets in rodents also has some technical shortcomings and its use under head-fixed conditions is rather limited. Here, we explore a novel version of this paradigm in which mice are trained to reach for water droplets instead of food pellets. We found that freely moving mice immediately engage in this water droplet reaching task and become fully proficient after 5 training sessions, performing hundreds of reaching trials per hour. Importantly, the "reach-to-grasp" kinematics for water droplets follow the same sequence described for classical pellet reaching.

Inspired by the classical "center-out" reaching task in primates, we next investigated whether mice were able to perform the task under head-restrained conditions and towards different target locations. We found that head-restrained mice can rapidly learn to locate, reach out and grab water drops presented in different target locations around their snout. Interestingly, not the whiskers, but the olfactory system is principally used for target localization. Optogenetic inactivation of the motor cortex halted the initiation, as well as the execution of ongoing reaching movements.

Taken together, reaching for water has the potential to become a universal and flexible behavioral platform for systems neuroscience research in mice.

Title: The influence of action reinforcement on perceptual decision-making

Authors: N. KUMAR¹, *P. K. MUTHA²

¹Indian Inst. of Technol. Gandhinagar, Gandhinagar, India; ²Indian Inst. of Technol. Gandhinagar, Palaj, India

Abstract: There is increasing appreciation that perceptual decision-making is based not just on features of the stimulus, but also actions we associate with that stimulus. This occurs because sensory predictions generated as action consequences are combined with sensory input during decision-making. Congruent with this, we recently showed that perceptual decisions were better when sensory feedback and predictions were aligned, even when the predictions were modified through learning. Importantly, instability in the modified predictions caused the perceptual system to transition to "natural" predictions for maintaining enhanced perceptual judgments. Why does the perceptual system go back to the default natural predictions? We hypothesized that this is because actions that generate these predictions have been reinforced through everyday experience. Thus reinforcing a different set of actions should create a new "natural" and cause the perceptual system to rely on those predictions. To test this, two groups of subjects adapted to a 10-degree visuomotor rotation via feedback about motor errors and task success. Following adaptation, subjects continued to experience the rotation while receiving feedback about only error (Group 1, non-reinforcement) or only success (Group 2, reinforcement). Subsequently, all subjects adapted to an additional 10-degree rotation, but stabilization of this learning was prevented by a concomitant tone discrimination task. Subjects then performed a perceptual task in which they searched for and reported the color of a predefined visual target that moved on a screen among other distractors while they also moved their unseen hand. Importantly, target motion was congruent with the hand, or rotated by 10 or 20 degrees relative to hand motion. We noted that accuracy of the color report in both groups was initially better for targets that were rotated by 20 degrees. However, for Group 1 subjects, accuracy gradually became better for targets whose motion was aligned with the hand, while for Group 2 subjects, accuracy became better for targets whose motion was rotated by 10 degrees relative to the hand. Thus,

reinforcement of the 10-degree adapted action caused subjects to rely on predictions derived from those actions for perceptual decision-making, but the lack thereof caused increased reliance on the default natural predictions. While this reaffirms that the perceptual system flexibly incorporates the most stable sensory predictions for perceptual judgements, these results suggest that this "stability" is defined by movement success. Thus, perceptual judgements are biased by sensory predictions derived from our most successful actions.

Title: Circle drawing as an objective indicator of handedness

Authors: *N. DOUNSKAIA

Arizona State Univ., Phoenix, AZ

Abstract: Whether a person is right- or left-handed can currently be established only by using subjective handedness questionnaires. However, recent findings of motor control research open an opportunity to develop objective indicators of handedness. It has been shown that in righthanded subjects, control of interaction torque at the shoulder and elbow is accomplished better by the dominant arm compared with the nondominant arm. This causes differences in the shape of the hand trajectories between the arms. In particular, our bimanual study of circle drawing suggested that the nondominant arm stronger deforms circular shapes han the dominant arm. This points to a possibility to use circle drawing as an indicator of handedness. To explore this hypothesis, we assessed quality of unimanual circle drawing in both arms of three groups of subjects, right-handed, left-handed, and ambidextrous. Arm dominance was assessed with two handedness questionnaires. Subjects were presented a template of a circle of 20 cm diameter and asked to repetitively draw a similar circle with the fingertip of each arm on a horizontal table. The circle drawing was performed at a comfortable speed and as fast as possible. The fingertip motion did not leave any visible traces. The table height was individually adjusted to restrict motion of the arm in the horizontal plane of the shoulder. Movements of the arm were recorded. Two trials of 20 sec duration were performed in each speed condition. The quality of circle drawing was assessed by computing the aspect ratio of each circle and averaging this number across the circles in each trial. Right-handed subjects produced more circular shapes compared with their left arm. This difference was more pronounced in fast movements. Left-handed subjects had no significant differences between arms in movements of either speed, although the trend in the fast condition was that the left arm movements were more circular. Ambidextrous

subjects produced more circular trajectories in right arm movements in both speed conditions. An additional finding was that during fast movements, the dominant hand of left-handed subjects distorted the circular shape substantially more than the dominant hand of right-handed subjects. These results extend our understanding of the influence of arm dominance on arm movement trajectories and control. They also indicate that the circle drawing test could potentially be used for objective assessment of handedness.

Title: Co-activation uses early antagonist response in upper limb postural control

Authors: *C. M. SALIBA¹, M. J. RAINBOW¹, W. S. SELBIE³, K. J. DELUZIO¹, S. H. SCOTT²

¹Mechanical and Materials Engin., ²Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; ³HAS Motion Inc, Kingston, ON, Canada

Abstract: The objective of this study was to determine the influence of co-activation on the response to a physical perturbation during a postural control task. We examined the effect of preperturbation muscle activity on the motor response of muscles stretched (agonist muscles) and shortened (antagonist muscles) by the perturbation. Subjects interacted with a KINARM End-Point robot (BKIN Technologies, Kingston, ON, Canada). The subjects moved the endpoint handle to the center of a target and a perturbation pulse (50 ms duration) applied a force to flex or extend the elbow. The perturbation was applied after a random hold time of 1 - 4 s. Trials were successful if the subject returned the handle to the target within 500 ms of perturbation onset and stayed inside the target for 1000 ms. Surface electromyograph (EMG) signals were recorded for muscles spanning the elbow. Background loads were used to increase the baseline activation of agonist muscles to high and low levels. Trials were also performed with agonist and antagonist muscles co-activated. Co-activation targeted baseline muscle activity equal to the levels achieved by the background loads using visual feedback of the EMG signal. Subjects completed the task with greater success when co-activating than when resisting background loads with similar agonist activation. Co-activation reduced overshooting and oscillations when recovering from the perturbation and returning to the target. Agonist muscles exhibited a short latency stretch response and gain scaling when activated through both co-activation and
background loads. Under the co-activation condition, antagonist muscles displayed a burst of EMG activity starting 80 - 100 ms post-perturbation. This early antagonist response was not observed in the background load condition, when the antagonist muscles were not pre-activated. Differences in hand position between the background load and co-activation conditions did not occur fast enough post-perturbation to be attributed to changes in intrinsic muscle properties. The response of the agonist muscles to the perturbation was similar in both the background load and co-activation conditions and did not explain the behavioral differences observed when co-activating. The early antagonist response occurred before reversal of the hand position, while the antagonist muscles were still shortening; thus, the response was not caused by a stretch reflex. This demonstrated an anticipatory response that provided an early braking mechanism to reduce overshoot and oscillations in the recovery from the perturbation, likely improving task performance.

Title: Fitts' law explanation based on human arm dynamics

Authors: *M. TAKEDA, I. NAMBU, Y. WADA Nagaoka Univ. of Technol., Nagaoka, Niigata, Japan

Abstract: During human arm reaching movements, a universal phenomenon occurs in which the end-point accuracy decreases as movement speed increases. More than half a century ago, Fitts conducted a pioneering research on this speed-accuracy trade-off by formulating the relationship between movement amplitude, duration, and accuracy. This relationship is generally known as Fitts' law, which describes the duration *D* of arm movement as a function of the amplitude *A* and target width *W*. When the target width *W* is considered to be an allowable error of the hand endpoint (i.e., the end-point accuracy), Fitts' law represents the speed-accuracy trade-off. In

previous studies, this law has been applied under various conditions (i.e., using different experimental tasks, devices, and subjects). Most, if not all, studies support Fitts' law. Thus, Fitts' law has been widely accepted as a practical evaluation tool for human performance modeling and human-computer interfacing. However, since Fitts' law is an empirically derived model, its theoretical background has not been sufficiently elucidated. To understand the mechanism of the human speed-accuracy trade-off, several studies have sought to improve Fitts' law by generating new models related to the central nervous system or musculoskeletal system. However, conventional model was based on kinematic theory and dynamics was not taken into consideration. Human arm movements are achieved by transforming motor commands through dynamics. Thus, speed-accuracy trade-off characteristics can be explained by the joint torque produced by motor commands. Here, we investigated whether the speed-accuracy trade-off described by Fitts' law can be better explained by joint torque, which is directly controlled by motor commands. To examine the relationships between the movement speed, end-point accuracy, and joint torque, we performed temporally and spatially constrained experiments. A positive correlation was observed between the integrated absolute torque and end-point error, which is a measure of end-point accuracy for the trial-averaged values of each experimental condition. These findings suggest the possibility that the speed-accuracy trade-off described by Fitts' law can be explained by human arm dynamics and its parameters.

Title: Competitive game influences risk-sensitivity in motor decision-making

Authors: *K. OTA^{1,3}, K. TAKIYAMA²

¹Fac. of Engin., Tokyo Univ. of Agr. and Technol., Tokyo, Japan; ²Dept. of Engin., Tokyo Univ. of Agr. and Technol., Koganei-Shi, Japan; ³Japan Society for Promotion of Sci. Res. Fellow, Tokyo, Japan

Abstract: Athletes are required to make a decision about where to throw a ball or where to kick a ball. Recent studies have shown that humans tend to be risk-seeking in motor decision tasks (Wu et al., PNAS, 2009). The risk-seeking strategy is robust; it is difficult to improve the strategy even after 9 days practice of 2250 trials (Ota et al., Sci Rep, 2016). However, it is unclear whether the risk-seeking strategy can be improved. Here we investigated the robust risk-

seeking strategy in motor decision task can be influenced by a virtual opponent in a competitive game because players unintendedly imitate opponent's behavior in a competitive game (Naber et al., PNAS, 2013). Twelve participants performed both a one-player reaching game to maximize total rewards and a competitive reaching game to obtain higher total rewards than an opponent. In each trial, the participants obtained higher rewards if their endpoint of a reaching movement was located closer to a reference line (300 mm from an initial position). However, no rewards were assigned if the endpoint was over the reference line. The participants required to make a decision about where to aim for under risk of no rewards. The participants first performed the one-player game for 5 blocks and then performed the competitive game for 12 blocks. Each block consisted of 10 trials. In the competitive game, the participants confronted either optimal or risk-averse opponent. Optimal opponent set its mean endpoint to be the each participant's optimal mean endpoint that maximized the expected rewards under the existence of their own motor variance. Risk-averse opponent set its mean endpoint farther away from the reference line than the optimal mean endpoint. Consistent with the previous studies, the risk-seeking strategy was adopted in the one-player game. The observed mean endpoint ($279 \pm 7 \text{ mm}$) was significantly closer to the reference line than the optimal mean endpoint $(272 \pm 7 \text{ mm})$ in the last block of the one-player game. However, compared with this block, the observed mean endpoint significantly decreased in the first block of the competitive game (270 ± 7 mm), suggesting that the participant's aiming point approached their optimal endpoint. Furthermore, when the opponent player was optimal, the observed mean endpoint gradually increased from middle to end of the competitive game. In contrast, it plateaued when the opponent player was risk-averse. These results indicate that the presence of the opponent player influences risk-sensitivity in motor decision-making.

Title: Control of arm reaching movements as a trade-off between movement variability and subquadratic effort

Authors: *V. BARRADAS PATINO¹, C. WANG², E. BURDET³, N. SCHWEIGHOFER² ¹Biomed. Engin., ²USC, Los Angeles, CA; ³Imperial Col. London, London, United Kingdom **Abstract:** Our previous study suggested that human arm reaching movements without visual feedback are planned as a trade-off between effort and movement variability arising from signal-dependent and constant motor noise (Wang et al., 2016). Modelling effort as a quadratic function of the motor command can predict qualitative differences between durations of movements in different conditions, but does not predict well the exact movement duration, nor decision making and movement speed in a variety of tasks (Shadmehr et al., 2016). The systematic prediction error of movement duration suggests the hypothesis that effort corresponds to a sub-quadratic function of the motor command. We thus test through simulation of planar arm movements considering a two link arm model with signal-dependent and constant noise how using $|u|^n$ with 1 < n < 2 as effort predicts motion features quantitatively. Cubic splines were used to parameterize the motor command and thus reduce parameter space dimension and speed up optimization. Prediction of arm reaching movement duration is improved with n > 1. This suggests that the central nervous system considers a sub-quadratic effort cost as well as variability due to signal dependent and constant noise to plan movement.

Title: EMG-controlled force field generation: Incorporating muscle geometry and muscle activation dynamics

Authors: *N. LOTTI, V. SANGUINETI

Dept. of Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genoa, Genova, Italy

Abstract: Muscle activity (EMG) has been often used as a control signal to operate a prosthesis. In isometric conditions, EMG activity may be assumed to reflect the force generated by that muscle. Based on this notion, myocontrollers can be used to predict in real-time the forces generated by individual muscles during isometric tasks. This approach has been used to virtually 'remove' individual muscles and to study the resulting adaptation phenomena. Similar approaches have been used to assess motor system modularity. These applications use a proportional myocontroller in conjunction with an isometric force control task, with the limb placed at a fixed location. Extension of this approach to actual movements, using a kind of EMG-controlled force field generation, would enable a deeper insight into adaptive and modular properties of the motor system. To do so would require to appropriately account for (i) the nonlinear dependence of muscle length on arm configuration and (ii) the muscle activation dynamics, which depends non-linearly on muscle length and its rate of change. As a step toward this direction, here we compare three different models of muscle geometry, characterised respectively by (i) constant moment arms; (ii) moment arms described by polynomial functions of the joint angles with fixed coefficients; and (iii) a polynomial model fitted to individual subjects' data. As regards activation dynamics, we also compare a linear model with a Hill-type muscle model, with realistic models of contractile and tendon elements. We focused on planar arm movements while grasping a robot manipulandum. We designed a motor task which alternates reaching movements between seven targets evenly distributed within the workspace, and isometric force steps while the hand is kept fixed within each of the spatial targets. Once a spatial target is reached, subjects had to generate 25 N force steps in twelve directions. We recorded movement kinematics, endpoint force and the activity of seven muscles. Using a constrained optimization procedure, we estimated muscle geometry and muscle activation parameters from these data, for each of the model variants. Fitting performance was assessed in terms of vector correlation, rotation and scaling between observed and predicted endpoint force trajectories. The different model variants exhibited acceptable reconstruction performance in both isometric and dynamic conditions. This suggests that myoelectrically-controlled force field generation in different areas of the workspace and during movements is a feasible way to probe motor system adaptation and possibly to deliver personalized forms of robot-mediated therapy.

Title: Whole body muscle activity in quasi-static force efforts

Authors: N. SPEIDEL¹, P. CHEMBRAMMEL², R. MCNISH⁴, S. N. MCKEEMAN³, *C. LOPEZ-ORTIZ⁵

¹Mechanical Engin., ²Healthcare engineering Systems Ctr., ³Kinesiology and Community Hlth., Univ. of Illinois at Urbana-Champaign, Urbana, IL; ⁴Dance, Univ. of Illinos at UrbanaChampaign, Urbana, IL; ⁵Kinesiology and Community Hlth., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: In the study of human motor control, the synergistic and antagonistic interactions between muscle groups play a large role in the movement and force exertion of the limbs. Determination of the degree to which different muscles are activated during a given action can provide significant insight into how the central nervous system organizes combinations of muscles to perform various tasks. In this poster, we report on the tests on eight participants with no known neurological disorders. All the procedures were approved by the local IRB and informed consent was obtained from all participants before enrolling in the study. The activity of 32 different muscles is compared across 16 different quasi-static force effort tasks to create a mapping between combinations of muscular activation and intended action by the user. Persistent homology, and two different statistical analysis methods, viz. principal component analysis and non-negative matrix factorization (NMF) are applied to the 32 electromyography signals and the six-degree-of-freedom force data to determine the muscles synergies that play the largest role for a given effort. The number of muscle groups in NMF is determined by the modified Akaike information criterion (AICc). The results of the three analysis methods are compared to better understand the mechanisms at play for synergistic muscle activations.

Title: Motor-evoked pain increases force variability in chronic jaw pain

Authors: *W.-E. WANG, A. ROY, S. COOMBES Dept. of Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Conventional approaches to studying motor variability in jaw function use experimental pain models to elicit pain via the delivery of capsaicin injections to the jaw. Evidence using this approach shows that increase in jaw pain is associated with increases in variability of jaw function. However, it is not clear whether individuals with chronic jaw pain also show increased motor variability of jaw force control. The purpose of this study was to investigate the effect of motor-evoked clinical pain on force production in chronic jaw pain. Seventeen participants with a history of jaw pain (> 6 months) and 19 pain-free healthy controls performed visually guided isometric jaw contractions at 2% and 15% of their maximum

voluntary contraction. Self-reported pain ratings (i.e. pre-task and post-task ratings) using a visual analog scale (VAS) were collected on a trial by trial basis. Psychological factors were measured using clinical questionnaires. The findings showed that the self-reported pain and force variability were higher in the jaw pain group relative to controls at both force levels. In the jaw pain group, the self-reported pain was higher at the high force level than at the low force level, whereas normalized force variability was greater at the low force level than the high force level. At the low force level, a multiple linear regression analysis found that disability days, pain intensity, disability score, anxiety, depression, and pre-post pain rating change explained 64.6% of the variance in motor variability. At the high force level, 45.6% of the variance in motor variability was explained by pain duration, pain intensity, anxiety, and the pre-task pain rating. Our observations demonstrate that motor-evoked clinical jaw pain is associated with increased motor variability, and this increase in variability can be predicted based on measures of self-reported pain and psychological measures.

Title: Probing motor priorities with electrical manipulation of neural noise scaling

Authors: F. LUNARDINI¹, D. STERNAD², *C. J. HASSON³

¹Electronics, Information and Bioengineering, Politecnico Di Milano, Milano, Italy; ²Departments of Biology, Electrical and Computer Engineering, and Physics, ³Dept. of Physical Therapy, Movement and Rehabil. Sci., Northeastern Univ., Boston, MA

Abstract: A hallmark of human movement is smoothness. Notably, movement trajectories are not only smooth but are maximally smooth, i.e. they follow minimum-jerk profiles. This phenomenon has been observed in a wide range of human actions and has been interpreted as evidence that the human neuromotor system prioritizes smoothness in motor planning. Conversely, it has been suggested that smoothness may not be a neuromotor priority per se but a consequence of multiplicative neural noise. A minimum-jerk movement minimizes neural command amplitudes, which in turn minimizes multiplicative noise, and therefore minimizes

task performance variance. Since both alternative theories, i.e., that smoothness is a by-product, or, is prioritized in of itself, lead to the same motor outcome - a maximally smooth movement, it has proved challenging to falsify either theory experimentally. To this end, we electrically manipulate the scaling relation of neuromotor noise and observe how the nervous system responds. Previous research showed under isometric conditions that applying a train of electrical pulses to a muscle decreases the coefficient of variation of force fluctuations (Jones et al., J Neurophysiol, 2002), a consequence of a partial reversal of motor unit recruitment. In our paradigm, we: 1) magnified this effect by applying a noisy train of stimulation pulses with an amplitude inversely related to arm acceleration, making large motor commands relatively less noisy than small ones, and 2) applied this acceleration-modulated electrical noise while humans performed an as-fast-as-possible accuracy-constrained elbow flexion movement with their right arm. We hypothesized that if smoothness is a by-product of end-point variance minimization, then when higher accelerations are made less noisy, humans should increase the jerkiness of their movements, allowing them to move faster for a given end-point variance. Conversely, if movement smoothness is a priority, subjects should maintain maximally smooth (minimum-jerk) movements, forfeiting the opportunity to move faster. In our experiment, subjects practiced under four randomized conditions (80 trials each): 1) no added noise, 2) acceleration-modulated electrical noise, 3) constant electrical noise, and 4) a sham condition with noise applied to the non-involved arm. Early results suggest that subjects do increase the jerkiness of their movement profiles when the scaling of their neural noise is electrically altered to make high accelerations less variable. Within a relatively short time, it appears that the nervous system can modify its control strategy to take advantage of its current noise properties.

Title: Sifts in strategic time points of a complex motor task with aging

Authors: *E. THOMAS¹, P. HILT², P. MANCKOUNDIA³, F. MOUREY¹, M. CASTERAN⁴ ¹Univ. De Bourgogne, Dijon Cedex, France; ²Italian Inst. of Technol., Ferrara, Italy; ³Service de Médicine Interne Geriatrie, Hosp. of Champmaillot, Dijon, France; ⁴Univ. de Lorraine, Lorraine, France

Abstract: In this study we compared several temporal characteristics in the whole body pointing movements of ageing and young subjects performing whole body pointing (WBP). As a movement used in daily life that involves significant inclination of the heavy trunk segment, it is important to understand for considerations of equilibrium. We examined two strategic time points during the task - first, the crossover point where the velocity of the Centre of Mass (CoM) in the vertical dimension outstripped the velocity in the anteriorposterior dimension and secondly, the time to peak of the COM velocity profile. Both time points occurred earlier in ageing subjects. The crossover point also showed adjustments with target distance in aging subjects while this was not observed in younger subjects. Studies with a model showed that this temporal adjustment with target distance fit into an optimal control strategy that emphasized stability rather than absolute work as an optimal control strategy. The lack of significant differences in movement duration eliminated this as a cause for the differences observed between the two groups. Comparisons of the head and angular excursions did not reveal any significant differences between the old and young subjects, hence indicating that the observed temporal shifts in the WBP aging subjects took place through modest adjustments of a common movement strategy.

Title: Searching for the genetic components of long-term memory for operant self-learning in *Drosophila*

Authors: *B. BREMBS, W. SUN Univ. Regensburg, Regensburg, Germany

Abstract: In contrast to many other forms of learning, the genetic components of operant selflearning, a kind of motor-learning, are still poorly understood. So far, only Protein Kinase C (PKC) and FoxP have been identified as necessary for operant self-learning. It is also unknown whether the training procedure used in *Drosophila* is capable of supporting long-term (i.e., 24h) memory. Here we tested mutants for the gene *radish*, coding for a RAP-like GTPase activating protein. We found that these mutants do not show any decrement in operant self-learning, but improved operant world-learning, where the flies do not need to show any motor-learning, but color-learning is sufficient. We also tested *rover* and *sitter* flies, alleles of the *foraging* gene, a member of the protein kinase G (PKG) family. We found that PKG does not seem to be involved in operant self-learning, either. We also replicated a difference in heat sensitivity between these two alleles that had been described previously. Both PKG variants as well as a different wild type strain (wild type Berlin) showed savings of the operant memory after a brief (60s) reminder training 24h after the initial training.

In conclusion, operant self-learning appears to be independent of both RAP-like GTPase activating proteins (*radish*) and PKG (*foraging*). Long-term memory of operant self-learning is also independent of PKG activity.

Title: Cortical map plasticity as a function of vagus nerve stimulation intensity paired with motor training

Authors: *R. A. MORRISON, T. DANAPHONGSE, S. SARKER, J. MONG, H. ZHANG, D. HULSEY, K. ADCOCK, S. A. HAYS, M. P. KILGARD, R. L. RENNAKER Univ. of Texas At Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with motor training enhances plasticity of movement representations in the motor cortex. A previous study demonstrated that there is an inverted-U relationship between stimulation intensity and VNS-dependent enhancement of plasticity in the auditory cortex after VNS-tone pairing. Low intensity (0.2 mA) and high intensity (1.6 mA) VNS drive significantly less cortical plasticity than moderate intensity (0.4mA or 0.8 mA) VNS. We sought to determine whether VNS current intensity similarly altered the degree of plasticity in the motor cortex when paired with motor training. To do so, we investigated the effects of a range of VNS intensities paired with forelimb training on reorganization of map representations in the motor cortex. Rats were trained on a motor task in which they pressed a lever twice in rapid succession to receive a food reward. Once proficient, rats were implanted with a vagus nerve stimulation cuff. After a week of recovery, rats were randomized to one of three groups: 0.4mA VNS, 1.6mA VNS, or sham stimulation. All groups returned for five days of training on the motor task, during which VNS at the appropriate intensity was repeatedly paired with forelimb movement. After the five days of VNS paired behavioral training, intracortical microstimulation (ICMS) was used to investigate map representations in the motor cortex. Preliminary data indicates that rats receiving 0.4mA VNS

display a significant increase in proximal forelimb representation in the motor cortex compared to 1.6mA and sham groups. Rats receiving 1.6 mA VNS fail to show an expansion in proximal forelimb representation compared to the sham group. These findings are consistent with the existence of an inverted-U effect on VNS-dependent plasticity in the motor cortex and may provide insight into optimization of VNS parameters for clinical implementation in motor disorders.

Title: Optogenetic stimulation leads to connectivity changes across sensorimotor cortex in nonhuman primates

Authors: *D. B. SILVERSMITH^{1,3}, A. YAZDAN-SHAHMORAD², V. KHARAZIA², P. SABES²

¹Bioengineering, Univ. of California San Francisco, San Francisco, CA; ²Physiol., Univ. of California San Francisco, San Fransisco, CA; ³Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: Brain stimulation is believed to modulate the excitability of neural circuits and increase the likelihood of neuroplasticity. The local effects of stimulation are an active area of investigation; however, the effects on network connectivity remain largely unexplored. Here, we tracked changes in network connectivity across sensorimotor cortex in response to stimulation. We used a large-scale optogenetic interface that enables stimulation of excitatory neurons (AAV5-CamKIIa-C1V1-EYFP) with simultaneous recording of surface potentials (μ ECoG) from primary somatosensory (S1) and motor (M1) cortices. In two macaque monkeys we explored connectivity dynamics using a simple stimulation protocol; we delivered 5 ms laser

light pulses at a frequency of 5 Hz at one or two cortical sites.

We quantified functional connectivity between S1 and M1 by measuring how neural activity propagates through the network. Optogenetic stimulation evokes a direct response in the stimulated area followed by a delayed (3-6 ms), indirect response in the other area. We calculated the inter-area connectivity by measuring the relative amplitude of the direct and indirect evoked responses and by computing the coherence of spontaneous activity between the stimulation site and the other area.

In general, stimulation strengthened the connectivity between S1 and M1. After 50 minutes of stimulation, there was a significant increase in the relative amplitude of evoked responses and in inter-area coherence at the stimulation frequency. To capture the dynamics of these changes, we tracked each of these measures across time. There was a trend of increasing connectivity with continued stimulation.

In addition to the trend of increased inter-area connectivity, stimulation led to heterogeneous changes across the network at a finer scale. To assess these changes, we measured the pairwise coherence during spontaneous activity. Stimulation evokes a network-wide pattern of activity, so the coherence during stimulation is different than the baseline coherence. This difference, which we call *input coherence*, predicted changes in coherence after stimulation, consistent with a Hebbian plasticity model. To further test this model, we delivered more complicated patterns of optical stimulation. Although there were more variable effects on the network, the *input coherence* continued to predict changes in connectivity.

Our results show that stimulation induces changes within and between cortical areas. Regardless of the complexity of the stimulation, connectivity across the network follows the coherence driven by the evoked activity, which is consistent with Hebbian learning.

Title: Effects of chronic antidepressant use on neurophysiological responses to tDCS post-stroke

Authors: *X. LI^{1,2}, S. M. MORTON^{1,2}

¹Dept of Physical Therapy, ²Biomechanics and Movement Sci. Grad. Program, Univ. of Delaware, Newark, DE

Abstract: Transcranial direct current stimulation (tDCS) has gained interest as an adjunct tool to promote motor recovery after stroke. While evidence has shown that tDCS can improve motor performance, there is more limited reporting on the neurophysiological brain changes induced by tDCS post-stroke in the absence of a motor task. Moreover, very few studies of persons with stroke consider the potential effects of medications on the efficacy of brain stimulation. Recently, it has been shown that selective serotonin reuptake inhibitors (SSRIs) alter the effects of tDCS in healthy individuals. Stroke survivors are often prescribed SSRI antidepressants either for the treatment of post-stroke depression or to help promote motor recovery. However, SSRIs may alter cortical excitability differently in healthy vs. stroke-affected brains, or in the acute vs. chronic administration of these drugs. Therefore, we aimed to investigate the neurophysiological effects of anodal tDCS in stroke survivors on vs. off antidepressants. Chronic, unilateral stroke survivors participated in the study, and were assigned to the control or antidepressant group based on their medications. Subjects received real and sham anodal tDCS over the lesioned hemisphere primary motor cortex (M1) over two sessions held at least one week apart. In each session, bilateral motor cortical excitability measurements were collected via transcranial magnetic stimulation before and after tDCS. We compared baseline excitability and responses to tDCS between groups. Results showed that at baseline, cortical silent period durations from the non-lesioned (NL) hemisphere were shorter in the antidepressant group than the control group, indicating less intracortical inhibition. Unexpectedly, motor evoked potential (MEP) amplitudes from the NL hemisphere increased in the antidepressant group after real tDCS, compared to either sham tDCS, or to the control group. All other comparisons were not significant. Given our results, we speculate that anodal tDCS over the lesioned M1 in stroke subjects taking antidepressants may have preferentially affected the excitability of transcallosal neurons, which in turn resulted in an increase in MEP amplitudes through complex inhibitory mechanisms in these subjects and not those not taking antidepressants. In summary, anodal tDCS over the lesioned M1 of stroke survivors seems to have complex effects on cortical excitability, with antidepressant medications and/or the presence of depression, as important factors. Further investigation is warranted and future tDCS studies in stroke should consider examining antidepressant medications as covariates.

Title: Female sex hormones modulate the response to low-frequency rTMS in the human motor cortex

Authors: *L. M. ROGERS^{1,2}, Y. Y. DHAHER^{1,2,3}

¹Shirley Ryan AbilityLab, Chicago, IL; ²Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; ³Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: Background: The importance of sex-specific research has been demonstrated in a growing number of studies but has yet to translate to rehabilitation therapy. Recently, adjuvant therapies aimed at creating short-term neuroplastic change to balance motor cortical excitability after stroke have been particularly effective at diminishing impairment and improving motor function, but few studies have considered the impact of fluctuating sex hormones on these interventions. Objective: Accordingly, the goal of this study was to evaluate the modulatory effect of sex hormones on cortical excitability and the response to repetitive noninvasive brain stimulation in healthy, normally cycling women. Our goal is the lay the foundation for understanding how cyclic fluctuations may impact the treatment of a chronic neurological disease such as stroke. Methods: Serum estradiol and progesterone levels were measured in six healthy female subjects (average age 31.3) every other day for two months. Three healthy males (average age 21) served as a comparison group. All subjects underwent sessions of repetitive Transcranial Magnetic Stimulation (rTMS), with corticomotor excitability tested before and after. Results: We found significantly enhanced rTMS-induced inhibition when serum estradiol concentrations were rising and progesterone concentrations remained low. In contrast, the effect on corticomotor excitability was reversed just after peak estrogen (post-estrogen peak) where the normally down-regulatory rTMS protocol resulted in significant facilitation despite serum estradiol levels remaining high. All six women exhibited enhanced inhibition when estradiol was rising; in all but one woman, excitability increased by at least 30% at post-estrogen peak. Conclusions: These preliminary findings suggest female sex hormones influence the effect of rTMS on corticomotor excitability, and that the nature of this influence varies across the menstrual cycle. More broadly, this study highlights the importance of sex-specific science in rehabilitation research.

Title: Vagus nerve stimulation dependent enhancement of motor cortex plasticity requires noradrenergic innervation

Authors: *D. HULSEY¹, M. SHEDD¹, J. MONG¹, R. L. RENNAKER², S. A. HAYS², M. P. KILGARD³

¹Behavioral and Brain Sci., ²Bioengineering, Univ. of Texas at Dallas, Richardson, TX; ³Behavioral and Brain Sci., Univ. of Texas At Dallas, Richardson, TX

Abstract: Pairing forelimb movements with vagus nerve stimulation (VNS) drives robust plasticity within primary motor cortex (M1). VNS activates cholinergic circuits, which are required for VNS-depended enhancement of plasticity. However, there may be multiple neuromodulatory mechanisms required for VNS-dependent enhancement of plasticity. Norepinephrine regulates plasticity, and the noradrenergic locus coeruleus is driven vigorously by VNS. However, the role of norepinephrine in VNS-dependent enhancement of plasticity is unknown. We hypothesize that noradrenergic innervation of M1 and/or basal forebrain is necessary for M1 plasticity associated with VNS pairing. To test this, we trained rats on a skilled lever press task emphasizing use of the proximal forelimb. After demonstrating proficiency on the task, rats received M1 injections of vehicle or DBH-Saporin to selectively deplete norepinephrine in motor cortex, and underwent implantation of a stimulating cuff electrode on the vagus nerve. Sham and NE-lesioned rats resumed training one week after surgery. After returning to pre-surgical performance, both groups received 10 sessions of training with VNS paired on successful trials. Intracortical microstimulation was performed to derive M1 maps within 24 hours of the final training session. Initial data suggests that sham lesioned animals who receive VNS pairing with successful trials show a robust expansion of proximal forelimb movements represented in M1. Noradrenergic lesion of M1 blocks this VNS-dependent expansion of proximal forelimb representation, indicating that cortical norepinephrine innervation is necessary for VNS driven plasticity. Ongoing experiments will determine whether noradrenergic input to the central cholinergic systems is required for VNS-dependent enhancement of plasticity.

Title: The effect of volitional movement on paired associative stimulation-induced plasticity

Authors: *A. O. ALOKAILY^{1,3}, M. YAROSSI⁴, S. V. ADAMOVICH² ¹Biomed. Engin., ²Dept of Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; ³Dept. of Biomed. Technol., King Saud Univ., Riyadh, Saudi Arabia; ⁴Biomed. Engin., Rutgers Univ., Newark, NJ

Abstract: Paired associative stimulation (PAS) is a recognized technique to induce neuro-plastic changes in the human motor cortex (M1). PAS modulates cortical excitability by pairing peripheral nerve stimulation with transcranial magnetic stimulation (TMS) of M1 in a timingdependent manner to induce Hebbian-like plasticity. To date, PAS is most often performed with the subject at rest. A key question about how to combine PAS and voluntary movement is the timing of stimuli with respect to muscle activation onset. Here, we investigate the effect of PAS on M1 excitability when the stimuli are delivered during preparation or execution of a voluntary movement. Thirteen healthy right-handed subjects (age: 26±3), (9 Male and 4 Female) participated in the experiment. Prior to each session, twenty trials were conducted without stimulation to compute the mean reaction time (RT) for timing of stimulation during PAS. Subjects were instructed to extend their right hand fingers activating the extensor digitorum communis (EDC) in response to a visual cue. Each PAS session consisted of 240 pairs applied at a rate of 0.2 Hz. All subjects completed the following four PAS sessions: Triggering the TMS during: 1) movement preparation (RT-50ms), 2) movement onset (RT), 3) movement execution (RT+50ms), and 4) conventional PAS at rest. TMS induced motor evoked potentials (MEPs) were measured in the muscles of interest prior to and following the intervention to asses changes in corticospinal excitability. The MEPs amplitude was used for statistical analysis. PAS triggered during voluntary contraction (RT+50) or at rest increased excitability, while PAS delivered at the same inter-stimulus interval during movement preparation (RT-50) decreased excitability. Additionally, these changes were significant only for the targeted EDC muscle and not the flexor digitorum superficialis (FDS) indicating a muscle specific effect. Unlike most of PAS studies, our focus was on hand extensors for its rehabilitation importance. The results of this preliminary investigation suggest that the direction PAS induced plasticity was dependent on the order of stimulation and voluntary movement onset. These findings have important implications for the incorporation of PAS into neuromotor rehabilitation training. Future investigations will explore the underlying neurophysiological mechanisms, and possible clinical applications.

Title: Voluntary control of residual antagonist muscles in transtibial amputees: Coactivation, reciprocal activation, and residual muscle plasticity

Authors: *S. HUANG, H. HUANG

Joint Dept. of Biomed. Engin., North Carolina State Univ., Raleigh, NC

Abstract: Electromyography signals recorded from residual muscles of transtibial amputees are a potential neural control source for feedforward myoelectric control of powered prostheses. However, the ability for transtibial amputees to activate their residual antagonistic muscles to reach coordinates in a two-dimensional (2-D) control input space via proportional myoelectric control has not been examined. Understanding the reachable control input space of the residual muscles is required in order to utilize the amputee user's residual muscles for myoelectric control of a powered prosthesis. Peripheral damage to residual muscles results in changes to mechanical properties of the muscle, damage to muscle sensory receptors, and disruption of afferent pathways from the muscle. Disruption of afferent pathways likely affects residual muscle recruitment patterns. The purpose of this study is to examine the voluntary residual muscle activation patterns of transtibial amputees when mapping out a reachable 2-D control input space that requires both coactivation and reciprocal activation of residual antagonistic muscles to maximize the control input space. We asked ten transtibial amputee subjects to move a computer cursor to define a reachable control input space, where the cursor's 2-D position was directly proportional to independent continuous myoelectric control signals from the residual lateral gastrocnemius and residual tibialis anterior. Our results show that the reachable control input space varied widely across amputee subjects ranging from 52% to 81% of the maximum possible control input space (see Figure). The amputee subjects used different strategies to expand their reachable control input space depending on their ability to perform coactivation and reciprocal activation using their residual muscles. Future development of powered prostheses using proportional myoelectric control should evaluate the amputee user's reachable control input space in order to design a controller that can align/adapt to the current state of the amputee user's residual muscle function.

Title: Music training differentially modulates motor cortical activity in healthy young adults

Authors: *P. IZBICKI, S. ANDERSON, E. STEGEMOLLER Neurosci. & Kinesiology, Iowa State Univ., Ames, IA

Abstract: Previous studies have demonstrated that music training may induce neuroplastic effects in the brain, especially in the motor cortex. Furthermore, research using transcranial magnetic stimulation (TMS) in healthy young adults has revealed that listening to music can modulate global motor cortical excitability. However, no research has shown if music training affects how motor cortical excitability is modulated by music listening. Thus, the aim of this study is to determine the effects of listening to music on motor cortical activity in healthy young adults with formal music training. Single pulse and paired pulse short interval intracortical inhibition (SICI) TMS were applied during three conditions: no music, relaxing music, and activating music. Motor evoked potentials (MEPs) were recorded from the first dorsal interossieous muscle using bipolar surface electromyography (Delsys). MEP amplitude was obtained and averaged across each condition. Participants were divided into groups of 1) formal music training < 5 years and 2) formal music training > 5 years. A 2 x 3 repeated measures ANOVA (using gender as a covariate) was completed comparing MEP amplitude between music conditions and music training groups. There was a statistically significant difference (p=0.043) in global motor cortical excitability between music listening conditions with no group effect. However, there was a near statistical difference (p=0.054) in intracortical inhibition between groups. The group with >5 years of training had decreased intracortical inhibition during music conditions as compared to the group with <5 years of training. This suggests that while listening

to music, increased music training has no effect on global motor cortical excitability but has an effect on intracortical inhibition. These results will further elucidate the mechanism by which music affects the motor cortex with implications in both music education and music therapy.

Title: Volitional control of inhibitory neuron subtypes

Authors: *A. MITANI¹, T. KOMIYAMA²

¹UCSD, LA Jolla, CA; ²Ctr. for Neural Circuits and Behavior Rm 304, Univ. of California San Diego, La Jolla, CA

Abstract: Animals have the ability to adapt their behaviors to new environmental demands. A dramatic example is found in closed-loop neural feedback tasks in which animals can modulate the activity of specific neuron(s) that are arbitrarily selected by the experimenters. However, brain circuits consist of diverse cell types and it is unknown how different cell types adapt to new demands. Here, we examined the adaptability of three subtypes of inhibitory neurons (INs) in a closed-loop task with two-photon calcium imaging with mice expressing GCaMP6f in parvalbumin (PV), somatostatin (SOM), and vasoactive intestinal peptide (VIP)-expressing INs. The same two nearby neurons were targeted over multiple sessions, and the mice were rewarded when the activity of the positive target neuron (N+) exceeds that of the negative target neuron (N-) beyond a set threshold. With all subtypes, mice learned to increase the reward rate over several days, but the strategies differed across cell types. When PV-INs were targeted, the activity of N- decreased, but SOM- or VIP-INs targeting led the activity of N+ to increase, with a mild decrease in N- activity in SOM-INs. These results extend the notion of adaptability of

individual neurons to INs and highlight the versatility of neural circuits in adapting to new demands in a cell-type specific manner.

Title: An ERP study of homeostatic plasticity in human motor cortex following artificial syndactyly

Authors: *S. M. LONG, M. M. GARDNER, M. A. GANNON, N. A. PARKS Psychological Sci., Univ. of Arkansas, Fayetteville, AR

Abstract: Examining topographical reorganization in human sensorimotor cortex following amputation and stroke has been instrumental in understanding the neural mechanisms of longterm plasticity and cortical reorganization. An equally vital component to understanding representational plasticity is the delineation of the short-term homeostatic mechanisms involved in the functional reorganization of motor cortex, which are proposed to drive these long-term adaptations. Here, we investigated these mechanisms of homeostatic plasticity in human motor cortex by measuring cortical motor event-related potentials (ERPs) during an artificial syndactyly paradigm. To simulate the digit movement restriction of syndactyly, the index and middle finger of the dominant hand were temporarily fused together with a topical skin adhesive. This fusion constrained the movement of the two digits, necessitating movement together as a single digit. Immediately following artificial syndactyly, baseline motor potentials were recorded in two bimanual motor response tasks: a cued choice response task and a cued go/no-go task. Participants were then given motor dexterity practice under the conditions of artificial syndactyly through several tasks (ex. Purdue pegboard). Motor potentials were again recorded following practice using the same bimanual motor response tasks. Participants returned for a second session where they completed the same procedures and tasks but without artificial syndactyly. Preliminary analyses of motor potentials elicited by the dominant hand indicate that artificial syndactyly resulted in reduced amplitude of early-phase lateralized motor potentials, followed by increased amplitude in the late-phase of the motor potential. These findings may reflect early functional homeostatic adaptations in the motor cortex in response to movement constraints induced by artificial syndactyly.

Title: Influence of age, motor cortex stimulation, and motor training on neuroplasticity

Authors: *C. L. MASSIE, A. BERCOVITZ, B. STAMPER, S. MCGUIRE, K. JEFFERS Occup. Therapy, Indiana Univ., Indianapolis, IN

Abstract: Age-related neuronal changes that impact motor function can lead to a decrease in effective motor control. Repetitive transcranial magnetic stimulation (rTMS) has the potential to modulate neuronal plasticity in healthy aging adults, which may yield changes in motor control. However, little research exists on the influence of age with motor practice or motor practice plus rTMS. The purpose of this study was to examine how rTMS alone, motor practice alone, and rTMS paired with motor practice influenced neuroplasticity and motor skills in healthy adults. Methods: Thirteen subjects participated in the three different intervention protocols, one per visit separated by a minimum of 48 hours. The interventions included 30 bouts of 6 seconds of wrist extension during the motor practice only, 30 trains of subthreshold 10 Hz stimulation during the rTMS only, and a combination of the two during the motor practice and rTMS intervention. To measure the effect of the interventions, the Box and Blocks Test (BBT), wrist extension force steadiness at 20%, and TMS outcomes (cortical excitability and short-interval intracortical inhibition) were assessed immediately before and after the intervention. Change scores for the TMS measures were calculated to measure neurophysiological changes from baseline and data were analyzed using an ANOVA. Results: The BBT data demonstrated a significant main effect for time for the right upper extremity (p=0.02), but not for the left upper extremity (p>0.05). During the force steadiness testing at 20% of max force, there was a main effect for time (p=0.025) but no difference between conditions. A significant interaction was observed in both TMS outcomes across muscles, conditions, and subjects. The combined intervention (motor practice plus rTMS) differentially targeted the extensors versus the flexors. Conclusions: This study highlights trends that rTMS coupled with motor practice has the potential to target active muscle groups (extensors in this study), while inhibiting inactive antagonist muscle groups (flexors). This finding adds to the understanding that pairing non-invasive brain stimulation with motor practice can have differential effects. This is an area of interest that should continue to be explored given the potential clinical implications of this approach.

Title: Task and region specific changes in resting state fMRI induced by short-term motor sequence and visuospatial learning

Authors: *C. THOMAS¹, A. STEEL¹, A. TREFLER¹, G. CHEN², C. I. BAKER¹ ¹Lab. of Brain and Cognition, ²Scientific and Statistical Computing Core, NIMH, Bethesda, MD

Abstract: While prior studies have reported changes in resting-state functional connectivity (rsFC) after learning, the specificity of such effects to particular tasks and regions has not been firmly established. Further, the extent to which any apparent training-related changes in rsFC are influenced by factors such as time-of-day are unclear. Here, we address these issues using a within-subject design involving 19 healthy adults over four experimental visits. Each visit included two scan sessions, at 1000 and 1400 hours (AM/PM). On visits 2 and 3 between the AM and PM scans, participants trained for 90 minutes on either a visuospatial-learning (VSL) or a left-lateralized motor sequence-learning (MSL) task respectively. On visits 1 and 4 (control visits), participants received no training allowing us to model diurnal changes in rsFC. We examined training-specific changes in rsFC in anatomically and functionally-defined task-related networks using seed-based correlation analysis with the bilateral hippocampi (HIPP) and motor cortices (MC), given their involvement in VSL and MSL, respectively. Both HIPP and MC networks showed diurnal fluctuations in connectivity. After controlling for diurnal fluctuations, the effect of VSL on HIPP was evidenced by a training-related decrease in connectivity between the hippocampi and sensorimotor, premotor, and lateral prefrontal cortex, but an increase in connectivity with anterior medial place area and putamen. In contrast, MSL evoked an increase in connectivity between MC and temporal and occipitotemporal cortices, but a decrease in connectivity between MC and the caudate nucleus. Better performance in MSL was positively correlated with an increase in connectivity between MC and putamen and cerebellum and these effects were lateralized to the trained cerebral and cerebellar hemispheres. Finally, we explored the impact of time-of-day and training on large scale resting-state networks. Time-of-day related fluctuations in rsFC in multiple networks were observed. However, short-term motor training strongly modulated the inter-network rsFC with a decrease in connectivity between dorsal motor network to posterior default mode network as well as connectivity between the somatosensory

network and right dorsal attention network. These results suggest that task- and region-specific effects of training can be detected using rsFC, but also underscore the importance of controlling for potential confounds in functional connectivity based analyses.

Title: Voluntary rehabilitation for promoting motor paralysis recovery in intracerebral hemorrhage model rats

Authors: *C. SATO, S. KOEDA, K. SUMIGAWA, M. MIKAMI, K. AKAHIRA, J. YAMADA Hlth. Sci., Hirosaki Univercity, Hirosaki city, Japan

Abstract: Following intracerebral hemorrhage (ICH), the enormous burden of secondary insults causes a deterioration of quality of life and health in surviving patients. Given the fact that the viability of severe stroke patients has increased with technological progress, the importance of post-stroke treatment becomes increasingly prominent. Motor paralysis in particular is one of the severe aftereffects that deteriorates not only bodily function but also mental health. Because recovery from motor paralysis requires long-term rehabilitation, establishment of new therapies is indispensable. Exercise is recognized to be beneficial for promoting recovery of motor function after stroke in general. However, the most effective kinds of exercise for the rehabilitation of motor paralysis are still unknown. Recently, the notion that motor function recovery is promoted by patients' individual psychological factors such as motivation has attracted much attention, but the mechanism of this effect is still unclear. In this study, the purpose was to compare the effects of forced and voluntary exercise for motor function recovery after collagenase-induced striatal ICH in rats. Male SD rats were placed on a stereotactic apparatus and injected with collagenase (200 U/mL) into the right striatum to induce ICH under deep anesthesia. ICH rats were randomly divided into forced exercise (F-Ex. group, n=7), voluntary exercise (V-Ex. group, n=8) and non-exercise (Non-Ex. group, n=10). The F-Ex. group was trained with forced treadmill exercise and the V-Ex. group was trained with voluntary wheel running. The rehabilitation period was 4-14 days after the surgery. Motor functions were assessed using the motor deficit score (MDS) and its subdivisions on days 0-15 in all groups. The animals in all groups were paralyzed severely at 1 day after surgery throughout the period.

Paralytic symptoms continued in the Non-Ex. rats for 2 weeks after the surgery. Both of the trained groups had higher scores in all subdivisions and higher total MDS score than the non-Ex. group. The recovery of the V-Ex. group was faster than that of the F-Ex. group. These data suggest that exercise promotes the recovery of motor function, and that exercise with motivation may be more effective than forced exercise.

Title: Influence of nerve regeneration on anterior cruciate ligament injury healing process in a rat model

Authors: *N. KANEMURA¹, T. KOKUBUN¹, Y. MORISHITA², K. MURATA³, A. NAKAJIMA³, K. MATSUI⁴, K. ONITSUKA⁵, S. FUJIWARA³

¹Saitama Prefectural Univ., Koshigaya City, Saitama, Japan; ²Grad. School of Hlth. and Social Services, Saitama Prefectural Univ., Koshigaya, Japan; ³Grad. Sch. of Hlth. and Social Services, Saitama Prefectural Univ., Koshigaya, Japan; ⁴Kawaguchi Municipal Med. Ctr., Kawaguchi, Japan; ⁵Tokyo Women Med. Univ. Yachiyo Med. Ctr., Yachiyo, Japan

Abstract: [Purpose]Anterior cruciate ligament (ACL) injuries are one of the most common knee trauma during sports activity. The injured ACL is less able to control knee movement. The abnormal knee movement can also damage the soft tissue. These results lead to the instability, loss of motor and sensory functions of the knee joints. Although ACL is thought not to heal spontaneously, we clarified that the ligament heals when normalizing the joint movement(Kokubun 2016).The purpose of this study was to evaluate neurogenesis during the process of ACL healing. [Methods]Adult Wistar male rats (11 weeks old) were randomly assigned to three groups, ACL transection (ACL-T; n=12), ACL transection and controlling abnormal joint movement (CAJM: n=12), Sham op (Sham; n=12). ACLs were harvested for PCR array analysis, histological analysis at 1, 2 and 4 weeks after surgery. Expression of 84 genes was analyzed using RT² PCR profiler PCR array analysis (Neurogenesis; Qiagen). These mRNA expressions were normalized respect to multiple internal housekeeping genes and analyzed using $\Delta\Delta$ CT method. We evaluated the histologic sections at 4 weeks groups using immunofluorescence methods for primary antibodies Protein Gene Product (PGP 9.5), growth associated protein 43 (GAP43), nerve growth factor (NGF), substance P. Secondary antibodies were used Dylight488 and Cy3. [Results] With cutoff more than two-fold change, Up-regulated gene expressions in CAJM were 20 at 1week, 44 at 2 weeks, 26 at 4 weeks, respectively. Up-regulated gene expressions in ACL-T were 11 at 1week,47 at 2 weeks, 22 at 4 weeks, respectively. In CAJM, PGP 9.5, NGF, GAP 43, positive nerves were observed in the bone attachment part of the ACL, the ligament surface, and the synovial membrane. But ligament regressed and neural elements were not observed in ACL-T. [Discussion] We observed to healing ligament at 2 weeks in ruptured ACL in a rat model in our previous study. Normalization of abnormal joint movement increases the expression of synapse formation, neuronal differentiation, growth factor transcription, neural plastic factor, and decreases that of apoptosis factor. Normal movement of the knee joint alters in biomechanical microenvironment changes of the joint. It was suggested that abnormal joint movement continued for a long period of time, the expression of related factors such as nerve regeneration and axonal outgrowth decreased, adversely affecting nerve regeneration. These findings might have important consequences for neural plasticity and regeneration in the neuromuscular system in the knee deficiency.

Title: Implicit learning in a visuomotor skill task mimics the SRTT

Authors: ***J. REIS**¹, M. ULBRICH², M. CURADO³, B. FRITSCH⁴ ²Neurol., ¹Univ. of Freiburg, Freiburg, Germany; ³Neurol., Univ. Med. Ctr. Freiburg, Freiburg, Germany; ⁴Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Motor skill learning contains implicit and explicit memory components that contribute to overall learning. The serial reaction time task is well known for its measures of sequence specific implicit learning, behaviorally expressed as increased reaction times when exposed to blocks of trials that differ from those containing a sequence. Here we probed, whether implicit

learning on a sequential isometric pinch force task would be observable as changes in reaaction time or as other performance measures, namelly target error, movement time, motor skill measure (adopted from Reis et al 2009) and movement smoothness. 46 healthy subjects performed the SRTT-SVIPT version on two consecutive days. Subjects were divided in 4 different groups (2 main experimental conditions, 2 control groups). In the main experiment subjects practiced either 11 random blocks OR 1 random block followed by 8 sequence containing blocks interleaved with 2 additional random blocks to assess sequence specific implicit learning.

In the sequence condition, subjects improved motor skill more than in the random condition. However, greater sequence specific learning was only observed in the reaction times but not in any of the motor execution variables.Interestingly, sujects anchored the beginning of the sequence implicitly to the first item in the sequence, since this was the only target that did not show reaction time prolongation when switched to teh random blocks.

These data suggest that during learning of an implicit version of the SVIPT, sequence specific learning is manifested in reaction times, but two particular item-associations are stored in parallel, one for the start of the sequence and one for the item-item-association.

Title: Modulation of the sodium potassium ATPase function and expression by transcranial direct current stimulation of the right sensorimotor cortex

Authors: *S. BENDAOUD¹, Z. AHMED²

¹Biology/Neuroscience, CUNY Col. of Staten Island, Staten Island, NY; ²Col. of Staten Island, Staten Island, NY

Abstract: Transcranial direct current stimulation (tDCS) is a noninvasive technique used in various therapeutic applications. Studies have shown that tDCS affects neuronal excitability. However, biological effects of tDCS on the underlying tissues remain unknown. The role Na⁺ K⁺ ATPase in the elicitation and maintenance of membrane potentials is established. In the present study, we investigated the effects of tDCS on Na⁺ K⁺ ATPase expression and modulation. Our findings show that the expression of Na⁺ K⁺ ATPase α 1 is significantly increased in sensorimotor cortex after single session cathode stimulation, single session cathode tDCS, and repeated cathode tDCS. Expression of Na⁺ K⁺ ATPase α 1 is significantly reduced in mice treated with single anode tDCS only. Atp1a1 mRNA expression is increased in mice treated with single

session cathode stimulation of the exposed right sensorimotor cortex. Expression of Na⁺ K⁺ ATPase α 3 is significantly increased in exposed sensorimotor cortex after single session of cathode stimulation, and repeated cathode tDCS. Expression of Na⁺ K⁺ ATPase al phosphoserine 943 is significantly increased in exposed sensorimotor cortex after single session of anode stimulation, and anode tDCS. Expression of Na⁺ K⁺ ATPase α1 phospho-serine 943 is significantly reduced in exposed sensorimotor cortex after single session of cathode stimulation and single session of cathode tDCS. Expression of phospho-Darpp-32 is reduced after single session of anode tDCS, but was increased after repeated anode tDCS. Expression of phospho-Darpp-32 is increased after single session cathode tDCS, but no significant changes seen after repeated session of cathode stimulation. Expression of Na⁺ K⁺ ATPase α1 phospho-serine 23 is increased in exposed sensorimotor cortex after single session anode stimulation, single session of anode tDCS, and repeated anode tDCS. Expression of Na⁺ K⁺ ATPase al phospho-serine 23 is reduced after single session of cathode tDCS. Expression of Na⁺ K⁺ ATPase β2 is increased in exposed sensorimotor cortex after single session of anode stimulation, and single session of anode tDCS. These results reveal that tDCS not only causes changes affecting neuronal excitability, but also affects molecular targets involved in the establishment of the membrane potentials. These molecular changes could play the underlying mechanism mediating the long term neurophysiological and functional changes caused by tDCS.

Abstract: Purpose. Cell-based restorative therapies are emerging as promising treatments for stroke. We studied the effects of autologous, bone-marrow derived, mesenchymal stem-cell (MSC) therapy on motor recovery following ischemic stroke.

Materials & Methods. Thirty-one stroke patients (mean age 52 ± 10 years; 20 males; 17 left hemisphere lesions) were enrolled as a part of the ISIS (Intravenous Stem cells after Ischemic Stroke) study, receiving intravenously delivered MSCs, standard medical care, physical therapy and occupational therapy. Study details are provided at:

<u>https://clinicaltrials.gov/ct2/show/NCT00875654?term=ISIS+stroke+stem+cells&rank=1</u>. MSC therapy was randomly administered after baseline assessments and patients were followed longitudinally for two years. The motor Fugl-Meyer Scale (FMS) was used as the main motor performance outcome measure. Lesion location and extent were estimated using 1mm³ T1-weighted brain images. Longitudinal mixed effects linear regression models were used to explore effects of time and treatment on the motor FMS.

Results. All stroke lesions involved the middle cerebral artery territory and most were large (mean volume 102.8 ± 63.4 ml). The mean motor-FMS for both treated and untreated patients increased from 35.4 + 28.1 at one month to 49.1 ± 29.8 at six months and 53.9 ± 30.9 at two years. Sixteen patients received MSC treatment with a mean delay of 33.6 ± 6.1 days and injected doses of 158.2 ± 111.2 million cells. No adverse treatment effects were observed. MSC treatment was associated with better motor performance at all times after treatment (p<0.05) (Figure 1).

Conclusions. This randomized control trial demonstrates that intravenous MSC treatment, given in the subacute period after ischemic stroke, can facilitate clinically significant motor recovery. Confirmation of these results in a larger sample of 400 patients using allogenic stem-cell treatment (RESSTORE http://www.resstore.eu/) is currently underway.

Title: Examining the proportion of brain devoted to various structures across certain mammalian orders

Authors: W. TOMITA¹, S. GRETA³, A. BURRE⁴, D. ROSTAMIAN², K. UNO², N. SCHOTTLER², *W. E. GRISHAM²

¹Neurosci., ²Dept Psychol, UCLA, Los Angeles, CA; ³Neurosci., Univ. of Chicago, Chicago, IL; ⁴Neuroscience, W.M. Keck Sci. Dept, Claremont McKenna Col., Claremont, CA

Abstract: Proportional scaling allows brains of vastly different size ranges to be compared by determining the relative amount of a brain that is dedicated to a given structure. Examining these relative proportions also provides a sense of the differential demand for the functions of a structure across different species and orders. We focused on primates and carnivores in comparison to representatives from 18 other orders and examined the proportional relationship of the hippocampus, striatum, thalamus, cerebellum, and neocortex as a function of the log brain size.

We used images from 61 species from 20 different orders, including 10 Primates and 17 Carnivores from the Comparative Mammalian Brain Collections

(<u>http://neurosciencelibrary.org/</u>). Histological details can be obtained from <u>http://neurosciencelibrary.org/explore/histoprocedures.html</u>. The volume of the whole brain as well as the volume of hippocampus, striatum, thalamus, cerebellum, and neocortex was determined via ImageJ. Cross-sectional areas were summed and multiplied by the sampling interval.

The proportion of the brain devoted to hippocampus, striatum, and thalamus was inversely related to the overall log brain volume. The hippocampus was proportionately smaller in both primates and carnivores relative to the remaining orders collectively. The striatum was proportionately smaller in carnivores compared to either primates or to the other orders collectively, and the striatal proportion did not change as a function of log brain size in

carnivores. The thalamus was proportionately smaller in primates relative to carnivores and the other orders considered collectively.

The neocortex and cerebellum showed different patterns. The proportion of brain devoted to neocortex was directly related to the log brain volume. The neocortex was proportionately larger in primates and carnivores than it was in the other orders collectively, but there was a lot of variation among species. The proportion of the brain devoted to the cerebellum showed no significant relationship with log brain volume. The cerebellum was proportionately smaller in primates relative to other orders collectively, but primates and carnivores did not differ. Species also varied enormously in the proportion of brain devoted to the cerebellum. Both the cerebral cortex and the cerebellum develop late in ontogeny. The proportional data reveal a high degree of variability in these regions relative to other regions. So a rule of late = variable may be suggested. Late developing structures may present more opportunity for various

Title: The auditory system of two pinniped species

Authors: *J. KRUEGER¹, E. C. TURNER², E. K. SAWYER², J. H. KAAS¹ ¹Psychology, ²Vanderbilt Univ., Nashville, TN

Abstract: Pinnipeds (sea lions, seals, and walruses) are carnivorous mammals who have adapted to a life on land and at sea. Very little is known about their central nervous system but recent studies have begun to characterize their sensory systems. Their ape-size brains are marked by an extensive arrangement of sulci and gyri and thus far appear to be similar in their organization to other carnivores such as cats. Here, we extend past anatomical studies from our lab of the northern sea elephant (*Mirounga angustirostris*) and the California sea lion (*Zalophus californianus*) investigating their somatosensory (Sawyer et al, 2016) and their visual (Turner et al, 2017) networks to include the auditory system. Utilizing Nissl substance, cytochrome oxidase, and vesicular glutamate transporters (VGluT 1 and 2), we identified the auditory brainstem, midbrain, and thalamic nuclei in addition to primary auditory cortex. We found that the cytoarchitectural organization of the cochlear nucleus (CN), the superior olivary complex

(SOC), the inferior colliculus (IC), the medial geniculate nucleus (MGN), and the core auditory region (A1) appeared to be similar between the elephant seal (n=1) and sea lion (n=1), with the former featuring slightly larger nuclei across the auditory system. Cytochrome oxidase stained sections of the elephant seal for example revealed a dorsal and ventral division of the CN, at least two subnuclei (the medial and the lateral divisions respectively) of the SOC, a clear division between the dense central nucleus and the dorsal cortex of the IC, the basic MGN subdivisions, and a strong layer IV band in auditory cortex. Similar observations were made with Nissl and VGluT2 in elephant seal and appeared to also hold true in the sea lion brain. Several auditory regions of these two pinniped species exhibited strong similarities with the auditory system of cats making cats an ideal reference for nuclei identification. Furthermore, some architectural similarities were also observed in ferrets and dogs. Thus, these results may provide additional insight in the evolution of large brains supporting a conservation of a set of auditory nuclei across species.

Title: Quantifying the spinal locomotor network-driven oculomotor behavior and its developmental adaptation in larval and adult frog

Authors: *J. BACQUE-CAZENAVE¹, F. LAMBERT¹, M. CAYREL¹, G. COURTAND¹, M. BERANECK², D. COMBES¹ ¹Univ. de Bordeaux INCIA - CNRS UMR 5287, Bordeaux Cedex, France; ²Univ. Paris Descartes, CNPP CNRS UMR8119, Paris, France

Abstract: Body movements require compensatory eye adjustments to maintain a stable visual field. Our previous data from *in vitro* experiments on *Xenopus laevis* revealed that during locomotion, this gaze stabilization is achieved not only by classical visuovestibular reflex feedback but also by feedforward signaling from the spinal locomotor central pattern generator itself. If the spino-extraocular pathway that conveys this efference copy of the locomotor pattern starts to be well known in larval and juvenile Xenopus, the resulting oculomotor behavior remained poorly investigated. This study aims to provide a fine *in vivo* quantification of compensatory eye movements produced by this efference copy before metamorphosis, during larval undulatory swimming, and after metamorphosis, during limb-based swimming. In both

developmental stages, swimming sequences were video-recorded at 500fps in semi-intact preparations lacking visuovestibular sensory inputs, allowing to track eye and tail or limb joints angular positions frame-by-frame. This provides a quantification of amplitude and time relations of the locomotor-induced oculomotor behavior. In larvae, tail undulations produce conjugated eye movements which amplitude (up to 30°) increased with tail movement amplitude (up to 60°) but not with tail swimming frequency (5-15Hz), allowing the animal to maintain a constant gain (eye/tail amplitude ratio, ~0.5) despite the swimming intensity. Eye and tail movement amplitude peaks occurred in phase but with a 10ms lag explainable by the synaptic delay in the spinoextraocular pathway previously estimated from our in vitro experiments. Moreover, those compensatory conjugated eye movements are relevantly modulated during swimming trajectory changes. The locomotor-induced oculomotor behavior seemed to become more robust during larval development. In the froglet, eye movement recordings showed a combination of convergent and retraction eye movements in phase with bilateral synchronous limb extension. Angular eye movement amplitude was much lower (up to 5°) than in larvae. The fine quantification of the locomotor-driven oculomotor behavior in larval and adult xenopus suggests a concomitant adaptation of the feed-forward spino-extraocular command with the maturation of vestibulo-ocular reflexes before and after metamorphosis. This study will bring important information to investigate 1/ interaction between the spino-ocular command and the vestibuloocular reflexes; 2/ cellular basis of spino-extrocular efference copy signaling.

Title: What lies below: A visual tour through Tritonia's brain

Authors: *W. N. FROST¹, M. BRITTON¹, A. FERRIER², J. WANG¹, N. WANG², C. J. BRANDON¹ ¹Dept Cell Biol. and Anat., The Chicago Med. Sch., North Chicago, IL; ²Dept. Biol., Lake Forest Col., Lake Forest, IL

Abstract: Gastropod mollusks have been extremely productive model systems for studies of the neural basis of behavior and learning. Key to this success has been the unusually large size and relatively low numbers of their neurons, and the fact that the neuronal somata are conveniently

organized in typical invertebrate fashion around a central neuropil, facing the experimenter, where they can be readily accessed with sharp electrodes. Inevitably, most recording efforts focus on the minority of neurons visible on the ganglion surface. However, many functionally important neurons lie below the surface layer, invisible and therefore largely unstudied. Our lab uses fast VSDs to optically record the action potentials of up to 200 neurons simultaneously. Because shifting the focal plane of the imaging lens allows recording from neurons at different depths, this work would benefit from a better understanding of how the neurons in the imaged ganglia are physically organized in the layers below the surface (e.g., their sizes, depths, and the number of layers). With this aim, we conducted a serial-section light microscopy study of Tritonia's cerebropleural and pedal ganglia. Ganglia dissected from adult Tritonia were fixed, embedded in epoxy, sectioned either vertically or horizontally at 2 or 5 micron intervals, and stained with Toluidine Blue. After photographing each section, the resulting images were rendered into movies to allow high resolution travel through each ganglion, top-to-bottom and side-to-side. Typical for invertebrate ganglia, *Tritonia's* neuronal somata surround a central neuropil, with each soma sending a single axon to either make local connections or to join axon bundles heading into nerves bound for other ganglia or the periphery. Resolution was sufficient to track many axons from their soma origin to their point of exit from the ganglion. Neurons were readily distinguishable by their large nuclei, which occupied 70-90% of the soma diameter. For the pedal as well as the cerebropeural ganglia, the layers of neurons lying between the sheath and the neuropil ranged from 1 to 8, depending on soma size. In the pedal ganglion, neuron somata ranged from 14 - 280 um in diameter, with the smallest neurons typically located closest to the neuropil. A complete section-by-section count for the pedal ganglion tallied 1885 total neurons. The largest of these had axons up to 55 um in diameter - significantly larger than the somata of the smallest neurons. This study represents the most detailed serial-section atlas of gastropod ganglia of which we are aware, and provides a clear view of the neuronal population under electrophysiological study in this well-established model system.

Title: Using gene expression to define the architecture of the zebra finch arcopallium

Authors: *T. M. KASER¹, M. WIRTHLIN², P. V. LOVELL³, C. V. MELLO³ ¹Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR; ²Computat. Biol. Dept., Carnegie Mellon Univ., Pittsburgh, PA; ³Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: The arcopallium (Arco), a major pallial subdivision of the avian telencephalon, receives projections from several other forebrain subdivisions, originates descending projections that target sub-pallial areas, and is a major output structure through which cortical-like circuits modulate sensory and motor systems. While an exact correspondence to mammalian structures has not been not fully established, some portions of the Arco are thought to correspond to pyramidal projection neurons in cortical layers 5/6, while others may correspond to pallial portions of the amygdala. In spite of its importance, relatively little is known about the internal organization of this brain area. Here we have conducted a gene expression analysis to define the molecular organization of the Arco in a songbird species, the zebra finch, using in situ hybridization for a set of Arco expressed transcripts (mostly derived from the zebra finch gene expression atlas, ZEBrA: www.zebrafinchatlas.org). We found that some transcripts (e.g. C1QL3, ETV1, PCP4, FEZF2) are expressed in broad patterns that help define the borders of the Arco even when they cannot be easily visualized by cytoarchitectonics in Nissl-stained sections. Other transcripts (e.g. SCUBE1, PLPP4/PPAPDC1A, SEMA6A, CBLN2, CCK, NECAB2, ZBTB20, CYP19A1, PLS3, KCNQ5, MGP, CNTN4, SNCA, PVALB, CRHR2, ANXA6) are expressed in patterns that are more discrete, allowing us to segment the Arco into at least five major domains, and further divide them into additional subdomains (e.g. lateral vs. medial dorsal, dorsal vs. ventral medial). We have also identified markers of the song nucleus robustus arcopallialis (RA), although the majority of these do not differentiate between RA and the lateral core of Arco, suggesting a possible evolutionary origin for this nucleus. While several identified Arco domains and sub-domains appear to correspond to Nissl-defined and/or previously described areas, others have not been previously reported, and/or cannot be easily visualized by Nissl. These results represent a first systematic segmentation of the Arco based on molecular criteria for the zebra finch, and provide a basis for future comparative analyses with other avian, reptilian, and mammalian brain organizations.

Title: Perineuronal nets development correlates with developmental and adult neuroplasticity related to song learning in the songbird brain

Authors: G. CORNEZ¹, E. JONCKERS², S. M. TER HAAR¹, O. SHEVCHOUK¹, S. GHORBANPOOR¹, G. F. BALL³, A. VAN DER LINDEN², C. A. CORNIL¹, *J. H. BALTHAZART⁴

Abstract: Perineuronal nets (PNN) are aggregations of extracellular matrix components surrounding the soma of specific neurons, mainly GABAergic interneurons expressing the calcium binding protein parvalbumin (PV+). In mammals, the development of PNN limits synaptogenesis around PV+ neurons and PNNs have been validated as a marker characterizing the end of critical periods for visual system development. In songbirds, song learning is limited to critical periods during ontogeny in closed-ended learners such as zebra finches and to specific phases of the annual cycle in open-ended learners such as canaries that are able to modify their song seasonally. Developmental and adult sensitive periods for song learning are associated with neuroplasticity in song control nuclei, including major morphological changes reflecting neurogenesis and synaptic reorganization The hormonal control of developmental and seasonal neuroplasticity is relatively well documented in songbirds but little is known about its possible regulation by PNN. Interspecific comparisons indicate however that more PNN are present in the song control nuclei of closed-ended compared to open-ended learners suggesting a relationship with song plasticity. To explore the expression of PNN throughout development, we used male and female zebra finch brains collected at different key ages in the song learning process (10, 20, 30, 40, 50, 60, 90, 120 days post-hatch, dph) and we quantified the expression of PNN and their colocalization around PV+ interneurons. The number of PNN and the % of PNN surrounding PV+ interneurons increased progressively during developmental song learning in 3 song control nuclei (HVC, RA and Area X). Females who never sing in this species had fewer PNN than males in HVC and RA, two song control nuclei involved in song production, and their number never increased with age so that they became different from males for all ages after 50 dph. Two separate experiments used adult male and female canaries treated with a subcutaneous Silastic implant filled with testosterone or left empty in control subjects to mimic what happens in the spring when the seasonal plasticity of the song ends and the song crystalizes. Testosterone significantly increased the number of PNN in these forebrain song control nuclei in both sexes. Together these data demonstrate that an increased expression of PNN in the songbird brain correlates with the end of sensitive periods for song plasticity and might thus limit further synaptic reorganization at the end of these periods of behavioral and neural plasticity.

Title: Developmental reconfiguration of the Drosophila ecdysis neural circuit

Authors: *A. R. LAZARCHIK¹, M. ROBERTS¹, H. LUAN¹, F. DIAO¹, F. DIAO¹, B. H. WHITE²

¹NIMH, NIH, Bethesda, MD; ²Labor Molec Bio, NIMH, Bethesda, MD

Abstract: Shedding the exoskeleton to permit further growth is an essential and recurrent step in the development of all insects and requires at each stage the execution of a stereotyped behavioral sequence, called an ecdysis sequence. The motor patterns-and body parts-required for the ecdysis sequence can vary dramatically from one developmental stage to the next, as they do in the fruit fly, Drosophila melanogaster, which undergoes a complete change in body plan at metamorphosis. Despite their profound behavioral differences, the ecdysis sequences of the larval, pupal, and adult fruitfly are all orchestrated by the release of a common, conserved set of neurohormones. The identity of some of the neurons that release these hormones change during development, indicating some malleability in the circuitry underlying ecdysis, but little is known about what changes occur in this circuitry downstream of the key hormones. To investigate changes in the downstream ecdysis circuitry, we have adapted several methods that allow us to track the development of neurons that express the receptors for the ecdysial hormones ETH, CCAP, and Bursicon. These methods include the previously published G-Trace (Evans et al., 2009, Nature Methods: DOI:10.1038/NMETH.1356) and Cre-Dog (Tang et al., 2015, Nat. Neurosci: doi:10.1038/nn.4081) methods, as well as a novel, Cre-recombinase-based method that we call Cre-Trace. Each of these systems relies on the expression of two different markers, one that is directly driven by the transcription factor Gal4, and identifies neurons that are currently expressing the receptor gene, and one that becomes immutably expressed in the neurons that express the receptor gene in response to activation of a recombinase. The latter marker records the complete expression "history" of the the receptor gene, i.e. all neurons that have expressed it—past and present. We have applied the Cre-Trace, which utilizes a split Cre molecule, to track the known changes in expression of Bursicon over development and find that it reports changes similar to those found by other methods. Application of Cre-Dog, which employs a GFPdependent split Cre molecule, suggests a previously undocumented change in CCAP expression in adult abdominal ganglia neurons. We are currently using the G-Trace method to map changes
in the expression of the Bursicon and ETH receptors. Preliminary evidence suggests broad developmental changes in the patterns of expression of both genes.

Title: Systematic identification of ocellar ganglion interneurons and their projections in the brain of *Drosophila melanogaster*

Authors: *J. GOLDAMMER¹, G. M. RUBIN², K. ITO³

¹HHMI: Janelia Res. Campus, Ashburn, VA; ²Howard Hughes Med. Inst. Janelia Farm Res. Campus, Ashburn, VA; ³Dept. of Zoology, Univ. of Cologne, Cologne, Germany

Abstract: Many flying insects possess a secondary visual system besides compound eyes - the so-called ocelli. The ocelli are involved for example in measuring ambient light levels to detect contrast between the sky and land for stabilizing the flight course (e.g. Mizunami 1994). The fruit fly Drosophila melanogaster has three ocelli located on top of the head, two lateral ocelli in the posterior and one medial ocellus in the anterior. Photoreceptors of each ocellus converge into a tripartite neuropil structure, the ocellar ganglion (OCG), which is attached to the dorsal part of the fly brain. As yet, we do not know how neurons in the OCG convey visual information to the brain. We screened several thousand GAL4 expression driver lines of Drosophila to identify and describe the morphology of neurons which innervate the OCG. By using the split-GAL4 intersectional strategy (Luan et al. 2006, Pfeiffer et al. 2010), we were able to generate stable fly lines whose expression patterns are specific to OCG interneurons. We also used the multi-color flip-out technique to provide detailed information about single cell morphology. Our screening revealed three major classes of OCG neurons: 1. Local interneurons, innervating only distinct OCG neuropil portions to for a patchwork of slightly overlapping fibers. 2. Ocellar output neurons consisting of four subgroups. A large axon type with branches in one or two OCG neuropils and terminals in the posterior slope. A cell type innervating all three OCG neuropils and terminals bilaterally in the posterior lateral protocerebrum. A cell type class innervating two OCG neuropils and terminals in the central posterior brain. A descending interneuron type innervating a lateral OCG neuropil and terminals in the contralateral posterior slope and the wing neuropil of the ventral nerve chord. 3. Ocellar input neurons consisting of three subtypes. Two

types with branches in the posterior brain and terminals in one or two OCG neuropils, and a cell type with numerous branches in several brain regions and terminals in all OCG neuropils. These OCG interneuron-specific driver lines can further be tested with optogenetic stimulation or silencing experiments to facilitate better understanding of their functions in visual processing.

Title: Anatomy and function of distinct groups of sensory neurons in the femoral chordotonal organ of *Drosophila*

Authors: A. S. CHOCKLEY, S. RATICAN, V. GODESBERG, A. BÜSCHGES, *T. BOCKEMÜHL

Dept. of Animal Physiol., Univ. of Cologne, Koeln, Germany

Abstract: Most terrestrial animals rely on legged locomotion (i.e., walking) for many behaviors such as foraging, courtship, and escape. To fit this behavioral variability, walking must be adaptable to internal and external perturbations, such as general motor output variability, unforeseen obstacles, and variations in the walking surface. Therefore, sensory signals must continuously encode and transmit the state of the extremities for animals to produce sensible locomotor output. The motor output required for locomotion in general relies on not only inherently rhythmic neuronal networks (central pattern generators) but also sensory signal-based modulation and adaptation of these networks. Insects have six ambulatory legs that must be coordinated during walking to reliably transport them through their environment. Insect legs contain many sensory organs that measure various aspects of walking, like tactile stimuli, the angular position of leg segments, and load. Among these structures, the femoral chordotonal organ (fCO), an internal proprioceptor in the proximal femur, has been well-studied. It contains dozens to hundreds of neurons, depending on the species; studies have shown that, in addition to detecting substrate vibrations, the fCO provides important information about the leg's state during walking by measuring the position, velocity, and acceleration of the femorotibial leg joint. In Drosophila, it is unknown whether these movement variables are measured by subgroups of fCO neurons. To address this and to characterize the internal organization of the Drosophila fCO in greater detail, we investigated the morphology and function of fCO neurons using ten Gal4 driver lines that sparsely label fCO primary sensory neurons. We found that the distribution of

these neurons within the fCO as well as their central projection patterns varied between Gal4 lines. We then optogenetically activated these neurons in quiescent flies while monitoring tibia position to test for influences on muscle activity. Notably, some Gal4 lines generated tibial flexion, some tibial extension, and some produced no response. Finally, we inhibited these fCO neurons optogenetically in the intact fly in a free-walking paradigm. While the effects on walking were mostly mild, there were clear qualitative differences between the various Gal4 lines, suggesting that these subsets of neurons encode different movement parameters of the femorotibial joint. Our findings add to the understanding of the functional structure of the dipteran fCO and the role of information about various movement parameters during walking.

Title: Non-visual functions of opsins in Drosophila larval mechanosensors

Authors: *D. GIRALDO-SANCHEZ¹, D. ZANINI¹, B. R. H. GEURTEN¹, M. ANDRÉS^{1,2}, M. C. GÖPFERT¹

¹Univ. of Göttingen, Goettingen, Germany; ²Ear Institute, Univ. Col. London, London, United Kingdom

Abstract: Evidence is accumulating that opsins can sense more than light. In Drosophila, opsins were recently implicated in larval temperature preference behavior and in hearing in adult flies. Here, we report that Drosophila larvae also require visual opsins for locomotion, and show that the proprioceptors that control locomotion express these opsins. Opsin mutant larvae had reduced muscle contraction amplitude, frequency of peristaltic contractions, locomotion speeds and crawling agility. A genomic rescue of the respective opsin gene restored normal locomotion. Opsin-dependent locomotion defects closely resembled the locomotion deficits of mutants whose chordotonal neurons are impaired. Promoter-fusions revealed that opsins are expressed in the serially arranged, proprioceptive chordotonal neurons in the larval body wall. Opsin expression was confirmed with antibodies, and chordotonal neurons seemed to be the only neurons that express opsins outside the larval eye. This strongly supports the idea that light-independent opsin functions evolutionarily predated their use as photoreceptor proteins.

Title: Generation and utilization of sensory signals encoding force decreases in insect legs

Authors: *S. N. ZILL¹, S. S. CHAUDHRY², C. J. DALLMANN³, T. HOINVILLE³, J. SCHMITZ³, A. BÜSCHGES⁴

¹Biomed. Sciences/Anatomy, J.C. Edwards Sch. Med., Huntington, WV; ²Marshall Univ., Huntington, WV; ³Dept. of Biol. Cybernetics, Bielefeld Univ., Bielefeld, Germany; ⁴Dept. of Animal Physiology, Inst. of Zoology, Univ. of Cologne, Cologne, Germany

Abstract: Information from sense organs that detect forces is integral to the control of posture and locomotion. Furthermore, some mechanoreceptors, such as FA1 Meissner's corpuscles of the feet, discharge when forces decrease. In insects, signals of force decrements occur in campaniform sensilla, receptors that detect forces as cuticular strains. However, the specific mechanisms underlying encoding of force decrements and their potential functions in walking have been not been determined. Sensitivity to decreasing forces is not apparently reflected in sensory membrane encoding properties but instead appears dependent upon mechanical properties of the cuticle. In the present experiments, we are characterizing sensory discharges to decreasing forces in stick insects and cockroaches to 1) gain insight into how they are generated and 2) delineate the extent of their effects in walking. Tests use extracellular recording (CS Groups 3, 4 and 6, leg muscles) and application of bending forces to legs as 1) ramp and hold functions and white noise stimuli and 2) joint torques calculated by inverse dynamics from ground reaction forces in freely moving animals. In experiments to date, sensory firing to decreasing forces was invariably phasic and strongly dependent upon the level of load: discharges were minimal/did not occur after large initial load offsets but vigorously reflected the rate of change of force during complete unloading of the leg. Current experiments indicate that these characteristics are also reflected in the motor discharges and activation of leg muscles as synergists elicited by campaniform sensillum stimulation and in discharges recorded during walking in cockroaches. In addition, tests using bending forces applied as ramp and hold functions have shown that sensory firing to decreasing force is strongly dependent upon the duration of the hold phase. We are currently evaluating the contributions of viscoelastic

properties of the cuticle and muscle tensions to this effect. Thus, the information about decreasing forces is strongly context dependent: receptors do not unequivocally encode the magnitude of force decline but are specifically tuned to detect rapid decreases in forces as they approach zero. The resultant sensory bursts can act as cues in detecting leg slipping prior to large changes in joint position and facilitate the onset of swing or compensatory leg lifting. These properties permit detection of critical signals of unloading without the computational cost required to continuously monitor body weight and also provide a specific mechanism for 'emergent' coordination of walking.

Title: Potential dopaminergic modulation rescues acoustic startle responses after lesions of the telencephalon in goldfish

Authors: A. N. OPALKA¹, N. FISCHER², C. A. ANZULEWICZ¹, *R. F. WALDECK¹ ¹Biology/ Neurosci. Program, Univ. of Scranton, Scranton, PA; ²Col. of Osteo. Med., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Goldfish react to a vibratory stimulus with a two-stage, C-shaped turn in the opposite direction of the stimulus known as the acoustic startle response. This response is mediated by Mauthner-cells (M-cells) located in the brainstem, which signal motor neurons in the spinal cord. Acoustic input stimulates the eighth cranial nerve and triggers this response. In previous studies, dopamine was found to enhance the eighth cranial nerve activity suggesting a dopaminergic pathway innervating the M-cell (Kumar and Faber, 1999). Further investigations revealed that full ablation of the goldfish telencephalon significantly decreased the likelihood of a complete startle response (Collins and Waldeck, 2006); however, the precise identification of any upstream influence or modulation of the M-cell in the brainstem has yet to be determined. Preliminary data found similar decreased mean startle angles (MSA) of the acoustic startle response between two different groups of goldfish that received medial telencephalon lesions or immersions of a dopamine D1 receptor (D1R) antagonist (Fischer et al., 2016). In this study, medial portions of the telencephalon were lesioned, and fish were then immersed in a D1R agonist to determine a rescue effect of the acoustic startle response after injury. Acoustic startle

responses were tested and recorded for three consecutive pre-testing days, a post-testing day to determine effect of the surgery, and three post-testing days after a D1R agonist immersion. Statistical analysis revealed no significant difference between the ratio of final post-testing day MSA after D1R dopamine administration to pre-testing average MSA. These findings suggest a rescue effect and possible dopaminergic modulation from the telencephalon to the Mauthner-cell circuitry. Future directions hope to reveal the precise dopamine involvement in this modified startle response and the neuroanatomical projections from the telencephalon to the brain stem.

Title: Comparative study of movement behavior and spiking patterns of the electrosensory nerves in glass catfish under sinusoidal electrical stimulation

Authors: *Y. ADACHI¹, K. TATENO²

¹Dept. of Life Sci. and Systems Engin., Kyushu Inst. of Technol., Kitakyushu, Japan; ²Dept. of Human Intelligence Systems, Kyushu Inst. of Technol., Kitakyushu, Japan

Abstract: Weakly electric fish use the electroreceptors for communication, prey detection, or predator detection. Glass catfish (Kryptopterus bicirrhis) is not electrogenic, but electroreceptive. Nerve impulses in their electroreceptors are modulated in response to electrical stimulation. A few report indicates that the sinusoidal electrical stimulation induces avoidance movements of glass catfish. It is not clear how electrical stimulation was coded as neural activity and induced avoidance movements. We investigated non-linear characteristics of electrosensory nerves of glass catfish to sinusoidal electrical stimulation and its associated behavioral responses. We first observed fish behavior during electric sinusoidal stimulation. Behavior responses of glass catfish to a weak sinusoidal electrical stimulation (250 nA, 500 nA, and 1000 nA) were observed in a circular aquarium located in a dark room. The sinusoidal stimulation current (1 - 100 Hz) was applied to the aquarium for 60 s. The electrical stimulation induced avoidance movements depending on the stimulation frequency and its amplitude. For 250 nA, 1 Hz of the stimulation evoked avoidance behavior. For 500 nA and 1000 nA stimulation, the glass catfish avoided the electrodes in the frequency of 1 - 40Hz, but not 100 Hz. Second, we observed spiking property of

glass catfish (5-7 cm long) were placed in an experimental chamber in which water of 20.3 ± 0.4 C was filled. The stimulation electrodes were placed near the anterior and posterior tips of the fish. Stimulation frequency were 1 - 100 Hz. Stimulation amplitudes were 400 - 2000 nA. Nerve impulses were recorded in an ampullary canal. Spontaneous nerve impulses showed periodic beating. The electrical stimulation altered impulse patterns in the low frequency range of 40 Hz or less. The impulse pattern alternations were also dependent on the amplitude. Nonlinear analysis classified the impulse patterns into 5 groups: periodic beating, quasiperiodic beating, bursting, transition, and unclassified. For the weak stimulation, the quasiperiodic beating or bursting patterns were predominantly observed below 40 Hz. In the low frequency range, the periodic beating patterns of the electrosensory nerves were altered to non-periodic beating or bursting and avoidance movements were observed. Those results indicate that the impulse pattern alternations of the electrosensory nerves were associated with avoidance movements.

Title: Activation profiles of Purkinje neurons during optomotor adaptation in larval zebrafish

Authors: *S. NARAYANAN, V. THIRUMALAI Natl. Ctr. For Biol. Sci., Bangalore, India

Abstract: It is believed that the cerebellum acquires and stores models of sensorimotor transformations. How these models are acquired and modified by learning is not clearly understood. Using the larval zebrafish as a model, we are working towards understanding how the cerebellar circuitry refines sensorimotor transformations to minimize errors in motor output.

We use a custom designed closed-loop behavior setup to engage larval zebrafish in an optomotor adaptation task. In this task, head-restrained zebrafish larvae are placed in a virtual environment that provides optic flow. Tail movements made by the fish are detected in real time and transformed to forward displacement in the virtual environment. When feedback gain of this closed-loop environment is changed, the fish modulate motor output to compensate for sensorimotor mismatches introduced by the gain change. Using this behavioral paradigm, we have currently identified two distinct modes of motor adaptation that occur at different timescales. A fast mechanism, that enables fish to correct for gain changes within a swim bout and a slow mechanism that builds up over several bouts. After adapting to the new gain, fish showed consistent changes in bout velocity, duration and inter-bout interval, indicating that they had acquired novel sensorimotor transformations. To investigate the neural basis of these sensorimotor transformations, we imaged activity in specific cerebellar cell types during motor adaptation. We find both motor and sensory components in the activity profiles of Purkinje cells. We are now looking at how these activity profiles are modulated with respect to the specific kinematic changes observed during motor adaptation. Preliminary analysis shows distinct gain related activity in Purkinje cells.

Title: The weakly electric fish Apternotus displays stochastic resonance

Authors: *W. M. SAIDEL¹, S. SHENDE², A. SHAH¹

¹Dept. of Biol., Rutgers, the State Univ. of NJ, Camden, NJ; ²Dept. of Computer Sci., Rutgers Univ., Camden, NJ

Abstract: Stochastic resonance (SR) is a property of periodic systems in which non-detected signals become detectable with the addition of white noise. Using either direct play-back of its electric organ discharge (EOD) or a sine wave with $f=EOD \pm f$ (where $0 \le f \le 8$), we used the Jamming Avoidance Reflex (JAR) of *Apternotus sp.* to determine if SR is a property of the neural circuit generating the JAR. A program developed in the LabView environment i) digitized the fish's EOD, ii) identified threshold transitions to calculate the CoV, iii) varied the output playback amplitude to the fish, iv) added white noise on demand, v) varied the Vrms of the noise signal when added to the output EOD signal, and vi) recorded and saved to file, the instantaneous EOD frequency. A playback that did not change the coefficient of variation (CoV) of the interpulse interval (IPI) of the EOD was considered subthreshold. Changes in the CoV after

adding varying amounts of noise to a playback or sine wave stimulation revealed the property of Stochastic Resonance, that is, the CoV changed, often by an order of magnitude. The CoV rose more with a smaller amplitude white noise than a greater amplitude when added in a subthreshold playback. In addition to the demonstration of SR, various filterings of the noise spectrum revealed important frequency ranges necessary to eliciting SR.

Title: How a soft surface releases its grasp: Radular opening in Aplysia californica

Authors: *C. E. KEHL¹, D. M. NEUSTADTER³, S. C. LU, 44118², H. J. CHIEL⁴ ¹Biol., ²Case Western Reserve Univ., Cleveland, OH; ³Calore Med. LTD, Or Akiva, Israel; ⁴Case Western Res. Univ., Cleveland, OH

Abstract: Biomechanics is the study of how the physical body both creates and constrains behaviors. Understanding biomechanics provides a necessary link to neural control, as it clarifies the constraints upon and opportunities available to the body. The biomechanics of soft bodied creatures, such as worms, slugs and squids have few limits to their degrees of freedom, making them particularly challenging to model. These systems can also serve as the inspiration for softbodied robots, which could navigate complex terrains or grasp delicate objects. The feeding grasper of *Aplysia californica* is a model system for understanding neural control. The grasping surface is a thin, finely toothed cartilaginous sheet that undergoes conformational changes as it opens and closes. The opening of this grasping surface has been attributed to the action of the I7 muscle, but experiments in our lab have shown only small effects from removing this muscle from intact behaving animals. In contrast, we have discovered fine muscular fibers that adhere to the radular surface. When activated, these fibers produce openings in reduced preparations. Lesions of these fibers greatly impede the opening of the grasper in vivo. We have created a 3D model based on high resolution MRI data, which simulates both intact graspers and those with sub-radular fiber lesions. This model validates the role of the sub-radular fibers in radular opening. Understanding the motor control of the feeding grasper is likely to have implications for understanding the function and dysfunction of other soft structures, such as tongues and the digestive system.

Title: Axonal dynamics during thermal block in unmyelinated axons

Authors: *M. GANGULY¹, M. W. JENKINS², E. D. JANSEN¹, H. J. CHIEL³ ¹Vanderbilt Univ., Nashville, TN; ²Case Western Reserve Univ., Cleveland, OH; ³Case Western Res. Univ., Cleveland, OH

Abstract: Elevated temperatures have been shown to cause propagation block of action potentials in both unmyelinated invertebrate and mammalian axons. Early work suggested that the block was due to potassium currents increasing in speed and "overwhelming" sodium currents. An exact mechanism of the block and the dependence of the block characteristics on axon diameters has not been studied. Recently, through analytical methods, application of infrared laser (IR) light and water bath experiments to Aplysia californica unmyelinated axons, and application of IR to shrew unmyelinated axons, it was shown that small-diameter axons can be blocked at temperatures lower than that required to block large-diameter axons. We explore the mechanism and scaling of axonal block using computational modeling. The computational model consists of an unmyelinated axon that is divided into three regions of different lengths. The first region, R1, is maintained at control temperature of 6.3 °C; the second region, R2, is maintained at a temperature of 25 °C, and the third region, R3, is once again maintained at the control temperature of 6.3 °C. The length of R1 is fixed, and an action potential is initiated at R1 that travels through R2 and R3. The length of R2 is the minimum length of axon required (Lthresh) to produce a block of action potential propagation for a specific axon diameter. The variation of L_{thresh} is shown to be directly proportional to the square root of axon diameter, as shown before through analytical and experimental studies. To confirm the role of potassium ion channels in this observation, dynamic conductance clamps were used along the axon so that the conductance of the various regions of the axon were modulated to mimic the membrane properties that were observed when potassium channels were present in those regions. It was observed through dynamic clamp studies that the traveling action potential wave experiences significant weakening starting at some distance proximal to the onset of the heated region R2. The extent of this distance is a function of the square root of the axon diameter, based on observations of the

spatial extent of the block currents. These studies are likely to provide guidance for the development of novel tools for control of neural activity using thermal modalities such as IR laser, conductive heating, RF or focused ultrasound.

Title: Mechanisms of motor neuronal recruitment for load response in feeding Aplysia

Authors: *J. P. GILL, H. LU, D. N. LYTTLE, H. J. CHIEL Dept. of Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Animals can flexibly and robustly respond to changing conditions in their environment. Understanding the neural mechanisms of flexibility could be useful. In the marine mollusk Aplysia, previous studies have shown a complex response to mechanical loading during feeding (Hurwitz and Susswein 1992). Animals recruit a stronger muscular response to small mechanical loads to generate more force. If mechanical loads are large enough to injure the animal, it may cut and release food. We seek to understand the neural control of this behavior. Previously we have shown that, as animals switch from grasping food (biting) to swallowing, activity increases in specific motor neurons that aid in retraction (Lu et al. 2015). Furthermore, in a reduced preparation capable of feeding behaviors (the suspended buccal mass; McManus et al. 2012), we have preliminary results suggesting that a small increase in mechanical load during swallowing may increase recruitment of these motor neurons, whereas a large increase may actually suppress activity in these neurons. What mechanism controls recruitment of the retractor motor neurons in adaptive responses to load? We have observed in feeding motor patterns a reciprocal relationship between the activity of large units on buccal nerves 3 and 2, corresponding to multiaction neurons B4/B5 and retractor motor neurons, respectively. B4/B5 have inhibitory connections to these motor neurons (Gardner 1993), and they can act as proprioceptors that respond to muscle stretching (Jahan-Parwar et al. 1983). Here we study a hypothesized role of B4/B5 in regulating retractor muscle activation under load. Such a mechanism may allow animals to flexibly adjust motor output in response to mechanical load and may suggest general principles for nervous systems in many other animals.

Title: Methodology for analyzing the performance of muscles of *Aplysia* californica as actuators for biohybrid devices

Authors: *F. R. YOUNG¹, V. A. WEBSTER-WOOD¹, O. AKKUS¹, U. GURKAN¹, H. J. CHIEL², R. D. QUINN¹

¹Mechanical and Aerospace Engin., Case Western Reserve Univ., Cleveland, OH; ²Biol., Case Western Res. Univ., Cleveland, OH

Abstract: A biohybrid robot relies on actuation to navigate areas of interest, allowing it to carry out specific tasks in an open environment. Such biohybrid robots often utilize cells from mammalian or avian sources to provide organic actuation. However, these cells require precise environmental conditions to function. To develop biohybrid robots for use in challenging environmental applications, more robust tissue is needed. To this end, muscle tissue from *Aplysia californica*, which can survive challenging environments, has been used as a robust actuator for biohybrid robots.

Muscles from the feeding apparatus of *Aplysia californica* have been selected as possible actuators. This allows the natural circuitry of the neuromuscular system, which has been well studied, to control the muscle. It is important to characterize the capabilities of the tissue constructs or native muscle tissues that provide propulsive force. Specifically, the I2 muscle has been isolated and characterized using a cantilever force characterization system. The muscle is attached between a flexible cantilever and a rigid base, such that the contraction of the muscle deflects the cantilever and the force can be calculated.

Using this platform, the force capabilities and fatigue properties of the muscle have been assessed under different stimulation protocols. These protocols are based on three ways of actuating the muscle using direct electrical stimulation, nerve stimulation, and neural circuit stimulation, because neuromodulation of muscle force through circuitry has been well documented in *Aplysia*. The cantilever force characterization platform was used to compare these

protocols. Stimulation via the ganglia, and thus via the natural neural circuitry, resulted in significantly higher force output than either direct electrical stimulation or nerve stimulation (p<0.05), with a mean force of 0.1 N. Additionally, direct electrical stimulation of the muscle resulted in the fastest rate of fatigue. In the future, the force and fatigue capabilities of the extrinsic muscles will be investigated to develop biohybrid devices capable of steering.

Title: Combining temporal structure with quantified bursting character aids in ENG classification

Authors: *J. P. SASSE, J. GILL, P. MYERS, M. CULLINS, H. LU, J. M. MCMANUS, H. J. CHIEL

Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Flexible and robust neural pathways are ubiquitous in animals. Behavioral flexibility is necessary to survive in unpredictable and changing environments. Previous work has demonstrated that variability in feeding behavior in the marine mollusk Aplysia californica can be useful to the animal - in general, motor components relevant to feeding show higher variability within animals, even as they vary less across different animals. (Cullins et al. Current Biology 2015). In this research, we have begun to investigate how to determine common patterns within this variability as a step towards automated analysis of neural recordings for behavioral prediction using a Bayesian network based neural net. Custom Mathematica software was written to carefully map the specific order of activation of motor neuronal bursts extracellularly recorded from the key protractor muscle (I2) and motor nerves (buccal nerves 2 and 3 and the radular nerve) that control the feeding apparatus (the buccal mass) of Aplysia californica during both biting and swallowing behaviors. Results of initial studies showed there is some conserved structure within individual animals and across different animals. Associating basic statistics for activity in each recording channel (i.e., duration of bursting, mean instantaneous firing frequency, and integrated rectified amplitude) with maps of conserved structure led to classification accuracy of 78% (n = 1000, std. error = 0.002 ± 0.001). This combination improved upon the success rate using only basic statistics (72%, n = 1000, std. error = $0.002 \pm$ 0.001) and only structural maps (70%, n = 1000, std. error = 0.002 ± 0.001) considerably. We plan to construct a neural net and to train it using the previously described structural and channel

information. Should this procedure lead to accurate behavioral classification, it will be of general interest as, in theory, the technique will be implementable within a wide range of biological signal analysis settings.

Abstract: Because of its large, identified neurons, the buccal ganglion of Aplysia californica is a model system for understanding the neural basis of feeding behavior, which provides insights into motivated behavior and multi-functionality. We are monitoring in real time the activity of multiple key neurons in the neural circuit that controls feeding behavior. To this end, we are combining nerve recordings of the circuit's motor output with recordings of cell bodies of neurons in the neural circuit using a two-dimensional, high-density (100 um pitch) microelectrode array (MEA, 120 electrodes). The majority of previous studies have focused on recordings from single neurons, or small groups of neurons. However, many interesting aspects of neural dynamics can only be understood by looking at large populations of neurons and their relationships to each other. We are using the MEA and at the same time recording from buccal nerves 2 and 3, the radular nerve and the I2 muscle to identify motor neurons on the array during motor patterns, and distinguish them from interneurons. We have successfully recorded from large identified neurons in the ganglion while recording one to one extracellular action potentials in the nerves. At the same time, we can monitor the extracellular potentials and current densities throughout the ganglion. Our preliminary data suggests this approach will provide deeper insights into a pattern-generating circuit.

Title: Global DNA methylation patterns in the brain of the black-capped chickadee (Poecile atricapillus)

Authors: S. D. AITKEN¹, C. A. BLACKMAN², I. C. WEAVER³, *L. S. PHILLMORE¹ ¹Psychology and Neurosci., ²Biol., ³Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Like other songbirds, black-capped chickadees (*Poecile atricapillus*) have specialized neural regions for song production, perception, and learning. In addition, they are well-studied for their spatial memory and its associated neural underpinning, the hippcampus. Previous research has typically focused on short-term neural changes in perceptual regions in response to acoustic stimuli; however, long-term changes in these regions have not been investigated to the same degree. DNA methylation is one of several persistent epigenetic mechanisms that change the accessibility of DNA to be transcribed; increased levels of DNA methylation block transcription and can affect behavioural memory formation and maintenance. We were interested in whether global patterns of DNA methylation in various regions (caudomedial nidopallium NCM, caudomedial mesopallium CMM, HVC, and hippocampus) differed between male and female chickadees. We were also interested in whether learning ability on an operant discrimination task was related to levels of methylation in perceptual regions. Using 5-Methylcytosine (5mC; a marker of DNA methylation) and NeuN-a neuronal marker, we labeled tissue from male and female chickadees that had participated in a discrimination paradigm. Preliminary results show there are no differences in levels of DNA methylation between males and females in perceptual regions, but there is evidence of lateralization of methylation between hemispheres in CMM. This study lays the groundwork for investigating acquired and heritable changes in DNA methylation at regulatory sites of genes involved in song perception and learning.

Title: Interspecific divergence of cis- and trans-regulation for gene expression associated with species-specific learned vocalization

Authors: *W. HONGDI, A. SAWAI, S. HAYASE, K. WADA Hokkaido Univ., Sapporo, Japan

Abstract: Birdsong is acquired through vocal learning with species-specific constraints. Over 3,500 songbird species produce their unique songs using evolutionally conserved song circuits across species. Interspecies variation of gene expression in the song circuits is considered a crucial regulatory factor for species-specific vocal learning. Previous studies showed that cisand/or trans-regulatory changes during evolution contribute to interspecific gene expression patterns. However, it remains unknown how the regulatory mechanism of interspecific gene expression affects species-specific learned vocal pattern. Here we show that gene expression in the song circuits is regulated by both interspecific divergence of cis- and trans-regulation, which are also associated with species-specific song pattern. Whole transcriptome analysis revealed 1,730 and 1,620 genes in RA and HVC, respectively, as differentially expressed genes between zebra finch (ZF) and owl finch (OF). Using species-specific SNPs between ZF and OF, 403 and 505 genes were differentially regulated with allelic imbalance bias in their F1 hybrid's RA and HVC, respectively. Analysis of regulatory mechanisms showed that both cis- and transregulations play important roles in interspecies different expression in the motor circuits nuclei. Furthermore, cis- and trans-regulated genes are significantly enriched in some cluster of genes that were significantly correlated with acoustic and sequence features of their learned song. These results suggest a potential contribution of both cis- and trans-mechanisms in the regulation of species-specific gene expression and song patterns.

Title: Enhancing vocal learning: Gene regulatory specializations in the song circuit

Authors: *L. CANTIN¹, M. WIRTHLIN², J. CAHILL¹, G. GEDMAN¹, A. R. PFENNING², E. D. JARVIS^{1,3,4}

¹The Lab. of the Neurogenetics of Language, The Rockefeller Univ., New York, NY; ²Computat. Biol., Carnegie Mellon Univ., Pittsburgh, PA; ³Howard Hughes Med. Inst., Chevy Chase, MD; ⁴Duke Univ., Durham, MA

Abstract: Vocal learning is a rare trait shared by a small number of distantly related species, such as songbirds, parrots, hummingbirds, cetaceans, bats, elephants, pinnipeds and humans. Similarities in behavior, development, learning and brain circuit structure are found across vocal learning species examined thus far, likely as a result of convergent evolution. In the vocal learning birds and humans, using high throughput transcriptome analyses our groups previously found convergent gene expression specializations (up- or down-regulation) of 10-100s of genes in song regions of birds and speech brain regions of humans relative to adjacent motor learning pathways. Here we begin to ask what are the molecular causes of the specialized gene expression. We performed H3K27ac ChIP-seq experiments on the song production nucleus of songbird (Taeniopygia guttata) RA (robust nucleus of the arcopallium) and the adjacent motor region and comparative genomic experiments across species to identify non-coding regulatory regions of the genes specialized in vocal learning brain regions. H3K27ac is generally associated with active enhancer DNA. Using native ChIP-seq, we identified several hundred H3K27ac peaks with significantly differential activity between chromatin of neurons in songbird RA and the adjacent motor regions, including a subset associated with specialized genes identified in RNA-seq transcriptome experiments. Aligned genomes of avian vocal learning species and their closest vocal non-learning relatives revealed many vocal learning specific accelerated regions in close proximity to specialized genes. We will next combine these data sets to determine whether accelerated regions have differential H3K27ac peaks between RA and adjacent motor areas. These findings suggest that epigenomic regulation at the level of enhancers with accelerated evolution could provide a basis for the molecular specializations associated with vocal learning brain regions. These experiments will help to identify the genetic mechanism in which vocal learning evolves and will benefit research for understanding vocal communication disorders.

Title: Targeting activity-dependent chromatin remodeling pathways to rescue deficits in learned vocal communication

Authors: *C. M. AAMODT¹, C. FUENTES MARTINEZ², J. T. WEISS¹, S. A. WHITE¹ ¹Neurosci. Interdepartmental Ph.D Program, ²Dept. of Biol. Chem., UCLA, Los Angeles, CA

Abstract: In striatal regions activated during learned vocalization, the transcriptional profiles of zebra finches and humans are more similar to each other than to more closely related non-vocal learning species. This makes the zebra finch essential for discovering drugs that treat communication deficits. Humans with learned vocalization deficits benefit from speech therapy, suggesting that pharmacologically targeting transcriptional machinery activated by experience could enhance the efficacy of environmental interventions. To investigate activity-dependent changes underlying vocal learning in the basal ganglia song nucleus Area X, we mined gene expression data generated via weighted gene co-expression network analysis and identified several candidate transcriptional regulators that are highly correlated to singing. Upregulation of the microRNA-128 (miR-128) host gene and downregulation of many miR-128 targets associated with human communication deficits were strongly correlated to singing. One target associated with auditory learning in rodents, histone deacetylase 3 (HDAC3), dynamically changed with singing at the protein level. Decreased HDAC3 (and other singing-induced changes in transcriptional regulators) leads to an increase in epigenetic marks associated with histone variant exchange. In line with this, we found a positive correlation between histone variant H3.3 protein and singing in adult birds.

Ginsenoside Rh2, a biologically active compound isolated from ginseng, has been shown to increase miR-128, and downstream pathways related to epigenetic modification in in vitro or peripheral systems. Ongoing experiments using oral administration of ginsenoside Rh2 to

juvenile birds learning their songs are aimed at determining whether or not this drug has an effect in vivo on song control neurons and song learning. Preliminary behavioral analysis suggests that activity-dependent chromatin remodeling underlying learned vocalization may be a promising therapeutic target for treating communication deficits in humans.

Title: Epigenetic mechanisms enable song specific auditory memories in songbirds

Authors: *M. L. PHAN, M. M. GERGUES, S. MAHIDADIA, R. BERNABE, J. JIMÉNEZ CASTILLO, D. S. VICARIO, K. M. BIESZCZAD Psychology, Rutgers Univ. Dept. of Psychology, Piscataway, NJ

Abstract: How do naturally salient sounds like conspecific vocal communication signals have unique access to memory encoding and storage? Long term memory (LTM) for auditory cues depends on neural mechanisms that rely on gene expression for auditory plasticity to encode specific sounds. Because gene expression is regulated by epigenetic mechanisms, we used a selective inhibitor of histone deacetylase 3 enzyme (HDAC3i) to determine whether histone acetylation may gate experience with conspecific vocalizations into long-term memory, following earlier work showing that rats treated with HDAC3i acquire sound-specific memory for the characteristic features of a synthetic but behaviorally-significant pure tone sound (Bieszczad et al., 2015). We now report that HDAC3i in the adult male songbirds enables the transformation of a limited experience with a conspecific song into LTM for that song in the caudomedial nidopallium (NCM). NCM is analogous to superficial layers of mammalian A1 or secondary cortex, and known to function in song discrimination and memory. NCM plasticity appears as stimulus-specific adaptation: evoked responses to familiar (remembered) sounds adapt more slowly than to novel (or forgotten) sounds. Thus, adaptation rate (slope of decrease in response amplitude as a function of song repetition number) between pre-exposed familiar (F) vs. completely novel (N) songs provides a measure of the neuronal strength of memory for familiar songs. Normally, >200 repetitions (200X) of a single conspecific song can produce LTM in adult male zebra finches (revealed in NCM neuronal plasticity >20h later). Here, exposure to only 20 repetitions (20X) of 8 novel zebra finch songs was sufficient to induce

neuronal memory to the 8 previously exposed F songs compared to 8 never-before-heard N songs when the limited exposure was followed by systemic injection of HDAC3i (n=8), but not of vehicle (n=6). Furthermore, we established a link between HDAC3 inhibition and song-specific memory enabled via gene expression. NCMs dissected from birds sacrificed 30-minutes after HDAC3i or vehicle injection reveal HDAC3i induced increases in *zenk* (aka *egr-1*) expression. Strikingly, the effects of HDAC3i on NCM electrophysiology and transcription were lateralized: only left NCM exhibited neuronal memory and increased *zenk* expression in HDAC3i-treated birds relative to vehicle-treated birds. Therefore, HDAC3i transforms sub-threshold auditory experiences into LTM by inducing a lateralized reorganization of the representations of specific, salient sounds, which may naturally gate privileged entry of conspecific vocalizations into long-term memory stores.

Title: Genomics and transcriptomics of ion channel genes in the vocal control system of the zebra finch

Authors: *S. R. FRIEDRICH¹, C. R. OLSON², C. V. MELLO¹ ¹Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; ²Dept. of Physiol., Midwestern Univ., Glendale, AZ

Abstract: Vocal learners acquire complex vocalizations through the imitation of tutors. Studies in zebra finches, a vocal learner songbird species, have revealed significant insights into vocal learning behavior, as well as the anatomical and functional organization of underlying circuitry. A great advantage of this model organism is that we have at our disposal a high-quality genome, brain cDNA/EST libraries, and extensive in situ hybridization and transcriptome datasets of brain gene expression. Because ion channels are essential in determining neuronal firing properties and conducting currents that initiate and propagate action potentials, we have been rigorously examining families of genes that encode ion channels. As a follow-up to our previous survey of potassium channels, we have now performed thorough analyses of sodium, calcium,

and chloride channels, as well as their accessory subunits. We first used genomics analysis to determine which ion channel-related genes are present in the zebra finch genome, making use of best reciprocal alignments and synteny to verify orthology to mammalian genes. We next used in situ hybridization and microarray (cDNA- and oligonucleotide-based) analyses to examine their expression within five key nuclei of the song system -- HVC, RA, and nXIIts in the direct vocalmotor pathway, and Area X and LMAN in the anterior learning-related pathway. We found that numerous members of these families are differentially regulated within several vocal nuclei in comparison to adjacent areas, and that many represent exquisite positive or negative markers of these nuclei (e.g. SCN3B, CACNB4, CACNA2D1.) From these expression patterns, inferences can be made about likely molecular determinants of excitability for each nucleus. Each nucleus is characterized by a diverse set of differentially expressed genes from each family, and there are no cases of unidirectional regulation across all nuclei for any examined channel, suggesting that each nucleus relies on a unique profile of ion channel genes. Of note, several calcium channels are positive markers for both HVC and Area X, suggesting shared upregulation that may be related to properties of the anterior forebrain pathway. These ion channel expression profiles provide insights into nucleus-specific versus shared determinants of firing properties in key vocal nuclei, and offer compelling targets for future manipulation studies.

Title: Development of a more efficient approach for generating germline transgenic songbirds

Authors: *M. T. BIEGLER^{1,2}, A. KEYTE^{3,2}, K. M. JUNG⁴, Y. H. PARK⁴, J. Y. HAN⁴, E. D. JARVIS^{3,2,1}

Abstract: The lack of efficient approaches for development of transgenic songbirds represents an obstacle in assessing the molecular basis of vocal learning. Lentiviral mediated germline transgene expression has been achieved in songbirds, but this approach only allows random knock-in of genes and requires manipulating hundreds of embryos to obtain at least one successful germline transgenic. Recent technical improvements in isolation of avian primordial germ cells (PGC), avian embryonic manipulation, and general CRISPR-Cas9 genome editing have theoretically made transgenic development in songbirds more efficient. Here, we adapted methods used in Galliform birds to attempt to isolate zebra finch PGCs and integrate transgenes into them. Separately, we have successfully used Cas9 targeting of guide RNAs to manipulate the genome of the zebra finch. We are employing these techniques to develop CRISPR-Cas9 expressing chimeras, some of which are currently being assessed for germline transmission. We hope to use Cas9 transgenic offspring to induce targeted knockout of candidate genes through both local viral injections and subsequent embryonic manipulations for global disruption.

Title: Update and applications of the zebra finch expression brain atlas (ZEBrA; www.zebrafinchatlas.org)

Authors: *C. V. MELLO, P. V. LOVELL

Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: We present here an annual update to the Zebra finch Expression Brain Atlas (ZEBrA; www.zebrafinchatlas.org). ZEBrA is a publicly accessible online resource for investigating the brain distribution of genes involved in the physiology, development, and maintenance of functional circuits in the brain of songbirds. It consists of an in situ hybridization database for transcripts expressed in the brain of adult male zebra finches (T. guttata), a songbird species and the major model organism for studying vocal learning. Its major features and recent updates include: (1) The In situ database - an expanding collection of high-resolution (0.46 μ m/pixel) digital images presented along with annotated drawings from a reference Histological Atlas. We have recently added ~150 image sets, so that ZEBrA currently houses more than 2,000 images (>100 GB) corresponding to ~660 brain expressed genes, including markers of all major nuclei that comprise the song system. (2) A reference Histological Atlas Browser - A set of 18 annotated drawings prepared in registration with Nissl- and Myelin-stained images of sagittal brain sections derived from the Karten/Mitra atlas. (3) A Neuroanatomical Marker Search Tool -

A search engine that allows users to retrieve a list of genes that are markers of a given structure, or of multiple structures. Markers of specific song nuclei are now highlighted in the homepage to facilitate access and use of the database. (4) Homepage vignettes that highlight and provide fast access to genes of great interest to songbird biology (e.g. song system markers), human speech and language disorders (e.g. FOXP2 and related targets), human neurological diseases, and membership in gene families (e.g. glutamate or GABA receptors). Recent uses of ZEBrA include: (1) utilizing the in situ database for validation and establishing cut-off criteria for microarray studies of the song system; (2) performing quantitative analysis of regional gene expression patterns, in search of molecular signatures of specific avian brain areas; (3) obtaining evidence of heterogeneity of cellular patterns of gene expression as a basis for cellular phenotyping within vocal control nuclei; (4) utilizing the ZEBrA platform and its embedded features as a resource that can be adopted by individual labs for cataloguing, storing and accessing high resolution brain gene expression data; (5) obtaining molecular data to characterize the internal organization of major avian brain subdivisions (e.g. arcopallium, mesopallium, hippocampus).

Title: Molecular specializations of the tracheosyringeal portion of the hypoglossal nucleus (nXIIts) in a vocal learning songbird, the zebra finch (Taeiniopygia guttata)

Authors: *N. HUIZINGA¹, P. V. LOVELL², C. V. MELLO²

¹Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; ²Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: The ability to imitate novel and complex vocal sounds (vocal learning) has been linked to the ability of forebrain circuits to modulate vocal and respiratory centers in the brainstem. Direct connections between forebrain and brainstem vocal areas have been found in all three vocal learning bird groups (songbirds, hummingbirds, parrots), as well as in humans where they comprise a projection from the laryngeal motor cortex to nucleus ambiguous in the brainstem. In contrast, such projections are absent in non-vocal learning organisms, including

avian orders like galliformes (chicken, quail) and columbiformes (pigeon, dove), as well as mammals like rodents and non-human primates. In birds, while motor neurons within the tracheosyringeal portion of the hypoglossal nucleus (nXIIts) innervate the syrinx, the vocal organ, a direct projection from forebrain nucleus robustus arcopallialis (RA) to nXIIts is only present in vocal learners. This RA-to-nXIIts projection allows for forebrain circuits to modulate vocal output, and is thought to be critical for the production of learned vocalizations. Given the importance of this projection, and the temporal and structural complexity of learned, compared to innate vocalizations, we hypothesized that songbird nXIIts might express unique properties that are essential for learned song, and absent in non-vocal learning birds. To test these hypotheses, we examined publically available microarray datasets (45K Agilent oligo array) from previous studies that compared nXIIts to the adjacent non-vocal supraspinal motor neurons (SSp) in order to identify molecular markers of nXIIts. We performed parallel analyses on the nXIIts/SSp of zebra finches and two non-vocal learning species (rock dove, quail), and subtracted the resulting marker lists to identify nXIIts markers unique to finches. Whereas numerous nXIIts transcripts were expressed in combinations that do not reflect the occurrence of vocal learning, a set of ~600 specializations were unique to zebra finch nXIIts, including several genes identified in previous screens (e.g. ROBO1, PVALB). Bioinformatics analyses reveal enrichment in genes related to axon guidance, glutamate receptor binding, and ion channel activity. In sum, our study reveals that the main avian vocal-motor output nucleus, common to both vocal learners and non-learners, expresses a large set of genes that are specific to vocal learners, and thus represent novel candidate modulators of learned vocalizations.

Title: Molecular specializations of vocal nuclei in zebra finches (Taeniopygia guttata) associated with neurotransmitter receptors, neuropeptides, and axonal guidance cues

Authors: *P. V. LOVELL, C. V. MELLO Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: Vocal learning, the ability of animals to acquire vocalizations through imitation, is a rare behavioral trait. Besides occurring in humans and possibly in a few mammalian groups, it is prevalent in songbirds, where it is subserved by a set of brain nuclei that control the vocal and respiratory organs. The connectivity and physiology of these vocal nuclei have been extensively studied in zebra finches (T. guttata). Previous efforts using cDNA and oligo microarrays to study adult finches have identified large sets of differentially expressed transcripts in nuclei HVC, RA, and nXIIts of the direct vocal-motor pathway (Lovell et al., 2008; Hara et al., 2012, Pfenning et al., 2015; Friedrich et al., 2016), and in striatal Area X (Hilliard et al., 2014) within the anterior pathway for vocal learning and plasticity. Bioinformatics analyses provided initial evidence for the differential regulation of genes of relevance to neuronal excitability and plasticity (e.g. ion channels, transmitter receptors, neuropeptides), as well as neuronal connectivity (e.g. axon guidance cues). We now report an in-depth and systematic examination of these gene families based on microarray analyses, as well as in situ hybridization data from the ZEBrA online database (www.zebrafinchatlas.org) and/or from previous published studies. We compared the expression patterns across major nuclei in both the vocal-motor and anterior pathways for ~200 genes in the above categories. Our results indicate that multiple members of these families are differentially expressed in various vocal nuclei, in comparison with the adjacent areas and in contrast to other gene family members. Factors like membership in a particular gene family, the receptor class with regards to the neurotransmitter type (e.g. excitatory vs. inhibitory vs. modulatory), or axon guidance category (e.g. ligand vs. receptor) did not predict which vocal nucleus showed differential regulation. While the data generally suggest that each vocal nucleus possesses a unique molecular profile, some general trends were noteworthy, namely most glutamate receptor types were down-regulated, whereas serotonin receptors were up-regulated. In sum, this is the first time that the expression of this large cohort of genes of relevance to the development, maintenance and physiology of the vocal control system in finches is evaluated in a systematic fashion. Our observations provide novel insights into molecular specializations of vocal control circuits in finches, identify candidate pathways related to patterns of connection between vocal nuclei, and point to candidate target genes for further mechanistic and regulatory studies.

Title: Experience dependent changes in immediate early gene expression in the auditory forebrain in response to conspecific song in female canaries (Serinus canaria)

Authors: *C. M. HAAKENSON¹, F. N. MADISON², G. F. BALL³ ¹Neurosci. and Cognitive Sci. Program, Dept. of Psychology, ²Dept. of Psychology, ³Univ. of Maryland, College Park, MD

Abstract: Female songbirds are thought to make mate choices based on aspects of male song quality. Male canaries (Serinus canaria) produce songs with "special" or "sexy" syllables composed of fast, frequency-modulated syllables that are especially attractive to females. These "special" syllables have been shown to be highly salient to female listeners and elicit high rates of sexual displays and enhanced immediate early gene (IEG) expression in the caudal mesopallium (CMM) and nidocaudal mesopallium (NCM), two major auditory areas important in processing conspecific song. The purpose of this study was to examine the effects of experience on activity in the auditory forebrain in female canaries. In this study, female canaries were placed on long days (14L:10D) for 6 weeks (photostimulated) then pair housed in sound attenuated chambers. After a brief acclimation period, females were exposed to either song with "special" syllables or song without "special" syllables for 14 days. After transfer to individual housing and one day of silence, birds were exposed to one of the aforementioned stimuli or silence for 90 minutes then sacrificed. Immunohistochemisty for the immediate early gene ZENK was used to detect neural activation in NCM and CMM. Preliminary data suggests that ZENK expression in both the CMM and NCM was higher in females chronically exposed to song containing "special" syllables, while ZENK expression was attenuated in females chronically exposed to song without special syllables. Follicle volume tended to be larger in the females who were exposed to the song with special syllables. This change in the forebrain ZENK response following exposure to preferred song may serve as a mechanism for increasing the likelihood of mating in environments with an abundance of high-quality mate options.

Title: Nature via nurture of vocal learning in hybrid songbirds

Authors: *K. WADA¹, A. SAWAI²

¹Hokkaido Univ., Sapporo, Hokkaido, Japan; ²Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Both nature and nurture influence learning process. Like human speech, birdsong is a learned vocalization regulated by both genetic and environmental factors. Songbird juveniles learn their songs, which are species-specifically constrained but individually unique, during the critical period of vocal learning. However, it is not well understood how genetic and environmental instructions modulate the vocal learning process. We examined song development in hybrid songbirds between zebra finch and owl finch, which possess species-specific traits at acoustics and sequence of syllables composed in the songs. The hybrid songbirds exhibit a wide variability of individual differences of song phenotypes under the tutoring environments of both parental species song playbacks. Half population of hybrid birds acquired intermediated patterns of both parental species. In contrast, the other population of hybrids acquired only either one of parental species songs. The individual variability of song was emerged from initiation of song production as the biased acoustic features. Intriguingly, even under the tutoring environment with single-species song playback, a population of hybrid birds developed the songs with nontutored parental species features, indicating the predisposition of learning intentions. Furthermore, the trend of predisposed-learning intention of song was differently biased among families. These results demonstrate nature via nurture for development of the individual uniqueness of vocal learning processes.

Title: Transcriptional clustering reveals molecular convergence between human and songbird vocal learning circuits

Authors: *S. ANNALDASULA¹, M. WIRTHLIN², G. GEDMAN³, E. D. JARVIS⁴, A. R. PFENNING²

¹Computat. Biol., ²Computat. Biol. Dept., Carnegie Mellon Univ., Pittsburgh, PA; ³Rockefeller Univ., New York, NY; ⁴Duke Univ. Hosp., Durham, NC

Abstract: Vocal learning is a complex trait evolved in a handful of lineages in mammals and birds, including humans and songbirds. Though phylogenetically distant, the brain circuits for vocal learning in these two groups display remarkable convergence in terms of their anatomy,

physiology, and molecular specializations. Previously, we discovered that multiple human and zebra finch vocal circuit regions that serve analogous functions also display significant convergence in transcriptional correlation, including songbird RA and Area X, and human Laryngeal Motor Cortex and Anterior Striatum, respectively. These transcriptional similarities between analogous brain regions were discovered by comparing the correlation of overall expression between regions. We now improve and expand upon these results by taking a reverse, 'gene-centric' approach. We developed computational algorithms to cluster the complete set of 10,783 human genes according to their co-expression across 3,681 human brain regions, and statistically relate the similarity of cluster transcriptional specialization across human and songbird anatomical regions. This set allowed us to identify sets of transcriptional modules that could support the functional properties of analogous human and songbird vocal learning brain regions. These clusters provide insight into the molecular basis for known properties of speech and song-associated brain regions, as well as suggest new molecular pathways that characterize these circuits. These findings provide information on the transcriptome changes that could serve as a causal mechanism in the evolution of vocal learning and other complex behaviors.

Title: Behavioral plasticity is related to adult neurogenesis in songbirds

Authors: *L. NIEDEROVA-KUBIKOVA¹, K. LUKACOVA¹, J. POLOMOVA¹, L. BACIAK², S. KASPAROVA²

¹Ctr. of Biosciences, Inst. Anim. Biochem. Gen., Bratislava, Slovakia; ²Dept. of NMR Spectroscopy and Mass Spectroscopy, Slovak Univ. of Technology, Fac. of Chem. and Food Technol., Bratislava, Slovakia

Abstract: Injury within striatum leads to neurogenic (acquired) stuttering in humans and abnormally high syllable repetition in songbirds such as Bengalese finch (*Lonchura striata domestica*) and zebra finch (*Taeniopygia guttata*). While the stuttering-like song occurs soon after the injury in Bengalese finches, it occurs only after a month in zebra finches. These

behavioral changes are accompanied with lesion recovery which is mostly due to the incorporation of newly born neurons. It has been proposed that the function of adult neurogenesis is to facilitate new memory formation and promote behavioral plasticity. Here we investigated 1/ if the neurogenesis and/or new neuron addition to vocal nuclei are associated with song variability in zebra finch and Bengalese finch and 2/ if the different time-course of stuttering may be caused by the different recovery rate and the newly added neurons into the injured striatum. First we studied the basal levels of neurogenesis in the neurogenic subventricular zone (SVZ) and new neuron incorporation into the striatal vocal nucleus Area X. We found that Bengalese finches had higher level of neurogenesis in most of SVZ and they showed also higher number of new neurons in Area X. The songs of zebra finches were more stereotypical than the songs of Bengalese finches, as shown by linearity and stereotypy scores. The level of neurogenesis in SVZ negatively correlated with the song linearity and stereotypy. In the second part of this study we performed bilateral neurotoxic lesions of Area X in zebra finches and Bengalese finches and employed magnetic resonance imaging for the longitudinal examination of the injury and its recovery in the same birds. This analysis is in progress. The results show that the behavioral plasticity is associated with higher neurogenesis in songbirds.

Title: Unilateral vocal nerve section alters new neuron survival in the zebra finch song system

Authors: *J. V. ARONOWITZ¹, C. O'BRIEN¹, A. PEREZ², S. RIBEIRO³, K. WASNER⁴, A. LOPEZ¹, E. RODRIGUEZ⁵, B. KOO¹, C. PYTTE¹

¹Psychology, Queens Col., Flushing, NY; ²Psychology, Grad. Center, City Univ. of New York, New York, NY; ³Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; ⁴Luxembourg Ctr. for Systems Biomedicine, Belvaux, Luxembourg; ⁵Neurobio., Duke Univ., Durham, NC

Abstract: Adult neurogenesis allows new neurons to be continually added to the adult brain. In the adult male zebra finch, the survival of adult-formed neurons in the song motor pathway nucleus HVC has been shown to be positively correlated with the quality of song production. This led to the idea that the degree of matching between expected and received auditory feedback during singing may contribute to the survival of new neurons engaged in song

production. Other regions of the song system that receive new neurons in adulthood are the basal ganglia nucleus Area X and the auditory region caudomedial nidopallium (NCM). These regions also respond to playback of the birds own song and therefore new neuron survival in these areas may similarly be sensitive to song feedback. To test this, we altered song structure by unilaterally denervating the syrinx and quantified new neurons in Area X and NCM in both hemispheres. Mitotically active cells were labeled with i.m. injections of bromodeoxyuridine (BrdU, 3x/day, for three days). Three weeks after the last BrdU injection, birds underwent left or right syringeal denervation by sectioning the tracheosyringeal nerve (nXIIts), which innervates the syrinx. Control birds received sham surgery. One week after surgery, we used immunohistochemistry to label BrdU and the neuron-specific protein Hu. There were no differences in numbers of new neurons between left and right hemisphere Area X in either control or nerve cut birds. Moreover, either a left or right nXIIts nerve cut resulted in a significant bilateral decrease in new neurons in Area X. Confirming earlier work, we found more new neurons in left than in right NCM in control birds. Interestingly, denervation primarily disrupted the left-side lateralization of new neurons. A left nXIIts nerve cut resulted in a significant decrease in new neurons in both hemispheres of NCM. A right nXIIts nerve cut did not alter overall numbers of new neurons but resulted in a reversal of lateralization such that there were more new neurons in the right NCM relative to the left. These results replicate and extend previously reported findings and suggest that new neuron survival throughout the song system may be influenced by song-related feedback, and differs depending upon brain region.

Title: Sex differences in the effects of chronic stress on dendritic remodeling in orbitofrontal cortex

Authors: *A. GUTIERREZ¹, V. SZALAVARI¹, C. WELLMAN^{1,2} ¹Psychological and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN; ²Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Stressful life events are linked to the development of several psychological disorders such as depression and posttraumatic stress disorder (Kendler et al., 1999). This link may be related to sex, with twice as many women suffering from stress-related disorders than men (Solomon & Herman, 2009). Dysfunction of medial prefrontal cortex (mPFC) and the

orbitofrontal cortex (OFC) has been implicated in stress-sensitive disorders, and both mPFC and OFC are sensitive to the effects of stress. For instance, dendritic remodeling in mPFC after chronic stress is sex-specific. Whereas male rats exhibit dendritic retraction after chronic stress, female rats show dendritic growth (Garrett & Wellman, 2009). Liston and colleagues (2006) demonstrated that male rats show dendritic growth in OFC following chronic stress. However, no studies have examined the effect of stress on neuronal morphology in OFC in female rats. Therefore, we compared dendritic remodeling of pyramidal neurons in OFC in male and female rats after exposure to chronic stress. Rats underwent chronic restraint stress (3h/d for 10d) and were perfused on the final day of restraint. Brains were removed and stained using the Golgi-Cox method. Pyramidal neurons in ventral and lateral OFC were reconstructed in three dimensions using Neurolucida and their apical and basilar morphologies were quantified. Spine density on apical and basilar terminal dendrites was also quantified using Neurolucida. We found a basal sex difference in unstressed rats for both apical and basilar dendrites, with female rats having longer dendrites compared to males. This sex difference is opposite that found in mPFC, where unstressed males have longer apical dendrites (Garrett & Wellman, 2009). Moreover, unstressed females had reduced spine densities relative to unstressed males. In agreement with previous studies (Liston et al., 2006), chronic stress increased apical dendritic length in OFC of male rats. This effect was most robust distal to the soma. In contrast, little dendritic change was observed in female rats. We also found a decrease in overall spine density in stressed male rats compared with unstressed rats, which parallels the effects of chronic corticosterone exposure (Gourley et all, 2013). There was no difference between stressed and unstressed females. These results expand upon previous data, and further suggest that stress can have differing effects on neuronal morphology in the prefrontal cortex of male and female rats, and that these effects can differ by subregion. These sex differences in dendritic remodeling in OFC may contribute to differential effects of stress on OFC-mediated behaviors such as reversal learning.

Title: BAG-1 deficiency impairs stress-induced neuroplasticity and alters gene expression in the mouse prefrontal cortex

Authors: *J. KOGAN¹, M. W. SCHELKE², T. G. RUBIN³, R. DAVIDSON¹, N. P. BOWLES¹, B. S. MCEWEN¹, J. D. GRAY¹ ¹Rockefeller Univ., New York, NY; ²Weill Cornell Med. Col., New York, NY; ³Albert Einstein

Col. of Med., Bronx, NY

Abstract: Bcl-2 associated athanogene 1 (BAG-1) is a molecular chaperone that binds to the glucocorticoid receptor (GR) and inhibits nuclear signaling. Decreased levels of BAG-1 mRNA have been observed in the prefrontal cortex of patients with bipolar disorder and schizophrenia. Additionally, BAG-1 protein levels are up regulated in the hippocampus of rats given chronic lithium or valproate, two drugs commonly used to treat bipolar disorder. While the etiology of these disorders is not well understood, exposure to chronic stress can exacerbate their symptoms and precipitate their onset. Repeated GR activation in response to chronic stress causes dendritic shrinkage in the prefrontal cortex in both rodents and humans. Molecular chaperones such as BAG-1 are critical for silencing GR signaling at low CORT levels and allowing for proper activation at high CORT levels. Studying BAG-1 deficiency in vivo will provide important insight into the molecular mechanisms of altered CORT signaling associated with certain mental illnesses and identify new potential targets for pharmacologic intervention. Here we evaluated the effects of BAG-1 deficiency on stress-induced neuroplasticity and gene expression in the mouse medial prefrontal cortex (mPFC). Separate cohorts of adult BAG-1 heterozygous knockout (BKO), and wild type (WT) mice were subjected to a 21d chronic restraint stress (CRS) and sacrificed 24h following the final stress. Brains were either processed for Golgi impregnation, transcardially perfused with 4% paraformaldehyde for immunohistochemical (IHC) analysis or dissected and flash frozen on dry ice for qRT-PCR analysis. Blood was collected for measurement of circulating CORT levels. Unlike WT mice, BKO animals failed to show dendritic remodeling after CRS. Previous work has also implicated the polysialated neural cell adhesion molecule (PSA-NCAM) in stress-induced plasticity. We observed increased levels of PSA-NCAM in the mPFC of BKO animals by IHC and increased mRNA levels of NCAM and the sialating enzyme ST8SiaIV. We hypothesize that deficient BAG-1 levels would lead to excess activation of GR signaling at baseline, potentially mimicking the effects of chronic stress and elevating PSA-NCAM, which then impairs neural remodeling when BKO are subjected to chronic stress. Experiments to evaluate differences in GR activation before and after stress, as well as other markers of stress are underway. These studies demonstrate the importance of BAG-1 levels in stress-induced neuroplasticity in the mPFC and suggest that BAG-1 deficiency may mimic the effects of chronic stress.

Title: The unusual suspects: Oligodendrocytes predict resilience vs. vulnerability in response to stress

Authors: *K. LONG¹, L. CHAO², T. C. NEYLAN³, D. KAUFER¹ ¹UC Berkeley, Berkeley, CA; ²Radiology, ³Psychiatry, Univ. of California, San Francisco, San Francisco, CA

Abstract: Post-traumatic stress disorder (PTSD) is a debilitating anxiety disorder that affects nearly 20% of individuals who experience a traumatic event; however, the majority of individuals will recover from the experience. Understanding the neural underpinnings of individual variation in resilience and susceptibility to stress is of critical importance to public health; however, the basis for differential susceptibility to anxiety remains poorly understood. Recent research has shown that PTSD patients have greater myelin content in the hippocampus when compared to trauma-exposed, yet unaffected individuals. Furthermore, previous work from the Kaufer lab has found that stress increases the production of oligodendrocytes (myelinproducing cells) in the hippocampus of rats; however, whether white matter is a contributing factor to these disorders or merely a secondary consequence remains largely unknown. In the present work, we investigated the hypothesis that stress-induced changes to oligodendrocytes and myelin are both predictive and causative of high anxiety. To test this, we used an animal model of severe stress to induce a spectrum of anxiety-like behavior in rats. Brains collected from animals were analyzed for oligodendrocyte, myelin, and synaptic markers using immunohistochemistry and confocal microscopy. Interestingly, we found that increased oligodendrocyte and myelin density of the hippocampus following stress predicted higher rates of anxiety. In a second set of experiments, we experimentally increase or block hippocampal oligodendrogenesis to test whether increasing oligodendrogenesis is necessary and sufficient to generate the behavioral expression of anxiety. These studies contribute to the understanding of

differential susceptibility to stress and may provide new avenues for PTSD biomarkers and therapies.

Title: HIF1a signaling modulates synaptic plasticity and adult neurogenesis following chronic intermittent hypoxia

Authors: *A. J. GARCIA, III¹, M. A. KHUU³, T. NALLAMOTHOU² ¹Emergency Med., ²The Univ. of Chicago, Chicago, IL; ³Emergency Med., Univ. of Chicago, Chicago, IL

Abstract: Several sleep disorders, such as sleep apnea, often correlate with a decline in cognitive performance among children and adults. Previous studies have shown that hippocampal plasticity and cognitive performance are impaired in animal models exposed to chronic intermittent hypoxia (CIH), a cardinal trait of sleep apnea. Moreover, our recent work has shown that CIH modulates adult neurogenesis in the hippocampus. While the effects of CIH appear to involve oxidative stress, the role of the pro-oxidant transcription factor, hypoxia inducible factor 1a (HIF1a) plays in this phenomenon remains to be resolved. Here we test the hypothesis that HIF1a signaling is necessary part of the signaling pathway for CIH to suppress synaptic plasticity and modulate neurogenesis in the hippocampus. Following ten days of CIH, hippocampal brain slices were prepared from wild-type and HIF1a heterozygous knockout (HIF^{+/-}) mice for electrophysiological or immunohistochemical studies. CIH suppressed long term potentiation in area CA1 and appeared to enhance adult neurogenesis in wild-type mice. However, long term potentiation from HIF1a^{+/-} mice was unaffected by CIH suggesting the involvement of HIF1a signaling for CIH to suppress synaptic plasticity. Ongoing experiments will identify the role CIH-induced HIF1a signaling plays to modulate hippocampal neurogenesis. These findings for role of HIF1a may be critical to understanding the molecular basis by which sleep apnea leads to cognitive decline.

Title: Network analysis of frontal cortical microcirrcuit dynamics after chronic stress hormone exposure and ketamine treatment

Authors: *R. N. MODA^{1,2}, M. MURDOCK^{1,2}, R. FETCHO^{1,2}, E. ALWAY^{1,2}, D. ROSENTHAL^{1,2}, K. LOPEZ^{1,2}, Y. MENG^{1,2}, T. HUYNH^{1,2}, C. LISTON^{1,2} ¹Neurosci., Weill Cornell Med. Col., New York, NY; ²Feil Family Brain & Mind Res. Inst., New York, NY

Abstract: Chronic stress alters neuronal morphology within the prefrontal cortex (PFC), inducing changes such as dendritic retraction and spine loss. Subanesthetic doses of ketamine, an NMDA antagonist, can act as a fast-acting antidepressant in treatment-resistant depressed patients, and these effects are associated with increased postsynaptic dendritic spine density in PFC pyramidal cells in fixed tissue studies. How changes in synapse number and dendritic morphology affect PFC microcircuit function, however, has yet to be established. In an effort to address this question, we investigated neural network dynamics in PFC microcircuits using two-photon calcium imaging and fiber photometry. Adult mice were intrancranially injected in the prefrontal cortex with a pan-neuronal GCaMP-expressing AAV virus (driven by the hSyn promoter), and either a microprism or an optic fiber was implanted to monitor the activity of GCaMP-expressing cells. PFC microcircuit activity was first quantified by two-photon calcium imaging through a microprism before and after a chronic, 10-day exposure to corticosterone, the principal murine stress hormone. The mice were then injected with an acute intraperitoneal dose of ketamine, and repeat imaging was performed 24-hours later from the same neural populations. PFC microcircuit activity was analyzed, and results suggest that chronic corticosterone exposure reduces correlated activity and disrupts multi-cell ensembles in network populations, which are rescued by ketamine treatment. Following the same chronic corticosterone protocol, we also used fiber photometry to record neural activity during tail

suspension. We found that an increase in mPFC activity precedes the shift from immobility to struggling in controls, which is reduced in mice subjected to chronic corticosterone and partially rescued in mice receiving ketamine treatment.

Title: Prefrontal somatostatin interneurons in action valuation processing and motivational anhedonia

Authors: ***R. N. FETCHO**¹, T. N. HUYNH³, B. S. HALL¹, F. LEE¹, C. M. LISTON² ²Brain and Mind Res. Inst., ¹Weill Cornell Med. Col., New York, NY; ³Weill Cornell Med., New York, NY

Abstract: Major depressive disorder (MDD) is a highly prevalent and debilitating mood disorder that is diagnosed based on a mixture of symptoms, but anhedonia-decreased interest in rewarding activities—is a core feature. Anhedonia can be caused by an inability to experience pleasure or by a lack of motivation to work towards obtaining a reward. Every decision to exert effort to obtain a reward involves action valuation computations- essentially a cost-benefit analysis of whether the positive value of the expected outcome of an action outweighs the negative value of the expected effort associated with that action. The anterior cingulate cortex (ACC), a stress-sensitive region of prefrontal cortex (PFC), has been consistently implicated in action valuation computations across species. Whether and how dysfunctional action valuation computations drive anhedonic symptoms in stress-related psychiatric disease is unclear. While extensive, groundbreaking work has characterized the effects of stress on PFC glutamatergic circuitry, less is known about the role of local inhibitory circuitry in stress-induced depressivelike behaviors, despite substantial evidence for changes in the inhibitory system in MDD patients. Here we investigated the role of one cellular subtype, somatostatin (SST)- expressing interneurons, in driving both healthy reward-seeking and chronic stress-induced anhedonic behavior. We recorded the activity of the ACC SST interneuron population through a chronically
implanted optical fiber (fiber photometry) in awake, freely behaving mice performing an effortful reward-seeking task under normal and chronically stressed conditions. Our initial results indicate that SST interneurons facilitate action valuation computations by dynamically regulating synaptic inputs to the ACC and that this process is disrupted in chronic stress states. This study will advance our understanding of stress-induced anhedonic behavior by focusing on a sparse but essential cell population that is understudied in the context of stress and depression.

Title: FAAH Genetic variation in mice leads to enhanced auditory fear extinction and increased frontolimbic circuit activity

Authors: *T. N. HUYNH, R. N. FETCHO, F. S. LEE, C. LISTON Weill Cornell Med., New York, NY

Abstract: Encoding and modulating memories of dangerous and threatening stimuli are critical adaptations, particularly when threats vary over time. PTSD is a debilitating disease involving intrusive memories of a traumatic event, which are due in part to the inability to modify responses to stimuli that are no longer threatening—a process known as extinction. Interestingly, there is a common human single nucleotide polymorphism (SNP) in the fatty acid amid hydrolase (FAAH) gene, the primary catabolic enzyme of the prototypical endocannabinoid, anandamide, which leads to the enhanced ability to extinguish fearful memories. Moreover, recently developed knock-in mice expressing this FAAH SNP display the same traits as observed in humans with this mutation. Previous studies demonstrate that humans containing the FAAH SNP and FAAH KI mice exhibit decreased anxiety as well as enhanced auditory fear extinction memory. Furthermore, humans and mice containing the FAAH SNP also exhibit increased fronto-amygdala projections which emerge during adolescence. It is well established that the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA) are involved with the regulation fear extinction learning and memory, thus the FAAH KI mice provides a unique, clinically-relevant tool to investigate how the activity in this circuit is modulated to strengthen extinction memory. We used fiber photometry to acquire activity dependent calcium dynamics in freely moving rodents via a chronically implanted fiber. Using GCaMP6S, which we virally

injected into the basolateral amygdala, we found that *FAAH* KI mice exhibit enhanced tonelocked activity at the beginning of an auditory fear extinction session which attenuates by the end of the extinction session relative to WT mice. Interestingly, BLA activity is similar in *FAAH* KI mice and WT mice on day 2 of extinction, despite decreased freezing levels in *FAAH* KI mice relative to WT mice. We next investigated projection specific activity using a dual virus approach to record from BLA-projecting mPFC neurons. We found that on day 1 of extinction, activity in BLA-projecting mPFC cells is similar in *FAAH* KI mice and WT mice; on the other hand, there is an increase in tone-locked activity in BLA-projecting mPFC cells on day 2 of extinction in *FAAH* KI mice. These results indicate that BLA-projecting mPFC neurons may be critically involved with the encoding of auditory fear extinction memories that is dependent on the endocannabinoid system.

Title: Frontostriatal circuit function in social interaction behavior and chronic social stress

Authors: ***B. S. HALL**¹, R. N. FETCHO¹, T. N. HUYNH³, A. M. RAJADHYAKSHA⁴, C. M. LISTON²

²Brain and Mind Res. Inst., ¹Weill Cornell Med. Col., New York, NY; ³Weill Cornell Med., New York, NY; ⁴Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Impairments in social functioning are a core component of many stress-related neuropsychiatric conditions including depression, schizophrenia and anxiety disorders. The underlying mechanisms that lead to social dysfunction in these conditions are not well understood, but are thought to involve the nucleus accumbens (NAc), a stress-sensitive area of the ventral striatum that regulates drives and motivation. The NAc integrates signals from a reward-processing network that includes the infralimbic (IL) region of the prefrontal cortex. The mechanisms by which IL:NAc projections influence social behavior and how they are altered by chronic stress have not been well defined. This work aims to investigate how projections from the IL modulate activity in the NAc and influence social interaction behavior in order to define circuit mechanisms by which these processes are altered by chronic stress.

Additionally, the cell population in the NAc is heterogeneous, comprised predominantly of D1 and D2 subtype medium spiny neurons (MSNs). This study also looks to understand the contribution of these different cell types to the stress responses observed. Using a rodent model of chronic stress (chronic social defeat stress) and fiber photometry in order to record from and manipulate specific neural populations and circuitry, we show how chronic stress affects IL:NAc signaling and whole NAc, as well as D1 and D2, activity and in the context of social interaction behavior. This work may elucidate mechanisms by which stress can lead to changes in reward circuitry that impact social interaction and contribute to social dysfunction in psychiatric diseases.

Title: Hippocampal engrams: Roles in stress susceptibility

Authors: *T. ZHANG, A. S. WONG, T. P. WONG Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Apart from mood changes, depression has been associated with a biased memory for negative stimuli. Neuroimaging studies suggest this cognitive bias is related to the enhanced functioning of the hippocampus. We hypothesize that the facilitated formation of hippocampal engram cells, known as cellular substrates for memory, is related to the cognitive bias for negative stimuli in an animal model of depression.

We employed a chronic social defeat model to examine the relationship between hippocampal engram cells and depression-related behaviours. The TetTag mouse model allows the tagging of activated neurons by a reporter gene LacZ. TetTag mice were stressed by social defeat, consisting of daily attacks by and co-housing with an aggressive mouse. Neurons activated in the first 2 days of social defeat were labeled by LacZ. After 8 total days of defeat stress, mice were separated into susceptible (exhibiting social avoidance) and resilient groups according to their social behaviour. Hippocampal engram cells were reactivated by an extra episode of social defeat to induce immediate early gene cFos expression. Neurons with both LacZ and cFos labeling represent engram cells.

We found more LacZ labeled hippocampal CA1 neurons in susceptible mice compared with

resilient and nonstressed control mice. Such group difference was still present when the dorsal and ventral hippocampus were analyzed separately. This finding suggests there are inherent differences in hippocampal activation between susceptible and resilient mice before the onset of depressive symptoms in susceptible mice.

Intriguingly, we also found significantly more engram cells in susceptible mice than other mouse groups in the CA1 region of both dorsal and ventral hippocampus. No difference in LacZ labeled and engram cells was found in the dentate gyrus. Our findings suggest susceptible mice may have an enhanced hippocampal memory for social stress. Given that a hyperactive hippocampus may be related to rumination in depression, our findings suggest that targeting hippocampal engram cells may be a novel therapy for depression.

Title: Medial prefrontal cortex versus orbitofrontal cortex: Teasing apart differences in plasticity after stress

Authors: *S. M. ADLER, S. E. BULIN, M. S. PATTON, M. GIROTTI, D. A. MORILAK Pharmacol., Univ. of Texas Hlth. At San Antonio, San Antonio, TX

Abstract: Cognitive inflexibility is a symptom dimension shared by several stress-related psychiatric disorders; it crucially contributes to their etiology and is exacerbated by stress. Unfortunately, deficits in cognitive flexibility are poorly treated by current medications. In order to create more efficacious treatments, we need to know more about the neurobiology of stress effects on cognitive flexibility. In rodents, the attentional set-shifting task (AST) can be used to evaluate two types of cognitive flexibility: reversal learning, which is mediated by the orbitofrontal cortex (OFC), and extra-dimensional set-shifting, which is mediated by the medial prefrontal cortex (mPFC).

We have identified two types of chronic stress that elicit behavioral deficits in each of these functions: chronic intermittent cold stress (CIC) selectively impairs reversal learning (p<.01), while chronic unpredictable stress (CUS) most robustly impairs extra-dimensional set-shifting

(p<.05). In recent work, we have found that each stress paradigm affects the functional outputs of the two brain regions very differently: after chronic stress, the OFC becomes hyper-excitable, while the mPFC becomes hypo-excitable. We have previously demonstrated this using mediodorsothalamus (MDT) afferent stimulation to evoke field potentials in these regions. Evoked field potentials in the OFC are considerably potentiated after 2 weeks of CIC stress compared to baseline (before stress); however, in the mPFC, evoked field potentials are decreased after 2 weeks of CUS.

Since the literature suggests that the mPFC has a decrease in apical spine density and dendritic complexity after chronic stress, we wanted to determine if, similar to our electrophysiological data, the OFC experiences the opposite effect. We have determined that, in male Sprague Dawley rats that undergo CIC stress, distal apical spine density in the medial OFC is significantly increased relative to non-stressed controls (p=0.0128). We plan on pursuing this further by using a larger cohort of animals in order to determine whether other regions of the OFC also have a similar effect. Additionally, we will be comparing this data to rats that undergo CUS in order to see if our stressor produces a decrease in spine density similar to what has been found in the literature. We will also perform Scholl analysis to determine if these groups also have differences in dendritic complexity. Finally, since functional changes in excitatory transmission correlate with altered AMPA receptor surface expression, we will also measure surface labeling of AMPA receptor subunits in the OFC and mPFC after chronic stress.

Title: HPA axis disruption alters glutamate signaling in the prefrontal cortex: Consequences for acute stress exposure and stress adaptation

Authors: *S. KINLEIN, F. SHAFFER, M. SAVENKOVA, I. N. KARATSOREOS Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: The brain-body response to stress is a set of biological countermeasures that promote adaptation and are crucial to survival. However, frequent, prolonged, or otherwise inappropriate responses to stress can lead to strain on physiologic function and eventually disease. The hypothalamic-pituitary-adrenal (HPA) axis is a key mediator of the stress response, and plays a

large role in the process of stress adaptation in the brain and hence in behavior. Here, we experimentally disrupt normal HPA function in male C57/B6 mice via noninvasive, oral corticosterone administration in order to determine how this system contributes to stress adaptation in the medial prefrontal cortex (mPFC), a brain area that is known to be affected by both acute and chronic stress. Our published data show this model blunts stress-induced corticosterone secretion, leads to abnormal behavioral responses to stress, and enhances stressinduced cfos mRNA expression in the mPFC. We hypothesized that this altered activity in the mPFC may be driven by changes in glutamate signaling. To test this, we measured the expression of genes coding for glutamate receptor subunits in the mPFC and also performed invivo biosensor recording of extracellular glutamate in the mPFC before, during, and after an acute stress exposure. We report altered glutamate signaling in the mPFC of HPA-disrupted mice that may account for the enhanced cfos expression we previously observed. As the mPFC undergoes structural and functional adaptation in response to repeated stress, which we propose occurs to prevent excitotoxic damage resulting from prolonged glutamate release, we also hypothesized that disruption of the HPA axis may affect the ability of neurons in the mPFC to properly adapt to repeated stress exposure. To test this, we exposed mice to repeated stress and quantified markers of oxidative stress in the mPFC. Together, our results suggest that disruption of normal HPA axis function can alter stress-induced glutamate signaling in the mPFC, and may also impair the ability of the mPFC to adapt to conditions of repeated stress exposure.

Abstract: For many decisions, the brain must combine both negative and positive motivators (costs and benefits). We recorded activity in a cortico-striosomal circuit in control and previously chronically stressed rats and mice during cost-benefit conflict task performance, and found aberrant activity in all elements of the circuit (Friedman et al. SfN 2017; Homma et al. SfN 2017). Based on our recordings, we hypothesized that a major effect of chronic stress on the cortico-striosomal circuit is a shift in excitatory-inhibitory (E-I) balance. To examine this hypothesis, we created Hodgkin-Huxley models of a normal circuit and a circuit whose connectivity (and therefore E-I balance) was altered by stress. We implemented a network consisting of excitatory, striosome-projecting prefrontal-prelimbic cortex neurons (PFC-PLs), striosomal spiny projection neurons (SPNs), and a fast-spiking interneuron (FSI; a well known source of feed-forward inhibition in the striatum). We adjusted the parameters of the model based on the experimentally observed responses of striosomal SPNs and FSIs to microstimulation of PFC-PL. After this tuning, we inserted into the model the activity of the PFC-PLs recorded in the control and stressed animals. The model of the control case successfully predicted a cascade of activation starting from PFC-PLs and continuing to FSIs, resulting in the inhibition of striosomal SPNs, as observed experimentally. The model also predicted the abnormal activity of striosomal SPNs and FSIs caused by stress. Additionally, our modeling approach enabled us to investigate the relative importance of abnormal PFC-PL activity versus the shift in E-I balance in accounting for the stress-induced changes in the activity of SPNs and FSIs. In order to do so, we inserted into the 'control' model the activity of the PFC-PLs recorded in stressed animals, and similarly we inserted into the 'stressed' model the activity of the PFC-PLs recorded in control animals. We demonstrate that a shift in the E-I balance is critical in explaining the effect of stress on the cortico-striosomal circuit using this model. This work has important potential implications for many neuropsychiatric disorders, in which a shift of E-I balance and/or a cortico-striosomal circuit may occur in conjunction with abnormal decision-making.

Title: Rescue and mimicking of chronic stress effects on cost-benefit decision-making by manipulation of a cortico-striosomal circuit

Authors: *D. HOMMA, A. FRIEDMAN, B. BLOEM, L. G. GIBB, K.-I. AMEMORI, D. HU, S. DELCASSO, A. S. HOOD, J. YANG, K. A. MIKOFALVY, T. F. TRUONG, S. E. TORO ARANA, D. W. BECK, N. NGUYEN, R. H. VORDER BRUEGGE, E. D. NELSON, K. A. GOOSENS, A. M. GRAYBIEL MIBR, MIT, Cambridge, MA

Abstract: Chronic stress often induces abnormal decision-making, but the underlying neuronal mechanisms for this effect are largely unknown. To understand the long-term effect of chronic stress on decision-making, we compared the behavior of normal and chronically stressed rats and mice in four different decision-making tasks performed on a T-maze. The cost-benefit conflict decision-making (CBC) options consist of high reward paired with high cost versus low reward paired with low cost. The benefit-benefit decision-making tasks consist of choices made between two rewards. The cost-cost decision-making task (CC) consists of equal rewards on each option paired with different cost levels. We over-trained rats and mice to stabilize choice variability and constructed psychometric functions. Rats and mice then underwent chronic stress procedures: immobilization or foot shock. Previously stressed animals were significantly more likely to choose high-reward, high-cost options than unstressed controls in the CBC task. However, they did not exhibit altered choice behavior in other tasks. We tested for a causal relationship between the aberrant choices in the CBC task and changes in the prefronto-striatal input preferentially targeting striosomes by injecting the prelimbic cortex (PFC-PL) with either AAV5-CaMKIIaeNpHR3.0-EYFP or AAV5-CaMKIIa-C1V1(E122T/E162T)-TS-EYFP. We found that optogenetic manipulation of activity in the striosome-targeting PFC-PL pathway can either

counteract or mimic the effects of chronic stress on choice. In our electrophysiological recordings (Friedman et al. SfN 2017; Gibb et al. SfN 2017), we found aberrant activity of striatal fast-spiking interneurons (FSIs) produced by chronic stress. Therefore, we performed optogenetic manipulation of parvalbumin interneurons (putative FSIs). Here, we show that optogenetic stimulation partially rescued the behavioral effects of stress on decision-making, increasing the frequency of low-cost, low-reward choices in the CBC task. We found long-term effects of the optogenetic manipulation, which lasted for up to one month without additional stimulation. To further test the involvement of striatal inhibitory interneurons, we injected IEM-1460, an inhibitor of GluR2-lacking AMPARs that preferentially blocks excitation of striatal FSIs. IEM-1460 infusion into the striatum shifted the animals' choice behavior in the CBC task, which was strongly correlated with the changes in firing rates of striosomal projection neurons and FSIs. Our study demonstrates that manipulation of elements of the cortico-striosomal circuit can rescue or mimic chronic stress effects on decision-making.

Title: A shift in the excitation-inhibition balance of a cortico-striosomal circuit underlies aberrant cost-benefit decision-making caused by chronic stress

Authors: *A. FRIEDMAN, D. HOMMA, B. BLOEM, L. G. GIBB, K.-I. AMEMORI, D. HU, S. DELCASSO, A. S. HOOD, J. YANG, K. A. MIKOFALVY, T. F. TRUONG, S. E. TORO

Abstract: The ability to combine costs and benefits is critical for resolution of motivational conflict during decision-making. Abnormal decision-making is a symptom in many neurological and neuropsychiatric disorders. We examined the long-term effects of chronic stress on rats and mice across four T-maze decision-making tasks: a cost-benefit conflict (CBC) task, in which a high-reward option is paired with high cost; two benefit-benefit tasks with similar or dissimilar rewards; and a cost-cost task with equal rewards but different costs. We find that chronic stress changed the ability to perform the CBC task (Homma et al. SfN 2017). In order to identify the mechanism underlying this abnormal CBC task performance, we focused on a cortico-striosomal circuit implicated in evaluation of cost and reward (Friedman et al. 2015). We previously demonstrated that in non-stressed rats, the striosome-projecting neurons in the rodent prelimbic region of the prefrontal cortex (PFC-PLs) are selectively engaged in CBC decision-making, and that PFC-PL activation inhibits striosomal spiny projection neurons (SPNs) via striatal fastspiking interneurons (FSIs). In the current study, we identified putative PFC-PLs neurons antidromically and identified putative striosomal SPNs orthodromically. Using waveform characteristics, we identified FSIs, which are a well known source of feed-forward inhibition in striatum. We demonstrate that chronic stress radically alters the functioning of each element of the cortico-striosomal circuit during performance of the CBC task. We simultaneously recorded from pairs of PFC-PLs with striosomal SPNs, PFC-PLs with FSIs, and FSIs with striosomal SPNs. We examined the effect of chronic stress on functional connections in these pairs. We found altered neural excitation-inhibition balance during abnormal behavioral integration of cost and benefit in the CBC task. We delivered electrical microstimulation in the PFC-PL of control and previously stressed rats and confirmed that chronic stress reduces activation of FSIs by the PFC-PL, reducing feed-forward inhibition of the SPNs and shifting the balance of excitationinhibition in the striosomes toward excitation (Gibb et al. SfN 2017). Our findings demonstrate that chronic exposure to stress has a profound long-term effect on a cortico-striosomal circuit. We suggest that the cortico-striosomal circuit is a potential therapeutic target for neuropsychiatric disorders with abnormal decision-making.

Title: Corticohippocampal NMDAR-GluN2B subunit deletion protects against stress-induced dendritic remodelling

Authors: *S. E. KANDIGIAN¹, A. NG¹, C. R. PINARD², A. HOLMES², H. C. BERGSTROM¹ ¹Dept. of Psychological Sci., Vassar Col., Poughkeepsie, NY; ²Lab. of Behavioral and Genomic Neurosci., NIAAA/NIH, Rockville, MD

Abstract: Glutamate transmission at NMDA receptors (NMDARs) play a crucial role in stressinduced structural plasticity in prefrontal cortex. NMDARs containing the GluN2B subunit are linked with various forms of developmental and experience-induced synaptic plasticity. One well-supported form of neuroplasticity is dendritic remodeling in the prefrontal cortex in response to stress, but the contribution of GluN2B-containing NMDARs in this process is unclear. Here we sought to establish a role of GluN2B in stress-related dendrite remodeling in the prelimbic cortex (PL) using mice lacking GluN2B in cortical and hippocampal CA1 subfield pyramidal neurons. Adult male GluN2B-floxed (Cre-positive; mutant) and GluN2B-floxed (Crenegative; control) mice (Brigman et al., 2012) underwent a chronic restraint stress regimen; mice were placed in ventilated 50 mL Falcon tubes for 2 hr/day for 10 consecutive days. Nonrestrained mice remained in the home-cage. On the final day of stress, adrenal glands were removed, weighed, and whole brains processed for Golgi staining to visualize dendritic structure. Layer II/III PL dendrites were completely reconstructed in 3D and morphometrically analyzed. Results revealed remodeling of the apical, but not basilar, dendritic tree after stress in controls, supporting previous work (Wellman, 2004). Stress-induced differences in PL apical dendritic structure were absent in mutants, suggesting NR2B expression in cortical and CA1 hippocampal pyramidal neurons is required for stress-induced apical dendrite remodeling in this brain region. There was also some indication for a retraction of the basilar tree after stress in mutants, as compared with controls. These findings extend prior evidence that NMDARs are critical mediators of stress-induced dendrite remodeling in the prefrontal cortex (Martin and Wellman, 2011), and advance our understanding of GluN2B in stress-induced synaptic plasticity.

Ctr. for Civilization Diseases, Univ. of Leipzig, Leipzig, Germany

Abstract: In the presence of a stressor, the brain orchestrates an adaptive biobehavioral response (e.g., by increasing stress hormone levels, McEwen 1998). These processes, in turn, can influence brain structure and function, as shown by human brain morphological changes after chronic or severe stressors (Sapolsky 1996). Rodent models suggest that neuroplastic changes can also occur rapidly following acute stress (Gould et al. 1998). While rapid neuroplasticity in humans has been demonstrated e.g. after motor learning (Taubert et al. 2016), it has not been shown after acute stress. We used 3T MRI to investigate human brain plasticity after an acute psychosocial stressor. 67 healthy men underwent either the Trier Social Stress Test (TSST, Kirschbaum et al. 1993) or a placebo version (Het et al. 2009) while blood, saliva, and psychometrics were sampled. T1-weighted MP2RAGE images (Marques et al. 2010) and pulsed arterial spin labelling (pASL) scans were acquired 45 min before and 65 min after the intervention. Changes in grey matter density (GMD) and cerebral blood flow (CBF) were identified with voxel-based morphometry (VBM, Ashburner & Friston 2000) and a voxel-based analysis of pASL data. The TSST elicited a pronounced physiological stress response relative to the placebo (e.g., ACTH, group-by-time: F(1.58,69.69)=20.58, $p_{GG}<0.0001$). The VBM-analysis showed a significant group-by-time interaction in two clusters at the cortical midline: a cluster in the anterior cingulate cortex (ACC; [-2,40,21], p_{FWE}=0.037) showed a decrease in GMD in the control and no change in the stressor group, while a cluster in the midcingulate cortex ([4,-12,48], p(FWE)=0.021) showed an effect in the opposite direction. GMD changes in the ACC were significantly associated with endocrine stress markers in the stressor group only (e.g., ACTH: $\rho=0.47$, p=0.02). Neither cluster showed a significant change in CBF (both p>0.1 uncorrected). We found rapid brain plasticity after acute psychosocial stress in areas that have

been associated with processing stressful (Dedovic et al. 2009) and self-relevant negative information (Grimm et al. 2009). While fast morphological changes in the adult brain have been related to cell-level phenomena (e.g., glial plasticity, Sagi et al. 2012), VBM findings have also been associated with other physiological parameters such as blood oxygenation (Tardif et al. 2017). It is conceivable that such parameters are affected by a stressful intervention and thus contribute to our effects. We here provide first evidence for rapid brain plasticity following acute psychosocial stress.

Title: Subtle hippocampal CA1 dendritic restructuring following chronic stress: Influence of a post-stress rest period and hippocampal CA3 BDNF downregulation

Authors: *J. B. ORTIZ¹, E. J. DAAS², A. FLEGENHEIMER², B. Q. LE², C. D. CONRAD² ¹Dept. of Psychology, ²Psychology, Arizona State Univ., Tempe, AZ

Abstract: Chronic stress often leads to hippocampal dendritic retraction in the apical region of CA3 pyramidal neurons without quantifiable changes in the dendritic complexity of CA1 pyramidal neurons. When chronic stress ends and a post-stress rest period without restraint is given, the reduction in CA3 dendritic complexity improves and becomes more complex. However, how a post-stress rest period affects CA1 neurons is unclear. Here, we investigated the relationship between CA3 and CA1 pyramidal neurons to determine whether dendritic restructuring in CA3 neurons corresponds with region-specific changes in the dendritic complexity of CA1 neurons. Young adult male Sprague-Dawley rats were chronically stressed by wire mesh restraint (6h/d/21d) and brains were removed soon after restraint ended (Str-Imm) or after a 21d post-stress rest period (Str-Rest). In addition, prior to restraint, we used RNA interference to downregulate BDNF in the CA3 region of the hippocampus, providing robust conditions to investigate the CA3-CA1 relationship. Consequently, rats were infused into the

CA3 area with either an AAV vector with a coding sequence against BDNF (shRNA) or a sequence with no known mRNA complements (Scr). Apical and basal dendritic complexity of CA3 and CA1 neurons was quantified by counting total dendritic bifurcations and total dendritic intersections using the Sholl analysis (20 µm distances from soma). The data reveal CA3 apical dendritic retraction in Str-Imm-Scr and Str-Rest-shRNA. For the CA1 apical area, gross dendritic arborization differences were not detected, as often found in the field, but the Sholl quantification revealed regionally-enhanced dendritic complexity that varied by distance from the soma at the distal apical dendrites (Str-Imm-Scr) and proximal basal dendrites (Str-Rest-shRNA). For the latter, significant increases in basal branch points were also detected with total branch point quantification method. Moreover, a correlation using all groups revealed a significant inverse relationship between CA3 apical dendritic complexity and CA1 basal dendritic complexity. The results demonstrate that chronic stress-induced CA3 apical dendritic retraction may relate to region-specific changes in CA1 dendritic complexity.

Title: Attenuated nucleus accumbens dopamine neurotransmission in a rodent model of antidepressant resistance

Authors: *S. J. TYE¹, A. WALKER¹, R. P. KALE², B. MORATH² ¹Psychiatry & Psychology, ²Mayo Clin., Rochester, MN

Abstract: Chronic adrenocorticotropic hormone-(1-24) (ACTH) treatment (100 µg/day; 14 days) induces antidepressant resistance in rodents. In this model, antidepressant response can be elicited via activation of nucleus accumbens (NAc) dopamine signaling. The present study aimed to determine the effects of ACTH pre-treatment on NAc dopamine neurotransmission using fast scan cyclic voltammetry and behavioral response to imipramine (10mg/kg), fluoxetine (10mg/kg), armodafinil (10mg/kg) or bupropion (10mg/kg) in the forced swim test. All treatments reduced immobility time in saline-treated control animals, however, only armodafinil and bupropion reduced immobility behaviors in ACTH-treated animals. NAc dopamine neurotransmission was attenuated in ACTH-treated animals relative to controls, and potentiated with either armodafinil or bupropion treatment. NAc dopamine receptor expression was upregulated in ACTH-treated animals relative to controls and Akt/GSK3 signaling was facilitated by armodafinil or bupropion to a greater degree in these animals. These data suggest

that ACTH treatment impairs NAc dopamine neurotransmission and induces a potentially compensatory up-regulation of dopamine receptors. Together, these data support a role for targeted antidepressant treatment with armodafinil or bupropion in individuals with deficits in dopamine neurotransmission, potentially resulting from HPA-axis dysfunction.

Title: Prior chronic stress exposure alters medial prefrontal cortex response to a novel stressor in a sex-dependent manner

Authors: *K. M. MOENCH, C. L. WELLMAN

Dept. of Psychological and Brain Science, Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Recurring exposure to stressful life events increases risk for certain psychological disorders, including depression and posttraumatic stress disorder. Further, women are twice as likely to be diagnosed with many of these disorder during their lifetime. Currently, the neurobiological mechanisms underlying these risk factors are poorly understood. One possibility is that lasting stress-induced changes in brain regions associated with stress-linked disorders, including prefrontal cortex, might result in sex-specific vulnerability to subsequent stress exposure. Brain-derived neurotrophic factor (BDNF) and neuropeptide Y (NPY) are potential stress-resiliency factors, and importantly, these two factors are capable of differentially modulating neural activity. Thus, we examined activity (via fos expression), BDNF, and NPY expression in medial prefrontal cortex (mPFC) subregions of chronically stressed male and female rats in response to a novel, acute stressor. Adult rats underwent chronic restraint stress (CRS; 3h/day for 10 days) or were left unstressed (No CRS). Either 24 hours (CRS-24h) or 7 days later (CRS-7d), rats were exposed to a 30-minute elevated platform stressor. Rats were euthanized ~60 min later and brains were removed and stained for fos, BDNF, and NPY. Stereological estimates of fos-positive cells and relative luminosities of BDNF-

expressing neurons were obtained. As subregions of mPFC can bidirectionally modulate the periventricular nucleus (PVN) of the hypothalamus, fos expression was also measured in this region to examine potential chronic stress-induced changes in neuroendocrine function. Compared to No CRS male rats, CRS-24h and CRS-7d male rats had suppressed fos expression in prelimbic cortex in response to an acute novel stressor, along with increases in BDNF and NPY expression. A similar pattern of changes was observed in infralimbic cortex, though only in CRS-24h male rats, suggesting subregion-specific differences in the lasting effects of chronic stress. Importantly, no acute stress-induced changes in fos, BDNF, or NPY expression in mPFC were observed in CRS females at either timepoint. In response to acute novel stress, CRS-24h, but not CRS-7d, male rats had decreased PVN fos expression. In contrast, while CRS-24h females appeared to have a typical PVN response to acute stress, CRS-7d females had a significant increase in fos expression. These data suggest that a lack of neural changes in stress-sensitive brain regions that modulate HPA axis responses immediately following chronic stress may increase female vulnerability to subsequent stress exposure, perhaps due to potentiated responses in the PVN.

Title: Sphingosine-1-phosphate receptor 3 in the medial prefrontal cortex: A novel target to promote resilience to stress

Authors: *B. CORBETT, N. SOTUYO, S. LUZ, J. PEARSON-LEARY, J. STAIB, S. BHATNAGAR Abramson Res. Ctr., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Repeated exposure to stress promotes depressive- and anxiety-like behaviors in animals and the development of psychiatric disorders in humans, including depression and posttraumatic stress disorder. However, not all stressed individuals develop stress-related psychiatric disorders. That is, some individuals are resilient to the effects of stress whereas others are vulnerable. In a paradigm of chronic social defeat in rats, we have identified subpopulations that are resilient or vulnerable to the neuroendocrine and behavioral effects of defeat. Rats that

exhibit passive coping strategies as evidenced by short latencies to be defeated (SL) in the resident-intruder paradigm are vulnerable to the effects of stress whereas rats that exhibit active coping strategies as evidenced by longer defeat latencies (LL) are more resilient. SL rats display increased depressive-like and anxiety-like behaviors compared to LL rats. However, the mechanisms underlying stress resilience and vulnerability remain unclear. We used a targeted PCR array approach to identify novel neural substrates underlying resilience and vulnerability. We found that in LL rats, the expression of sphingosine-1-phosphate receptor 3 (S1PR3) was increased in medial prefrontal cortex (mPFC) neurons. S1PR3 is a G-protein coupled receptor that is associated with reductions in inflammation in the periphery. The mPFC regulates the stress response and affective-like behaviors, morphological changes occur in the mPFC after stress and its activity is dysfunctional in stress-related affective disorders. We used a viral vector to overexpress S1PR3 in the mPFC of rats and found that S1PR3 overexpression decreased depressive- and anxiety-like behavior, reduced c-Fos expression, and reduced expression of the inflammatory cytokines interleukin 1 beta (IL1 β) and tumor necrosis factor alpha (TNF α). Virally mediated S1PR3 knockdown in the mPFC produced the opposite effects. We investigated whether the ability of S1PR3 to decrease neuronal activity or to reduce inflammation in the mPFC may be mechanisms that promote resilience. We found that chemogenetic inhibition of the mPFC simulated some, but not all, behaviors associated with resilience. In S1PR3 knockdown rats, we found that preventing increases in TNF α by viral knock down reversed the increased depressive- and anxiety-like behavior produced by S1PR3 knockdown. Based on these results, we propose that S1PR3 in the mPFC promotes resilience by reducing neuronal activity and reducing TNF α in the mPFC. We conclude that the S1PR3 is a novel receptor that promotes behavioral and neuroendocrine responses characteristic of resilient individuals.

Title: Vagus nerve stimulation upregulates the production of 5HT1A and 5HT1B receptors in hippocampal neurons of a chronic restraint stress model of depression

Authors: H. SHIN¹, J. PARK², *U. NAMGUNG²

¹Daejeon Univ., Daehak-ro 62, Korea, Republic of; ²Daejeon Univ., 96-3 Yongun-dong, Korea, Republic of

Abstract: Recent studies show that vagus nerve stimulation (VNS) can be used to improve neurological disorders including depression. Here we investigated whether VNS is involved in regulating the responsiveness of hippocampal neurons in relation to depression-like behavior in rats. We induced depression-like state by chronic restraint stress (CRS) in rats and mice, and applied them acute and chronic modes of VNS. Chronic VNS was performed on a daily basis for 2 weeks using a cervically implanted microelectrode. c-Fos protein was induced in the solitary nucleus and serotonergic raphe nucleus 2 h after VNS. We found that 5HT1A and 1B receptor levels were decreased in the hippocampus of CRS animals and elevated to a similar level as in control 24 h after the acute VNS. Immunofluorescence analysis confirmed the hippocampal localization of receptors in the dentate granule cells and CA1 and 3 pyramidal neurons. In CRS animals having chronic VNS, hippocampal 5HT1A and 1B receptors were increased 2 weeks after VNS, and phospho-Erk1/2 protein levels were similarly regulated in hippocampal neurons as well. Behavioral forced swimming test revealed that the chronic VNS in CRS animals improved the immobility score compared to sham-stimulated control. Our results suggest that VNS may improve depression-like behavior via the activation of serotonergic neurons in the hippocampus.

Title: Development of a hippocampal circuit-specific knockout of FOSB gene

Authors: *A. J. WIRTZ¹, A. L. EAGLE², A. ROBISON³ ¹Physiol., ²Dept. of Physiol., ³Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Hippocampal (HPC) circuits, such as the neurons that extend from ventral HPC (vHPC) to nucleus accumbens (NAc), are important for memory and play a critical role in depression and addiction, however the molecular mechanisms underlying this are not understood. We have recently discovered a role for Δ FosB, a chronic activity-dependent transcription factor encoded by the *FosB* gene that drives gene expression underlying cellular function of HPC neurons. In order to better understand the role of Δ FosB in vHPC-NAc projection neurons, we sought to develop a mouse model with a knockout (KO) of the *FosB*

gene. We mated a *floxed FosB* strain (*FosBfl/fl*) with a Cre driver line (Nts2-Cre) with expression in HPC in order to knockout (KO) Δ FosB in HPC. NtsR2-Cre-driven *FosB* KO mice had a lack of Δ FosB expression in sub granular neurons in the dentate gyrus of the hippocampus. These mice also displayed decreased memory and were susceptible to stress, similar to what we had previously found when we silenced Δ FosB transcriptional activity in HPC. We next injected a retrograde HSV-Cre into NAc to drive GFP expression and KO *FosB* in vHPC projections to this region and found that Δ FosB is induced in these projections by cocaine, which is blocked in *FosB* KO mice. Studies are currently ongoing to produce a circuit-specific KO. However, these preliminary findings indicate that Δ FosB is important for normal hippocampal function and its expression (and inhibition) in the HPC-NAc circuit may be specifically crucial to stress susceptibility and drug seeking.

Title: Chronic cocaine and stress alter spine morphology of hippocampal pyramidal neurons

Authors: *A. R. ST. GERMAIN¹, A. L. EAGLE², A. ROBISON³ ¹Physiol., Michigan State Univ., Brighton, MI; ²Dept. of Physiol., ³Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Drug addiction is characterized by the continued seeking and taking of drugs despite adverse consequences, and this relapse to drug seeking can be precipitated by stress. Moreover, stress-related diseases, such as mood and anxiety-related disorders, are highly comorbid with drug addiction. The hippocampus, a brain region essential for learning and memory, has been implicated in addiction, as the user typically makes associations between the drug and the environment that can prompt craving and relapse, and in stress responses and mood disorders. Thus, in order to better treat these diseases, we require a better understanding of the synaptic underpinnings of both hippocampus-driven drug associations and hippocampal responses to

stress. Excitatory signaling in the hippocampus occurs at dendritic spines, small postsynaptic specializations whose number, size, and shape correspond to synaptic number, strength, and maturity, respectively, and we sought to measure the effects of chronic drug or stress exposure on the morphology of these spines. To visualize spines, we performed stereotaxic surgery to inject herpes simplex virus (HSV) expressing green fluorescent protein (GFP) into the dorsal and ventral hippocampus of adult male C57/Bl6J mice. We treated mice chronically with cocaine (20 mg/kg i.p. for 10 days) in a novel environment or exposed mice to 10 days of chronic social defeat stress (CSDS). We then conducted epiflourescent confocal microscopy of fixed brain tissue to quantify the morphologic changes in dendritic spines. Our initial observations suggest that, in dorsal hippocampus CA1 pyramidal neurons, chronic cocaine increased mushroom (mature) spines and decreased thin (immature) spines with no change in total spine density. We are also using HSVs to explore the molecular mechanisms of drug- and stress-dependent hippocampal spine changes, with particular emphasis on drug- and stress-induced transcription factors and their regulators. Ultimately, this research could lead to a better understanding of the common cellular, synaptic, and molecular pathways dysfunctional in addiction and mood disorders, and potentially provide novel targets for therapeutic intervention in these comorbid diseases.

Title: Circuit-specific genomic and functional dissection of male and female resilience to social stress

Authors: *E. S. WILLIAMS¹, A. L. EAGLE², C. E. MANNING³, R. L. NEVE⁴, A. ROBISON³

¹Pharmacol. & Toxicology, ²Physiol., ³Neurosci., Michigan State Univ., East Lansing, MI; ⁴MIT, Cambridge, MA

Abstract: Depressive syndromes are a major cause of morbidity, affecting nearly 300 million globally, and often arise in response to life stress. Aside from its obvious social and financial burden, a striking characteristic of depression is that it affects women nearly twice as often as men. The impact of depression and the disparity in numbers of affected men and women have been recognized for some time, but the molecular underpinnings of the disease remain unknown. This knowledge gap is critical, as treatments remain ineffective in a large number of patients and no sex-specific therapies are known. Neurons in the hippocampus, particularly those that project to the nucleus accumbens, are mediators of stress responses, but little is known of the regulation of this circuit at the level of cell function or gene expression. Here, I use a novel witness chronic social defeat stress (CSDS) mouse model that is amenable to both sexes to investigate the role of the transcription factor Δ FosB in the regulation of ventral hippocampal-nucleus accumbens (vHPC-NAc) projection cells in susceptibility or resilience to CSDS. This circuit has gained recent attention in mood disorder research as it has been shown that reduced activity in these neurons promotes resilience to CSDS. Additionally, our group has shown that the transcription factor Δ FosB is required for hippocampal learning, and its expression is induced in the vHPC by stress or antidepressant treatment. Taken together with our knowledge of its role in resilience in other brain regions, this makes Δ FosB an exciting prospective target for the regulation of vHPC-NAc neuronal function in response to stress. Here, I follow work from our group showing that general inhibition of Δ FosB function throughout the vHPC (but not dHPC) promotes susceptibility to subchronic stress, and show that overexpression of Δ FosB in vHPC reduces cell excitability. Moreover, we explore both basal and stress-induced sex differences in the excitability of vHPC-NAc projection cells, and uncover differences that may underlie sexual dimorphism in susceptibility to mood disorders. With these findings, I hypothesize that stressinduced Δ FosB in vHPC-NAc neurons mediates changes in the function of these neurons and regulates gene expression to promote resilience to social stress in a sex-dependent manner.

Abstract: Stressful and traumatic experiences can contribute to mood disorders in some individuals while others are resilient. Though we know that the hippocampus plays a crucial role in stress responses, it is unknown how changes in hippocampal function, particularly at the level of gene expression, may drive resilience to stress. We have recently described a critical role for hippocampal expression of the transcription factor Δ FosB, encoded by the *FosB* gene, in learning, but its role in stress is unknown. Using the chronic social defeat stress (CSDS) model of depression, we have investigated the role of hippocampal Δ FosB in stress resilience in male mice. Here we show that Δ FosB is induced by CSDS and antidepressants. Inhibition of Δ FosB transcriptional activity in ventral, but not dorsal, hippocampus of adult male mice enhances susceptibility to CSDS. Moreover, using a novel dual-virus CRISPR system, we show that silencing of the *FosB* gene in adulthood in specific hippocampal cells projecting to nucleus accumbens also increases susceptibility to the social withdrawal phenotype of CSDS, while silencing of the *FosB* gene in ventral hippocampal cells projecting to amygdala is anxiolytic. These behavioral phenotypes are reversed by overexpression of Δ FosB in the same cells. Taken together, these data suggest that Δ FosB expression in response to stress regulates hippocampal cells projecting to nucleus accumbens to promote resilience to the social withdrawal phenotype of depression, while Δ FosB expression in hippocampal cells projecting to amygdala may drive stress-induced anxiety. We are currently investigating potential sex differences in Δ FosB's role in these hippocampal projections in response to social stress using a modified witness model of CSDS. These findings offer new insight into the transcriptional mechanisms underlying the etiology of mood- and anxiety-related disorders.

Title: Circuit-specific FOSB gene silencing in ventral hippocampal projections underlies differential behavioral phenotypes associated with psychiatric disease

Authors: ***A. L. EAGLE**¹, C. E. MANNING², E. S. WILLIAMS³, P. A. GAJEWSKI⁴, F. M. BOYCE⁶, R. L. NEVE⁷, I. S. MAZE⁸, A. ROBISON⁵

¹Dept. of Physiol., ²Neurosci., ³Pharmacol. Toxicology, ⁴Genet., ⁵Physiol., Michigan State Univ., East Lansing, MI; ⁶Neurol., Massachusetts Gen. Hosp., Cambridge, MA; ⁷Viral Vector Core, MIT, Cambridge, MA; ⁸Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Ventral hippocampus (vHPC) projection circuits play a critical role in psychiatric disease, including depression, addiction, posttraumatic stress disorder, and anxiety disorders. Glutamatergic vHPC afferents to limbic regions such as the amygdala (AMY) and nucleus accumbens (NAc) are uniquely important in maladaptive emotional behaviors associated with psychiatric disease. Gene expression regulates HPC function, however the role of altered gene expression in vHPC circuits and its contribution to maladaptive emotional behaviors is unknown. Δ FosB, a truncated splice product of the FOSB gene, is a stable activity-dependent transcription factor that we have previously demonstrated to be critical for normal HPC function, making it a potential mediator of gene expression-dependent changes in vHPC projections. The goal of this project was to determine the role of Δ FosB in vHPC circuits and how it may contribute to maladaptive behaviors related to psychiatric disease. We used circuit-specific viral-mediated CRISPR silencing of the FOSB gene in vHPC projections to AMY or NAc and assessed a battery of emotional behaviors. We first found that non-specific inhibition of Δ FosB in vHPC impaired place preference conditioning to cocaine, and altered anxiety & fear learning. Moreover, FOSB silencing specifically in vHPC-NAc projections impaired place preference conditioning but did not affect fear & anxiety. Conversely, FOSB silencing specifically in vHPC-AMY decreased anxiety and impaired avoidance learning, but did not affect place preference conditioning. Viral-mediated rescue of Δ FosB expression in the FOSB silenced circuits reversed these effects. TRAP-Seq (Translating Ribosomal Affinity Purification followed by RNA sequencing) in FOSB silenced circuits indicates that these effects are driven by specific patterns of gene expression which may underlie physiological changes in vHPC projection neuron activity. Collectively, these findings demonstrate that Δ FosB regulates circuit-specific vHPC neuron function via changes in gene expression, and that this may underlie maladaptive emotional behaviors associated with psychiatric disease. Furthermore, they suggest that Δ FosB and its gene targets in vHPC projections neurons may serve as promising therapeutic inroads for multiple psychiatric diseases.

Abstract: Pyramidal neurons in cortex expressing S100a10 (p11) are considered essential for the antidepressant action of selective serotonin reuptake inhibitors (SSRIs), yet the physiology and serotonergic modulation of these neurons are not well understood. Here, we examine the characteristic properties and serotonergic modulation of GFP-positive S100a10 cortical neurons, then probe their response to the stress of prolonged social isolation and to chronic treatment with fluoxetine. In group-housed mice, S100a10 neurons display a biphasic serotonin response with brief inhibition followed by excitation. In socially-isolated mice, however, S100a10 neurons lose this serotonergic "signature" and the excitatory component is supplanted by strong inhibition. In these stressed mice, chronic treatment with fluoxetine in drinking water restores serotonergic excitation of S100a10 neurons. However, we observed that the fluoxetine-treated mice display behavioral heterogeneity with suggestive parallels to human reactions to SSRIs. Additional experiments revealed that a subset of SSRI-treated mice displayed anxiety-like behaviors together with an apparent overshoot of normal excitatory responses to serotonin in S100a10 neurons. To investigate state-dependent molecular changes in S100a10 cortical neurons, we pursued cell type-specific mRNA purification by translating ribosome affinity purification. Data from 4 groups (group-housed, socially-isolated, fluoxetine-treated, and fluoxetine-anxious mice) reveal substantial changes in the gene expression of S100a10 neurons when social isolation disrupts and chronic fluoxetine restores or exaggerates serotonergic excitability. Intriguingly, anxiety upon fluoxetine appears to reflect SSRI-hyper-responsiveness in S100a10 neurons, rather than a failure to respond to treatment.

Title: Infralimbic prefrontal cortical structural and functional projections to the limbic forebrain: A combined viral genetic and optogenetic analysis

Authors: *B. MYERS¹, M. WOOD², O. ADIL², S. FOURMAN², J. P. HERMAN² ¹Biomed. Sci., Colorado State Univ., Fort Collins, CO; ²Univ. of Cincinnati, Cincinnati, OH

Abstract: The prefrontal cortex is critical for contextual appraisal, executive function, and goaldirected behavior. Additionally, the infralimbic (IL) subregion of the prefrontal cortex has been implicated in stress responding, mood, and fear memory. However, the specific circuit mechanisms that mediate these effects are largely unknown. To date, IL output to the limbic forebrain has been examined largely qualitatively or within a restricted number of downstream sites. In order to quantify IL presynaptic input to structures throughout the forebrain, we utilized a lentiviral construct expressing synaptophysin conjugated to mCherry. Thus, allowing quantification of IL efferents that are specifically synaptic, as opposed to fibers of passage. Additionally, this approach permits IL innervation to be determined on a sub-structural level within the multiple heterogeneous nuclei of the limbic system. To examine the functional output of the IL, as well as structure-function relationships, we optogenetically activated IL output neurons and histochemically quantified neuronal activation throughout the limbic forebrain using fos-related antigen (Fra). Our quantification of synaptophysin-mCherry indicated that the IL provides robust synaptic input to a number of regions within the thalamus, hypothalamus, amygdala, and bed nucleus of the stria terminalis (BST), with limited input to the hippocampus and nucleus accumbens. Specific nuclei with the greatest innervation density included the medial dorsal and paraventricular nuclei of the thalamus, the posterior and lateral nuclei of the hypothalamus, the medial and basomedial regions of the amygdala, and anteromedial and anterolateral aspects of the BST. Furthermore, there was a high concordance between structural connectivity and functional activation. Optogenetic activation of IL output neurons induced the greatest activation in the posterior hypothalamic nucleus, medial amygdala, basolateral amygdala, and midline thalamic nuclei. Interestingly, some regions receiving substantial synaptic input did not have significant increases in Fra immunoreactivity, including the lateral hypothalamus and BST. Collectively, these studies represent a step toward a comprehensive and

quantitative analysis of output circuits of the IL. This large scale efferent quantification or 'projectome' also opens the door for data-driven analyses of the downstream synaptic mechanisms that mediate the integrative aspects of organismal stress responding.

Title: Long-term lactate and oxygen measurements in group housed animals

Authors: D. V. AILLON, S. GABBERT, E. KERNER, S. GROTH, E. NAYLOR, D. GWARTNEY, B. BARRETT, *D. A. JOHNSON, D. A. JOHNSON Pinnacle Technology, Inc, Lawrence, KS

Abstract: Wireless recording of in vivo biosensor activity provides second-by-second resolution of brain analytes within a specific region of a freely-moving animal. Observation of these parameters from multiple animals in a co-housed environment can provide valuable insight into the physiology underlying group housed behavior. Pinnacle developed a cage system capable of long-term housing, video tracking, RFID monitoring and wireless recording of physiological parameters from two animals over multiple days. Lactate and oxygen changes were measured continuously for seven days from two rats co-housed in the enclosure and compared to animals that were individually housed. Physiologically relevant changes in oxygen consumption corresponding with play behavior were measured. Lactate concentration was observed to change with sleep/wake state in a manner consistent to previously reported studies. Movement artifact was negligible even during periods of active animal activity. Sleep/Wake analysis noted differences between singly housed animals and group housed animals. The cage system is designed to accommodate food, water and bedding as well as programmable IR lighting for tracking animal behavior during lights off periods. Rats were implanted with guide cannulas (BASi) bilaterally into the frontal cortex region. After recovery from surgery (1 wk) a lactate biosensor (80 um diameter) and an oxygen sensor (180 um disc) were inserted into the cannulas and the sensors were connected to a wireless potentiostat in a head-mounted enclosure. Rats were co-housed for seven days with sensor, video and RFID data collected. All procedures were previously approved by the University of Kansas ACUC. Post-processing software was used to

continually differentiate both rats using a combination of telemetry, RFID tagging and video tracking algorithms. Resolution of video occlusion events was accomplished by verification of the RFID tag signature for an unknown animal on one of four RFID antennas placed in each quadrant of the cage.

Title: Neurogenic and stress-ameliorating effect in hippocampus and hypothalamus of OVX mice model with chronic TM extraction administration

Authors: *K. KIM, H. BAEK, M. PARK, B. KO, K. KIM, S. YI Soonchunhyang Univ., Asan, Korea, Republic of

Abstract: *Tenebrio molitor* (TM) is an edible insect-derived material. In our previous study, as a result of chronic oral administration of TM extract to the OVX-mice model, density and thickness of bone tissues were increased and it appears that neurogenesis in hippocampal dentate gyrus tended to be improved. Therefore we hypothesized this ameliorating effect of menopause-related problems in TM-treated mice model might be related to interaction between hormonal

changes and stress regulation, particularly hypothalamic-pituitary-adrenal (HPA) axis in the body, together with neurogenesis mechanism. In this study, we administered Vehicle or TM extract to non-OVX-mice or OVX-mice model for 4 weeks. We collected brain tissues and blood, and performed blood chemistry, immunohistochemistry (IHC; AVP, GR, CRF and DCX) and Western blotting (WB; GR, CRF and DCX) at the hippocampus and hypothalamus. According to our metabolic data, body weight was significantly increased in OVX/TM group than OVX/Veh group and that was not different between NON groups. Serum estradiol-17β level and glucocorticoid level did not show difference between TM- and Veh-administered groups. However, it was demonstrated by IHC and WB results that doublecortin (DCX) expression was increased in TM- groups than Veh-administered groups. On the other hand, glucocorticoid receptor (GR) expression was significantly decreased in TM- groups than veh-administered groups and very interestingly, the GR expression site tended to be particularly concentrated in the subgranular zone (sgz). This is very meaningful because it is the place where the neuroblasts are located. In addition, the expression of vasopressin (AVP) and corticotropin releasing factor (CRF) was significantly reduced in the PVN area. Taken together, it is thought that chronic administration of TM extract may have the potential to alleviate systemic stress in postmenopausal animal models, and may have an impact on the regulation of HPA axis and neurogenesis correlation.

Abstract: During the past decade, various behavioral and molecular manifestations of the neuropsychiatric disorders in zebrafish were well characterized to be equivalent to humans.

Unlike rodents, a standard depression model in zebrafish is still a prerequisite. Seeking a resemblance to the subordination, aggression, humiliation and bulling of the social defeat model in rodents, we designed the Chronic Predator Stress (CPS) model in zebrafish (Danio rerio). This model follows resident-intruder paradigm where the intruder (Danio rerio) is exposed to (direct) belligerent encounters of an aggressive resident fish (Metriaclima callainos) for a very short period and later separated by a partition (indirect). After the 5-day CPS paradigm, depression-like phenotype was evidently observed through relevant behavior tests (Social Interaction, Anhedonia, Novel Tank Test. Further molecular studies using telencephalon region (corresponding to hippocampus of mammals) of the subject fish indicated significant reduction in the expression of the neurotrophic factors and dysregulation of the downstream intracellular signaling cascade associated with CREB activation. CPS exposure indicated a significant contrariety in the expression of various neuronal and glial populations in the telencephalon compared to the control fish.

After the accomplishment of the construct, face and discriminative validity, we evaluated this model for predictive validity using two antidepressants of different origin i.e, Fluoxetine (slow) and Ketamine (rapid) and their actions on phenotype and physiologiocal recovery. Our results indicate that the CPS model can be utilized as an alternative in in vivo animal model for depression which eventually can be useful as a tool to screen of novel potential antidepressants.

Title: A new framework for identifying molecular drivers of resilient neural circuit activity

Authors: ***R. HULTMAN**¹, M. JONES³, L. MA², K. ULRICH¹, D. CARLSON¹, L. CARIN¹, K. DZIRASA⁴

²Dept. of Statistical Sci., ¹Duke Univ., Durham, NC; ³Human Longevity Inst., San Diego, CA; ⁴Duke Univ. Med. Ctr., Durham, NC

Abstract: Neural circuit disruptions have been increasingly appreciated as contributing directly to behavioral dysfunction. Identifying molecular contributors to specific neural circuit activity may provide a more promising route to efficacious drugs that target specific circuit-level causes of behavioral dysfunction. Here we describe an innovative, transdisciplinary pipeline that takes

advantage of multisite in vivo neurophysiology, RNA-Seq, machine learning, and targeted viral manipulation strategies, for identifying and validating molecular drivers of specific neural circuit activity. We dissect neural circuitry underlying stress-susceptibility in a well-characterized mouse model of susceptibility to chronic stress: The chronic social defeat stress (CSDS) paradigm.

Using in vivo neurophysiology in freely behaving mice, we recorded an endophenotype of stresssusceptibility: pre-frontal cortex 2-7Hz oscillatory activity. We then measured the reactivity of this neural signature in a forced interaction test (FIT). Prefrontal cortex tissue was microdissected and gene expression was detected according to neural circuit activity using RNA-Seq. We found that gene pathways associated with the mitochondrial complex ii were upregulated in animals with the putative resilient neural signature prior to stress exposure. We then used AAV manipulations to demonstrate that differential regulation of this pathway drove resilience to chronic social defeat stress. Finally, we demonstrate that we can enhance the predictor of resilience using multi-site in vivo recordings that incorporate other brain regions that contribute to a PFC-driven neural circuit signature, including nucleus accumbens, basolateral and central amygdala, ventral hippocampus and ventral tegmental area.

Here we demonstrate that combining in vivo neurophysiology and Next Generation Sequencing can be a powerful approach for the identification of molecular drivers of specific neural circuit function with regard to stress-related pathology. Applying such approaches more widely will be essential for the development of circuit-based psychopharmacotherapeutics.

Title: Local microinfusion of pituitary adenylate cyclase-activating polypeptide into the infralimbic cortex alters ACTH sensitivity and behavioral coping strategies

Authors: *S. E. MARTELLE¹, B. A. PACKARD¹, E. M. COTELLA², J. HERMAN² ¹Psychiatry, Univ. of Cincinnati, Cincinnati, OH; ²Psychiatry, Univ. of Cincinnati, CINCINNATI, OH

Abstract: Among its many roles, pituitary adenylate cyclase-activating polypeptide (PACAP) acts as an excitatory neuromodulator influencing neurotransmitter release and reuptake.

Recently, PACAP has emerged as a regulator of stress responding. For instance, PACAP knockout mice exhibit abnormal anxiety-like behaviors and polymorphisms of PACAP and its receptor are associated with post-traumatic stress disorder in humans. In the current study, we investigated the effects of PACAP in the infralimbic cortex (IL), known for its role in maladaptive stress responses. We hypothesized that IL injections of PACAP would increase excitatory input to the intercalated cells of the amygdala and thus inhibit the central amygdala, reducing anxiety-like behavior. Cannulated adult male Sprague-Dawley rats were microinjected with PACAP (1 ug/side; n=12) or vehicle (sterile saline, 0.5 ul/side; n=10) into the IL 30 minutes prior to a forced swim test (FST). Blood was sampled via tail clip at 15, 30, 60, and 120 minutes post initiation of the FST for analysis of HPA responsiveness. Animals pretreated with PACAP had decreased incidence of swimming (p=0.02) and dived more often (p=0.006) than controls, suggesting alternative active coping approaches. Furthermore, PACAP-treated animals had decreased adrenal responsivity (p=0.03), a measure of adrenocortical function that could be an indication of reduced sensitivity to ACTH at the level of the adrenal cortex. When undergoing a passive avoidance test one week later, animals that had previously been treated with PACAP displayed a decreased cross-over latency during habituation, further suggestive of alternate coping strategies. Analysis of Fos indicated that intra-IL PACAP does not differentially activate primary targets in the basolateral or central nuclei of the amygdala, necessitating future studies investigating how PACAP is affecting HPA axis responsiveness and coping strategies.

Title: Differential effects of ventral hippocampal corticosterone and its receptors on accumbal dopamine output in drug-naïve and amphetamine withdrawn rats

Authors: *B. BRAY^{1,2}, M. A. WEBER^{1,2}, G. L. FORSTER^{1,2} ¹Basic Biomed. Sci., ²Ctr. for Brain and Behavior Res., Univ. of South Dakota, Vermillion, SD

Abstract: Alterations in stress and dopamine levels can motivate goal-oriented behavior and prompt drug use in withdrawal. Amphetamine withdrawal is associated with dysphoria and hypersensitivity to stress in humans and rats that can prompt relapse. This effect may be mediated by enhanced stress-induced corticosterone (CORT) in the ventral hippocampus

(vHipp), as is observed in rats. vHipp CORT can induce glutamate release and the vHipp sends glutamatergic projections to the nucleus accumbens shell (NAcS) to enhance dopamine output and reward salience. To directly test whether vHipp CORT can enhance NAcS dopamine output, a stress-relevant concentration of CORT (0.24 ng total) was infused into the vHipp of anesthetized drug-naïve adult male rats, and rats in amphetamine withdrawal. Resulting NAcS dopamine output was measured by in vivo chronoamperometry. In drug-naive rats, vHipp CORT enhances NAcS dopamine output, peaking 55 min post infusion. This suggests a novel mechanism by which stress exposure could enhance reward value to promote goal-oriented behavior. In amphetamine withdrawal, vHipp CORT reduces NAcS dopamine output, peaking 20 min post-infusion, returning to baseline at 55 min post-infusion, then decreasing again, peaking at 80 min post-infusion. This suggests stress-induced vHipp CORT could contribute to dysphoric states that prompt relapse in withdrawal. These findings support an opponent-process theory of addiction, in which blunted dopamine reward responses and enhanced CORT stress responses negatively reinforce drug-taking. Preliminary data suggests these findings are specific to CORT in the ventral dentate gyrus/subiculum regions of the vHipp, as CORT infused into the dorsal vHipp or anteriorly into the CA1/CA3 regions do not alter NAcS dopamine output. CORT can act on glucocorticoid (GR) or mineralocorticoid (MR) receptors. vHipp GRs are thought to be excitatory; whereas vHipp MRs may be excitatory or inhibitory. Here we show that blocking vHipp MRs or vHipp GRs abolishes the CORT-induced NAcS dopamine increase observed in control conditions and augments CORT-induced decreases of NAcS dopamine output in amphetamine withdrawal, although GR antagonism produces these effects at a greater magnitude than that observed for the MR antagonist. These findings suggest that vHipp GRs and MRs contribute to vHipp CORT induction of NAcS dopamine output both in control conditions and in amphetamine withdrawal. Overall, our findings suggest vHipp CORT could play an important role in driving positive stress coping mechanisms in healthy conditions, with dysregulation of this system potentially contributing to relapse in withdrawal.

Title: Cell type specific and region specific knockdown of glucocorticoid receptors: sex specific effects on the HPA axis and behavior

Authors: *J. SCHEIMANN, R. MORANO, P. MAHBOD, J. P. HERMAN Univ. of Cincinnati, Cincinnati, OH

Abstract: Hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis has been implicated in psychiatric disorders such as major depressive disorder (MDD), Post-Traumatic Stress Disorder (PTSD), and possibly anxiety. Normally, glucocorticoid release consequent to HPA activation promotes adaptive responses that may equip the animal for future threats, via enhanced memory and altered emotionality. However, under conditions of excessive activation, these changes may be maladaptive leading to different excitatory and inhibitory drives within important limbic regions and their projections.

Lesion studies suggest that the medial prefrontal cortex (mPFC) and ventral subiculum (vSUB) are critical for cessation of the HPA axis via polysynaptic signaling to the hypothalamus. We have shown that knocking down GR in the PFC leads to changes in HPA activation and depressive like behavior (as shown as increased immobility in the forced swim test). In this study, we sought to determine if the HPA and behavioral effects of GR downregulation are primarily due to loss of GR on excitatory projection neurons of the PFC and vSUB. To achieve region-specific down-regulation, we injected an adeno-associated virus (AAV) expressing Cre Recombinase under the CAMKIIa promotor into either the PFC or VSUB of mice with a floxed GR exon 3 (f/f) or wildtype (wt) littermate controls. Three weeks after injection of virus, male (n=9-11), and female (n=11-12) mice, aged 30-60 weeks were given a battery of behavioral tests that are thought to assess anxiety-like behavior (open field or elevated plus maze), depressive-like behavior(forced swim test), and behavioral inhibition (passive avoidance). There was no effect of PFC-specific GR deletion on open field or passive avoidance behavior in either males or female mice. Moreover, there were no differences in HPA axis activation after an acute stressor in f/f mice versus wildtype controls. In contrast, vSUB GR deletion in male mice decreased open arm entries in the elevated plus maze and decreased cross-over latency in the passive avoidance task (reduced behavioral inhibition). There were no differences in female mice. In addition, vSUB GR deletion increased stress-induced corticosterone release, again, only in males. These data suggest an important role for the GR in modulating vSUB, but not PFCmediated, stress responsiveness and emotional reactivity in a sex-dependent manner.

Title: The impact of acute stress on the expression of brain adenosine receptors

Authors: *B. A. BAUSTIAN, E. BAUER, A. BELL, P. J. CLARK Iowa State Univ., Ames, IA

Abstract: Our lab and others have shown that exposing rodents to a single episode of acute stress can produce long-lasting reductions in wheel running that persist months after the stressor is no longer present. We hypothesize that chronically reduced running may be related to maladaptive changes of central-mediated fatigue pathways. Adenosine signaling in the brain is a key contributor to central-mediated fatigue. Under heightened metabolic demand, adenosine is produced from the catabolization of the cellular energy source, adenosine triphosphate (ATP), and can act as a neuromodulator by promoting fatigue-related behavior primarily through activity at adenosine A1 and A2a receptors. Adenosine receptor expression may upregulate following metabolic demands of sufficient intensity, such as acute stress, which may produce a more rapid onset of central fatigue and contribute to persistently reduced wheel running activity. Therefore, we explored the effects of a single episode of acute uncontrollable stress on the expression of adenosine receptor protein in the striatum, as well as other brain areas where adenosine modulates fatigue behavior including the hippocampus, prefrontal cortex, and hypothalamus. We exposed adult C57BL/6J mice to a series of uncontrollable tail shocks (acute stress) or left them undisturbed in home cages (control). The mice were sampled at either 24 hours or 4 weeks by transcardial perfusion with phosphate buffer and paraformaldehyde. Immunohistochemistry was performed on thin brain sections to detected A1 and A2A receptors. Brain sections will be imaged and densitometry will be performed to semi-quantitatively measure the density of adenosine receptors in brain regions. Data collection is underway. We hypothesize A₁ and A_{2a} receptor expression will upregulate across all brain regions following acute stress by at least the 4-week time point. A widespread increase in brain adenosine receptors may be relevant to the modulation of increased fatigue-related behavior and reductions in physical activity following stressful experiences of sufficient intensity.

Title: Food restriction alone exercise alone or the combined during adolescence rescue elevated anxiety and deficits in memory and social function resulting from variant BDNF Val66Met single nucleotide polymorphism through GABAergic mechanisms in the dorsal hippocampus

Authors: *Y.-W. CHEN¹, H. ACTOR-ENGEL¹, F. LEE², C. J. AOKI¹ ¹Ctr. for Neural Sci., New York Univ., New York, NY; ²Dept of Psychiatry, Weill Cornell Med. Col., New York, NY

Abstract: Val to Met substitution at codon 66 (Val66Met) in Brain-Derived Neurotrophic Factor (BDNF) leads to reduced activity-dependent secretion of BDNF. In humans, this SNP has been associated with anxiety disorder, structural abnormalities of the hippocampal formation and cognitive impairments. Our previous data link anxiety-like differences in BDNF-Val66Met knock-in (BDNF^{Met/Met}) mice with reduced GABAergic innervation of the dorsal hippocampus (doi: 10.1093/cercor/bhw210). Others have also shown that both food restriction (FR) and exercise (EX) elevate BDNF levels in the hippocampus.

We investigated whether FR and/or EX during adolescence restore behavioral deficits in BDNF^{Met/Met} mice. Four groups of male and female pubertal BDNF^{Met/Met} mice and their wild-type littermates, all singly housed, were reared as follows during adolescence: EX (housed with a wheel from P36-44), FR (from P41-44), and FR-plus-EX (housed with a running wheel from P36-44 and FR from P41-44, an animal model of activity-based anorexia) and CON (no FR and no EX). After recovery from these treatments for >7 days, we assessed the animals' anxiety-like behavior, spatial and object recognition memory and social preference and recognition. Animals were sacrificed at P60 to measure GABAergic innervations and $\alpha4\beta\delta$ -GABA_A receptor levels on their pyramidal neurons in the dorsal hippocampal CA1 by electron microscopic immunocytochemistry.

During early adulthood, male BDNF^{Met/Met} mice display increased anxiety-like behavior and impairment of spatial and object recognition memory and social recognition. EX, FR, and FR-plus-EX to BDNF^{Met/Met} mice during adolescence had no effect on anxiety-like levels, and EM confirmed that GABAergic innervation remains low. However, EX, FR, and FR-plus-EX showed differential restorative effects on spatial, object recognition memory, and social recognition deficits, and EM suggests that these are mediated by changes in $\alpha 4\beta\delta$ -GABA_AR levels. Female BDNF^{Met/Met} mice display normal spatial memory, but elevated anxiety-like behavior and impairments in object recognition memory and social recognition. FR and FR-plus-EX normalized their anxiety-like levels and improved their object recognition memory, with changes in $\alpha 4\beta\delta$ -GABA_AR levels. Social recognition deficits found in BDNF^{Met/Met} female mice may be via altered GABAergic innervation in distal dendrites.

Thus, FR and/or EX during adolescence normalizes anxiety, cognitive and social abnormalities exhibited by BDNF^{Met/Met} mice. Our study highlights sex differences in the effects of BDNF

Val66Met SNP on anxiety and cognitive functions, and their potential causal and restoring mechanisms.

Title: Optogenetic induction of LTD in the Medial Prefrontal Cortex results in set-shifting deficits

Authors: *S. E. BULIN¹, K. M. HOHL¹, D. A. MORILAK²

¹Pharmacol., UT Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; ²Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Stress-related mood and anxiety disorders, like depression and posttraumatic stress disorder (PTSD), are highly prevalent yet poorly treated. Relapse and residual symptoms remain problematic, and a poor understanding of the neurobiology underlying these illnesses has limited the development of new treatments. Imaging studies have shown reduced activity in the mPFC in both depression and PTSD, associated with deficits in executive functions, including impaired cognitive flexibility, that not only represent symptoms of these illnesses, but also contribute causally to their development and maintenance. Such changes presumably involve aberrant forms of neural plasticity in the mPFC. Similarly, chronic stress compromises cognitive flexibility, and is likely to disrupt the plasticity that normally underlies this executive process. Cognitive flexibility mediated in the mPFC can be measured using the attentional set-shifting test, and chronic unpredictable stress (CUS) induces a deficit of cognitive flexibility on this test. Further, we have previously shown that CUS attenuates the response of the mPFC to stimulation of the excitatory afferent from the mediodorsal thalamus (MDT). Thus, we are using optogenetics to investigate if directly inducing plastic changes in the mPFC is sufficient to alter cognitive flexibility. Glutamatergic neurons in the MDT were selectively infected either with the ChETA variant of channelrhodopsin by injecting an AAV5-CAMKII-ChETA viral vector, or with control AAV5-CAMKII-GFP, and allowed 6 weeks for expression and trafficking of the channel to terminals innervating the mPFC. Rats were anesthetized with chloral hydrate and baseline field potentials evoked by MDT stimulation were recorded in the mPFC for 15 min. Optical LTD was induced by stimulating mPFC terminals. The mean amplitude of evoked responses, recorded for 3 hr after stimulation, was reduced to 75% of baseline, indicating a
depressed response (n=4; p <0.0001). This depressed response was not observed in control GFP animals. (n=4; p>0.05) Then using this procedure, we induced LTD in awake rats to test the effect of LTD on set-shifting. ChETA injected rats (n=9) that received the LTD protocol 1-hr prior to set-shifting took significantly more trials to reach criteria than controls (n=8; p <0.0001). These results suggest that inducing LTD in the MDT-mPFC pathway is sufficient to produce cognitive deficits similar to those observed after CUS. By contrast, future experiments will explore if inducing LTP in the mPFC will restore healthy behaviors compromised by CUS.

Title: Social stress produces a long-term activation of locus coeruleus neurons in adolescent vs. adult female rats

Authors: *A. L. CURTIS, H. GUAJARDO, G. ZITNIK, R. VALENTINO Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA

Abstract: Women suffer double the incidence of psychiatric disorders related to stress compared to men. While the symptoms of such psychiatric disorders like depression are similar in males and females the range of vulnerabilities and sensitivity to likely causal factors remains unknown. This has encouraged investigations of factors thought to participate in the onset of such disorders like stress. A component of the stress response is activation of the locus coeruleus (LC)norepinephrine system. Stress-induced LC activation is mediated by corticotropin-releasing factor (CRF) and is associated with enhanced arousal and changes in cognitive flexibility. This study examined the effects of adolescent and adult social stress using the resident-intruder model on LC activity in unanesthetized female rats. Single unit LC activity was recorded before and during resident-intruder stress on the first and fifth days of 5 consecutive daily exposures. The resident was a lactating female and LC activity was recorded from the intruder. Spontaneous LC neuronal activity was compared between adult and adolescent rats before and during the stressor. We found that LC activity was similarly increased in adult ($160 \pm 19\%$ C, 27 cells, 3 rats) and adolescent (156 + 10%C, 60 cells, 4 rats) females on day-1 of social defeat (SD). However, by day-5 of SD, LC neuronal activation in adolescents further increased to $201 \pm 10\%$ C (43 cells, 4 rats), but stress-induced LC activation in adults declined to 123 + 10%C (24 cells, 2 rats) on day5 of SD. This suggests that LC activity in adolescents may be sensitized by repeated stress and this differs from the reduced LC response to stress shown in adult females. This finding is interesting because it is suggested that adolescence is a period of stress vulnerability when brain circuits associated with emotion and decision-making are in ongoing maturation. In conclusion, we found that LC neurons of adolescents were more sensitive to social stress than those of adult female rats. These findings of enhanced reactivity to stressful experiences during adolescence may serve to underscore the critical vulnerability of this developmental stage and how it may lead to an elevated incidence of stress-related psychiatric disorders in women.

Title: Social stress activates amygdalar corticotropin releasing factor and brainstem enkephalinergic afferents to the rat locus coeruleus in adolescent male rats depending on coping strategy

Authors: *M. URQUHART¹, B. A. REYES², X.-Y. ZHANG³, R. VALENTINO³, E. J. VAN BOCKSTAELE⁴

¹Pharmacol. and Physiol., Col. of Medicine, Drexel Univ., Philadelphia, PA; ²Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; ³Dept. of Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA; ⁴Dept. of Pharmacol. & Physiol., Drexel Univ. Col. Of Med., Philadelphia, PA

Abstract: Adolescence is a crucial time of increased neuronal plasticity, rendering this period particularly vulnerable to stress. A common stressor encountered during this period is social stress. An ethologically relevant animal model of social stress is the resident-intruder model. Using this model, we have shown that social stress engages distinct amygdalar corticotropin-releasing factor (CRF)- and nucleus paragigantocellularis (PGi) opioid-containing afferents to the locus coeruleus (LC) in adult male and female rats, that segregate according to coping strategy as determined by the latency of the rats to assume a defeat posture. Here, we identified the neural circuitry that activates the LC following social stress in adolescent male Sprague-Dawley rats. Prior to social defeat exposure, rats were injected with the retrograde tracer,

Fluorogold (FG) into the LC. Three days following FG injection, rats were subjected to repeated (5 days) social defeat or control manipulation, and perfused 90 minutes after the last session. Sections through the lower brain stem and forebrain were collected and processed for immunocytochemical detection of c-fos, a marker of neuronal activity, FG and CRF or enkephalin (ENK). Consistent with our previous tracing studies, retrogradely labeled neurons from the LC were distributed throughout the rostro-caudal segments of the central nucleus of the amygdala (CeA) and PGi. Cell counts revealed that c-fos expression in the CeA was significantly increased in the short latency to defeat (SL) rats (P < 0.01) when compared to control and LL latency (LL) rats. Triple labeling of c-fos, FG and CRF revealed that 78% of c-fos and FGimmunoreactive neurons in the CeA of SL rats also expressed CRF, which was significantly higher (P < 0.05) when compared to control and LL rats. In the PGi, approximately 34% of c-Fos and FG-immunoreactive neurons of LL rats also expressed ENK, which was significantly higher (P < 0.05) when compared to control and SL rats. These results are consistent with previous studies in male adult rats and underscore that that social stress engages distinctly different regulation of the LC depending on coping strategy that may translate to distinct behavioral and physiological consequences.

Title: Sex-specific behavior and dorsal raphe 5-HT neuronal excitability in response to acute and chronic stress

Authors: *D. T. CHU, D. K. OLIVER, D. SARGIN, E. K. LAMBE Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: A severe and widespread mood disorder, major depression affects about 15 % of the population. Significantly, women are twice as likely to develop a depressive illness as men.

Despite the high prevalence of this disease, its neurophysiological correlates are not completely understood. The most widely used antidepressant treatments target the serotonin (5-HT) system, especially the 5-HT neurons in the dorsal raphe nucleus, which play an important role in stress response and emotional regulation. We have recently shown that chronic social isolation stress in male mice decreases 5-HT neuronal excitability in the dorsal raphe nucleus and produces a depressive-like phenotype (Sargin et al., eLife, 2016). Here, we examined potential sex differences in the regulation of 5-HT neuronal excitability at baseline and in response to stress. In a combined set of behavioral and electrophysiological studies, we investigated anxiety- and depressive-like behaviors and dorsal raphe 5-HT neuronal excitability in male and female mice. Compared to male mice, female mice showed significantly increased anxiety in the open field test at baseline. Under acute forced swim stress, female mice showed a significantly greater depressive-like response. To investigate 5-HT neuronal excitability, we performed whole cell patch clamp electrophysiology in dorsal raphe slices obtained from adult male and female mice. At baseline, in response to strong depolarization 5-HT neurons of female mice showed attenuated action potential firing compared with 5-HT neurons of male mice indicating reduced excitability. In response to acute stress, 5-HT neurons in male mice were less excitable, while those in females remained unaffected. Ongoing experiments are further probing the cellular mechanisms underlying the sex differences in behavior and 5-HT neuronal physiology under baseline conditions and in response to stress.

Title: Cellular sites for interactions between the endocannabinoid metabolic enzyme monoacylglycerol lipase and norepinephrine in the rat frontal cortex

Authors: *E. J. VAN BOCKSTAELE¹, K. MACKIE², B. A. REYES³ ¹Dept. of Pharmacol. & Physiol., Drexel Univ. Col. Of Med., Philadelphia, PA; ²Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; ³Pharmacol. & Physiol., Drexel Univ., Philadelphia, PA

Abstract: Endogenous cannabinoids or endocannabinoids (eCB), derived from phospholipids are one of the most ubiquitously distributed modulators in the brain. Involved in various physiological and pathological conditions, eCB release from post-synaptic neurons mediate their

actions through the activation of cannabinoid receptors that are often localized on pre-synaptic axon terminals. We have shown that cannabinoid type 1 receptors (CB1r) are positioned to presynaptically modulate norepinephrine (NE) release in the rat frontal cortex (FC) and that these are directly apposed to neurons containing the eCB synthesizing enzyme diacylglycerol lipase (DGL). DGL functions to synthesize 2-arachidonoylglycerol (2AG) in the post-synaptic neuron. While DGL synthesizes the eCB 2AG, the metabolic enzyme monoacylglycerol lipase (MGL) serves to degrades the eCB. These enzymes are also thought to be differentially distributed, with DGL being localized post-synaptically in somato-dendritic processes and MGL more frequently localized pre-synaptically, in axon terminals. In the present study, we investigated cellular sites for interactions between noradrenergic afferents and cortical neurons expressing MGL using immunofluorescence and immunoelectron microscopy. Tissue sections were collected through the FC and processed for immunocytochemical detection of MGL, CB1r and the norepinephrine transporter (NET) or the NE synthesizing enzyme, dopamine-beta-hydroxylase (DBH). Immunofluorescence microscopy revealed co-existence between MGL, CB1r and DβH or NET in varicose processes in the FC. Ultrastructural analysis, using immunogold-silver labeling for MGL and immunoperoxidase labeling for NET or D\u00dfH, confirmed that NET or D\u00ffH-labeled axon terminals also exhibited MGL-immunoreactivity in the FC. Taken together, these data indicate anatomical substrates for proposed interactions between the eCB metabolic enzyme, MGL, and the noradrenergic system in the FC.

Title: Gender-specific changes in hippocampal synaptic plasticity and cognitive performance in C57BL/6J mice exposed to maternal separation

Authors: *G. TALANI¹, G. SARIGU², F. VEDELE², M. PETRELLA², D. COLOMBO², E. SANNA²

¹Inst. of Neurosci., Natl. Res. Council, Monserrato, Italy; ²Dept. of Life and Envrn. Sciences, Section of Neurosci. and Anthrop., Univ. of Cagliari, Monserrato, Italy

Abstract: Repeated maternal separation (MS) in newborn rodents is a powerful experimental model for investigating the consequences of neonatal stress on ethanol (EtOH) sensitivity as well as the neurochemical mechanisms involved in the long-term impairments at brain level in

adulthood. Because previous work suggested that the effect of MS on voluntary EtOH drinking appears to be gender-specific, the aim of the present study was to evaluate the long-term effects of MS on EtOH voluntary consumption and long-term hippocampal plasticity and compare the outcome between males and females C57BL/6J adult mice. Male or female pups were separated daily from the dam for 360 min (from PND 2 to 17). On PND 60, mice were tested for their voluntary EtOH consumption by using the two-bottle free choice paradigm. Extracellular and patch-clamp recordings were performed in order to evaluate possible changes in hippocampal synaptic plasticity as well as GABAergic and GLUergic transmission. As previously shown, MS male but not females mice showed a marked increase of EtOH intake and preference. Long-term depression (LTD) but not potentiation (LTP), induced in the CA1 hippocampal subfield, was enhanced in MS male but not females. In parallel, MS male mice showed an impaired performance on the Barnes maze with a decrease of long-term spatial memory when compared with control animals. Conversely, females exposed to MS did not differ from their control counterparts when tested in the Barnes maze. Patch-clamp experiments revealed, in the CA1 pyramidal cells, a significant enhancement of GABAergic sIPSC frequency and a decrease in the amplitude and decay time constant of GLUergic sEPSCs. Interestingly, a single injection of βethynyl estradiol in MS male mice at PND2, completely prevented the MS-associated long-term changes of both voluntary EtOH consumption and hippocampal synaptic plasticity, suggesting that this treatment produces a protective effect against MS stress. Overall, our findings strengthen the idea that MS produces long-lasting modifications on plasticity at both excitatory and inhibitory synapses, effects that may be relevant for the altered cognitive performance and sensitivity to EtOH. These results, herein add to previous evidence supporting the idea of genderspecific sensitivity to stress associated to MS, and suggest that hormones may affect the outcome of early life although the neurobiological mechanisms behind these changes need further investigation. Title: Paraventricular thalamic regulation of habituation to repeated stress: Molecular and network mechanisms

Authors: B. CORBETT¹, S. LUZ², *S. BHATNAGAR³

¹Abramson Res. Ctr., ²Children's Hosp. of Philadelphia, Philadelphia, PA; ³Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: In the field of stress neurobiology, habituation is defined as a decreasing and learned response to a familiar stressor over time. Disrupted habituation is a signature of post-traumatic stress disorder (PTSD), causing devastating effects for those afflicted. Understanding the molecular and neural substrates underlying habituation may allow for improved therapies for PTSD patients. In rats, we model habituation using the repeated restraint stress paradigm. Exposure to this moderately intense stressor increases the expression of immediate early genes in certain brain regions, induces the production of stress-related hormones, and elicits struggle behavior. All of these responses are highest on day 1 of restraint and attenuate by the 5th to 7th exposure. We have previously identified the posterior paraventricular thalamic nucleus (pPVT) as a crucial brain region that promotes habituation. However, the underlying molecular mechanisms and specific neural connections among the pPVT and other brain regions that mediate habituation are unknown. Using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), we investigated the role of the pPVT in regulating the stress response. We demonstrated that chemogenetic inhibition of the pPVT disrupted neuroendocrine habituation to 5 days of 30min daily restraint exposure, consistent with our previous data using neurotoxic lesions. Additionally, we found that chemogenetic inhibition of a subset of pPVT neurons that project to the medial prefrontal cortex (mPFC), which negatively regulates the stress response, was sufficient to attenuate habituation. We hypothesize that pPVT neurons, in particular those that project to the mPFC, play a critical role in the abiity to habituate to stress. Finally, we investigated whether activity-regulated cytoskeleton-associated protein (Arc) induction within the pPVT was a molecular mechanism of habituation. Arc is an immediate early gene that reduces excitatory synapse number. We found that Arc expression was increased in the pPVT on day 1, but not day 5 of restraint in naïve rats and that Arc knockdown in the pPVT attenuated habituation. We hypothesize that Arc-mediated restrictions in excitatory synapse number during the first exposures to restraint are a critical mechanism underlying habituation of the stress response. Our findings offer new insight into the role of the pPVT in regulating the stress response and are amongst the first to provide potential molecular and network mechanisms underlying stress habituation.

Title: Effect of corticotropin-releasing factor on noradrenergic locus coeruleus neurons in cannabinoid type 1 receptor knock out mice

Authors: *R. WYROFSKY¹, L. G. KIRBY², E. J. VAN BOCKSTAELE¹ ¹Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; ²Ctr. for Substance Abuse Res. and Dept Anat. and Cell Biol, Lewis Katz Sch. of Med. At Temple Univ., Philadelphia, PA

Abstract: The noradrenergic system has been shown to play a key role in the modulation and regulation of stress responses, arousal, mood, and emotional states. Dysregulation of noradrenergic transmission, which has been shown to play a key role in the modulation and regulation of stress responses and emotional states, can lead to the development of several stressrelated psychiatric disorders. As the primary mediator of stress-related inputs to the noradrenergic locus coeruleus (LC), corticotropin-releasing factor (CRF) increases LC neuronal discharge rates and induces norepinephrine (NE) release in target regions. The endocannabinoid (eCB) system has been shown to modulate stress responses in multiple brain regions and is thought to act as an "anti-stress" neuromediator. We have shown that cannabinoid receptor type 1 (CB1r) and CRF co-localize within individual axon terminals in the core and peri-LC areas, and that these are characterized by morphologically distinct synapses as revealed by electron microscopy. Using anterograde tract-tracing from the amydala, we also demonstrated that the eCB system is positioned to directly regulate CRF release from this limbic afferent. Mice lacking the CB1r are known to exhibit anxiogenic-like phenotypes and have altered stress responses. In the present study, we sought to investigate the effect of CRF on LC-NE activity in male and female wild type (WT) and CB1r knock-out (KO) mice. Whole-cell patch-clamp recordings of LC-NE neurons were conducted in 250 µm thick horizontal brain slices obtained from 4-5 week old C57/B6 CB1r KO mice and their WT littermates. An optimal dose of 300nM CRF was first determined in male WT mice. Preliminary results, in WT subjects, show that bath application of 300nM CRF significantly increases LC-NE excitability compared to baseline in both sexes, as measured by the number of spikes elicited by a range of increasing current pulses. Additionally, 300nM CRF caused an increase in input resistance in both males and females. Interestingly, both male and female CB1r KO mice had heightened basal LC-NE excitability that was comparable to the level of excitability caused by 300nM CRF in WT littermates. Bath application of 300nM CRF did not cause any further increase in LC excitability. Taken with our previous anatomical data showing co-existence of CB1r with CRF in single afferents innervating the LC, some of which originate from the amygdala, these data indicate that the eCB system regulates LC-NE neuronal activity, which has significant implications for mediating stress responses.

Title: Sex differences in cytokine expression following sub-chronic variable stress

Authors: *J. R. RAINVILLE, G. E. HODES

Sch. of Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Depression affects more than 300 million people worldwide, and the risk of experiencing a depressive episode is twice as high for women as it is for men. Pro-inflammatory cytokines and the activation of inflammatory pathways have been associated with depression. Many autoimmune and inflammatory diseases also have a higher incidence in women, presenting the possibility that sex-specific peripheral immune system responses to stress may influence sex differences in susceptibility to depression. The purpose of this study is to examine how peripheral cytokine expression may reflect differences in stress susceptibility between sexes. We used a 6-day subchronic variable stress (SCVS) model, in which stressed female but not male mice express depression-associated behaviors (Hodes et al., 2015) to observe the effects of sex and stress on peripheral cytokine expression. Animals were exposed to a combination of foot shock (0.45 mA/ 2 sec/ 100 in 1 hour), tail suspension and restraint stress, one a day, two times, over the course of 6 days. Blood was drawn from animals within 20 minutes of stress exposure (restraint stress) on the last day of SCVS. Multiplex ELISA was used as an unbiased screen to quantify plasma expression levels of 27 different cytokines. The overall pattern of expression indicated that male and female peripheral immune systems respond to stress differently following 6 day SCVS. In general, cytokines that were significantly affected by stress in males were increased compared to male controls. In females, stress generally decreased cytokine levels compared to same sex controls. The following cytokines were significantly (p<0.05), and oppositely regulated in stressed male and female mice after 6 day SCVS: CXCL1, VEGF, CCL5, IL-1α, Eotaxin, and IL-13. The exceptions to this pattern were the cytokines CXCL2 and M-CSF which were both significantly increased males and females following stress. The expression of VEGF, IL-13, CCL5, IL-1α in all treatment groups were positively correlated with each other, suggesting a potential interconnection of these inflammatory pathways in response to stress in both sexes. These results were further correlated with behavior results from a novelty suppressed feeding test that was conducted after the blood draw. CCL5 levels were positively correlated with latency to eat in males (p<0.05), but not in females. LIX levels were positively correlated

with latency to eat in all groups. Eotaxin levels were negatively correlated with latency to eat in stressed animals of both sexes. Together these data suggest that sex specific cytokine patterns of expression may be able to indicate stress susceptibility in both sexes.

Title: Transcriptional sex differences in the nucleus accumbens and hippocampus following subchronic and chronic variable stress

Authors: M. TSYGLAKOVA¹, J. RAINVILLE², A. JOHNSON², B. SMITH², *G. E. HODES² ¹Translational Biology, Med. and Hlth., Virginia Tech. Carilion Sch. of Med. and Res. Institute, Roanoke, VA; ²Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Depression and anxiety are common and debilitating mood disorders, and they are more prevalent in females than males. Previously, we reported that sub-chronic (6 days) variable stress (SCVS) induced behavioral stress susceptibility in females but not males. These behavioral effects were accompanied by sex specific changes in transcription of the Nucleus Accumbens (NAc) determined by RNA sequencing (Hodes et al. 2015). Here, we took a candidate gene approach based on pathway analysis of genes that sex specifically regulated the effects of stress on plasticity, neurotransmitter levels and immune function in the nucleus accumbens (NAc) following 6 days of stress. We examined expression of these genes in the NAc and hippocampus of male and female mice following chronic (28 days) variable stress (CVS). These two brain regions were examined as they both show sex specific regulation of plasticity that has been associated with the effects of stress on behavior (Bangasser et al, 2007, Brancato et al., 2017, Christoffel et al, 2011, 2012, McEwen et al. 2001, 2016, McKittrick et al, 2000, Shors et al. 2001, 2004). Males and females exposed to CVS both demonstrate stress susceptibility across a behavioral test battery. We hypothesized that different transcriptional patterns would emerge at 6 and 28 days within the same brain areas. Specifically we characterized whether expression in males and females at 28 days followed the same or opposite sex patterns found at 6 days. We found that for many of these candidate genes males expressed transcriptional patterns more similar to females (than males) at 6 days. For example, After 6 days of variable stress we found that transcription for the adonosine receptor 1 (Adora1) which can regulate both dopamine and

glutamate was significantly down regulated in the NAc of females whereas by 28 days it was down regulated both sexes in the NAc (trend: p=0.08) and hippocampus (p=0.01). The gene encoding the serotonin transporter (SLc6a4) was initially upregulated in the NAc of stressed females following SCVS whereas following CVS it was upregulated in males compared to females (p=0.02). Vascular endothelial growth factor A (Vegfa) was significantly down regulated in the NAc of stressed females following SCVS, at 28 days it was no longer significantly regulated by stress in the NAc of either sex but was down regulated in the hippocampus of both sexes (p=0.003). These data suggest that changes in gene expression occur first in the NAc of females after SCVS and may be followed by similar changes in the NAc of males and the hippocampus of both sexes following 28 days of variable stress.

Title: Paired fighting causes social withdrawal and leukocyte recruitment to the cerebral ventricle in an IL-1R1 dependent manner

Authors: *D. J. DISABATO¹, D. P. NEMETH², X. LIU², G. GORANTLA³, J. P. GODBOUT¹, N. QUAN²

¹Neurosci., ²Biosci., ³The Ohio State Univ., Columbus, OH

Abstract: Chronic stress is associated with an increase in prevalence of mental health complications such as anxiety and depression. We have previously reported that repeated social defeat (RSD) causes microglial activation, monocyte infiltration into the brain, and increased IL-1 β signaling in association with prolonged anxiety-like behavior. We hypothesized that interleukin-1 β (IL-1 β) signaling in the brain was the key player in this stress-mood disorder interaction. In the present study, we used a modified social stress paradigm paired fighting (PF) to induce social stress. Following exposure to six days of PF, C57BL/6 mice displayed general withdrawal in a social interactivity test with juvenile C57BL/6 mice. The experimental mice also experienced a decreased latency to immobility in the tail suspension test. Mice exposed to paired

fighting had increases in neutrophils and Ly6C^{hi} reactive monocytes in circulation. Parallel to this, PF mice had an increased number of peripherally-derived leukocytes in the cerebral ventricle. To examine the significance of IL-1 signaling in these processes, we used our genetic model of global IL-1 receptor 1 knockout, the IL-1 restore model (IL-1R1^{r/r}). After PF, IL-1R1^{r/r} mice did not display the same social withdrawal or reduced latency to first immobility in tail suspension. In addition, IL-1R1 deletion did not prevent the increase in circulating Ly6C^{hi} monocytes after PF, but it did reduce the number of peripheral leukocytes in the cerebral ventricle. Next, we injected IL-1 β intracerebroventricularly (icv) in mice exposed to PF. Following PF, icv-IL-1 β injection did not affect microglial morphological alterations. Nonetheless, icv-IL-1 β injection in PF increased peripheral macrophages within the cerebral ventricle and exacerbated affective behavior. Taken together, these results show that IL-1R1 signaling plays a crucial role in stress-induced affective behavior and central IL-1 β administration augments the neurobehavioral deficits associated with paired fighting stress.

Title: Exploring the role of GPR83, a newly deorphanized G-protein coupled receptor, in stress and immune function

Authors: *L. M. LUEPTOW¹, L. MIORIN², A. FAKIRA³, M. SCHOTSAERT², A. GARCIA-SASTRE², L. DEVI³

¹Icahn Sch. of Med. At Mount Sinai, New York, NY; ²Microbiology, ³Pharmacol. Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Considerable research has demonstrated the complex interplay between the brain, stress, and immune function. Additionally, most immune organs have direct innervation from the CNS, along with the presence of many neurotransmitters and neuropeptides, and often, these signaling molecules can have a profound effect on immune function. GPR83, a G-protein coupled receptor recently identified as the receptor for the neuropeptide PEN, is expressed in a

number of rodent brain regions that are critically involved in the regulation of stress, mood and behavior. In addition, previous research suggests GPR83 is also highly expressed in the spleen, thymus and specific T-cell populations. GPR83 has shown to be differentially regulated following exposure to the glucocorticoid dexamethasone, with an up-regulation of GPR83 in rodent thymocytes, but a down-regulation in various brain regions. This suggests dynamic regulation of GPR83 in neuroendocrine activation, potentially in stress and anxiety. Previous research has also shown GPR83 knockout mice to be resilient to stress-induced anxiety following an acute stressor. To further investigate the role of GPR83 in stress, wild type and GPR83 knockout mice were exposed to chronic stress. Both WT and KO mice showed significantly decreased latency to immobility in the forced swim test as compared to non-stressed mice, suggesting knockout of GPR83 does not protect against stress-induced depressive-like behavior. To better characterize GPR83 in immune function, we investigated GPR83 expression in various immune cell types. Using flow cytometry, we found GPR83 to be highly expressed on numerous immune cell types, including CD4+ and CD8+ T-cells, FoxP3+ T-cells, and NK cells. Low dose infection of PR8 (H1N1) to female GPR83 KO mice resulted in elevated viral RNA levels, and reduced levels of various cytokines in the lungs as compared to wild type control mice at day 5 after infection. In addition, reduced infiltration of CD4+ and CD8+ T-cells, as well as FoxP3+ T-cells to the lungs of GPR83 KO mice was observed by flow cytometry analysis. To explore the potential neuronal pathways that activate GPR83 in peripheral immune organs, we injected attenuated pseudorabies virus tagged with GFP into the spleen or thymus of mice, and examined viral expression following 72 hrs of retrograde transport. GFP expression was observed in parts of the raphe nucleus, periaqueductal grey and central amygdala, regions involved in somatic regulation and the modulation of pain and stress. Based on these observations, we believe further characterization will reveal the GPR83-PEN receptor system to be an important mediator of stress and immune function.

Title: Distribution of type 1 interleukin-1 receptor in the central nervous and neuroendocrine systems in mouse

Authors: *X. LIU¹, A. SONG¹, D. NEMETH¹, L. ZHU¹, N. QUAN² ¹The Ohio State Univ., Columbus, OH; ²Dept Biosci., Ohio State Univ., Columbus, OH

Abstract: Interleukin 1 is a pleiotropic cytokine that mediates diverse functions in the central nervous system and neuroendocrine system through its receptor, type I interleukin-1 receptor (IL-1R1). In the past, efforts have been made to visualize IL-1R1 mRNA and protein. However, due to the fact that IL-1R1 is often expressed at very low levels, it remains difficult to distinguish IL-1R1 expressing cells from labeling artifacts generated by the visualization procedures including *in situ* hybridization and immunohistochemistry. In the present study, we remapped the IL-1R1 distribution in an IL-1R1 reporter mouse line in which IL-1R1 mRNA and protein were tracked by the endogenous tdTomato fluorescence and HA tag respectively. Endothelial IL-1R1 mRNA and protein was found throughout the brain and spinal cord, with highly elevated expression in the olfactory bulb and paraventricular nucleus of hypothalamus. Neuronal IL-1R1 mRNA was identified in selective brain regions including dentate gyrus, dorsal raphe nucleus, arcuate nucleus and cerebellum. In addition, IL-1R1 mRNA and protein were found in the cells of the anterior lobe of pituitary, but not in the posterior lobe of pituitary and adrenal gland. The distribution of IL-1R1 in the CNS and neuroendocrine systems shown by the current study suggests additional targets of IL-1 stimulation.

Title: Chronic IL-1 suppresses hippocampal neurogenesis via dentate neuronal IL-1R1

Authors: *D. NEMETH¹, X. LIU², G. GORANTLA², D. J. DISABATO³, N. QUAN⁴ ¹Inst. For Behavioral Med. Res., Columbus, OH; ³Neurosci., ²The Ohio State Univ., Columbus, OH; ⁴Dept Biosci., Ohio State Univ., Columbus, OH

Abstract: Neurogenesis in the central nervous system plays a critical role in neuronal plasticity and memory. Previous reports showed chronic Interleukin-1 β (IL-1 β) decreases neurogenesis; however the mechanism of this phenomenon is not understood. In this study, we examined the expression patterns of Interleukin-1 Receptor 1 (IL-1R1) and the impact of chronically expressed IL-1 β on hippocampal neurogenesis. Using a genetic IL-1R1 reporter mouse (IL-1R1^{GR/GR}), IL-1R1 mRNA expression is visualized via tdTomato fluorescence. IL-1R1 expression was found in

brain endothelial cells and neurons of the dentate gyrus. Restricting IL-1R1 expression to glutamatergic neurons (VglutCre-IL-1R1^{r/r}), allowed IL-1R1 to be expressed exclusively in these dentate gyrus neurons. Interestingly, IL-1R1 expressing neurons do not express doublecortin, indicating neuronal IL-1R1 is not expressed on the proliferating neural progenitor cells. Chronic IL-1 β expression in the DG, via an adenoviral vector, induced local activation of microglia and neuronal death in the WT and VGLUTCre-IL-1R1^{r/r} animals but not IL-1R1 deficient (IL-1R1^{r/r}) animals. When proliferating neurons are tracked by EDU labeling, chronic IL-1 β caused decreased EDU+ cells within the subgranular zone (SGZ) in WT and VGlutCre-IL-1R1^{r/r} but not IL-1R1^{r/r} animals. These results show IL-1R1 is located on the mature neuronal population of the dentate gyrus and IL-1 acts upon these receptors to indirectly suppress neurogenesis.

Title: Microglial recruitment of monocytes to the brain underlies reoccurring anxiety in stress-sensitized mice

Authors: *J. P. GODBOUT¹, M. D. WEBER², J. F. SHERIDAN³

¹Neurosci., Ohio State Univ. Dept. of Neurosci., Columbus, OH; ³Inst. for Behavioral Med. Res., ²Ohio State Univ., Columbus, OH

Abstract: Repeated social defeat (RSD) is a murine stress model that promotes long-term "stress-sensitization", in which exposure to sub-threshold stress causes re-establishment of anxiety. We previously reported that RSD-induced anxiety depends on trafficking of monocytes to fear and threat appraisal brain regions. We hypothesize that RSD drives the production of inflammatory monocytes that are recruited to the brain by microglia, and these monocytes augment pro-inflammatory signaling that reinforces activation of threat circuitry. To address this, we used the CSF-1R inhibitor, PLX5622, to deplete microglia. Subsequent removal of the inhibitor allows microglia to rapidly repopulate. Here, we show that elimination of microglia after RSD prevented the recruitment of monocytes to the brain and recall of anxiety in stress-sensitized mice. Furthermore, microglia were depleted prior to RSD and allowed to repopulate. The phenotype of microglia was assessed by measuring behavioral and cytokine reactivity to peripheral LPS administered 24 days after RSD. We report that mice exposed to RSD displayed

a prolonged reduction in social interaction to peripheral LPS and exaggerated pro-inflammatory cytokine expression from microglia. Importantly, repopulating microglia in mice exposed to RSD normalized social interaction and reduced microglial pro-inflammatory cytokine expression to levels similar to non-stressed mice. These data demonstrate that microglia depletion/repopulation can be used to prevent microglial priming. Collectively, microglial priming may underlie monocyte recruitment to the brain and re-establishment of anxiety in stress-sensitized mice.

Title: Extramedullary monopoiesis underlies stress-sensitization and recurring anxiety

Authors: *D. B. MCKIM¹, J. P. GODBOUT², J. F. SHERIDAN³ ¹The Ohio State Univ., Columbus, OH; ²Neurosci., Ohio State Univ. Dept. of Neurosci., Columbus, OH; ³Inst. for Behavioral Med. Res., Ohio State Univ., Columbus, OH

Abstract: In humans, chronic stress is associated with an increased prevalence of mental health complications including anxiety and depression. Repeated social defeat (RSD) in mice recapitulates key deficits associated with psychosocial stress in humans. We showed that exposure to sub threshold stress 24 days after RSD caused the recurrence of anxiety that was dependent on monocyte trafficking from the spleen to the brain. We hypothesized that extramedullary production of monocytes in the spleen contributed to enhanced monocyte trafficking and recurring anxiety following psychosocial stress. RSD caused profound mobilization of hematopoietic stem progenitor cells (HSPCs) into circulation that accumulated and substantially proliferated in the spleen. For instance, RSD significantly increased the presence of all sub-types of hematopoietic colony forming units (CFU) in blood and spleen. Moreover, there was a 30-fold increase in the number of Lin-/Sca1+/cKit+ (LSK) progenitor cells in the spleen after stress that were actively proliferating (S/G2/M cell cycle phase). Next, competitive bone marrow adoptive transfer was used to assess the presence of splenic HSPCs. RSD significantly increased the presence HSPCs in the spleen (28-fold) that engrafted into host

bone marrow. EdU pulse chase experiment revealed that RSD potently induced proliferation of HSPCs within the red pulp of the spleen. Moreover, a BrdU pulse chase experiment showed that RSD significantly increased the presence of proliferating splenic CD11b+/BrdU+ monocytes. This increase in monocyte proliferation in the spleen persisted for at least 1 month as detected by BrdU pulse chase. These data indicate that RSD caused extramedullary monopoiesis in the spleen that persisted for at least 1 month. To determine the necessity of this splenic reservoir for recurring anxiety, mice were splenectomized. Splenectomy either before or after RSD both prevented the recurrence of anxiety following acute stress 1 month after RSD. We conclude that splenic monopoiesis promotes recurring anxiety following psychosocial stress in mice. The fundamental observation that psychosocial stress caused chronic extramedullary monopoiesis in the spleen has numerous implications for negative health outcomes associated with chronic stress. We specifically showed here that extramedullary monopoiesis underlies monocyte trafficking and recurring anxiety following psychosocial stress. These data reveal a novel immune mechanism connecting stress to prolonged behavioral complications.

Sci. on Fatigue, ⁶Dept. of Psysiology, Osaka City Univ. Grad. Sch. of Med., Osaka, Japan

Abstract: Fatigue may be a bio-alarm for sustainable working performance. Past neuroimaging studies have shown differences in gray matter morphometry and in task-related brain activities between fatigued and unfatigued subjects or states. Recent studies using resting state functional

magnetic resonance imaging (RS-fMRI) have suggested that spontaneous co-activating brain regions, termed as resting state networks (RSNs), may potentially differ from fatigue states. However, it is still unclear how RSNs are associated with subjective fatigue during cognitive performance. In this study, we conducted a RS-fMRI study to clarify temporal changes in RSNs before and after mental fatigue. We recruited 32 healthy volunteers who did not complain any fatigue in daily life. RS-fMRI scans were performed before and after fatigue-inducing session in which participants performed working memory task for 45 minutes. During a period of the 5-min RS-fMRI scans, subjects were asked to view a fixation cross, and not to sleep. As a working memory task, we adopted a 2-back task where subjects were asked to view successively presented numeric characters (form 1 to 4), and to answer whether a newly presented character was identical or not compared with that appeared two presentation before. For the data analysis, we used the predefined 20 components of RSNs (Smith et al., 2002), and run dual regression to compare the RSNs connectivity between before and after fatigue. The comparison of RSNs revealed that the visual RSN significantly decreased after fatigue session. The analysis of correlation between RSNs revealed that the correlation between default mode and attention networks significantly changed after fatigue session: these two networks were in significantly negative correlation before, but not after the fatigue. It is known that the default mode network is deactivated when attention network is active during cognitive tasks directed towards external stimuli, indicating that these two networks function in antagonistic manner. Taken together, the present study indicates that acute mental fatigue may induce disorganization between default mode and attention networks, potentially underlining a mechanism for impairment of sustainability in cognitive performance.

Title: A haplotype of the mineralocorticoid receptor gene promotes the stress-induced shift from 'cognitive' to 'habit' learning

Authors: *L. WIRZ¹, M. REUTER², J. WACKER³, A. FELTEN², L. SCHWABE¹ ¹Cognitive Psychology, Hamburg, Germany; ²Differential and Biol. Psychology, Bonn, Germany; ³Differential Psychology, Hamburg, Germany

Abstract: Stress induces a shift from hippocampus-dependent, 'cognitive' toward dorsal striatum-dependent, 'habitual' memory. Not all individuals are susceptible to this shift under stress, yet the source of these individual differences is largely unknown. Based on pharmacological studies pointing to a critical role of the mineralocorticoid receptor (MR) in the stress-induced shift toward striatal learning, we hypothesized that variants in the MR gene contribute to individual differences in the effects of stress on the engagement of multiple memory systems. In two independent experiments, healthy participants were genotyped, exposed to a stressor (Trier Social Stress Test) or control manipulation and performed a probabilistic classification learning task that can be solved using hippocampus-dependent single-cue or dorsal striatum-dependent multi-cue strategies, while EEG (experiment I) or fMRI (experiment II) measurements were taken. Stress did not affect learning performance per se, but led to a shift from hippocampal to striatal learning strategies and this shift was more pronounced in carriers of a six SNPs-comprising haplotype containing at least one copy of the alleles of two MR variants associated with increased MR functionality ([rs2070951] MR-2G/C C, [rs5522] MR-I180V I). The stress-induced shift toward dorsal striatal processing was paralleled by an increase in the feedback-related negativity, an event-related potential thought to reflect, at least partly, striatal processing, as well as by enhanced amygdala and caudate nucleus activation. Carriers of the MR haplotype showed reduced amygdala and hippocampus activation under stress. Additionally, stress resulted in reduced functional connectivity between the amygdala and the hippocampus and this reduction was particularly pronounced in MR haplotype carriers. Already at rest, the MR haplotype was linked to increased amygdala-caudate nucleus connectivity. Our results indicate that genetic variants associated with enhanced MR expression facilitate a stress-induced shift from hippocampal toward dorsal striatal learning, most likely via impaired hippocampal processing and reduced amygdala-hippocampus crosstalk, which allows the dorsal striatum to guide behavior under stress.

Title: Stress modulates motor memory consolidation

Authors: *N. DOLFEN¹, B. R. KING¹, L. SCHWABE², S. P. SWINNEN¹, G. ALBOUY¹ ¹Movement Control and Neuroplasticity Res. Group, Dept. of Kinesiology, KU Leuven, Leuven, Belgium; ²Univ. of Hamburg, Hamburg, Germany

Abstract: It is suggested that the specific combination of hippocampal activity during initial motor sequence learning (MSL) and post-training sleep is necessary to optimize motor memory consolidation. The current study investigates whether exposure to stress, a factor known to disrupt hippocampal activity during learning, compromises the subsequent consolidation of motor sequence memory. Thirty-seven healthy young adults were exposed to a stressor (i.e. socially evaluated cold pressor test; SECPT) (stress group, n = 20) or control procedure (no stress group, n = 17) *before* they were trained on an eight-element bimanual MSL task. Participants were retested on the motor task 24 hours (including a night of sleep) after initial training to assess memory consolidation. Autonomic and endocrine responses to stress were assessed by measuring heart rate and blood pressure as well as salivary cortisol (i.e., principal stress mediator hormone), respectively. Results revealed that participants in the stress group, as compared to the no stress group, showed significant increases in blood pressure and heart rate during stress exposure. 80% of the participants in the stress group were classified as "cortisol responders" (n = 16) as they showed an increase in cortisol of at least 2 nmol/l after the SECPT intervention (Schwabe et al., 2008, PNEC). Cortisol concentration in responders was significantly elevated as compared to their own baseline as well as the no stress group prior to and immediately following initial training. Importantly, while both groups showed comparable motor performance (in terms of both movement speed and accuracy) during the initial training session, the magnitude of performance improvement was significantly lower in the stress group as compared to the no stress group during the 24h-retest. Our results provide the first evidence that stress exposure prior to motor learning selectively disrupts subsequent memory consolidation processes. It is speculated that stress exposure challenged the recruitment of the hippocampus during initial acquisition of the motor memory and therefore compromised subsequent sleep-related motor memory consolidation.

Title: The effects of psychological and physiological stress on spatial reasoning skills

Authors: *B. ROMAGNA, B. P. GEE

Psychology, Western Connecticut State Univ., Danbury, CT

Abstract: Research has identified stress as a paradoxical pressure, acutely impeding cognitive processing (Sliwinski, Smyth, Hofer & Stawski 2006) while simultaneously improving memory and mental health in chronic, predictable doses (Buchanan & Lovallo 2001; Parihar, Hattiangady, Kuruba, Shuai & Shetty 2011). The question of how stress impacts our mind and body remains largely unanswered. This study evaluated spatial reasoning ability as a function of stressor type. Human subjects performed a mental rotation task (Shepard & Metzler 1971) during psychological (loud, misleading feedback) and physiological (cold pressor test) stress. For each trial, participants viewed a pair of geometrical shapes varying in spatial orientation, and decided whether the stimuli were identical or mirrored objects. Task performance was based on reaction time and proportion correct. After a block of trials were completed for each stress and control condition, stress levels were measured, such as self-report scales, cardiovascular function, and salivary concentrations of cortisol and alpha-amylase. In the cold pressor test condition, both speed and accuracy were better than the control condition (warm water hand submersion). The psychological stress condition did not affect performance as much as the physiological stressor. Biomarkers of stress were also most affected by the cold pressor test. The results showed that physical stress can adversely affect cognitive function, while psychological stress may need to be high before significant cognitive impairment is observed. We theorized that physiological and psychological stressors contradistinctively activate the stress response.

Title: Interactive influence of sex, stressor timing, and the BclI glucocorticoid receptor polymorphism on stress-induced alterations of long-term memory

Authors: *T. J. DUFFY¹, H. E. NAGLE¹, A. M. DAILEY¹, M. K. FIELY¹, B. E. MOSLEY¹, A. R. SCHARF¹, C. M. BROWN¹, M. B. EARLEY¹, K. L. HESS¹, J. K. HANDEL¹, M. R. RIGGENBACH¹, M. T. ROSELER¹, L. E. WIREMAN¹, J. J. HIPSKIND¹, B. R. RORABAUGH², P. R. ZOLADZ¹ ¹Psychology, Sociology, & Criminal Justice, ²Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH Abstract: The BclI polymorphism of the glucocorticoid receptor (GR) gene (NR3C1) is a common polymorphism that has been associated with increased GR sensitivity, blunted cortisol responses to stress, and increased susceptibility for stress-related psychological disorders. Given the extensive work implicating glucocorticoid signaling in the effects of stress on learning and memory, we predicted that the BclI polymorphism might influence such effects. Two hundred and thirty-five healthy individuals were exposed to the socially evaluated cold pressor test or a control condition immediately or 30 min prior to learning a list of words that varied in emotional valence and arousal level. Participants' memory for the words was tested immediately (recall) and 24 h after learning (recall and recognition), and saliva samples were collected to genotype participants for the *Bcl*I polymorphism. The results showed that stress administered immediately before learning exerted sex- and genotype-dependent effects on long-term memory. Specifically, stress enhanced long-term memory selectively in male non-carriers of the BclI risk allele (G). Stress had no effect on females or male risk allele carriers. Stress administered 30 min before learning selectively impaired long-term recognition memory in risk allele carriers. These findings suggest that carriers of the BclI polymorphism may retain a sensitized stress response system. They also suggest that the association between the *Bcl*I polymorphism and increased susceptibility for stress-related disorders might relate to its influence on emotional memory systems.

Title: FKBP5 polymorphisms influence pre-learning stress-induced alterations of learning and memory

Authors: *P. R. ZOLADZ¹, A. M. DAILEY¹, H. E. NAGLE¹, M. K. FIELY¹, B. E. MOSLEY¹, C. M. BROWN¹, T. J. DUFFY¹, A. R. SCHARF¹, M. B. EARLEY¹, K. L. HESS¹, J. K. HANDEL¹, M. R. RIGGENBACH¹, M. T. ROSELER¹, L. E. WIREMAN¹, J. J. HIPSKIND¹, B. R. RORABAUGH² ¹Psychology, Sociology, & Criminal Justice, ²Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: FK506 binding protein 51(FKBP5) is a co-chaperone of heat shock protein 90 and significantly influences glucocorticoid receptor sensitivity. Single nucleotide polymorphisms (SNPs) in the *FKBP5* gene are associated with altered hypothalamus-pituitary-adrenal (HPA) axis function, changes in the structure and function of several cognitive brain areas, and increased susceptibility to post-traumatic stress disorder, major depression, bipolar disorder, and suicidal events. The mechanisms underlying these associations are largely unknown, but it has been speculated that the influence of these SNPs on emotional memory systems may play a role. In the present study, 112 participants were exposed to the socially evaluated cold pressor test (stress) or control (no stress) conditions immediately prior to learning a list of 42 words. Participant memory was assessed immediately after learning (free recall) and 24 h later (free recall and recognition). Participants provided a saliva sample that enabled the genotyping of three FKBP5 polymorphisms: rs1360780, rs3800373, and rs9296158. Results showed that stress impaired immediate recall in risk allele carriers. More importantly, stress enhanced long-term recall and recognition memory in non-carriers of the risk alleles, effects that were completely absent in risk allele carriers. Follow-up analyses revealed that memory performance was correlated with salivary cortisol levels in non-carriers, but not in carriers. These findings suggest that *FKBP5* risk allele carriers may possess a sensitized stress response system, perhaps specifically for stress-induced changes in corticosteroid levels, which might aid our understanding of how SNPs in the FKBP5 gene confer increased risk for stress-related psychological disorders and their related phenotypes.

Title: Stress responsiveness alters human performance on tests of executive function under varying air quality conditions in a built environment

Authors: *A. A. WALF¹, L. HALDERMAN², A. MURALI³, D. RIVERA⁴, Z. LIN³, A. DYSON^{5,6}, J. DRAPER^{5,6}

Abstract: When considering how individuals' respond in a built environment some of the characteristics of the space that can be considered are related to air quality, such as carbon dioxide levels (CO2). Here the effects of exhaled CO2 levels in a room scale environment for human subjects' self-reports of their perception of the space, stress responding, and executive function were assessed. The hypotheses tested were that: 1) higher exhaled CO2 levels in room will increase self-reported stress ratings and reduce executive function of human room occupants; 2) the Amplified Modular Phytoremediation System (AMPS), designed by the Center for Architectural Science and Ecology (C.A.S.E.), will reduce carbon dioxide levels in the room coincident with reducing self-reported stress ratings and enhancing executive function of human room occupants; and 3) there are individual differences (relating to stress responsiveness/disposition) for these measures in different room air quality conditions. Human subjects were tested in three different air quality conditions (baseline low CO2, high CO2, and remediated low CO2 by AMPS) on standard self-report measures of stress/anxiety (State and Trait Inventory of Somatic and Cognitive Anxiety) and executive function (Trail Making, Digit-Symbol Substitution Task, Compound Remote Associates Test, short- and long-term verbal memory, Mental Rotation, n-back). The findings suggest differences in how individuals respond on standard measures of stress/mood and executive function under high CO2 conditions that can be remediated by AMPS. These patterns of poor responding under high carbon dioxide concentrations were particularly pronounced in individuals with high stress responsiveness. For example, subjects with low stress responsiveness had better performance in the Compound Remote Associates test than those with high stress responsiveness under baseline and remediated low CO2 conditions, compared to high CO2 conditions. Together, the data from this experiment provide proof-of-concept that AMPS has the capacity to reduce carbon dioxide levels in a room produced by individuals' occupancy in that space and that there are measurable effects on individuals' reported symptoms, stress, and cognitive function that depend upon stress responsive disposition of subjects.

Title: Influence of Neurexan® on brain activity in responses to deviant stimuli during an auditory oddball task

Authors: *M. A. KRYLOVA¹, G. SUROVA², S. ALIZADEH¹, H. JAMALABADI¹, M. SCHULTZ³, M. WALTER^{2,1,4}

¹Translational Psychiatry, Univ. Clin. For Psychiatry and Psychotherapy, Tübingen, Germany; ²Clin. Affective Neuroimaging Lab., Magdeburg, Germany; ³Biologische Heilmittel Heel GmbH, Baden-Baden, Germany; ⁴Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: Background: Neurexan®, a medicinal product sold over the counter (OTC), contains four ingredients; Passiflora incarnata (passionflower), Avena sativa (oats), Coffea arabica (coffee) and Zincum isovalerianicum (zinc valerianate). Neurexan® has been investigated in patients with symptoms related to acute stress, nervousness/restlessness, and insomnia. The previous research suggested an attenuated neuroendocrine stress response in healthy volunteers induced by Neurexan® (Doering et al. 2016). This study further explores the effects of Neurexan® on cognitive performance and attention that can be assessed by the oddball paradigm. It is generally recognized that stress is associated with cognitive impairments. Expecting that Neurexan[®] reduces the stress level, we hypothesized that the subjects in the placebo group would be more susceptible to distraction compared to treatment group. Methods: In a randomized, placebo-controlled, double-blind, two-period crossover trial, brain responses to the unattended auditory oddball task of 39 healthy, moderately stressed males were measured with 64-channel electroencephalogram (EEG) after intake of a single dose of Neurexan® or placebo. The paradigm consisted of 80% standard tones and two types of deviant tones (10% frequency deviant; 10% duration deviant), presented in a pseudo-randomized order. The standard tone was composed of eight equally loud sinusoidal tones (fundamental frequency 330 Hz and seven harmonic partials) and had the duration of 100 ms. The deviants were either 40 ms shorter (duration deviant) or 1.25 semitones higher (frequency deviant). *Results:* Significant effect of Neurexan® on the latency of mismatch negativity (MMN) (decreased latency under treatment) was observed with repeated-measures ANOVA. The main effect of the *treatment* (F(1,37)=4.297, p=0.045, $\eta^2 = 0.104$) and significant *treatment* x *devianttype* interaction (F(1,37)=8.828, p=0.005, η^2 =0.193) were found. Further Wilcoxon-test for paired samples showed that this reductione of latency was present for the frequency deviant

stimuli (z(37)=-2.85, p=0.004).

Conclusion: Significant reduction of MMN latency in the Neurexan treatment group suggests that Neurexan® induces subtle primary processing changes in term of reaction time. *References:* Doering B.K., Wegner A., Hadamitzky M., et. al. Abstract: Hormonal contraception (HC) can modify the stress response and memory processes. However, these studies often ignore HC type, delivery method, drugs delivered, and dosing schedule, all factors that differ across the many HC formulations and which might affect outcomes. Timing within one HC type might also exert effects. For example, unlike implants, oral HC and vaginal rings deliver hormones for a set period followed by a period of no hormones. Disregarding these factors make it difficult to interpret when and how HC may be exerting effects.

To examine if HC phase (active vs. inactive) differentially influences stress effects on free cortisol responses and working memory performance, we tested 16 women using monophasic 28-day HC containing 7 inactive days. Women were seen twice, once during days 8 to 21 (active phase) and once during days 24 to 28 (inactive phase). Women completed an n-back task, followed by a stressor (cold pressor), and later completed the n-back task again. Three saliva samples were collected; a baseline sample, immediately pre-stress, and 19-minutes post-stress. A 2 (HC phase) x 3 (time: baseline vs. pre-stress vs. post-stress) repeated-measures ANOVA on salivary cortisol levels (n=9) revealed a 2-way interaction with increases across all three time points during the active phase, and a decrease from baseline to pre-stress and increase from pre-stress to post-stress during the inactive phase. Additional 2 (HC phase) x 2 (time: baseline vs. post-stress) repeated-measures ANOVA revealed increases from baseline to post-stress during the active phase. ANOVA revealed increases from baseline to post-stress during the active phase. ANOVA revealed increases from baseline to post-stress during the active phase only.

A 2 (HC phase) x 2 (load: 0-back vs. 2-back) x 2 (time: pre-stress vs. post-stress) repeatedmeasures ANOVA on WM performance before and after stress (n=16) revealed stress-induced increases in correct responses during the 0-back but decrements during the 2-back. We also found a marginal 3-way interaction with the above pattern observed during both HC phases, but with smaller overall changes during the inactive phase. A similar 2 (HC phase) x 2 (load) x 2 (time) repeated-measures ANOVA on reaction time for correct responses revealed a significant 3-way interaction, with stress-induced increases during the 0-back and decreases during the 2-back during the active phase, but increases during both loads during the inactive phase. Our findings suggest that women experience differential effects of stress on salivary cortisol responses and cognition depending on HC cycle phase. Together, these results help inform how a woman's HC might affect her day to day life, and also suggest that HC type and position in the HC cycle must be considered in future studies investigating the potential effects of HC.

Title: ADRA2B deletion variant influences time-dependent effects of pre-learning stress on long-term memory

Authors: *B. E. MOSLEY¹, A. M. DAILEY¹, H. E. NAGLE¹, M. K. FIELY¹, C. M. BROWN¹, T. J. DUFFY¹, A. R. SCHARF¹, M. B. EARLEY¹, K. L. HESS¹, J. K. HANDEL¹, M. R. RIGGENBACH¹, M. T. ROSELER¹, L. E. WIREMAN¹, J. J. HIPSKIND¹, B. R. RORABAUGH², P. R. ZOLADZ¹ ¹Psychology, Sociology, & Criminal Justice, ²Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Extensive work over the past few decades has shown that certain genetic variations interact with life events to confer increased susceptibility for the development of psychological disorders. The deletion variant of the *ADRA2B* gene, which has been associated with enhanced emotional memory and heightened amygdala responses to emotional stimuli, might confer increased susceptibility for the development of post-traumatic stress disorder (PTSD) or related phenotypes by increasing the likelihood of traumatic memory formation. Thus, we examined whether this genetic variant would predict stress effects on learning and memory in a non-clinical sample. Two hundred and thirty-five individuals were exposed to the socially evaluated cold pressor test or a control condition immediately or 30 min prior to learning a list of words that varied in emotional valence and arousal level. Participants' memory for the words was tested

immediately (recall) and 24 h after learning (recall and recognition), and saliva samples were collected to genotype participants for the *ADRA2B* deletion variant. Results showed that stress administered immediately before learning selectively enhanced long-term recall in deletion carriers. Stress administered 30 min before learning impaired recognition memory in male deletion carriers, while enhancing recognition memory in female deletion carriers. These findings provide additional evidence to support the idea that *ADRA2B* deletion variant carriers retain a sensitized stress response system, which results in amplified effects of stress on learning and memory. The accumulating evidence regarding this genetic variant implicates it as a susceptibility factor for traumatic memory formation and PTSD-related phenotypes.

Title: Unhealed wounds: Childhood maltreatment is associated with heightened brain response to 33 msec subliminal aversive cues

Authors: *P. S. REGIER¹, A. M. TEITELMAN², K. JAGANNATHAN¹, A. R. CHILDRESS¹ ¹Dept. of Psychiatry, ²Sch. of Nursing, Univ. of Pennsylvania, Philadelphia, PA

Abstract: INTRODUCTION: Childhood maltreatment is associated with neurobiological changes, such as decreased grey matter and increased brain response to fearful, traumatic, and other emotional stimuli in fronto-limbic/striatal areas. Prior studies have suggested that maltreatment is more prevalent among women and low-income families. In this study, we recruited young women from a family planning clinic (Title X) that prioritizes low-income families, and we compared them to a group of young women recruited from the surrounding area (mostly college students). We tested whether a relationship between childhood maltreatment and the brain response to aversive cues is robust enough to be detected even when the aversive cues are presented subliminally - entirely outside conscious awareness. METHODS: Young women (age=21.9) were recruited from a Title X family planning clinic (clinic sample, n=34) and from the surrounding university (community sample, n=20). Childhood maltreatment was assessed with the childhood trauma questionnaire (CTQ), and brain activity was measured with BOLD fMRI in response to 33 msec evocative [food, romantic, and aversive (vs. neutral)] cues. Total scores from the CTQ were used as a covariate of interest for each of the evocative (vs. neutral) cue contrasts for all participants (n=54), the clinic sample (n=34), and the community sample (n=20). Thresholds for all whole-brain fMRI correlation analyses were set at p < 0.005 and k > 0.005200. RESULTS: The clinic population had significantly higher CTQ scores than the community sample (p < 0.05). There was a positive correlation of higher CTQ scores with heightened brain response to aversive (but not sexual or food) cues in one large cluster (k>2000) that extended from the anterior orbitofrontal cortex to the nucleus accumbens to the midbrain. Importantly, the clinic (but not the community) sample showed a positive correlation of increased brain response with CTQ scores that mirrored the results from the overall analysis. CONCLUSIONS: Increased prior adversity was associated with an increased brain response to aversive cues in frontolimbic/striatal regions, observed primarily in the clinic sample. These results suggest that the link between prior adversity and a heightened brain sensitivity to later stressful stimuli is strong enough to be detected even when the "stressor" is minimal (33 msec) and entirely outside awareness. The relationship was stronger in the clinic sample, highlighting a potential vulnerability to stressors in this disadvantaged group, while simultaneously offering a potential brain target for screening pharmacotherapeutic or behavioral interventions.

Title: Magnetoencephalographic and cardiac parameters are changed in employees with permanent hearing loss - A quantitative analysis in elderly workers

Authors: R. HUONKER, J. MÜLLER, J. LUKAJEWSKI, P. JAUER, O. W. WITTE, *F. RICHTER

Univ. Hosp. Jena, Jena, Germany

Abstract: In Germany estimated 4 to 5 million employees work in jobs with hearing impairing noise exposure. Noise induced hearing loss is the second most common work-related disease. In hearing impaired people auditory recognition is worsened and listening effort is enhanced resulting in higher mental load. We assume that this induces not only psychical but also physical stress that could be analyzed qualitatively and quantitatively either by questionnaires or by recording of magnetoencephalographic (MEG) activity and of vegetative and cardiac parameters. Our two groups of probands worked either in the beverage industry or in symphonic orchestras. One control group (16 normal hearing workers, mean age 59 years) and two groups (13 participants, mean age 56 years) with moderate hearing impairments (average 45 dB SPL) in the frequency range of 3-4 kHz were stimulated with tone pips at 65 dB SPL with different pitches overlaid by random noise. In a "one back task" the subjects had to decide whether the next to last pip had a higher or lower frequency than the last pip, and correct responses were rewarded. Two different stimulus conditions were presented, either at a constant pitch difference or with pitch difference adjusted to the actual error rate. We recorded the MEG and auditory evoked magnetic fields for analyzing the distribution of the sources, the electrocardiogram, arterial oxygen saturation and breathing frequency. From the electrocardiogram we calculated the square root of the mean squared differences of successive heart beat intervals (RMSSD) and the HF-power as parameters of heart rate variability. The discrimination threshold in the control group was significantly lower (122 Hz) compared to the hearing impaired group (300 Hz). In both groups alpha activity in the MEG increased by 0.1 to 0.15 Hz towards higher frequencies during the hearing task. However, in the hearing impaired group the alpha activity was higher already at rest (9.5 Hz) than in the control group (9.25 Hz). Heart rate significantly increased during the hearing task in both groups. Heart rate variability and HF-power at rest were significantly lower in the hearing impaired group, and RMSSD and HF-power further decreased during the hearing task, thus indicating an attenuated influence of the parasympathetic nervous system. These data

provide objective evidence that cardiovascular parameters are affected already at rest by the increased mental load and have to be considered in occupational medical care in the prevention of worsening of work-related hearing damages. The long term alterations to the cardiovascular system caused by noise induced hearing damage can be objectified and reflect stress.

Title: Anxiety/depressive-like behaviors without the change of the HPA axis by mild stress can be improved treadmill exercise in rats

Authors: *K. ISHIDA¹, K. KOIKE², A. MARUYAMA¹, Y. UENISHI¹, T. GYOUDA¹, Y. SUGIYAMA¹

¹Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; ²Saarland Univ., Homburg, Germany

Abstract: The onset or development of depression could be caused by chronic stress. While exercise has stress-buffering effects, the therapeutic effect of exercise against anxiety/depressivelike behaviors is not fully understood. The objectives of this study were, at first, confirm that chronic forced swim stress induces anxiety/depressive-like behaviors after stress exposure, and then investigate whether treadmill exercise alleviates the anxiety/depressive-like behaviors induced by forced swim stress through the alteration of hypothalamic-pituary-adrenal (HPA) axis response. It has been found that forced swim stress exposure as rats were placed in a glass cylinder (35 cm high \times 24 cm diameter) filled to a depth of 25 cm with water (25 \pm 1 degrees). A 6-min test was repeated each day, induced abnormal behaviors including forced swim 21 days after stress exposure using forced swim test, open field test and elevated open-platform test. These abnormalities were inhibited by repeated administration of the antidepressant, imipramine, suggesting that these behaviors are anxiety/depressive behaviors. Moreover, treadmill exercise ameliorated depressive behaviors induced by chronic forced swim stress. Interestingly, there was no significant difference of the HPA axis response including serum corticosterone level among groups. These data suggest that the treatment effect of exercise may be not through the alteration of the HPA axis. These results also suggest that the HPA axis changes may be not as responsive as behavioral measures. Further research is needed to explore the mechanism of chronic forced swim stress. In summary, forced swim stress induces anxiety/depression-like behaviors without the change of the HPA axis. Moreover, treadmill exercise ameliorates anxiety/depression-like behaviors induced by chronic forced swim stress not affecting on the HPA axis response. These

data suggest that treadmill exercise may rescue anxiety/depression-like behaviors without the HPA axis in mild stress rat model.

Title: Susceptibility to post-traumatic stress disorder is comorbid with reduced mitochondrial capacity in mice

Authors: *G. PRESTON¹, T. EMMERZAAL², F. KIRDAR¹, E. MORAVA-KOZICZ¹, T. L. KOZICZ²

¹Tulane Univ. Sch. of Med., New Orleans, LA; ²Anat., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands

Abstract: Psychopathology is frequently associated with mitochondrial dysfunction in patients. Post-traumatic stress disorder (PTSD) is a debilitating psychiatric disorder that affects millions of people worldwide. Induced by exposure to a traumatic event, the presentation of the disease in terms of duration and symptomatology is highly heterogenous, and the severity of the inducing trauma does not predict the severity of the disorder. This suggests the possibility of an underlying genetic metabolic factor. We therefore investigated whether susceptibility to PTSD is associated with mitochondrial dysfunction. We exposed 48 wildtype male mice of the FVB.129P2 ("sighted" FVB) background to a PTSD-induction paradigm previously shown to reliably induce PTSD-like symptomatology with a similar presentation to that of PTSD in humans. The inducing trauma was inescapable electric foot shock, administered in two decontextualized sessions over two consecutive days. PTSD-susceptible animals were diagnosed through a series of behavioral tests to identify some physical symptoms of PTSD: hyperarousal, hypervigilance, and sleep cycle disruption. Those 12 animals most and least clearly displaying PTSD-like symptomatology were identified, brain tissue was collected, and mitochondria were isolated. The activities of the electron transport chain (ETC) complexes I, II, III and IV, as well as citrate synthase, were measured by spectrophotometric assay using a Konelab autoanalyzer to determine mitochondrial activity and density, respectively. Comparing ETC activity and mitochondrial density to PTSD-like symptomatology reveals a statistically-significant inverse relationship between PTSD susceptibility and mitochondrial capacity (p=0.016). Our results indicate that susceptibility to PTSD in mice is comorbid with reduced mitochondrial capacity. To demonstrate that mitochondrial dysfunction is sufficient to induce PTSD susceptibility, we are

currently inducing PTSD in a strain of transgenic mice with genetically-induced suboptimal mitochondrial function, and assaying for a concordant increase in PTSD susceptibility. We are also investigating how reduced mitochondrial capacity affects activation of large scale brain networks and endocrine functions involved in stress response.

Title: Antagonizing the GABA_A receptor during behavioral testing improves spatial memory in chronically stressed rats

Authors: *K. NISHIMURA, J. B. ORTIZ, C. D. CONRAD

Psychology, Arizona State Univ., Tempe, AZ

Abstract: Chronic stress leads to a dysregulated hippocampal inhibitory tone that may contribute to poor hippocampal-dependent spatial learning and memory. The present study examined whether the spatial memory deficits that occur following chronic stress could be overcome by antagonizing the γ -aminobutryic acid (GABA_A) receptors, a prominent inhibitory receptor for GABA in the hippocampus. Young adult male Sprague-Dawley rats were chronically stressed (STR, wire mesh restraint, 6h/d/21d) or assigned to a non-stressed control group (CON). When chronic restraint ended, rats were tested on a 2-trial object placement (OP) task at a challenging delay (3hr) that would result in chance performance without intervention. Rats were also tested over the next few days on an object recognition task to measure non-spatial memory and the elevated plus maze (EPM) to assess anxiety profile. In CON rats, injections of bicuculline (BIC, 0, 0.25, 0.5 mg/kg, i.p.) 30 min prior to testing, facilitated object placement at both the 0.25 and 0.5 mg/kg doses. In contrast, STR rats required the highest dose (0.5 mg/kg) of BIC to improve their performance on the object placement task, as the lower dose (0.25 mg/kg) and vehicle were ineffective. Motivation to explore the objects and anxiety profile were unlikely to explain these results, based upon the performances on object recognition and EPM. These findings reveal different dose response functions for BIC in control and chronically stressed rats, with

chronically stressed rats requiring a higher dose of BIC to achieve spatial memory ability as observed in the controls. While the literature demonstrates that chronic stress disrupts hippocampal inhibitory tone, the current study reveals that a single injection of a GABA_A receptor antagonist can restore hippocampal-dependent spatial memory in chronically stressed subjects.

Title: Sex differences in the role of adult neurogenesis in the development of learning and memory dysfunction following chronic stress

Authors: *T. P. O'LEARY¹, B. LEE², D. ESPINUEVA¹, J. S. SNYDER¹ ²Psychology, ¹Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Adult neurogenesis in the hippocampus is involved in visuo-spatial learning and memory, and also regulation of the hypothamic-pituitary-adrenal axis and stress-related behaviour. Although, neurogenesis has been shown to buffer the effects of chronic stress on expression of depressive-like behaviours, it is not yet known if adult neurogenesis acts in a similar way to buffer negative effects of chronic stress on learning and memory function. Sex differences exist in the effects of chronic stress on learning and memory, and thus the role of adult neurogenesis during chronic stress likely differs between male and females. To address this possibility, we used a transgenic rat that expresses the herpes simplex virus thymidine kinase, under the glial fibrillary acidic protein promoter (GFAP-TK). Administration of the anti-viral drug valganciclovir leads to death of mitotic neural precursor cells in the GFAP-TK rat. Beginning at 6 weeks of age, GFAP-TK rats were given valganciclovir orally for 6 weeks (twice per week), which leads to a near-complete ablation of adult-neurogenesis in the dentate gyrus. At 13 weeks of age, rats then completed 21 days of chronic restraint stress, with 6 hours of daily restraint stress. Following restraint stress, visuo-spatial learning and memory was assessed with a modified Morris water maze procedure, in which stress during testing was increased using cold 16 °C water. Rats completed acquisition training for 3 days (4 trials per day) with a probe trial (60 sec) on the following day to assess memory for the escape platform location. Typical effects of chronic stress were observed, with reduced body-weight gain in restrained rats, and also increased adrenal weight in restrained male, but not female rats. Restraint stress did not impair

learning and memory ability in either GFAP-TK or wild-type male rats. In female rats, however, restraint stress improved learning performance in wild-type rats. In female GFAP-TK rats, learning performance of restrained and control rats was similar, but in the probe trial restrained GFAP-TK rats performed worse than controls. These results indicate that the chronic restraint stress paradigm used was not sufficient to impair performance in wild-type male and female rats. In GFAP-TK rats, however, restraint stress impaired memory performance in female rats, suggesting that neurogenesis may buffer the deleterious effects of chronic stress on memory ability specifically in females. These findings may indicate a sexually dimorphic role for adult neurogenesis in the etiology of cognitive dysfunction within depression and stress-related disorders.

Title: Method for affective profiling for anxiety-like behavior in rodent model

Authors: J. STATZ¹, R. MCCARRON², J. GOODRICH¹, S. L. CIARLONE¹, M. L. MEHALICK², S. T. AHLERS³, P. B. WALKER², *A. E. TSCHIFFELY⁴ ¹Naval Med. Res. Center, HJF, Silver Spring, MD; ²Neurotrauma, ⁴Dept. of NeuroTrauma, ³Naval Med. Res. Ctr., Silver Spring, MD

Abstract: Traumatic brain injury (TBI) is a frequent injury in military conflicts, often caused by exposure to overpressure (shock) waves from devices such as improvised explosive devices. Studies indicate high rates of co-morbid mTBI and posttraumatic stress disorder (PTSD). Specifically, Ahlers and colleagues (2012) demonstrated blast-exposed rats display PTSD-like behavior, indicating possible relationships between blast and PTSD development. Moreover, both stathmin and corticosterone levels are increased post-blast in the rodent brain and serum, respectively. These markers typically indicate increased anxiety and are altered as a result of both fear and stress responses. However, not every blast-exposed subject will display anxiety-like behavior and may display phenotypes similar to controls. Therefore, including animals from experimental groups that do not appear anxious may obscure results that would demonstrate differences due to blast. To account for this, normal and abnormal behaviors can be determined from the control group, and the experimental group can be split into those displaying normal behaviors ("unaffected") and anxiety-like behaviors ("affected"). These subgroups can then be

compared separately to controls for a better understanding of changes that blast exposure may cause in behavior and molecular variables. Data sets consist of molecular variables (e.g., blood or protein biomarkers) and behavioral data that identify the "affected" group. Using an affective profiling approach introduced by Richter-Levin and his colleagues (2015), control animal behavioral data was analyzed to determine boundary values for normal behavioral results. These boundary values were then applied to the experimental group's behavioral data, and animals whose behavior fell outside this range were separated into an "affected" experimental group; remaining animals were labeled "blast-unaffected". Using these procedures, data for molecular variables were then compared. When this method was used on test data containing behavioral data from an elevated zero maze and stathmin and corticosterone levels, clear differences in the average values between "affected" and "unaffected" groups were present. This method shows promise as another method to study effects of blast, while accounting for animals whose data may obscure results due to similarities to control animals.

Title: Stress-induced deficits in latent inhibition in GDNF-deficient mice

Authors: *C. K. BROWN, C. V. BUHUSI, M. BUHUSI Dept. Psychology, Utah State Univ., Logan, UT

Abstract: Stress may induce adaptive or maladaptive organismal responses depending on the individual's genetic makeup. Glial-derived neurotrophic factor (GDNF), a growth factor supporting the survival and physiology of dopaminergic neurons, is upregulated in response to stress and is essential for adaptive brain responses to chronic stress. Heterozygous GDNF mice, which have reduced GDNF expression, and wild-type littermates were tested for learning and attention impairments under standard experimental conditions and after a chronic stress regimen. Freezing behavior in response to pre-exposed and non-pre-exposed stimuli paired with foot shocks was analyzed to assess latent inhibition, as a measure of selective attention. Analyses indicated a main effect of pre-exposure (F(1,47)=59.89, p<0.01), stress (F(1,47)=4.64, p<0.05),
and a pre-exposure x stress interaction (F(1,47)=6.35, p<0.05). Post-hoc analyses showed that all unstressed mice as well as the wild-type stressed mice showed latent inhibition (p<0.05); in contrast, GDNF-deficient mice did not show latent inhibition after chronic stress (p>0.05). Immunohistochemical staining procedures were used to evaluate neuronal activation in brain regions relevant to latent inhibition, and revealed significant differences between GDNF-deficient mice and controls in the prefrontal cortex and nucleus accumbens. Our results support the role of chronic stress in triggering maladaptive brain responses in vulnerable individuals, with important implications for the onset of psychiatric disorders such as schizophrenia or PTSD.

Title: The pregnane x receptor is implicated in the therapeutic mechanism of finasteride

Authors: *L. J. MOSHER^{1,2}, J. L. STAUDINGER², M. BORTOLATO¹ ¹Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; ²Pharmacol. and Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: Tourette syndrome (TS) is a neurodevelopmental disorder characterized by recurring motor and phonic tics, which are preceded by a sense of discomfort known as a premonitory urge. TS symptoms are contributed to by an inability of the brain to filter out irrelevant sensory information. As such, these patients have deficits in sensorimotor gating processes, which aim to discriminate between relevant and irrelevant stimuli and can be measured by prepulse inhibition (PPI) of the startle reflex. TS symptoms are underpinned in part by hyperdopaminergic systems within the cortico-striato-thalamo-cortical loop. In accordance, dopamine (DA) agonists have been extensively studied in preclinical models of TS to replicate various aspects of the disorder. For example, D1 receptor agonists induce PPI deficits and stereotyped behaviors in mice. Current therapies for TS are often not effective or are associated with side effects that decrease patient compliance. To address this issue, our lab has been studying the contribution of

neurosteroids (NS) as potential therapeutic candidates. Converging evidence supports a role for NS in modulating the DA system and clinical data supports the hypothesis that NS contribute to TS pathogenesis and symptom fluctuations. One of the most important clinical observations in support of this role is the heightened stress sensitivity observed in these patients, which implicates allopregnanolone (AP). We have previously demonstrated that both stress and systemic AP administration exacerbate TS like symptoms, including PPI deficits, in animal models. In addition, we have also shown that blocking the production of AP with the 5α -reductase inhibitor finasteride alleviates symptoms in both adult males with TS and ablates PPI deficits induced by D1 receptor agonists in mice. However, the contributing molecular mechanisms of these findings remain unclear.

Previous preliminary research from our lab has indicated that the mechanism of AP does not directly involve the GABA_A receptor so we have expanded our studies to other potential receptors. Recent data has demonstrated that AP can bind to the pregnane X receptor (PXR) and has highlighted a function for this receptor in DA-AP interactions within the brain. We found that mice deficient of PXR are resistant to AP (15mg/kg)-induced PPI deficits. In addition, we found that finasteride (50mg/kg) is not effective in these mice to ablate the PPI deficits induced by the D1 agonist SKF 82958 (0.3mg/kg). These data suggest that PXR mediates the effects of AP in the regulation of sensorimotor gating; however, more research is needed to determine how this receptor modulates DA signaling.

Title: Altered stress adaptation, glucose metabolism, and increased susceptibility for mood disorders in a mouse model with decreased mitochondrial complex I function

Authors: *T. L. EMMERZAAL¹, E. VASILEIOU¹, B. GEENEN¹, K. SCOTT², B. H. GRAHAM³, W. J. CRAIGEN³, E. MORAVA², R. RODENBURG¹, T. L. KOZICZ⁴ ¹Radboudumc, Nijmegen, Netherlands; ²Tulane Univ., New Orleans, LA; ³Baylor Col. of Med., Houston, TX; ⁴Anat., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands

Abstract: An increasing body of evidence points toward the involvement of suboptimal mitochondrial function (SMF) in depression and other mood disorders. Several clinical and preclinical studies show that depression is associated with altered mitochondrial structure and function. Furthermore, stress, a major risk factor for depression, directly influences mitochondrial function. There is a surprising high association between mitochondrial disease and

depression as well, which is estimated to be around 50%. This is significantly higher than the expected 16% depression prevalence in the general population. These findings suggest that SMF is causal in depression, however, this notion has not been substantiated yet. In this study, we tested the hypothesis that SMF influences the animals' stress response and impacts various biological domains linked to the pathobiology of depression. To test this hypothesis, a new genetically engineered mouse model was used. These animals have a deficiency of the NDUFS4 protein (Ndufs4def mice), a structural protein of complex I (CI), an essential component of the electron transport chain and oxidative phosphorylation. This deficiency leads to a 25% reduction of CI activity in the brain compared to WT mice. Despite this reduction, Ndufs4def mice exhibited no differences in body weight and temperature, physical activity (distanced travelled and velocity in the open filed), and motor coordination (Rotarod-test) compared to their WT littermates. After exposure to a chronic variable stress protocol, a well-validated animal model for depression, Ndufs4def mice showed increased anxiety like behavior (open field) as well as a disturbed day-night rhythm compared to WT animals, a symptom that can also be seen in individuals with depression. Furthermore, preliminary results suggest an altered glucose metabolism and stress response in the Ndufs4def mice. To provide mechanistic insights, we assessed the activation of brain nodes implicated in the pathobiology of depression. The expression of the protein FOS, a surrogate marker of neuronal activation, revealed distinct activation of several brain regions of WT and Ndufs4def mice. These results indicate a difference in functional coupling within and an altered balance between major brain networks, a well-established phenomenon in individuals with depression. In conclusion, here we report on distinct chronic stress-evoked responses in various biological domains in Ndusf4def and WT mice, supporting our hypothesis that suboptimal mitochondrial function mediates the impact of stress on mental health.

Title: Corticotropin releasing factor in the medial septum impairs spatial learning in rats

Authors: *K. WIERSIELIS, M. SALVATORE, H. LEFEBO, H. JANG, A. CERETTI, V. CANTORAL, D. BANGASSER Temple Univ., Philadelphia, PA

Abstract: Stress can disrupt a variety of cognitive processes, including learning and memory. Previous studies in rodents have demonstrated that central infusions of the stress-neuropeptide, corticotropin releasing factor (CRF), can disrupt mnemonic processes. However, where CRF is working within the brain to regulate cognition is largely underexplored. A candidate region for direct CRF regulation is the medial septum (MS), because this forebrain cholinergic nucleus is critical for spatial learning and CRF receptors are found on cholinergic neurons therein. Here we assessed whether administering CRF directly into the MS impaired spatial learning in male and female rats. Specifically, we infused different doses of CRF or vehicle into the MS prior to testing on an object location task, which tests spatial learning, and a novel object recognition task, which does not test spatial learning. On the object location task, we found that CRF in the MS reduced time spent exploring the displaced object compared to the familiar object, suggesting that this manipulation impairs spatial learning. In addition, males were more sensitive to this effect than females, such that a low dose of CRF in the MS that had no effect in females disrupted object location learning in males. In the novel object recognition task, CRF in the MS did not decrease preference for the novel object in either sex, suggesting that the effects of CRF in the MS are specific to spatial learning. Future experiments will examine the influence of circulating ovarian hormones in regulating sensitivity of the MS to CRF. Collectively, these studies reveal that CRF in the MS selectively impairs spatial learning, especially in males, highlighting an unexplored mechanism by which stress can regulate cognition. Clinically, these findings suggest that drugs which block the effects of CRF represent a viable therapeutic option to treat cognitive deficits that characterize certain stress-related psychiatric disorders.

Title: Chronic stress regulation of sustained attention and cholinergic dendritic morphology in rats

Authors: *A. TELENSON¹, B. WICKS², J. BERGMANN³, M. SHORE³, N. NEWCAMP³, A. CERETTI³, S. ECK³, A. HALL³, K. WIERSIELIS⁴, J. TUCCI³, D. A. BANGASSER⁵ ¹Psychology, ²Psychology and Neuroscienc Program, Temple Univ., Philadelphia, PA; ³Temple Univ., Philadelphia, PA; ⁵Dept. of Psychology and Neurosci. Program, ⁴Temple Univ., Philadelphia, PA

Abstract: Chronic stress can impair attention and exacerbate symptoms in disorders with cognitive deficits as a key feature, including schizophrenia, attention deficit hyperactivity disorder, and bipolar disease. However, the neurobiological mechanisms by which chronic stress disrupts attention remain largely unknown. Using a 6 day chronic variable stress procedure for rats, we tested how chronic stress affects attention and neurons critical for attentional processes. To test attention, we used a sustained attention task, where rats are trained to distinguish signal from non-signal trials. We found that chronic variable stress impaired performance on signal trials, especially in male rats when attentional demands were high. It has been previously shown that accuracy on signal trials require cholinergic neurons in the nucleus basalis of Meynert (NBM) in the basal forebrain. In other brain regions, such as the amygdala and hippocampus, chronic stress is thought to affect cognition by altering the morphology of dendrites on neurons within these regions. We wanted to determine whether chronic stress alters the morphology of dendrites on NMB cholinergic neurons. To address this question, we developed an innovative approach to label cholinergic neurons in rats by virally injecting a Cre-dependent fluorescent marker into the NBM region of rats genetically modified to express Cre-recombinase under control of the choline acetyltransferase promoter. Using this approach, our preliminary data is finding that chronic variable stress expands the morphology of NBM cholinergic dendrites, particularly at regions distal from the cell body, in male rats. Future studies are planned to test for similar morphological changes in female rats. This is the first study, to our knowledge, suggesting that chronic stress can induce hypertrophy of cholinergic dendrites. If supported with more subjects, this result would suggest that chronic stress impairs attention by affecting inputs into the NBM via the regulation of the morphology of cholinergic dendrites.

Title: The effects of corticotropin releasing factor in the nucleus basalis of meynert on sustained attention in male and female rats

Authors: *S. ECK, B. WICKS, N. DUNCAN, M. SALVATORE, S. COHEN, J. BERGMANN, A. CERETTI, A. HALL, D. BANGASSER Temple Univ., Philadelphia, PA

Abstract: Attention is disrupted in a variety of disorders, including schizophrenia, attention deficit hyperactivity disorder, and post-traumatic stress disorder. One characteristic that all of these disorders share is their sensitivity to stress. Despite these connections, the neurobiological mechanism by which stress modulates attentional processes remains largely underexplored. We aim to fill this gap in the literature by studying the effects of corticotropin releasing factor (CRF) on performance on a sustained attention task (SAT) in rats. In this task, rats are trained to discriminate signal from non-signal trials. Previously, our lab has shown that central administration of CRF causes a dose-dependent impairment in performance on SAT in both male and female rats. Now, we are trying to determine where exactly in the brain CRF is exerting this effect. Previous studies have shown that accurate performance on signal trials depends on cholinergic neurons in the nucleus basalis of Meynert (NBM) of the basal forebrain, while accurate performance on non-signal trials is linked to GABAergic neurons in the NBM. We have shown that CRF receptors are present on both cholinergic and GABAergic neurons in this brain area, making the NBM a likely target for CRF's modulation of sustained attention. To test this idea, we infused CRF into the NBM and examined its effect on SAT. We found that intra-NBM infusions impaired performance on non-signal trials, but not on signal trials, suggesting that CRF in the NBM is altering the function of GABAergic neurons. Interestingly, the effect of CRF in the NBM appears to be more pronounced in males, suggesting a sex difference in CRF sensitivity in this region. Collectively, these results implicate novel CRF-GABA interactions in the NBM, especially in males. Moreover, these data suggest that blocking CRF signaling may be a viable therapeutic option for treating the stress-related attention impairments of various disorders.

Title: Corticotropin releasing factor differentially activates brain networks in males and females

Authors: *M. SALVATORE¹, K. WIERSIELIS², D. E. WAXLER³, D. A. BANGASSER⁴ ¹Psychology, Temple University, Philadelphia, PA; ³Dept of Psychology, ⁴Dept. of Psychology and Neurosci. Program, ²Temple Univ., Philadelphia, PA

Abstract: Women are more likely than men to suffer from psychiatric disorders that have hypersecretion of the stress neuropeptide corticotropin releasing factor (CRF) as an etiological factor, suggesting sex differences in CRF sensitivity. In rodents, sex differences in sensitivity of specific brain regions to CRF have been identified. However, regions do not work in isolation, but rather form circuits to coordinate distinct responses to stress. Here we examined whether CRF activates different circuits in male and female rats. Following central administration of CRF or vehicle, brain tissue was collected and processed to visualize the immediate early gene cFOS in stress-related areas known to contain a high density of CRF receptors. Neuronal activation in these areas was then assessed by quantifying cFOS positive cells. Functional connectivity was gauged by correlating cFOS profiles between regions and then identifying differences in correlations for aCSF-treated and CRF-treated groups. This analysis revealed baseline differences in connectivity between males and females, where activation was more highly correlated between brain regions in females than in males. Additionally, analyses showed that CRF altered the functional connectivity of different circuits in males and females. For example, CRF altered correlations with the dorsal raphe (DR) in males and correlations with the bed nucleus of the stria terminalis (BNST) in females, suggesting sex differences in stress-activated circuits controlling mood and anxiety. This study reveals sex differences in the way brain regions work together in response to CRF. These differences could drive different stress coping strategies in males and females, perhaps contributing to sex biases in psychopathology.

Title: Evaluating stressor controllability effects in female rats

Authors: *I. P. FALLON¹, M. V. BARATTA¹, N. R. LESLIE¹, S. D. DOLZANI^{1,2}, L. E. CHUN¹, A. M. TAMALUNAS¹, L. R. WATKINS¹, S. F. MAIER¹ ¹Psychology and Neurosci., ²Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO

Abstract: The degree of behavioral control a subject (rat to human) can exert over an adverse life event is one of the most potent variables yet discovered that modulates the impact of that event. That is when a subject is provided with a controlling response the behavioral and neurochemical sequelae are blunted or eliminated. Prior work has established that the protective effects of behavioral control are mediated by the prelimbic region (PL) of the medial prefrontal cortex which provides top-down inhibitory regulation of stress-responsive structures such as the serotonergic dorsal raphe nucleus (DRN). However, virtually all the work has been conducted in male subjects. Here we demonstrate that behavioral control in females does not mitigate stress-induced behavioral outcomes (EXP 1) nor DRN activation (EXP 2). Furthermore, behavioral control in females does not engage DRN-projecting PL neurons (EXP 3). Pharmacological activation of the PL restored the stress-buffering effects of control (EXP 4). The present findings suggest that reduced benefit from coping responses may represent a novel approach for understanding differential sex prevalence in stress-related psychiatric disorders.

Abstract: Anxiety is a normal or adaptive response, as the fight-flight reaction, which prepares the body for an emergency, is presented by different circumstances and clinical manifestations. Its important function is related to survival, fear, anger, sadness or happiness, the treatment of anxiety is with classic anxiolytics such as benzodiazepines (BZP), which, produce several adverse effects. For this reason, new molecules have been synthesized, with lower adverse effects than those BZP. Different groups, designed, synthesized and evaluated the anxiolytic effects of melatonin analogues (MT), in particular, those with a benzyl or phenyl group in position 1 of the indole ring, with good anxiolytic-like effects in rats, these are in function of the substituents. The objectives of this work are the synthesis of a new series of 8 MT analogues, M3A.3, M7A.2, M7A.3, M8A.2, M8A.3, M8A.4, M3B-3 and M3C.3. Whose evaluation was In Vitro, rat isolated tissue and In Vivo, Marble-Buryng Test in mouse. Obtaining then, that the conformational analysis and the incorporation of the substituent in position 1 has no influence and the electronic density on the ring is not altered. In Vitro, MT analogues, produce tissue relaxation. In Vivo, compound M3A.3, shows a good anxiolytic-like effect similar to MT. These data lead us to propose that the strategy of finding prototypes by analogy, provides a greater probability of obtaining substances with the desired pharmacological activity.

Title: Behavioral and neurobiological effects of social housing conditions on male Long-Evans rats: Elevated plus-maze and open field

Authors: M. E. HASTINGS¹, R. M. CAIN¹, M. L. HOLLAND¹, R. J. STAMM¹, J. A. WILLNER¹, D. M. HAYES², *P. A. JACKSON¹ ²Psychology, ¹Radford Univ., Radford, VA

Abstract: Many research scenarios require animals to be singly housed for collection of individual data. However, rats are naturally social animals and thrive when allowed to engage in stimulating species-specific behaviors such as burrowing in bedding, mutual grooming, and wrestling. Animal welfare concerns suggest that rats should not be housed individually or without bedding due to known behavioral alterations, as well as increased levels of the stress hormone corticosterone. To address these concerns, new housing methods are being developed that allow for moderate social interaction without compromising the integrity of data collection. Specifically, barrier style housing utilizing a perforated cage divider allows rats to be housed in a social, but separated, manner. In this form of housing, rats can see, smell, and touch one another, but cannot have full body contact. The current study examined how this separated style of housing affected behavior and stress physiology in adult, male Long-Evans rats compared with three other common styles of housing. These included a social condition where rats were housed in pairs with bedding, and two solitary conditions where rats were housed individually either with bedding or with a wire floor. Each animal spent four weeks in its respective housing condition before behavioral testing in an elevated plus-maze (EPM) and open field (OF) apparatus to measure anxiety and locomotor activity. Rats were also tested in the Morris Water Maze (see Cain et al.). Initial analysis of data from the EPM suggested no significant differences in percent time spent in the open arms of the apparatus, but there was a trend towards increased activity in animals in the solitary-wire floor condition. Additionally, initial analysis of data from the OF suggested no significant differences in distance traveled or time spent in the center of the open field. After behavioral testing, rats were sacrificed and plasma samples, isolated from trunk blood, were collected for corticosterone analysis via enzyme-linked immunosorbent assay (ELISA). Results from this study should provide new insight into the efficacy of barrier style housing as an alternative to previous solitary housing methods.

Title: Behavioral and neurobiological effects of social housing conditions on male Long-Evans rats: Morris water maze

Authors: R. M. CAIN, M. E. HASTINGS, M. M. GALLAGHER, J. A. SAAD, J. A. WILLNER, P. A. JACKSON, *D. M. HAYES Psychology, Radford Univ., Radford, VA

Abstract: Rats are social creatures and emerging evidence suggests that they should not be housed individually during research due to elevated stress levels, increased non-stereotypic behaviors, lack of stimulation, disturbances in sleep patterns, alterations in feeding habits, potential vulnerability to disease, and a risk to overall wellbeing. Despite their social nature, research protocols often require single housing of rats, to collect individual data or samples. New caging scenarios that allow for more social interaction without compromising data collection would therefore be useful. One such scenario utilizes a barrier through which rats can partially interact with one another (see, smell, and touch) while remaining physically separated. The current study compared this new housing condition to three other commonly used housing practices (social, solitary-bedding, and solitary-wire floor) to examine effects on spatial learning and hippocampal neurogenesis in adult, male, Long-Evans rats. Importantly, elevated stress levels are associated with decreased neurogenesis; the production of new cells in the brain. Neurogenesis involves four stages in various regions of the brain: proliferation, differentiation, maturation, and integration. In the hippocampus, neurogenesis occurs in the dentate gyrus, a region involved in spatial learning and memory. After being in the housing conditions for four weeks, animals were tested on a battery of behavioral tests (see Hastings et al.) culminating with the Morris Water Maze (MWM) task to assess various domains of spatial ability. There were no main effects of housing on latency to platform or percent time spent in thigmotaxis during the acquisition phase of the MWM task. Similarly, no differences were found for percent time spent in target quadrant during a probe trial of the MWM task. These preliminary findings suggest no differences in spatial memory across the housing conditions. After behavioral testing, brain tissue was extracted in preparation for sectioning and staining for expression of Ki67, an endogenous marker for cell proliferation. It is expected that animals housed in the solitary conditions will exhibit lower levels of cell proliferation in the hippocampus than animals in the social or separated conditions. Additionally, it is expected that the animals in the new housing condition will exhibit similar levels of cell proliferation as animals housed socially. The results of this study may be useful for making future animal husbandry decisions in research settings.

Title: Sex differences in HPA and metabolic responses to early life stress in rats

Authors: *H. SHI

Miami Univ., Oxford, OH

Abstract: Sex differences exist in the regulation of energy homeostasis and the HPA axis. Stress during early life causes dysregulation of the HPA axis and metabolism. We hypothesized that chronic stress during adolescence differentially affected energy homeostasis and the stress response in male and female rats, which could extend to adulthood. Randomized, daily one-hour restraint stress was employed in 12 male and 12 female Sprague Dawley rats, starting on postnatal day (PD) 32 and lasting through PD 44. Age and metabolic profile-matched control groups (12 males and 12 females) received the same procedures as the stress groups but did not undergo restraint stress. Rats were either terminated an hour following stress on PD 44, or 20 days following stress on PD 64 by decapitation, and trunk blood samples were taken for the measurements of plasma estradiol (E2) and testosterone (T). Circulating levels of corticosterone (CORT), an indicator of HPA axis activation, was measured using serial blood samples collected before, during, and after stress or non-stress conditions. Body weight (BW), food intake (FI), and body composition were measured throughout the experiment. Both stress male and female rats significantly reduced BW and FI during the stress period. In males the degree of reduced FI was equal to and thus accounted for their reduced BW; however, in females the reduced FI did not fully account for their reduced BW. Additionally male reduction of BW, fat, and lean mass extended to adulthood even after stress was no longer present. On the first day of chronic stress, both males and females had increased CORT levels in response to stress. Stress males sustained an elevated CORT level throughout stress, whereas stress female CORT level returned to that of controls, indicating adaption to the stressor. E2 levels were similar among male groups, but were lower in stress females compared to control females during adolescence, and this E2 difference extended to adulthood. T levels were similar among female groups, but reduced in stress males compared to control males during adolescence; however, such difference did not extend to adulthood. These results suggest that when compared to females, male rats exposed to early life stress exhibit an increased sensitivity to metabolic disturbances that continue to adulthood, most likely due to HPA axis dysregulation. Further insights as to how adolescent females are able to protect themselves from stress-induced HPA dysregulation, but not gonadal dysregulation later in life, remain to be seen. Our data provides implications as to how sex differences exist in the adolescent human stress response, with consequences that impact adulthood.

Title: Divergence in cognitive performance under chronic stress is associated with the hippocampal whole transcriptomic modification

Authors: *S. H. JUNG¹, M. L. BROWNLOW¹, M. PELLEGRINI², R. JANKORD¹ ¹Applied Neurosci. Br., U.S. Air Force Res. Lab., Columbus, OH; ²Dept. of Molecular, Cell, and Developmental Biol., Univ. of California, Los Angeles, CA

Abstract: Individual susceptibility determines the magnitude of stress effects on cognitive function. The hippocampus, a brain region of memory consolidation, is vulnerable to stressful environments, and the impact of stress on hippocampus may determine individual variability in cognitive performance. Therefore, the purpose of this study was to define the relationship between the divergence in spatial memory performance under chronically unpredictable stress and an associated transcriptomic alternation in hippocampus, the brain region of spatial memory consolidation. Multiple strains of BXD recombinant inbred mice went through a 4-week chronic variable stress paradigm followed by the Morris water maze (MWM) test to assess hippocampaldependent spatial memory performance and grouped animals into low and high performing groups based on the cognitive performance. Using hippocampal whole transcriptome RNAsequencing data, differential expression, PANTHER analysis, WGCNA, Ingenuity's upstream regulator analysis in the Ingenuity Pathway Analysis® and phenotype association analysis were conducted. Our data identified multiple genes and pathways that were significantly associated with chronic stress-associated cognitive modification and the divergence in hippocampal dependent memory performance under chronic stress. Biological pathways associated with memory performance following chronic stress included metabolism, neurotransmitter & receptor regulation, immune response and cellular process. The Ingenuity's upstream regulator analysis identified 247 upstream transcriptional regulators from 16 different molecule types. Transcripts predictive of cognitive performance under high stress included genes that are associated with a high occurrence of Alzheimer's and cognitive impairments (e.g., Ncl, Eno1, Scn9a, Slc19a3, Ncstn, Fos, Eif4h, Copa, etc.). Our results show that the variable effects of chronic stress on the hippocampal transcriptome are related to the ability to complete the MWM task and that the modulations of specific pathways are indicative of hippocampal dependent memory performance. Thus, the divergence in spatial memory performance following chronic stress is related to the unique pattern of gene expression within the hippocampus.

Title: Investigating the fear-reducing effects of controllable stress with a robust activity marking system

Authors: *N. R. LESLIE¹, M. V. BARATTA¹, A. T. SØRENSEN², B. J. KEDL¹, L. R. WATKINS¹, Y. LIN³, S. F. MAIER¹

¹Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; ²Ctr. for Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; ³McGovern Inst. for Brain Research, Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The degree of behavioral control over some aspect of an adverse life event potently modulates the outcome of that event. Prior work has demonstrated that controllable stress impacts subsequent fear-related processes. Behavioral control a) blunts later fear expression; b) facilitates fear extinction; and c) prevents the spontaneous recovery of fear. The fear-reducing effects of behavioral control require activation of the medial prefrontal cortex, specifically the infralimbic region (IL), during both the stress experience (Time A) and later fear testing (Time B), suggesting that control potentiates the IL response to later fear-related stimuli. Here we use a Robust Activity Marking (RAM) system to determine if specific ensembles of neurons within the IL are activated during both Time A and Time B. We used an AAV-based RAM system containing a synthetic activity-regulated promoter that is strongly induced by neuronal activity, and a modified Tet-Off system for temporal control. In EXP1, male rats were injected with AAV-RAM-mKate2 into the IL and maintained on doxycycline-treated chow (Dox) until 96 h before stress treatment. Subjects received controllable, uncontrollable, or no stress, and the IL neuronal ensemble activated by stress exposure was labeled by RAM. Animals were placed back on Dox and subjected to auditory tone conditioning 48 h later. Following the tone test subjects were sacrificed and brain sections were stained for the immediate early gene Fos in order to label IL ensembles triggered by the tone test. Subjects previously exposed to controllable stress

exhibited reduced fear expression to the conditioned tone compared to uncontrollable stress and no stress controls. Correspondingly, co-labeling of RAM (Time A) and Fos (Time B) in the IL was increased by prior behavioral control. Surprisingly, when the above experiment was conducted in females (EXP 2) we found no effect of controllability on fear expression nor IL RAM and Fos co-labeling. These results indicate that, in males, the activation of IL neuron populations during controllable stress may potentiate activity of those same cells during later fear-related stimuli, effectively reducing expression of the fear response. In females the protective effect of behavioral control was absent suggesting that the neural processing of coping responses differs between the sexes.

Title: The autism-mutated ADNP is a risk factor for post-traumatic stress: Protection with the regulatory neuropeptide PACAP

Authors: *I. GOZES, S. SRAGOVICH Sackler Sch. Med/Tel Aviv Univ., Tel Aviv, Israel

Abstract: Trauma may occur as a result of life-threatening events such as combat, terrorist attacks, accidents, and natural disasters. Following the stressful event, most survivors of trauma naturally resume their normal lives. However, some trauma victims suffer from long-lasting stress reactions that may worsen over time, and could develop into post-traumatic stress disorder (PTSD).

Activity-dependent neuroprotective protein (ADNP) discovered and first characterized in our laboratory as vital for mammalian brain formation was found to be one of the leading genes mutated *de novo* and causing an autistic syndrome. ADNP is regulated by vasoactive intestinal peptide (VIP), as well as by pituitary adenylate cyclase-activating peptide (PACAP), which change its content toward neuroprotection. In this respect, PACAP was identified as a known master regulator of stress response, and has been tightly associated with PTSD in a sex-dependent manner. Interestingly, the PACAP-regulated ADNP is also sexually dimorphic. Furthermore, children with autism may be at increased risk for both encountering traumatic events and developing traumatic sequelae.

In the current study, the impact of the Adnp genotype and the efficacy of PACAP pre-treatment were tested in a unique mouse model of Adnp-haploinsufficiency subjected to stressful conditions. Mice were pre-treated twice daily with PACAP for one month, followed by a 48 hour period of solitude in a clean cage under constant bright illumination (stressful conditions). Anxiety levels were tested using the elevated plus maze, and complemented by cognition and social activity tests. Our results revealed that impairments displayed in stress-challenged Adnp^{+/-} mice in the novel object recognition and the social memory tests were normalized to the Adnp^{+/+} phenotype by PACAP treatment. Odor discrimination test revealed that the affected olfaction in challenged mice was partially restored by PACAP. The assessment of anxiety-related behavior in the elevated plus maze showed that challenged mice exhibited altered behavior, also normalized by PACAP. Interestingly, significant sex differences were observed with Adnp^{+/-} males more susceptible to stress in the object and social recognition tests.

Our findings suggest a correlation between ADNP levels and PTSD. Thus, low ADNP transcript expression level may indicate a worse response to stressful events, which can be successfully ameliorated by PACAP treatment. Altogether, this could establish ADNP as a possible biomarker, identifying people who are either prone to develop PTSD or already suffering from its symptoms.

Title: Nosema parasitism in the honey bee brain: A neuroethology approach toward a honey bee stressor implicated in colony losses

Authors: *S. L. GAGE^{1,2}, C. KRAMER³, S. CALLE⁴, A. RODRIGUES⁴, M. CARROLL⁴, M. HEIEN³, G. DEGRANDI-HOFFMAN^{4,2}

¹Carl Hayden Bee Res. Center, USDA-ARS, Tucson, AZ; ²Entomology, ³Chem. and Biochem., Univ. of Arizona, Tucson, AZ; ⁴Carl Hayden Bee Res. Ctr., USDA-ARS, Tucson, AZ

Abstract: *Nosema* sp. is an internal parasite of the honey bee, *Apis mellifera*, and one of the leading contributors to colony losses worldwide. This parasite is found in the honey bee midgut, and has profound consequences on the host's physiology. *Nosema* sp. impairs foraging

performance in honey bees, but whether this is due to effects on the bee's neurobiology is unclear. In these studies, we ask three main questions: (1) Does *Nosema* sp. affect brain physiology, (2) is there a behavioral effect, (3) and if there are neurobiological consequences, can they be mitigated through nutrition? To address these questions, we infected newly emerged bees with *Nosema ceranae* spores. At approximate nurse and forager ages, we measured amino acid and biogenic amine levels in the brain, and evaluated learning and memory with an odorassociative conditioning assay using the proboscis extension reflex. We detected significant effects of *N. ceranae* infection on amino acid concentrations, some of which were age-specific; as well as altered serotonin, octopamine, dopamine, and L-dopa concentrations. In the behavioral assays, nurse-aged bees infected with *N. ceranae* significantly outperformed controls in odor learning and memory—suggestive of precocious foraging; but by forager age, infected bees were slower to learn and showed memory impairment. These findings suggest *N. ceranae* parasitism affects the brain of the honey bee and behavioral tasks may be compromised. These results yield new insights into the host—parasite dynamic of honey bees and *N. ceranae*, as well as the neurochemistry of odor learning and memory in healthy and parasitized individuals.

Title: Evidence that chronic stress-induced prefrontal dendritic spine loss and working memory impairment are not sexually-differentiated in adult rats

Authors: *R. M. ANDERSON¹, M. MAHANNA¹, S. ROMIG-MARTIN¹, J. J. RADLEY^{1,2} ¹Psychology Dept, Program in Neurosci., ²Interdisciplinary Dept. of Neurosci., Univ. of Iowa, Iowa City, IA

Abstract: Stress exposure is widely implicated in psychiatric illnesses, although in recent years attention has been directed toward the fact that females show a higher incidence of stress-related affective disorders than males. Hippocampal and prefrontal dysfunction are widely implicated in stress-related disorders, and laboratory rodent models of chronic stress have advanced our understanding of the resultant structural and functional impairments in these cortical regions. Paradoxically, much of the rodent literature shows intact, and in some cases even enhanced cognitive functioning in females following chronic stress. Work and others have previously

shown that chronic stress in male rats leads to dendritic spine attrition in the medial prefrontal cortex (mPFC) and accompanying working memory impairments, however, we have not previously critically evaluated these effects in female rats. Here we examine dendritic spine morphological alterations in the prelimbic region (PL) of mPFC, and working memory functioning, in both female and male rats exposed to 14 days of chronic variable stress (CVS; daily exposure to different stressors at unpredictable times over 14 days). In the first experiment, cohorts of male and female rats were subjected to CVS or unstressed control conditions, and then were perfused for neuronal morphological analyses on day 15. Pyramidal neurons in layers II/III of PL were selected for intracellular fluorescent dye-filling, followed by high-resolution 3D imaging and analysis of spine density and morphometry. CVS-exposure decreased spine density on PL pyramidal neurons in both males and females as compared to respective within-sex control treatments (by 16% and 11%, p < 0.05). In the second experiment, cohorts of male and female rats were trained on the delayed alternation task using a *T*-maze to measure spatial working memory. After training, a subset of male and female rats was subjected to 14 d CVS, and all rats were submitted to behavioral testing on days 15-18. Both groups of CVS-treated male and female rats showed impairments in working memory performance and increased corticosterone levels as compared with same-sex unstressed controls (p < 0.05 for each). These studies extend our previous work showing that the adverse effects of chronic stress on prefrontal structural and functional plasticity have broad effects that are not well-differentiated between adult male and female rats, and suggest that cognitive resilience shown in female rodents following prolonged stress exposure does not generalize to the prefrontal endpoints examined here.

Abstract: Mitochondrial respiratory disorders are characterized by a chronic energy deficit due to mutations in the nuclear or mitochondrial genome affecting the oxidative phosphorylation (OXPHOS) responsible for ATP synthesis. Leber's hereditary optic neuropathy (LHON) is a rare and intractable maternally inherited disorder characterized by severe loss of bilateral vision and permanent blindness. Most mutations map in mitochondrial-encoded subunits of the rate-limiting OXPHOS complex I, leading to impaired ATP production, loss of retinal ganglion cells and degeneration of optic nerve axons. Among the three primary mitochondrial mutations associated with LHON, the m.11778A>G mutation is the most severe and affects the mitochondrialencoded subunit ND4 of complex I. Intriguingly, an association between the m.11778A>G mutation in LHON and multiple sclerosis has been predominantly observed in female patients and is referred to as LHON-MS. To understand the underlying molecular pathogenesis of LHON-MS, we performed a skin biopsy on a 34-years old female patient carrying the m.11778A>G mutation. She presented with vision loss at age 27 affecting both near and distant vision, which progressed to headaches, VA of 20/280 OD, 20-160 OS, some color desaturation on Ishihara plates, and bilateral ceocentral scotoma on visual field testing. At age 31, she developed additional symptoms inconsistent with LHON, including urinary retention, bladder spams, loss of sensation, otalgia, muscle and joint and radicular symptoms of pain and numbness in the arms, which led to the diagnosis of LHON-MS. Our live-cell mitochondrial respiratory studies revealed that the proband's fibroblasts exhibited a substantial bioenergetic deficit with a decreased basal consumption oxygen rate and ATP-linked respiration, when compared to agematched healthy fibroblasts. Diseased fibroblasts had a severe decrease of spare respiratory capacity, which stunted their ability to respond to a surge in ATP demand resulting in an energy crisis. We performed a mitochondrial morphometric analysis by transmission electron microscopy, which revealed small mitochondria with sparse and short cristae in the proband's fibroblasts. They rarely exhibited a branched mitochondrial configuration, indicative of abnormal mitochondrial connectivity and dynamics. Thus, our mitochondrial ultrastructural analyses are congruent with our findings from our functional studies on mitochondrial bioenergetics parameters, revealing the ATP crisis as one of the mechanisms leading to selective cell death in patients affected with LHON-MS.

Title: Epigenetic modifiers induce an energy metabolic shift accompanied by increased mitochondrial biogenesis in differentiating neuroprogenitor cells

Authors: *M. N. UITTENBOGAARD¹, C. BRANTNER³, J. S. LIU⁴, A. E. CHIARAMELLO² ²Anat & Regenerative Biol, ¹George Washington Univ. Med. Ctr., Washington, DC; ³Nanofabrication and Imaging Ctr., George Washington Univ., Washington, DC; ⁴Ctr. for Neurosci., Children's Natl. Med. Ctr., Washington, DC

Abstract: A hallmark of brain metabolism is the tight coupling between energy demand and supply, which involves a constant regulation of mitochondrial homeostasis and bioenergetics at all stages of brain development. The brain, a highly energy-demanding organ, is highly dependent on mitochondrial homeostasis for ATP production via oxidative phosphorylation (OXPHOS). Thus, the question of how mitochondrial biogenesis is regulated becomes of paramount importance in order to maintain a tight coupling between energy demand and supply to insure proper neural development and survival. Our previous studies have shown that the neurogenic basic Helix-Loop-Helix (bHLH) transcription factor NeuroD6 increases the number of bioenergetically competent mitochondria at the onset of neuronal differentiation. The main question addressed in this study is the interplay between epigenetics and mitochondrial energy metabolism in a neuronal context, which has remained largely unexplored. It is well established that pan-HDAC inhibitors induce differentiation of neuronal progenitor cells. We investigated whether sodium butyrate (NaBt) could modulate mitochondrial bioenergetics and biogenesis and subsequently enhance neuronal differentiation. To address this question, we took advantage of our engineered neuroprogenitor-like PC12-NeuroD6 (PC12-ND6) cells and E17.5 hippocampal neurons expressing high levels of NeuroD6. Our collective findings show that: 1) NaBt increases the mitochondrial biomass by stimulating mitochondrial biogenesis via the TFAM-NRF-1 axis; 2) NaBt induces a mitochondrial ultrastructural remodeling accompanied with increased cristae, consistent with increased bioenergetics parameters; 3) NaBt induces a metabolic shift toward OXPHOS for ATP synthesis, resulting in enhanced mitochondrial respiration and spare respiratory capacity; 4) modulation of the mitochondrial biomass using gain-and loss-offunction-like pharmacological assays has exposed mitochondrial biogenesis as a key event to enhance the neuronal progenitor competency to differentiate. In conclusion, our study provides evidence for a novel developmental epigenetic layer coupling mitochondrial energy metabolism to neuronal differentiation.

Title: Assessing the impact of glucose and lactate for presynaptic ATP generation during sustained transmission at the calyx of Held

Authors: *S. J. LUCAS¹, C. B. MICHEL², V. MARRA¹, J. L. SMALLEY¹, M. H. HENNIG³, B. P. GRAHAM², I. D. FORSYTHE¹ ¹Univ. of Leicester, Leicester, United Kingdom; ²Univ. of Stirling, Stirling, United Kingdom; ³Edinburgh Univ., Edinburgh, United Kingdom

Abstract: The brain has high energy demands which increase during intense neuronal activity. There is an established relationship between increased brain activity, blood flow and cognition in which energy provision for synaptic transmission is crucial. Presynaptic terminals have particularly high metabolic demands causing local activity-dependent metabolic constraints on physiological transmission and contributing to pathological injury during stroke, traumatic brain injury or neurodegeneration. We have used high frequency stimulation and changes in energy substrates to induce metabolic stress at the calyx of Held/MNTB synapse in the auditory pathway. Energy depletion was achieved under conditions of saturated oxygen and without pharmacological block of respiration, by washout of extracellular metabolic substrates, while measuring glutamatergic synaptic transmission. Patch clamp recording from MNTB neurons in mouse brainstem slices showed that glucose depletion enhanced EPSC depression during high frequency stimulation and slowed recovery of EPSC amplitude. Depletion of presynaptic ATP (achieved by patching the presynaptic terminal to allow diffusion with the patch pipette) also impaired transmitter release in an analogous manner. Computational modelling of these experimental data demonstrated that the impaired transmission was caused by a reduction in the number of functional release sites and slowed vesicle pool replenishment, rather than a sustained change in release probability. Lactate maintained presynaptic function in the absence of glucose. When glucose was perfused in the aCSF as the sole energy substrate, lactate generated from glial cells did contribute to the maintenance of synaptic transmission, but that the terminal was also using glucose directly. We conclude that lactate contributes to supporting presynaptic function, but that glucose is a major presynaptic energy substrate. Presynaptic metabolism is a physiological constraint on synaptic transmission; exploring these physiological limits will give insights into preserving brain function and cognition following hypoxic insults.

Title: Rapid fluctuations in nucleus accumbens oxygen levels induced by arousing stimuli: Relationships with changes in brain glucose and metabolic neural activation

Authors: *E. A. KIYATKIN, K. T. CAMERON-BURR, E. SOLIS, Jr. Behavioral Neurosci Br., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: Proper entry of oxygen from arterial blood into the brain is essential for maintaining brain metabolism under normal conditions and during functional neural activation. However, little is known about physiological fluctuations in brain oxygen and their underlying mechanisms. To address this issue, we employed high-speed amperometry with platinum oxygen sensors in freely moving male rats. Recordings were conducted in the nucleus accumbens (NAc), a critical structure for sensorimotor integration. Rats were exposed to different arousing stimuli (brief auditory tone, a 1-min novel object presentation, a 3-min social interaction with a conspecific, and a 3-min tail-pinch). We found that all arousing stimuli increased NAc oxygen levels. Increases were rapid (4-10-s onset latencies), modest in magnitude (1-3 µM or 5-15% over baseline) and duration (5-20 min), and generally correlated with the arousing potential of each stimulus. Two strategies were used to clarify the mechanisms underlying the observed increases in NAc oxygen levels. First, we showed that NAc oxygen levels phasically increase following intra-NAc microinjections of glutamate that excite accumbal neurons. Therefore, local neural activation and subsequent local vasodilation are involved in mediating physiological increases in NAc oxygen induced by arousing stimuli. Second, by employing oxygen monitoring in the subcutaneous space, a highly-vascularized area with no metabolic activity, we determined that physiological increases in NAc oxygen also depend on a rise in blood oxygen levels caused by respiratory activation. Due to the co-existence of different mechanisms governing oxygen entry into brain tissue, NAc oxygen responses differ from fluctuations in NAc glucose, which, within a normal behavioral continuum, are regulated exclusively by neuro-vascular coupling due to the highly stable levels of glucose in the blood. Finally, we discuss the relationship between physiological fluctuations in NAc oxygen and glucose, and metabolic brain activation assessed by intra-brain heat production.

Title: Assessing affective behaviors in mice lacking the creatine transporter

Authors: *Z. I. ABDULLA¹, J. L. PENNINGTON², K. C. UDOBI¹, N. LATUSHKA², M. R. SKELTON¹

¹Neurol., Cincinnati Children's Res. Fndn., Cincinnati, OH; ²Univ. of Cincinnati, Cincinnati, OH

Abstract: Changes in bioenergetics are seen in a variety of mental illnesses. While most of the work has focused on changes in mitochondrial function, the role of energy buffers such as creatine (Cr) have not been thoroughly investigated. Cr is a nitrogenous amino acid that acts as a spatial and temporal ATP buffer in cells with a high-energy demand. We have developed Cr transporter (Crt) knockout (Slc6a8-'y) mice to better understand how the loss of Cr affects brain function. Slc6a8-/y mice have elevated levels of serotonin (5-HT) in the hippocampus and prefrontal cortex. Increased 5-HIAA, a metabolite of 5-HT, is found in the hippocampus and neostriatum of these mice. Additionally, *Slc6a8*-/y mice are hypersensitive to parachloroamphetamine, a 5-HT mediated stimulant. It is well established that 5-HT activity is a crucial factor in affective behaviors, and it is important to note that Cr has been shown to influence these types of behaviors as well. An acute dose of Cr produced an equally antidepressive effect as fluoxetine in the tail suspension test (TST). Additionally, it was demonstrated that Cr supplementation reduced depression-like measures in the forced-swim test in females, but exacerbated effects in males. If 5-HT is important for affective behaviors and depleting Cr from the brain results in augmentations to 5-HT, will a lack of Cr result in an altered affective phenotype? To address this, we tested wild-type and $Slc6a8^{-/y}$ mice in measures of anxiety, sociability, and depression. Elevated zero maze revealed a trend toward decreased latency to enter the open arms in KO males and heterozygous females (HET), and increased head dips in HETs. Social preference revealed an interesting sex dependent result, in which the presence of cellular Cr was associated with increased sociability in females, but decreased sociability in males. No differences were observed in TST, which reveals a lack of sensorimotor deficits in the $Slc6a8^{-/y}$ mice.

Title: Leptin absence in early life causes long-term disturbances in energy balance that can be restored by early intervention

Authors: *A. M. RAMOS LOBO, P. S. TEIXEIRA, I. C. FURIGO, A. M. LIMA, J. DONATO, Jr

Physiol. and Biophysics, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: The adipocyte-derived hormone leptin is essential for the regulation of energy balance. However, some studies have suggested that in early life leptin functions are associated with neuronal development and dependent of a critical neonatal period.

To determine the effects of the early absence of leptin signaling in adulthood and whether these effects can be reversed by reactivation of leptin signaling in adult life or weaning, a LoxP-flanked transcription-blocking cassette was inserted in the Lepr gene to generate mice *null* for the leptin receptor. They were bred with animals expressing Cre-ERT2 fusion protein under the human ubiquitin C promoter sequence. Consequently, tamoxifen injections can induce Cre Recombinase activity and restore *Lepr* gene expression in adult (10 weeks) or young (4 weeks) Ubi-LepRNull mice.

As a validation of the model we assessed the number of leptin-responsive cells in the brain through an acute leptin injection. LepRNull mice exhibited no leptin responsive cells and the neural projections from the arcuate nucleus (ARH) to the paraventricular nucleus were disrupted, and were both restored in Ubi-LepRNull mice, as was their response to leptin.

Adult LepRNull and Ubi-LepRNull mice were morbidly obese and hyperphagic. Six weeks after tamoxifen treatment, adult Ubi-LepRNull mice restored normal food intake but were heavier and had larger adiposity, they also displayed lower energy expenditure and locomotor activity than Ubi mice. Ubi-LepRNull mice had lower glycaemia as well as higher glucose and pyruvate tolerance than Ubi mice, although they remained insulin resistant. Their brain weight was partially recovered compared to Ubi mice.

We next examined the parameters that were not restored after adult LepR reactivation in young mice. After tamoxifen injections young Ubi-LepRNull mice recovered normal body weight and food intake, together with normal energy expenditure and locomotor activity, as well as their glycemic homeostasis by early reactivation of LepR, although their brain mass remained lighter.

These results suggest that lack of leptin signaling in early life causes long-term changes in energy balance and glucose homeostasis regulation, although ARH projections can be normalized after *Lepr* reactivation in adults, and that weaning is a critical period for leptin's role.

Title: High fat diet impairs hippocampal intrinsic excitability and memory and sex-dependently alters insulin signaling in hippocampus

Authors: *N. TANDON, L. T. THOMPSON Univ. of Texas At Dallas, Richardson, TX

Abstract: Modern western diet with excess energy-dense fats disturb metabolic homeostasis promoting obesity and type-2 diabetes. Cognitive deficits have been clinically observed in humans suffering from obesity and diabetes, and intensely studied in animal models fed high fat diets (HFDs) from weaning. However, sex-differences are rarely systematically analyzed and compared. Previous studies from our lab with an outbred Long Evans (LE) rat HFD model showed impaired spatial memory in both sexes, correlating with significantly reduced intrinsic excitability of hippocampal CA1 pyramidal neurons (enhanced post-burst AHPs). Notable sexdifferences in hormone signaling were observed, wherein HFD induced clinically relevant symptoms of type 2 diabetes in males (obesity, loss of blood glucose control, elevated insulin), but not in females (normal weight and blood glucose control, reduced insulin). Sex-differences were also found in insulin-dependent intrinsic excitability of CA1 neurons; HFD male neurons lost all insulin sensitivity while HFD female neurons had increased sensitivity. Our objectives are to study the effects of HFD in the CA1 region: 1. on proteins involved in Ca2+-dependent intrinsic excitabilitySK2 channels and the Ca2+ sensors calmodulin and hippocalcin; and 2. to understand the induced sexual dimorphism in insulin sensitivity and on proteins involved in insulin signaling pathways. Age-matched HFD or control LE rats were used. Rat brains were either flash frozen for western blotting or perfused for IHC/IFC analysis of protein expression in CA1. Our results show diet-dependent increases in SK2 channel and hippocalcin protein

expression, consistent with increases in medium- and slow-AHPs in CA1 neurons of HFD rats and with impaired spatial memory our laboratory previously reported. Only HFD females showed upregulation in insulin signaling pathways, i.e. increased expression of insulin receptor protein and upregulation of Akt protein phosphorylation. HFD sex-dependently alters insulin signaling in the hippocampus of females but not males. Considering these profound differences, treatment strategies designed to ameliorate cognitive deficits caused by obesity and type-2 diabetes must be sex specific.

Title: Nutrient shuttling in hypothalamic astrocytes is linked to the whole body energy metabolism

Authors: *J. KIM¹, J. LEE², B. PARK³

¹Div. of Life Sci., Incheon Natl. Univ., INCHEON, Korea, Republic of; ²Div. of Life Sci., ³Incheon Natl. Univ., Incheon, Korea, Republic of

Abstract: Astrocytes are the most abundant cells in the central nervous system, yet they have often been relegated to a less than prominent role in the control of complex brain functions supported by neuronal circuits. The regulation of food intake and energy expenditure is tightly linked to the hypothalamic neural circuits. However, the direct contribution of astrocytes in this system is ill defined. Nutrients availability in the brain is crucial for neuronal functions in which astrocytes have also been deeply implicated. In this study, we identified active roles of hypothalamic astrocytes as a sensor of nutrient concentration and a primary modulator to maintain the whole body energy metabolism. We found that the impairment of nutrient shuttling from the blood vessel to the neurons led to the abnormality of energy intake and glucose production utilizing genetic mouse model in which peroxisome proliferator-activated receptor gamma (PPAR gamma) genes are time-specifically ablated in astrocytes in the pathogenesis of obesity. Collectively, we argue an important role of hypothalamic astrocytes in the regulation of the whole body energy homeostasis.

Title: Activation of Adenosine A2A or A2B receptor sub-types causes hypothermia in mice

Authors: ***J. CARLIN**¹, S. JAIN², C. XIAO¹, J. A. AUCHAMPACH³, K. A. JACOBSON², O. GAVRILOVA², M. L. REITMAN² ²NIDDK, ¹NIH, Bethesda, MD; ³Dept. of Pharmacol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Background: Adenosine has been implicated in mediating torpor in small mammals during hibernation or fasting. Adenosine has been known to elicit hypothermia for over 80 years. One mechanism of adenosine-induced hypothermia is proposed to be via adenosine A_1 receptors (A_1AR) in the nucleus of the solitary tract. In mice, adenosine also acts peripherally on A_3 receptors (A₃AR) on mast cells, causing hypothermia from activation of histamine H₁ receptors during a shock response. However, we observed that adenosine-induced hypothermia still occurs in mice lacking both A₁AR and A₃AR. Therefore, we tested if the other two adenosine receptors, A2AAR or A2BAR can mediate hypothermia. A2A agonists cause vasodilation and both A2AAR and A_{2B}AR RNA are widely expressed, but there is little information on the possible role of A_{2A}AR or A_{2B}AR in regulating body temperature set point or causing hypothermia. Methods: Adenosine agonists were administered intraperitoneally (i.p.) or intracerebroventricularly (i.c.v.) and core body temperature and physical activity were monitored by telemetry in freely active mice. Wild type mice, mice lacking mast cells (Kit^{W-sh/W-sh}), and mice lacking $A_{2A}RAR$, $A_{2B}AR$, or $A_1AR + A_3AR$ were studied. Results: We found that A_{2A}AR agonists CGS-2160 (0.5mg/kg ip) and PBS-0777 (3mg/kg, i.p) are cause hypothermia in WT, but not and Adora2a1 -/-, Adora3 -/- mice. A2AR agonist hypothermia was accompanied by severe hypometabolism and hypoactivity, resembling, a torpor-like state. CGS-2160 hypothermia is intact in *Kit^{W-sh/W-sh}* mice, demonstrating that mast cells are not required, and associated with reduced energy expenditure, reduced activity, and behavior in a temperature gradient test. PBS-0777 (0.03mg/kg i.c.v) caused hypothermia in Adora1 -/-, Adora3 -/- mice and suggests a centrally mediated mechanism. A2BAR agonist BAY60-6583 (1mg/kg ip i.p) causes hypothermia in WT, but not Adora2b-/- miceand Adora1-/-, Adora3-/- mice via A_{2B}AR. BAY60-6583 hypothermia is intact in Kit^{W-sh/W-sh} a mice and associated accompanied by with rreduced energy expenditure and , reduced aactivity, and behavior in a temperature gradient test. BAY60-6583 (0.004mg/kg icv i.c.v) caused hypothermia

equivalent to a 250-larger ip dose, in Adora1 -/-, Adora3 -/- mice and suggests consistent with a

centrally mediated mechanism. BAY60-6583 activated neurons in temperature and metabolism related regions of the brain as were visualized with c-fos immunohistochemistry. Conclusion: Adenosine agonists can cause hypothermia via $A_{2A}AR$ or $A_{2B}AR$. Thus, agonists for each of the four adenosine receptors can independently elicit hypothermia in mice.

Title: The impact of running on the expression of brain adenosine receptors

Authors: *E. BAUER, B. A. BAUSTAIN, A. BELL, M. R. CARLSON, P. J. CLARK FSNH, Iowa State Univ., Ames, IA

Abstract: Regular participation in physical activity is associated with a reported decrease in central-mediated fatigue, however, the precise mechanisms are not well understood. Adenosine is a product of cellular adenosine triphosphate (ATP) consumption and can act as a neuromodulator during metabolic demand. Adenosine signaling in the brain is known to play a significant role in the modulation of fatigue. Previous work from our group found that 6 weeks of wheel running potently reduces the adenosine 1 (A_{R1}) & 2a (A_{R2A}) receptor mRNA throughout the rat striatum. The purpose of this study was to determine if wheel running also reduces the expression of adenosine receptor protein in the striatum, as well as other brain areas where adenosine modulates fatigue behavior including the hippocampus, prefrontal cortex, and hypothalamus. Therefore, adult male C57BL/6J mice were individually housed with access to running wheels or in standard cages for 3 or 8 weeks. Following 3 and 8 weeks, mice were transcardially perfused with saline and paraformaldehyde. Immunohistochemistry was performed on thin brain sections to detected A_{R1} and A_{R2A} . Brain sections will be imaged and densitometry will be performed to semi-quantitatively measure the density of adenosine receptors in brain regions. Data collection is underway. We hypothesize A_{R1} and A_{R2A} expression will decrease across the all brain regions, as a result of peripheral increases of adenosine entering the brain during running. A widespread reduction in brain adenosine receptors may contribute to reduced sensations of fatigue in individuals that regularly exercise, and may have implications for the pro-cognitive and anti-depressant effects of exercise.

Title: Lateral but not medial hypothalamic AMPK activation occurs at the hypoglycemic nadir in insulin-injected male rats: Impact of caudal dorsomedial hindbrain catecholamine signaling

Authors: *H. N. ALHAMAMI, K. P. BRISKI

Univ. of Louisiana At Monroe, Monroe, LA

Abstract: The hypothalamic energy sensor adenosine 5'-monophosphate-activated protein kinase (AMPK), an important regulator of counter-regulatory responses to hypoglycemia, responds to pharmacological manipulation of hindbrain AMPK activity. Dorsomedial hindbrain A2 noradrenergic neurons express hypoglycemia-sensitive metabolo-sensory biomarkers, including AMPK. Here, adult male rats were pretreated by intra-caudal fourth ventricular administration of the selective neurotoxin 6-hydroxydopamine (6-OHDA) to determine if catecholamine signaling from the aforesaid site controls hypothalamic AMPK activation during insulin-induced hypoglycemia (IIH). Animals were sacrificed at neutral protamine Hagedorn insulin-induced hypoglycemic nadir (coincident with A2 AMPK activation and regulation of dorsomedial hindbrain noradrenergic input to the hypothalamus) for micro-punch dissection of arcuate (ARH), ventromedial (VMH), paraventricular (PVH), dorsomedial (DMH) nuclei and lateral hypothalamic area (LHA) for Western blot analysis of AMPK, phospho-AMPK (pAMPK), and relevant metabolic neuropeptides. IIH elevated LHA and reduced VMH pAMPK protein, profiles that were respectively unchanged or increased by 6-OHDA. PVH and ARH pAMPK was resistant to IIH, but augmented in ARH of neurotoxin- plus insulin-treated rats. ARH neuropeptide Y (NPY) and pro-opiomelanocortin (POMC) proteins were correspondingly increased or refractory to IIH; 6-OHDA pretreatment normalized NPY and increased POMC expression after insulin injection. Results demonstrate site-specific (ARH/VMH) inhibition of pAMPK by dorsomedial hindbrain catecholamine signaling, causing normalized sensor activity in hypoglycemic male rats. It is unclear if these examples of sensor deactivation reflect enhanced local energetic stability by this hindbrain-to-hypothalamus communication. Catecholaminergic suppression versus stimulation of IIH-associated hypothalamic catabolic (ARH POMC/VMH

steroidogenic factor-1) or anabolic (ARH NPY) neuropeptide profiles, respectively, may involve local AMPK-dependent against -independent mechanisms.

Title: Role of hindbrain adenosine 5'-monophosphate-activated protein kinase (AMPK) in hypothalmic AMPK and neuropeptide adaptation to recurring insulin-induced hypoglycemia

Authors: *S. K. MANDAL, K. P. BRISKI

Basic Pharmaceut. sciences, Univ. of Louisiana At Monroe, Monroe, LA

Abstract: Glucose counter-regulatory dysfunction correlates with impaired activation of the hypothalamic metabolic sensor adenosine 5'-monophosphate-activated protein kinase (AMPK). Hypothalamic AMPK is controlled by hindbrain energy status; we examined here whether hindbrain AMPK regulates hypothalamic AMPK and metabolic neurotransmitter maladaptation to recurring insulin-induced hypoglycemia (RIIH). Brain tissue was harvested after single versus serial insulin dosing for Western blot analysis of AMPK, Phospho-AMPK (pAMPK), and relevant biosynthetic enzyme/neuropeptide expression in micro-punch dissected arcuate (ARH), ventromedial (VMH), dorsomedial (DMH) nuclei and lateral hypothalamic area (LHA) tissue. The AMPK inhibitor compound c (Cc) or vehicle was administered to the caudal fourth ventricle ahead of antecedent NPH injections. RIIH caused site-specific elevation (ARH, VMH, LHA) or reduction (DMH) of total AMPK protein versus acute hypoglycemia; Cc respectively exacerbated or attenuated this response in the ARH and VMH. Hindbrain AMPK correspondingly inhibited or stimulated LHA and DMH pAMPK expression during RIIH. RIIH elicited Cc-reversible augmentation of VMH glutamate decarboxylase profiles, but stimulated (ARH pro-opiomelanocortin; LHA orexin-A) or decreased (VMH nitric oxide synthase) other metabolic neurotransmitters without hindbrain sensor involvement. Results demonstrate acclimated up-regulation of total AMPK protein expression in multiple hypothalamic loci during RIIH, and document hindbrain sensor contribution to amplification of this protein profile in the VMH. Concurrent lack of net change in ARH and VMH tissue pAMPK implies adaptive reductions in local sensor activity, which may/may not reflect positive gain in energy state. It remains unclear if 'glucose-excited' VMH GABAergic and/or ARH pro-opiomelanocortin

neurons exhibit AMPK habituation to RIIH, and whether diminished sensor activation in these and other mediobasal hypothalamic neurotransmitter populations may contribute to HAAF.

Title: Fluoxetine-induced mitochondrial and molecular effects in the hypothalamus of overfed rats

Authors: *G. FEITOZA, S. C. SILVA, C. M. FREITAS, A. A. PEDROZA, A. I. DA SILVA, C. J. LAGRANHA

Federal Univ. of Pernambuco, Vitória de Santo Antão, Brazil

Abstract: Obesity strongly contributes to the onset of chronic diseases as well as to higher morbidity and mortality worldwide. Specially at early ages, obesity have taken epidemic proportions. The energy imbalance linked to obesity is particularly mediated by mitochondrial dysfunction that represents one of the most inducers of the obesity pathophysiologic process. Several central regulators are involved in mitochondrial function like mitochondrial uncoupling protein 2 (UCP 2), that plays a key role in the central homeostatic mechanisms and reactive species (RS), and AMP-activated kinase (AMPK), that stimulates cellular catabolic pathways and mitochondrial biogenesis. Although obesity treatment with antidepressants like fluoxetine (also known as Prozac) has becoming clinically relevant, there are no scientific reports related to mitochondrial effects. With this our aim was to evaluate the effect of fluoxetine (Fx) treatment during 21 days (from 39 to 59 days of age) on mitochondrial and molecular parameters in the hypothalamus of overfed rats. To induce neonatal overnutrition, the primary litter size was reduced on the third day of life to 3 pups per litter (Small litters group-SL; n =8). In normal litters, the size was adjusted to 9 neonates per mother (Normal litters group-NL; n =9). The Fxtreatment started with 39 days of age, using 10mg/Kg B.W. (i.p. injection) in male Wistar rats of both groups. At 60 days of age was evaluated mitochondrial oxygen consumption (MOC) at different states (St2-basal respiration; St3-ADP-stimulated respiration; St4-resting respiration; Vmax-uncoupled respiration) and the respiratory control ratio (RCR) with complexes I or II substrates; RS production with complex II substrates, AMPK and UCP 2 mRNA expression. Related to MOC analysis, the neonatal overnutrition induces reduction in St 3 (30%), increase in St 4 (44%) and reduction in RCR (59%) with complex I substrates. In addition, overnourished

rats showed increased St 2 (92%) and St 4 (59), and reduction in St 3 (30%) and in RCR (36%) with complex II substrates. Fx-treatment reverted the effects of neonatal overnutrition in MOC with complex II substrates: decreased St 2 (32%), increased St 3 (46%), decreased St 4 (20%) and increased Vmax (53%); with improvement of RCR (75%) and tendency to reduction in RS production. Fx also increased AMPK and UCP 2 expression in overfed rats (170% and 146%, respectively). Our results suggest that Fx-treatment improves mitochondrial oxygen consumption in obese rats mainly by enhanced phosphorylation capacity and regulation of central energy metabolism. The present study received financial support from FACEPE.

Title: Non-monotonic effect of temperature on cortical-evoked potentials

Authors: *M. GOTOH^{1,2}, K. NAGASAKA^{1,2,3}, I. TAKASHIMA^{1,2}, S. YAMAMOTO¹ ¹AIST, Tsukuba, Japan; ²Univ. of Tsukuba, Tsukuba, Japan; ³JSPS Res. fellow, Tokyo, Japan

Abstract: Body temperature interacts with various biological activities and shows fluctuations around the normal temperature. Although temperature plays an important role in the brain via numerous energy exchanges, few studies have investigated whether and how temperature modulates neural information processing. Given that the activity of proteins is monotonically (and mostly positively) correlated with temperature, it has been assumed that neuronal activity changes monotonically with the temperature. However, the brain is composed of various types of neurons (e.g. excitatory and inhibitory neurons) that interact with each other in a complex manner. Therefore, determining whether the effect of temperature on neural processing *in vivo* follows the previous assumption is important.

To answer this question, we performed an *in vivo* rat experiment to examine how the temperature in a local brain area affects local field potentials. We delivered electrical stimulation to the ventral tegmental area (VTA) and measured the evoked potentials from the prefrontal cortex (PFC) using a silver ball electrode placed on the cortical surface. To control the temperature of the PFC, we developed a water heating/cooling system. A coil-shaped stainless steel tube was embedded inside the chamber on the PFC, and then temperature-controlled water flowed through the stainless pipe, regulating the temperature of the cortical surface via thermal conduction as the saline filled the chamber. During the experiments, we measured the temperature using a thermocouple thermometer inserted at a depth of 1 mm. The temperature prior to thermal regulation was ~27°C (initial temperature).

In contrast to the previous assumption, temperature affected the amplitude of the evoked potentials non-monotonically. The effect on the amplitude was negatively correlated around the normal initial temperature (~20-35°C). The amplitude decreased as the temperature increased, whereas it increased as the temperature decreased. The amplitude was maximized at a temperature ~8°C lower than the initial temperature, and further cooling further decreased the amplitude. Administering Gabazine (a GABA_A receptor antagonist) into the chamber eliminated the non-monotonic correlation effects on the amplitude, revealing the monotonically positive correlation.

Our data suggest that the net amplitude of the evoked potentials decreases at higher temperatures because both not only excitatory but also inhibitory neurons are affected in a positively correlated manner. These findings suggest that a mediator exists to regulate the brain temperature and control neural activity.

Title: Courtship changes in a Drosophila model of classic galactosemia

Authors: V. BAGGETT¹, A. KEHRER², J. FRIDOVICH-KEIL⁴, *T. ZARS³ ¹Biol. Sci., ²Div. of Biol. Sci., ³Univ. of Missouri, Columbia, MO; ⁴Human Genet., Emory Univ., Atlanta, GA

Abstract: Classic Galactosemia (CG) is a rare genetic disorder affecting about 1 in 60,000 newborns annually, with no treatment other than immediate removal of dietary galactose. Even with dietary restrictions, individuals with the loss of galactose-1-phosphate uridyltransferase (GALT) have many associated chronic complications. Chronic complications include cognitive disorders, ataxia, and decreased fertility. The current *Drosophila melanogaster* model of CG (GALT^{AP2}) has allowed us to investigate behavioral consequences of the loss of GALT. In an

attempt to more closely mimic the genetic changes in the human disease, we have generated two additional alleles (GALT³ and GALT⁴) in *Drosophila* through removal of the catalytic domain of GALT using CRISPR/Cas9. To better understand the connection between loss of GALT and reduced fertility, we investigated the courtship behavior of GALT^{AP2} and GALT^{C2} control flies. We continue to investigate GALT³ and GALT⁴ behavioral changes. We found a decrement in copulation latency in GALT^{AP2} flies. This provides a model for genetic and pharmacological intervention strategies in a genetic model of CG.

Title: Central role of melatonin on food intake and energy balance

Authors: *D. C. BUONFIGLIO, R. PARTHIMOS, R. CERQUEIRA, F. G. AMARAL, J. A. DA SILVA, A. M. RAMOS-LOBO, R. A. MATOS, J. S. DA SILVA, Jr, L. CLEMENTE, J. CIPOLLA, Neto Physiol and Biophysics, Univ. of Sao Paulo, Sao Paulo, Brazil

Physiol. and Biophysics, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Feeding behaviour is under the control of several hypothalamic nuclei, many hormones and neurotransmitters regulate food intake. Melatonin (Mel), a hormonal mediator of photoperiodic information to the central nervous system, promotes energy homeostasis through the establishment of a proper energy balance. Its administration reduces food intake, body weight and abdominal fat in rodent models. *In vitro*, rhythmic Mel treatment synchronizes leptin secretion by adipocytes. However, the mechanism through which Mel reduces body weight is unclear. We aimed to investigate how Mel regulates energy intake and energy expenditure, promoting a proper energy balance.

Male *Wistar* rats were assigned to Control, Control+Mel, Pinealectomized (PINX) and PINX+Mel groups. Mel (1mg/kg) was added to the drinking water exclusively during the dark phase for 13 weeks. Rats were subjected to a 24-hour fasting test, an acute leptin responsiveness test, cold challenge and circadian euthanasia. Western Blot and qPCR analyses were performed in hypothalamus and Brown Adipose Tissue (BAT).

Mel treatment reduced food intake, body weight and adiposity. Response to fasting was

unaltered in all groups. In the leptin responsiveness test, PINX rats showed no response on body weight, food intake or hypothalamic phosphorylation of STAT3 after acute leptin injection. mRNA analysis revealed a reduction of *Agrp* and *Orexin* expressions in the PINX+Mel group and an increase of *Agrp*, *Npy* and *Orexin* expressions in the PINX group. PINX rats had lower UCP1 protein levels in the BAT and lower thermogenic response to cold challenge. We showed that melatonin absence led to impaired acute response to leptin, pointing to a possible leptin resistance. On the other hand, in addition to reducing energy expenditure in BAT, melatonin treatment reduces orexigenic genes expression which leads to reduced food intake, body weight gain and adiposity in Mel treated rats, that may be mediated by a sensitization of leptin signalling pathway by melatonin. Title: Assessing sex-differences in the effects of intranasal insulin on spatial memory impairments of young LE rats on a chronic high-fat diet

Authors: *N. DOS SANTOS¹, L. T. THOMPSON²

¹Sch. of Behavior and Brain Sci., ²Behavioral & Brain Sci., Univ. of Texas At Dallas, Richardson, TX

Abstract: High fat diets (HFDs) produce physiological and cognitive impairments, with symptoms including hyperglycemia, hyperinsulinemia and memory deficits. Most studies, however, fail to include female subjects, which prevents sexual differences to be characterized. Previous research from our lab has shown that unlike males, female rats fed a HFD do not develop hyperglycemia, and remain sensitive to exogenous insulin both peripherally and centrally (on CA1 pyramidal neurons, critical for memory consolidation). At the same time, endogenous concentrations of insulin are lower in HFD females than in controls, higher in HFD males than in controls, leading to development of insulin resistance. While CA1 neurons in both

male and female rats have larger post-burst AHPs (reduced intrinsic excitability), male HFD neurons are insulin-insensitive, while female neurons maintain insulin sensitivity. Insulin is critical not only for transport of glucose and fatty acids, but insulin-signaling pathways also contribute to cognitive functioning and to memory. To assess potential sex-dependent reversal of cognitive deficits by intranasal insulin (or saline control), LE rats were fed a HFD chronically for 10 or 15 wk from weaning, and spatial memory was assessed in an unrewarded spontaneous alternation task (SAT) after intranasal treatment. After 10 wk on the HFD, less severe memory deficits were observed in both male and female rats than after the longer duration on the diet. At 10 wk, intranasal insulin treatment reversed these mild cognitive impairments in both male and female rats. By 15 wk on the HFD, when significant differences in circulating insulin and in insulin sensitivity are shown, intranasal insulin treatment is expected to improve cognitive function in females only. Differences in fasted blood glucose and in insulin-tolerance responses (time series measures of blood glucose pre- and post-intranasal insulin) are being assessed in control and HFD male and female cohorts after 10 or 15 wk on their respective diets, and corticosteroid and insulin concentrations in both plasma and cerebrospinal fluid are being measured to assess other treatment effects on the rats, on their behavior, and on their response to treatment.

Title: Neuronal stimulation triggers neuronal glycolysis and not lactate uptake

Authors: C. DÍAZ-GARCÍA¹, R. MONGEON¹, C. LAHMANN¹, D. KOVEAL¹, H. ZUCKER¹, *G. YELLEN^{2,1} ¹Neurobio., ²Harvard Med. Sch., Boston, MA
Abstract: Brain metabolism supports a variety of neuronal activities, ranging from neurons that constitutively fire action potentials, to neurons that remain silent most of the time but burst at very high frequencies upon stimulation. However, the metabolic pathways allowing neurons to cope with these large dynamic variations in energy demand are not fully understood. During brain excitation, the increase in cerebral blood flow and glucose consumption is almost ten times higher than the increase in oxygen consumption in the activated area. This mismatch indicates that the glycolytic conversion of glucose to lactate exceeds the rate of mitochondrial fuel oxidation. Although the increased energy demand occurs mainly within neurons, some have suggested this glycolysis occurs mainly in astrocytes, which then shuttle lactate to neurons as their primary fuel. Using the metabolic biosensor Peredox, expressed in dentate granule neurons from acute hippocampal slices, we find that neurons increase the cytosolic NADH/NAD⁺ ratio in response to synaptic or antidromic stimulation. These metabolic responses do not depend on astrocytic stimulation by glutamate release, nor do they require neuronal uptake of lactate, as revealed by an increased metabolic response in the presence of blockers for monocarboxylate transporters or the enzyme lactate dehydrogenase. Inhibition of glycolysis at the level of the enzyme GAPDH, significantly decreases the metabolic responses to stimulation. Our results suggest that this transient of neuronal glycolysis acts as a metabolic "first responder" to meet the increased energy needs of the stimulated neuron.

Title: Ghrelin signaling regulates GABA neurons of the nucleus of the solitary tract

Authors: *M. P. CORNEJO¹, P. N. DE FRANCESCO¹, G. GARCIA ROMERO¹, E. PORTIANSKY², M. REYNALDO¹, J. M. ZIGMAN³, M. PERELLO¹ ¹IMBICE, La Plata, Argentina; ²Facultad de Ciencias Veterinarias, UNLP, LAI, La Plata, Argentina; ³Intrnl. Med. - Psychiatry, Universityof Texas-Southwestern Med. Ctr., Dallas, TX

Abstract: The nucleus of the solitary tract (NTS) is a major sensory nucleus in the dorsal medulla that receives cardiovascular, visceral, respiratory, gustatory and orotactile information. It forms part of the dorsal vagal complex, which mainly regulates autonomic neural circuits. Ghrelin is a stomach-derived peptide hormone and its receptor, the growth hormone

secretagogue receptor (GHSR), is a G protein-coupled receptor highly expressed in the brain. The NTS is known to express GHSR, but the identity and the physiological role of GHSRexpressing neurons of the NTS are uncertain. In this study, we used a transgenic mouse model in which the enhanced green fluorescent protein (eGFP) is expressed under the control of the GHSR promoter (GHSR-eGFP mice) to perform a neuroanatomical and functional characterization of GHSR-expressing neurons of the NTS. We first mapped the neuroanatomical distribution of eGFP neurons within the NTS. Then, we explored the phenotype of eGFP neurons of the NTS using IHC against specific markers of neuronal populations known to be present in this brain area. In order to explore the physiological role of GHSR-expressing neurons of the NTS, we exposed GHSR-eGFP animals to different experimental protocols known to activate the NTS and to involve ghrelin signaling, and then we examined the pattern of expression of the marker of cellular activation c-Fos in eGFP positive cells. Overall, we found that GHSRexpressing neurons were located throughout the extension of the NTS, but preferentially forming two clusters: one rostral, mostly comprising the ventral subnucleus, and one caudal, mostly involving the parvicellular subnucleus. We also found that a population of GHSR-expressing neurons is GABAergic. Finally, eGFP neurons of the NTS failed to show an increase in c-Fos in response to the experimental protocols performed to GHSR-eGFP mice.

Title: Sex-related differences in neonatal fluoxetine treatment in brainstem's mitochondrial bioenergetics

Authors: *T. SILVA¹, G. F. B. BRAZ², S. C. A. SILVA², C. M. FREITAS², A. I. DA SILVA², C. J. LAGRANHA²

¹Federal Univ. of Pernambuco, Vitória De Santo Antão, Brazil; ²Federal Univ. of Pernambuco-CAV, Vitória de Santo Antão, Brazil

Abstract: Mitochondria are dynamic organelles that perform several interconnected actions. In eukaryotic cells, mitochondria represent the most important ATP producer site and is the major

source of Reactive Species (RS). In the brain, the high O_2 consumption combined to its specialized characteristics, such as, prevalence of polyunsaturated fatty acid, amine content, RS production by monoamine oxidase and the presence of excitotoxic amino acids, make this tissue particularly vulnerable to RS damage. Hefty evidences have demonstrated that mitochondria dysfunction is the hub of several neuronal disorders. Studies suggest that mitochondria dysfunction in brainstem is involved in cardiovascular diseases (CVDs) due to the dysregulation of cardiovascular homeostasis and systemic blood pressure control by modulating the sympathetic vasomotor tone. Although equally harmful for both genders, mitochondrial dysfunction seem to be less severe on females. Evidence that estrogen plays a crucial role in protection is in line with the antioxidant function attributed to sex hormones. Previous study from our laboratory have shown that neonatal fluoxetine treatment may improve mitochondrial bioenergetics in different areas of the brain; however, until now there is a lack in the literature concerned to sex-related differences in mitochondrial bioenergetics and neonatal fluoxetine treatment. The treatment was carryout during the lactation time using 10mg/Kg B.W. (i.p. injection) in female and male Wistar rats. Was evaluated body weight and brainstem mitochondrial oxygen consumption with complex I substrates, respiratory control ratio (RCR), RS production and Krebs cycle enzyme (i.e citrate synthase-CS activity). Our results showed that male has higher basal oxygen consumption, RS production and CS activity, but a tendency to show lower RCR. However, neonatal fluoxetine treatment significant increases ADP phosphorylation capacity, RCR, CS activity, in addition to a remarkable decrease in RS production. Our results suggest that neonatal treatment with fluoxetine positively modulates male's mitochondria, decreasing the main factor responsible to mitochondrion and cellular damage, the reactive species in brainstem. The present study receives financial support from FACEPE.

Title: Fed and fasted brain glucose metabolism determined by imaging mass spectrometry

Authors: *H. A. FERRIS^{1,2}, A. KLEINRIDDERS^{3,2}, M. L. REYZER⁴, M. RATH³, M. SOTO², J. SPRAGGINS⁴, R. M. CAPRIOLI⁴, C. R. KAHN²

¹Univ. of Virginia, Charlottesville, VA; ²Integrative Physiol. and Metabolism, Joslin Diabetes Ctr., Boston, MA; ³Central Regulation of Metabolism, German Inst. of Human Nutr., Nuthetal, Germany; ⁴Mass Spectrometry Res. Ctr., Vanderbilt Univ., Nashville, TN

Abstract: Glucose is the primary energy source for the brain and crucial for normal brain function. While in vivo imaging techniques may be used to assess where in the brain glucose is delivered, they do not provide information on how that glucose is metabolized. Knowledge of how glucose is utilized in specific brain regions is critical for understanding the mechanisms of diabetes-associated cognitive dysfunction, which is presumably being driven in part by recurrent hyper- and hypoglycemia. To generate a more comprehensive view of regional glucose metabolism we applied several molecular biology techniques to dissected brain regions, including immunohistochemistry, qPCR, western blotting and enzyme assays. In addition, measurement of multiple glucose metabolites across the brain, at a resolution of 100 microns, was performed using imaging mass spectrometry (IMS). By combining these techniques, we show clear differences in the regional fate of glucose in the brain, which are altered by the fasted state. Glucose can be metabolized by the glycolytic or pentose phosphate pathways. We show that there are low levels of hexose bisphosphate (a glycolytic intermediate) and high levels of the pentose phosphate pathway enzyme glucose-6-phosphate dehydrogenase (G6PD) in myelinated structures, such as thalamus. Conversely, the neuron-rich amygdala and cortex have low levels of G6PD, and high hexose bisphosphate as evidenced by IMS. The regional differences in glycolysis were not evident when comparing expression or activity of phosphofructokinase, the glycolytic enzyme responsible for generating hexose bisphosphate. Interestingly, ATP, the energy product primarily generated by glycolysis coupled to the TCA-cycle, was highest in several myelinated structures including the corpus callosum and internal capsule. Comparison of mice in the fed versus fasted state demonstrated similar regional differences in hexose bisphosphate and ATP but, a significant increase in lactate production in the cortex and amygdala was observed in the fasted state. These data demonstrate the importance of direct measurement of multiple metabolic intermediates across brain regions to determine the ultimate fate of glucose in health and disease states. IMS provides a powerful new tool for investigating the impact of changing glucose levels on brain homeostasis.

Title: Alpha-tocopherol exposure effect over weight and dyslípidaemia of obese infant rats induced by perinatal sucrose rich diet

Authors: *I. ZARCO DE CORONADO¹, M. A. HERRERA², M. J. GARCÏA³ ²BIOLOGIA CELULAR, ³FARMACOLOGÏA, ¹UNAM, Mexico DF, Mexico

Abstract: Perinatal administration of high rich sucrose diet (HSD) is associated with obesity, dyslipidemia and hippocampal damage in rat offsprings. Oxidative stress has been associated with these alterations. Alpha tocopherol is a well known antioxidant. The present project focused on the effects of this antioxidant over the high rich sucrose diet exposed infant rats. Two weeks pregnant Wistar rats were supplied with plane water (Control) or 20% sucrose solution divided in three experimental groups: E1 (born in time) and E2 (2 days delayed births). The third group E3 was supplied with sucrose solution with Alpha tocopherol (400U/100ml). Food, liquid solution ingested and body weight of dams and offsprings were determined twice by week. At 25 days of life the glucose, triglycerides and cholesterol were measured on blood samples. The controls animals drank around 40% liquid and the experimentals around 70%. The weight of the E3 offsprings was the same than controls and the E1, E2 groups were elevated (P=0.05). Experimental offsprings were hyperglycemic but not to a significant level. The triglycerides showed not significant increment in experimental offsprings. The cholesterol was elevated in the experimental groups with statistical significance (females P=0.05 and males P=0.001). These results suggest an antioxidant activity of alpha tocopherol blocking obesogenic effect of sucrose solution but not dyslipidaemia. We considerate that the differences may be a result of some placental, mammary gland or blood brain barrier factors.

Title: The PACAP and VIP receptor, VPAC2R, regulates glucose and fat metabolism at rest and during psychogenic stress in adult female C57BL6 mice

Authors: *E. KOZLOVA^{1,2}

¹Cell Biol. and Neurosci., Univ. of California Riverside, Richmond, CA; ²Cell Biol. and Neurosci., Univ. fo California Riverside, Riverside, CA

Abstract: Several lines of evidence implicate PACAP as an important regulator of central and peripheral components of the stress axes (Hashimoto et al, 2011). PACAP also acts as an important hormonal regulator of lipid and carbohydrate metabolism (Giodanetto et al, 2013; Gray et al, 2001; Tomimoto et al, 2004, 2008). PACAP proves to act through a PACAP-specific receptor PAC1R and VIP/PACAP shared receptors, VPAC1R and VPAC2R. Unlike VPAC1R and PAC1R, VPAC2R is found in adipose tissue (Wei et al, 1996; Delgado et al, 1999). PACAP effects, mediated via VPAC2R signaling, produces lipolysis (Akesson et al, 2003) and improves glucose-dependent insulin secretion and insulin sensitivity (Ma et al, 2015). However, the results of insulin tolerance testing (ITT) in VPAC2R-deficient (VPAC2R KO) mice, which appear different in males and females, are inconclusive (Asnicar et al, 2002). Therefore, VPAC2R KO and wildtype (WT) female mice were used to further study the role of VPAC2R in glucose and fat metabolism in female C57B16 mice (Harmar et al, 2002, Tan et al, 2015). Mean basal glucose values were significantly greater in VPAC2R KO vs WT after 8 hr ON fast but not after 5 hr morning and 11 hr ON fast. Results from GTT (11 hr fast ON; 2.0 g/kg glucose) and weak ITT stimulation (5 hr morning fast, 0.75 UI) showed no effect of genotype. However, with stronger ITT (8 hr fast, 0.5 UI), VPAC2R KO females showed less insulin sensitivity at 60 min postinjection. Peak stress-induced hyperglycemia (immobilization, 1.5 hr) was more robust in VPAC2R KO mice vs WT: 320.6 and 229.8 mg/dL for KO and WT, respectively (p=0.019). The absence of group differences in stress-induced corticosterone levels suggests similar psychogenic stimulation however, VPAC2R KO but not WT showed greater stimulated plasma epinephrine (p<.05). The results suggest that abnormal VPAC2R gene expression may contribute to a diabetic phenotype that may be associated with increased sympathetic activity which has also been associated with PACAP signaling via PAC1R. The significance of intestinal permeability that may contribute to diabetic profiles was also examined (Turner, 2009). Mice received 60 mg/kg FITC-dextran. VPAC2R KO and WT mice showed moderate but similar gut integrity. Therefore, altered gut function and/or permeability are not likely the cause of abnormal glucose metabolism in VPAC2R KO mice. At sacrifice, mean normalized levels of liver lipids were no different in VPAC2R KO vs WT but the former showed an apparent reduction in normalized brown adipose fat wt (BAT, p=.083). Liver Oil Red O was noticeably less in VPAC2R KO mice. These results indicate that VPAC2R activity in female mice may participate in glucose and fat metabolism.

Abstract: The brains energy demand is high as it accounts for about 20% of the body's energy consumption, however only for about 2% of the total body weight. In humans glucose is the brains obligatory energy substrate and is almost fully oxidized. Oxygen and glucose are essential for the mitochondrial energy metabolism in order to generate energy in form of adenosine triphosphate through the oxidative phosphorylation.

Cerebral hypoperfusion is characterized by a diminished blood flow through a tissue and strongly correlates with accelerated aging and advanced neurodegeneration. One of the most prominent features of hypoperfusion is glucose and oxygen reduction. Ischemia, tissue damage and poorly vascularized cancer can restrict oxygen supply leading to metabolic stress and potentially apoptosis.

Enhanced autophagic activity buffer metabolic stress and also contribute in maintaining the cellular energy balance. Thus, changes in glucose and oxygen availability induce an adaptive response that may allow for extended survival.

In our present study, we aimed to analyze the crosstalk between the energy homeostasis with autophagy in primary cortical neuronal culture. *In silico* pathway analyses revealed that several pathways including glycolysis, citric acid cycle, protein biosynthesis and mitochondrial electron transport chain are affected, apparent by changes not only in metabolite levels but also connected metabolite level ratios. In addition, cortical astrocytes contribute in the cellular adaptation towards glucose and oxygen reduction by enhancing glucose transporter protein levels. Moreover, the neuroenergetic needs are also counter balanced by significant changes in the autophagic degradation activity.

Taken together, our results implicate that in primary neuronal cultures the neuroenergetic needs are compensated by altered major energy metabolism pathways associated with autophagy.

Title: Dissecting neuronal cell-type specific control of neurovascular coupling using DREADDs

Authors: *C. ECHAGARRUGA¹, Q. ZHANG², P. J. DREW³

¹Biomed. Engin., The Pennsylvania State Univ., State College, PA; ²Ctr. for Neural Engineering, Dept. of Engin. Sci. and Mechanics, The Pennsylvania State Univ., University Park, PA; ³Dept. Engin. Sci. and Mechanics, Pennsylvania State Univ., University Park, PA

Abstract: Changes in local neural activity drive vasodilation and vasoconstriction of the cerebral vasculature, and understanding the cellular mechanisms of this control is important for interpreting hemodynamic signals. Previous work has suggested that activity of interneurons is the primary drivers of arteriole diameter changes (Cauli 2004; Uhlirova et al. 2016). To test the role of neural activity in manipulating vascular tone, we virally expressed DREADDs (Designer Receptors Exclusively Activated by a Designer Drug) pan-neuronally, or exclusively in excitatory neurons in the somatosensory cortex of awake mice, allowing us to bi-directionally manipulate neural activity. We assayed resting vascular tone and vascular responses to voluntary locomotion (Gao and Drew 2016; Gao, Greene, and Drew 2015) using two-photon microscopy. Suppressing the activity of all neurons caused a decrease in the resting diameter and a decreased hemodynamic response relative to vehicle injections, while suppressing the activity of only excitatory neurons had no effect. This work suggests that interneuron activity controls hemodynamic tone and responses during natural behaviors.

Title: Optical coherence tomography reveals spatio-temporal dynamics of capillary stalls in awake mice

Authors: *E. ERDENER¹, J. TANG¹, A. SAJJADI¹, C. B. SCHAFFER², D. A. BOAS¹ ¹Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA; ²Biomed Engin., Cornell Univ., Ithaca, NY

Abstract: Objective: Optical coherence tomography (OCT) allows label-free capillary imaging with high spatio-temporal resolution and can be utilized to understand the details of capillary dysfunction and small vessel disease. Capillary stalls were previously shown to occur in myeloproliferative disease models with increased circulation of red blood cells. In this work, using OCT microangiography, we studied the stall dynamics within cerebral microcirculation in awake healthy mice. Methods: C57BL/6 mice (4-6-month-old) with chronic cranial windows were trained to stay attached to a cradle. Imaging was done in trained mice without anesthesia and during rest. In each mouse, 600x600 µm areas were imaged, using a spectral-domain OCT system (Axial and transverse resolution: 3.5 µm, 10x objective). For each area, 60 angiograms were acquired with ~9 second interval. Raw data were processed to yield the maximum intensity projection images of capillaries. ~200 segments were observed in each region, 150-250 µm below the cortical surface. We manually counted stalling segments indicated by abrupt drops in intensity to get their prevalence, frequency and duration. Capillary RBC velocities were measured using dynamic light scattering OCT in CD1 mice (2-3 month-old) with acute windows, under isoflurane anesthesia. Results: In awake mice (n=7), 7.5 \pm 2.5% of all capillaries within the imaging area were stalling during any given 9 minute imaging period, each stall lasting for 15±5 seconds. At each time point, 0.5+0.4% segments in a region were stalled. In areas with a higher prevalence of stalls, each segment was stalling more frequently and/or for a longer duration $(R^2=0.42)$. When imaging was extended to 18 min, more stalling segments could be detected,

with ~70% of all stalling segments detectable within the first 9 min. When imaging was repeated after one month, stall incidence in the same cortical area remained constant and 45-50% of stalling capillaries were coincident in the repeated sessions. Segments with a higher stall frequency in the first session were more likely to be detected to stall during the next session (P<0.001). More than 80% of stalling segments were at the venous side of the microcirculation, with lower RBC velocities than nonstalling segments in the same cortical region (P<0.001). Conclusion: These data suggest that capillary stalls in the brain in awake mice are very frequent and consistent observations. These events can be imaged and quantified by OCT angiography in an extremely efficient manner. Investigation of the frequency, distribution and duration of capillary stalls can be a promising tool for a greater understanding of diseases of microcirculation.

Title: Microvascular effects following traumatic ocular injury

Authors: *A. M. MELCHIADES NOZIMA¹, J. I. CASTRO², M. LEDO², M. HARPER⁵, S. MARTINEZ-CONDE³, S. L. MACKNIK⁴

¹Adriana Nozima, Brooklyn, NY; ²Dep. of Ophthalmology, ³Dept. of Ophthalmology, ⁴Dept. of Ophthalmology., SUNY Downstate Med. Ctr. Col. of Med., Brooklyn, NY; ⁵Univ. of Iowa, Iowa City, IA

Abstract: Blast mediated injuries from Improvised Explosive Devices are strongly associated with severe ocular morbidity and visual impairment and are the leading cause of combat-related injuries in Operation Enduring and Iraqi Freedom. Eye-related injuries cost an estimated \$2.2B in medical care per year. Residual physical symptoms reported after blast exposure includes headache, nausea, light and noise sensitivity and visual disturbances, and visual outcomes from a direct closed-globe eye injury, or complications resulting from the Traumatic Brain Injury, are understudied. In this study, we documented both *in vivo* microvascular dysfunction in the retina as a function of a blast, but also explored the effects of a therapeutic intervention to halt/reserve the degeneration. The objective of this study was to determine if clinically available blood flow regulating drugs-currently not used to treat retinal damage-may serve to ameliorate retinal

degeneration in those who experienced blast-related traumatic injuries. We used 80 mice split into three cohorts related to how long after the blast (7 days, one month or four months) they were studied and a control group. Our hypothesis is that when arterial flow is pathologically reduced, for example by ocular injury, all of the flow in the downstream capillary beds is reduced uniformly. We tested this hypothesis with Confocal Laser Endomicroscopy (CLE) *in vivo* imaging to examine the blood flow through the arteriolar vessels and into capillary beds. We used the same techniques that we have used before when studying epilepsy models in mice. This technique also identifies mural cells such as pericytes, which have the ultimate active control point for blood flow and regulate non-uniform blood flow in capillary beds. Dysfunctional mural cell-driven non-uniform blood flow can then lead to cell death due to the failure of local oxygenation gradients within the capillary bed. Our hypothesis concerning the mechanistic pathway of action of nitric oxide precursors (i.e. L-Arginine) is that they improve capillary blood flow and prevent ischemia/hypoxia by dilating arterioles and microvessels that would otherwise vasospasm or restrict due to TOI. CLE revealed a significantly different vasospasm rate among cohorts, which are postulated as deriving from mural cell dysfunction in TOI.

Title: Sex differences in changes in the vasculature of the subventricular zone niche with age

Authors: *K. L. ZULOAGA¹, C. S. BJORNSSON², E. WAIT³, W. MANKOWSKI³, Y. WANG², A. R. COHEN³, S. TEMPLE²

¹Dept. of Neurosci. & Exptl. Therapeut., Albany Med. Col., Albany, NY; ²Neural Stem Cell Inst., Rensselaer, NY; ³Depart of Electrical and Computer Engin., Drexel Univ., Philadelphia, PA

Abstract: In the adult brain, neurogenesis occurs in the subventricular zone (SVZ) lining the lateral ventricles, but declines markedly with aging. Blood vessels within the SVZ play a vital

role in the neural stem cell niche by promoting proliferation, neurogenesis and guiding the chains of migrating neuroblasts. Here we sought to determine how the structure of this vascular stem cell niche differs between sexes and how it changes with age. Mouse SVZ wholemounts at 2, 18 and 22 months were immunostained for laminin to label blood vessels and doublecortin to label neuroblasts. Using 3D computer-based image analysis, we assessed changes in vessel diameter, vessel tortuosity and organization of the neuroblast chains. In addition, we used uptake of EdU, a thymidine analog, to assess progenitor cell proliferation. We found that vessel tortuosity increases slightly with age, yet sex differences do not emerge until 22 months of age, when males have more torturous vessels than females. Vessel diameter in the SVZ changes with age in a sex-dependent manner. Young females have smaller vessel diameters than males, however, their vessel diameters increase between 18 and 22 months of age. Conversely, in males, vessel diameters steadily decrease with age. Thus, although young males start with larger vessels than females, by 18 months the males have smaller vessels, a difference that is exacerbated by 22 months. With regard to the progenitor cells, the chains of migrating neuroblasts become disorganized and less linear at 18 months but surprisingly this organization improves by 22 months, especially for the females. While both sexes show a decline in proliferation with age, as expected, females have significantly less proliferation than males at 18 months. In conclusion, we have found complex, sex-dependent changes in the SVZ niche vasculature with age that correlate with changes in proliferation of progenitor cells.

Title: Optogenetic stimulation of pericytes lacking alpha smooth muscle actin produces a decrease in capillary blood flow *In vivo*

Authors: *D. A. HARTMANN¹, R. I. GRANT¹, S. A. HARRILL², T. NOONAN², A. Y. SHIH¹ ¹Neurosciences, Med. Univ. of South Carolina, Charleston, SC; ²Col. of Charleston, Charleston, SC

Abstract: Vascular mural cells surrounding the cerebrovasculature are responsible for modulating blood supply in accordance with the metabolic demands of the brain. It is widely accepted that vascular smooth muscle cells on arterioles can regulate blood flow. However, whether pericytes can control blood flow at the level of capillaries remains highly debated. To test the hypothesis that pericytes throughout the capillary bed have the capacity to influence blood flow, we stimulated individual pericytes in vivo using two photon excitation of channelrhodopsin (ChR2), as done previously (Hill, et al. Neuron, 87(1):95-110, 2015). Although the PDGFRBeta-Cre promoter was used to drive ChR2 expression in both smooth muscle cells and pericytes, two photon optogenetics enabled spatially-precise stimulation of pericytes on capillaries and not vascular smooth muscle cells of upstream arterioles. Simultaneously, with the same two photon laser used for pericyte excitation, we measured capillary diameter and red blood cell velocity after labeling the blood plasma with intravenous fluorescent dextrans. We found that pericyte excitation for 60 seconds produced, on average, a ~20% reduction in capillary diameter and blood cell velocity throughout the cortical microvasculature (1-9 branch points distal to the penetrating arteriole), which included territories that lacked alpha smooth muscle actin, a key component of canonical vascular contractile machinery. In addition, we found that blood flow remained halted in a large proportion of vessels (~40%) even 1 minute after stimulation. Importantly, identical stimulation parameters did not produce hemodynamic changes in control mice expressing cytosolic YFP or membrane-bound GFP in pericytes. Further, the observed decrease in vessel diameter and blood cell velocity in response to pericyte ChR2 stimulation was inhibited when we applied fasudil, a Rho kinase inhibitor and clinically-used vasodilator, to an intact dura. Our results suggest that pericytes, even those in territories without alpha smooth muscle actin, have the capacity to modulate blood flow. Considering that 20% diameter decreases and sustained stoppages in capillary flow are not typically seen with normal brain capillaries in vivo, our findings may provide new insight into how pericytes respond during pathologies such as stroke or traumatic brain injury (Yemisci, et al. Nat Med 15(9):1031-7, 2009; Hall, et al. Nature 508(7494):55-60, 2014). In these and other disease states, excessive depolarization of pericytes throughout the capillary bed may lead to poor brain perfusion.

Title: Oxygen-extractor, an efficient software to measure partial pressure of oxygen with 2-photon phosphorescence lifetime imaging

Authors: *E. CHAIGNEAU¹, M. ROCHE¹, M. BARRETT², B. WEBER², S. CHARPAK¹ ¹Inserm U1128, Paris, France; ²Inst. of Pharmacol. and Toxicology, Zurich, Switzerland

Abstract: During the last decade, several sensors based on oxygen-dependent quenching of phosphorescence have been developed to measure brain oxygenation. Some of them can be combined to 2-photon microscopy to measure partial pressure of oxygen (pO₂) at micrometer resolution *in vivo*.We used 2-photon phosphorescence lifetime microscopy (2PLM), in the olfactory bulb of anesthetized rodents, to measure vascular pO₂ and flow in control conditions and during odor stimulation. The high spatial resolution of 2PLM revealed the presence of erythrocyte associated transients (EATs) in capillaries (Lecoq et al. 2011, Parpaleix et al. 2013) and allowed to determine the physiological values of pO₂ in brain vessels and neuropil of awake mice (Lyons et al. 2016). All our data were acquired and analyzed with a custom-built software named Oxygen Extractor and written in LabVIEW and MATLAB.

We describe here the experimental paradigms and the algorithms used by Oxygen Extractor to acquire data and calculate red blood cell (RBC) flow, hematocrit and pO_2 at a chosen set of points in the brain. We have developed two data acquisition methods. The first one is a sequential method, where the 2-photon beam is parked at one point for a given acquisition time, and then moved to another point for the same acquisition time, and so on, until the whole set of points has been explored. The second one is a "quasi-synchronous" method that we call the "kinetic mode". In this mode, the beam is moved from one acquisition point to another, every 250-500 μ sec, the whole sequence of points being repeatedly explored during the acquisition time. In addition to that, the laser power can be adjusted at each individual point. The analysis functions developed allow measuring the mean pO_2 as well as pO_2 as function of time or of the

distance to individual RBCs (required to calculate EATs). Experimental data stress the importance of using pO_2 calibration curves that accurately match the experimental *in vivo* conditions. Oxygen Extractor allows to incorporate such calibration curves, either provided by the chemists or built on site, i.e. below the objective. Finally, the Oxygen Extractor software will be accessible on our laboratory web site with all the information required to realize accurate pO_2 measurements in the rodent brain.

Title: Coupling of dentate granule cell activity and micro-vessel hemodynamics *In vivo* regulates adult hippocampal neurogenesis

Authors: *J. SHEN¹, D. WANG², G. KIRSCHEN¹, Q. XIONG¹, J. XIA², S. GE¹ ¹The Dept. of Neurobio. & Behavior, State Univ. of New York At Stony Brook, Stony Brook, NY; ²Dept. of Biomed. Engin., Univ. at Buffalo, Buffalo, NY

Abstract: The adult hippocampus continuously generates new dentate granule cells in response to ongoing neuronal activity within its circuits. A variety of external factors known to enhance adult neurogenesis, such as exposure to enriched environments (EEs), are also known to elevate the activity of mature dentate granule cells (DGCs). However, how hippocampus-related stimuli and behavior impact adult neurogenesis remains largely unknown. Given that the generation and integration of new dentate granule cells is metabolically costly, and that local blood flow dictates nutrient and oxygen supply, we hypothesized that DGC activity would directly recruit an increased local blood supply to support EE-induced enhanced neurogenesis. Here, we used a miniature microscope to detect both neuronal activity and local blood flow in micro-vessels simultaneously in the dentate gyrus (DG) of freely behaving mice. We discovered that the activity of DGCs is coupled to local micro-vessel hemodynamics. Interestingly, we observed a temporal delay of blood flow velocity elevation in comparison to the onset of increased neuronal firing. Furthermore, we found that the increase in blood flow paralleled the potentiation in neuronal activity, albeit with a more prolonged kinetic profile. Importantly, this increase of micro-vessel flow velocity was attenuated by both chemogenetic and pharmacological approaches, which preliminary evidence suggests may abolish experience-induced enhanced neurogenesis. Together, our results reveal a new mechanism whereby the adult hippocampal

circuit regulates its local metabolic environment in conjunction with its neuronal activity to promote neurogenic homeostasis.

Title: Statistical modeling of cerebral vessel morphometry and blood flow in wildtype and tissue-plasminogen activator deficient mice

Authors: *T. STEVENSON¹, R. C. STEVENSON³, L. FREDRIKSSON⁴, E. J. SU³, G. G. MURPHY², D. A. LAWRENCE³

²MBNI/Physiology, ¹Univ. of Michigan, Ann Arbor, MI; ³Dept. of Intrnl. Med., Univ. of Michigan Med. Sch., Ann Arbor, MI; ⁴Dept. of Med. Biochem. and Biophysics, Karolinska Inst., Stockholm, Sweden

Abstract: BACKGROUND: The serine protease tissue-plasminogen activator (tPA), classically known for its role regulating fibrinolysis, is also expressed on the abluminal side of the vasculature in the CNS. Though tPA has been implicated in a variety of neurological processes, its intimate association with the vasculature and its activity-dependent release properties were shown to be coupled in a study demonstrating tPA^{-/-} mice to have an attenuated functional hyperemia response following whisker-barrel stimulation. Recently, however, an analysis of the cerebral vasculature in adult tPA^{-/-} mice demonstrated significant reorganization of vessel architecture, compared to their C57BL/6J wildtype littermate controls, with tPA^{-/-} mice having a reduction in larger smooth-muscle covered vessels and an increase in smaller capillary blood vessels.

OBJECTIVE: Therefore, to determine if the previously reported attenuated neurovascular coupling response is an indirect consequence of architecture or a direct consequence of tPA's action, a statistical approach to modeling the cortical capillary morphometry and blood flow in wildtype and tPA^{-/-} mice was taken.

METHODS: To confirm the report of aberrant cerebrovasculature architecture in tPA^{-/-} mice and

to gather the necessary statistics for blood flow modeling, a more comprehensive vessel analysis was done using SeeDeepBrain (SeeDB) clearing technology. 500uM thick slabs of brain tissue were cleared from tPA^{-/-} mice and their wildtype counterparts and vessel architecture was analyzed after doubly labeling the vasculature with a FITC-gelatin cast and a FITC-tomato lectin glycocalyx intercalating dye.

To model blood flow, instead of using specific measured capillary cortical networks, statistics on capillary diameter, length, and blood flow were reproduced by creating an ensemble of bifurcating branching networks.

RESULTS: In a preliminary analysis of vessel architecture, tPA^{-/-} mice were found to have significantly more blood vessels than wildtype mice. In addition, baseline cortical blood flow measurements using laser speckle revealed tPA^{-/-} mice to have a significantly higher basal rate of blood flow than their wildtype controls, which is consistent with the observed differences in vascular architecture and suggests that the denser capillary bed in tPA^{-/-} mice results in a functionally elevated basal blood flow rate.

CONCLUSIONS: This data will provide important insights into how the cerebrovasculature architecture can affect blood flow regulation, which has implications for the role attributed to tPA in neurovascular coupling.

Title: Early progressive and preferential vulnerability and reorganization among subsets of cutaneous microvascular innervation in diabetic monkeys and humans especially involving different populations of sensory fibers that contain the vasodilatory calcitonin gene-related peptide

Authors: ***G. HOUK**¹, C. NOTO², P. J. ALBRECHT¹, J. P. WYMER³, C. E. ARGOFF⁴, B. C. HANSEN⁵, F. L. RICE⁶

¹Integrated Tissue Dynamics, LLC, Rensselaer, NY; ²Anesthesiol., Yale Univ. Sch. of Med., New Haven, CT; ³Neurol., Univ. of Florida Sch. of Med., Gainesville, FL; ⁴Neurol., Albany Med. Col., Albany, NY; ⁵Univ. of South Florida Sch. of Med., Tampa, FL; ⁶Integrated Tissue Dynamics LLC, Rensselaer, NY

Abstract: Major complications of diabetes include peripheral neuropathy and a breakdown in cutaneous microvascular circulation particularly affecting distal limbs (i.e. "stocking/glove") resulting in loss of sensation, often accompanied by chronic pain, and in gangrenous deterioration requiring amputation. Yet, surprisingly little is known about the normal components and distribution of cutaneous microvascular innervation and how it affected during the onset and progression of diabetes. Herein, we used large skin specimens from the hands of aging Rhesus monkeys to conduct multi-molecular immunofluorescence microscopic profiles of the microvasculature and its innervation in normal monkeys and those that naturally developed type 2 diabetes. The non-vascular tactile innervation had previously been profiled in the same specimens (see Paré et al., J. Comp. Neurol. 2007, 501:543 for methodological details). Having profiled neurovascular pathologies in these large specimens, we used the same multi-molecular "ChemoMorphometric Analyses" (INTiDYN CMA) to profile the microvasculature and its innervation in small 3mm punch biopsies taken without consequence from the lateral margin of the foot in cohorts of nondiabetic human volunteers (n=16) and diabetic patients with painful (n=29) and non-painful (n=12) diabetic neuropathy (PDN vs NPDN) who had no imminent loss of skin integrity. Procedures were approved by the Albany Medical College IRB. Cutaneous microvascular arterioles, precapillary aretioles, and even capillaries have a well known extensive C-fiber sensory innervation that contains the potent vasodilatory peptides CGRP and Substance P whose role has mostly been attributed to normal anti-inflammatory responses. Otherwise, most normal vasoregulation has focused on vasoconstrictive action of noradrenergic sympathetic innervation, with vasodilatation largely viewed as passive under reduced sympathetic activity. In nearly all of the diabetic monkey and humans, nearly all of the CGRP innervation was absent first on the AVS and then on the arterioles regardless of the diabetes duration, beginning perhaps as early as metabolic syndrome. By contrast, the sympathetic innervation persisted even in long term diabetes. Moreover, the CGRP innervation increased among capillaries in the papillary dermis while a *de novo* innervation with cholinergic characteristics gradually appears among the precapillary arterioles. These results indicate that there are distinct functional subsets of CGRP that are uniquely vulnerable or persistent during the onset and progression of diabetes that could be targeted to prevent subsequent loss of skin integrity.

Title: The problem of inversion of coupling function-metabolism-blood flow in the brain

Authors: *M. NEBIERIDZE¹, M. DEVDARIANI², L. DAVLIANIDZE², N. SIKHARULIDZE², L. GUMBERIDZE², I. KVACHAKIDZE², N. MITAGVARIA² ¹CBF and metabolism, ²I. Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: On the basis of analysis the results of own acute and chronic experiments on rats and the published data the issues of adequate local blood flow changes in the brain, caused by changes in functional activity - a phenomenon known as coupling function - metabolism - blood flow is described. In particular, the issues of regulation of local cerebral blood flow in condition of so-called nonworking brain, in cases of sensory stimulation, functional loading, changes in emotional tension and motor activity. The correlation of local blood flow and electrical activity of the brain is also analyzed. The special attention is paid to the problems of maintenance of a homeostatic range of cerebral blood supply and caused by its breach the inversion of mentioned coupling and its transformation into a new one - blood flow - metabolism - function with possible disturbances in the functioning of the brain.

Title: Structural and hemodynamic comparison of synthetic and anatomical cerebral capillary networks

Authors: *A. SMITH, M. PEYROUNETTE, A. LARUE, V. DOYEUX, Y. DAVIT, S. LORTHOIS

Inst. De Mecanique Des Fluides De Toulouse, Toulouse, France

Abstract: A computational method is presented for generating 3D synthetic, random capillary networks which match the topological, geometrical and functional properties of the cerebral

microcirculation. This enables production of larger capillary networks than can currently be extracted using high-resolution imaging modalities. These networks can then be coupled to lower-resolution data sets of whole-brain vasculature (capillaries unresolved) to model blood flow and mass transport, and to validate equivalent continuum/hybrid models. Another motivation is to reveal the dominant structural features of cerebral capillary networks, enabling us to tune these features to model different brain regions or pathological states such as Alzheimer's disease. Previous works (Linninger et al, Ann Biomed Eng, 2013; Su et al, Microcirc, 2012) lacked physiological basis, and although resulting networks conformed to expected global morphometric properties, they were not subjected to thorough topological or functional analysis.

In contrast, our approach is based on the physiological assumption that the maximum separation of tissue cells from the nearest capillary is limited by the diffusion distance of oxygen (Lorthois & Cassot, J Theor Biol, 2010). Previously, synthetic, space-filling 2D networks were constructed by placing one point randomly in each cell of an $n \times n$ grid; from this set of points, Voronoi diagrams were extracted with the edges producing a 2D capillary network with mainly three capillaries per vertex, a characteristic feature of cerebral capillary networks. Here, we present a 3D extension of this approach and compare the resulting structural and hemodynamic properties to those of anatomical cerebral capillary networks.

In 3D, Voronoi diagrams produce polyhedrons with many capillaries at each vertex. To derive a network with only bifurcations, clusters of vertices were systematically merged and capillaries were then randomly removed. The resulting network structures were compared to capillary regions extracted from human and mouse anatomical data sets (Cassot et al, Microcirc, 2006; Tsai et al, J NeuroSci, 2009; Blinder et al, Nat Neurosci, 2013), showing excellent agreement. Geometrical metrics included the mean/S.D. of capillary lengths and edge/length/vertex densities. To measure the interconnected network topology, capillary loops were identified and the mean number of edges per loop, loop length, and number of loops per edge were compared. The spatial arrangement of capillaries was compared by studying the distribution of extravascular distances. Finally, the permeability was computed as a hemodynamic measure of blood flow conductivity.

Abstract: The most common form of dementia is Alzheimer's disease, making it a major health problem. While studied intensively, no cure or even clear diagnostic procedures have been found yet (Nelson JNEEN 2012). A recent study (Iturria-Medina Nat Com 2016) has shown that a significant decrease in blood flow arises in the onset of Alzheimer's disease. In vivo two photon microscopy of cortical vasculature in APP/PS1 mouse models suggests that the mechanism underlying this blood flow reduction is capillary occlusions due to leucocytes adhering to inflamed blood vessel walls (Cruz-Hernandez Neuroscience meeting 2016). However, these techniques generate massive amounts of anatomical and functional data that are difficult to interpret without proper theoretical and numerical frameworks. Here, we develop a model describing blood flow in large microvascular networks that accounts for complex blood rheology (hematocrit-dependent viscosity and non-linear phase separation at bifurcations, Pries Microvasc Res 1989). We validate it by comparison with in vivo measurements in mice and extrapolate the model to humans. We then quantify the impact of capillary occlusions on regional perfusion for both species.

The numerical simulations, based on an iterative algorithm derived from Newton's fixed point method (Lorthois, Neuroimage 2011) are run in 4 post-mortem mice anatomical networks with more than 10,000 vessels each acquired by two-photon imaging (Tsai J Neuroscience 2009). For human we use a dataset composed of 300 μ m thick slices (over 20,000 vessels per slice) acquired by confocal microscopy (Cassot Microcirculation 2006). We correct post-mortem vessel variations in both dataset using shape-preserving transformations based on available in vivo measurements.

We validate our model and corrections by direct comparison with in vivo red blood cell velocity measurements performed in mice (Santisakultarm AJPHCP 2012, Taylor JCBFM 2016). We then investigate, for both humans and mice, the impact of an increasing percentage of capillary occlusions on regional perfusion, defined as the sum of flows in all arterioles supply the studied domain. We observe a clear linear dependence in both species, with similar slopes and no threshold effect. Our results imply that even a small percentage of occluded vessels (2-4%) yield a drastic reduction of regional perfusion (5-12 % in mice and humans), which is of the same order of magnitude as observed experimentally in APP/PS1 mice. Finally, we show that these slopes are controlled by the capillary network connectivity and spatial distribution of occlusions across the network, while only slightly affected by uncertainties on vessel diameters.

Title: Hypoxia-induced vascular responses in the adult mouse brain

Authors: *M. D. SWEENEY¹, A. MONTAGNE¹, R. D. BELL², K. KISLER¹, A. J. BRUMM³, B. V. ZLOKOVIC¹

¹Zilkha Neurogenetic Institute, Dept. of Physiol. and Biophysics, USC, Los Angeles, CA; ²Neurosci. Res., Pfizer Res. Kendall Square, Cambridge, MA; ³Nikon Instruments, Inc., Melville, NY

Abstract: Mild continuous hypoxia is a phenomenon observed in several central nervous system (CNS) conditions including diabetic retinopathy, chronic hypoperfusion, and Alzheimer's disease (AD). Pericytes, mural cells that cover capillaries, become dysfunctional and degenerate in ischemic stroke, diabetic retinopathy and AD. Pericytes are vital orchestrators of key neurovascular functions including blood-brain barrier (BBB) integrity, cerebral blood flow (CBF), and angiogenesis. Increased CBF and angiogenesis are physiological responses in brain elicited by a mild hypoxic state. The transcriptional regulation of these structural/functional hypoxic responses has never before been investigated in the adult brain, nor has its corresponding impact on brain microvascular health. Adult wild-type mice exposed to mild continuous hypoxia up to 21 days show a 60% increase in capillary diameter at day 3 and 53% increase in red blood cell velocity by day 7 in the somatosensory cortex using longitudinal multiphoton imaging. Immunohistochemistry reveals an increased regional rate of microvascular density, suggesting that some brain regions are more susceptible to mild hypoxia. Additionally, RNA-sequencing analysis of differentially expressed genes from brain microvascular cells after mild continuous hypoxia reveals significantly upregulated expression of the Gene Ontology categories including cytoskeleton reorganization, cellular response to stress, cell division, etc. Furthermore, since pericyte-deficient mice are reported to have disrupted oxygen availability and BBB dysfunction, pericyte deficiency is hypothesized to impair the normal physiologic response to mild continuous hypoxia in adult brains. Altogether, elucidating the transcriptional, structural and functional responses to mild continuous hypoxia in the adult brain is vital to inform therapeutic efforts to combat hypoxic insults and/or microvascular dysfunction in numerous CNS disorders such as diabetic retinopathy, chronic hypoperfusion, and AD.

Title: Perivascular macrophages mediate the cerebrovascular and cognitive dysfunction in DOCA-salt hypertension

Authors: *M. M. SANTISTEBAN, G. FARACO, G. RACCHUMI, J. ANRATHER, C. IADECOLA Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Hypertension (HTN) is a leading risk factor for stroke and dementia. About half of patients with HTN are salt-sensitive, and a high sodium diet is an additional risk factor for these devastating neurovascular diseases. Deoxycorticosterone (DOCA)-salt HTN is a recognized model of HTN driven by sodium retention and brain renin-angiotensin system (RAS) activation. However, it is unknown whether essential mechanisms regulating the cerebral circulation are altered in DOCA-salt mice, and, if so, whether these alterations are associated with cognitive impairment. To this end, C57BL/6 mice were implanted with 50mg DOCA pellets SQ and received 0.9% NaCl drinking water for 3 weeks. Cerebral blood flow (CBF) was measured in the somatosensory cortex by laser-Doppler flowmetry through a cranial window. DOCA-salt increased systolic blood pressure (BP; 148 \pm 3 vs 112 \pm 3 mmHg in controls; p<0.01), and attenuated the CBF increase induced by whisker stimulation (WS; 16.0 \pm 1.1 vs 22.4 \pm 0.6 %; p<0.01) or by neocortical application of acetylcholine (ACh; 13.5 \pm 0.9 vs 22.8 \pm 1.1 %; p<0.01), without affecting the response to the smooth muscle relaxant adenosine (p>0.05). This cerebrovascular dysfunction was associated with cognitive impairment shown by decreased

exploration of the novel object (52.7 ± 1.7 vs 71.6 ± 1.2 % total exploration time; p<0.01) and time spent in the target quadrant during Barnes Maze (37.8±2.8 vs 49.9±1.6 sec; p<0.01). Perivascular macrophages (PVM) express AT1 receptors and Nox2, and, as such, may be a key source of radicals mediating the cerebrovascular effects of brain RAS overactivity. To test this hypothesis, brain PVMs were depleted by icv administration of clodronate (CLO) liposomes. BP was not affected by CLO in either control or DOCA mice (p>0.05). PVM depletion improved both novel object exploration time (p<0.01) and time spent in the target quadrant of Barnes Maze (p<0.05), while also restoring the CBF responses to both WS (DOCA-CLO 19.6±0.9%; p<0.05) and ACh application (DOCA-CLO 20.0±1.7%; p<0.05). Next, we tested whether reactive oxygen species (ROS) are involved in the cerebrovascular dysfunction. We observed a 45% upregulation in gp91 mRNA expression in isolated cerebral vessels from DOCA mice, which was prevented by PVM depletion (p<0.05). Furthermore, application of the ROS scavenger MnTBAP rescued CBF responses to both WS ($20.3\pm0.9\%$; p<0.05) and ACh ($19.0\pm0.8\%$; p<0.05) in DOCA-salt HTN. We conclude that PVMs play an important role in the cerebrovascular and cognitive dysfunction of DOCA-salt HTN. PVMs may have a unique role in mediating the detrimental effects of HTN on the brain, and could therefore become a novel cellular target for therapy.

Title: Increased cerebral blood flow response due to specific optgenetic stimulation of parvalbumin positive interneurons

Authors: M. K. DAHLQVIST, *K. J. THOMSEN, M. J. LAURITZEN TransNeurogroup, Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Fast spiking parvalbumin positive (PV+) interneurons spike with a frequency up to 200 Hz. The gamma activity in the brain (30-90 Hz) is an interaction between PV+ interneurons

and pyramidal neurons, where synchronization of PV+ interneurons allows the pyramidal cells to fire within specific time intervals. Fast spiking is energy consuming and is therefore greatly dependent upon energy substrates supplied by the blood. We hypothesise that gamma activity per se induces cerebral blood flow (CBF) increases during states of increased neuronal activity and energy demand.

3-5-month-old transgenic mice with channelrhodophsin-2 (ChR2) -expressing PV+ interneurons were used. The mice were stimulated in three ways: by whisker pad stimulation (15 s, 2 Hz, 1.5 mV, 1 ms pulses), optogenetic laser light (473 nm, 15 s, 100 Hz, 2 mW, 7.5 ms pulses), and both simultaneously. Tissue partial pressure of oxygen, total extracellular electrical activity and CBF responses were monitored. Blockers of neuronal signalling were applied in the following order: MK-801 (300 μ M) (N-methyl-D-aspartate receptor (NMDAR) blocker) + NBQX (200 μ M) (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) blocker); Gabazine (20 μ M) (synaptic gamma-aminobutyric acid receptor (GABAR) blocker); and lastly, TTX (20 μ M) (tetrodoxin).

Optogenetic stimulation of PV+ interneurons resulted in a CBF response independent of pyramidal neuron activation. MK-801 + NBQX abolished the CBF response to whisker pad stimulation as expected, but did not affect the CBF response to light stimulation. It also abolished gamma activity during all three stimulation types. Subsequent synaptic GABAR blockade augmented the CBF response to light stimulation. CMRO₂ (cerebral metabolic rate of oxygen) responses to optogenetic stimulation paralleled the CBF responses. All responses were abolished when TTX was applied. Light stimulation alone induced much less gamma activity than either whisker pad stimulation or simultaneous light + whisker pad stimulation. We found that CBF and CMRO₂ responses to light stimulation of PV+ interneurons are dependent on neuronal events, but are not dependent on NMDAR and AMPAR activation or on gamma activity and thereby the interaction with PV+ interneurons. When synaptic GABA was blocked, CBF and CMRO₂ responses to light and light + whisker pad stimulation increased, possibly due to decreased inhibitory tone. We conclude that PV + interneuron activation but not gamma activity is necessary and sufficient to induce CBF and CMRO₂ responses.

Title: SUVN-I6107: A novel muscarinic M1 receptor positive allosteric modulator (M1-PAM) addresses cholinergic side effects

Authors: *A. K. SHINDE, S. YATHAVAKILLA, A. VUYYURU, R. MEDAPATI,, G. VENKATA RAMALINGAYYA, J. TADIPARTHI, N. GANUGA, N. MUDDANNA, S. DARPELLI, V. UTHUKAM, D. SISODAYA, N. PATIBANDLA, M. SRIRANGAVARAM, V. MEKALA, R. SUBRAMANIAN, V. GOYAL, K. BOJJA, S. KOMMINENI, S. MANCHINEELLA, R. NIROGI Suven Life Sci., HYDERABAD, India

Abstract: Improving the cholinergic neurotransmission reduces the symptoms of AD. Thus, modulating the cholinergic system through muscarinic receptors could be a viable option for developing new treatments for Alzheimer's disease (AD). Recently published literature suggests that positive allosteric modulator of muscarinic M1 receptor causes cholinergic side effects, which may limit their clinical use. SUVN-I6107 is one of our lead M1-PAM. It was evaluated for its binding potential at the orthosteric and allosteric site of muscarinic receptors and its ability to potentiate the effect of acetylcholine in the reporter gene assay. The pharmacokinetics and brain penetration was evaluated in rodents. The efficacy of SUVN-I6107 was evaluated in animal models of cognition. The effect on the modulation of soluble amyloid precursor protein- α $(sAPP-\alpha)$ was studied in rat cortex. Effect on the neuronal oscillations was evaluated in combination with donepezil. Cardiovascular safety was assessed using the patch clamp technique. The cholinergic side effects were evaluated in mice and dogs (gastro intestinal transit and salivation). SUVN-I6107 is a M1-PAM with no agonistic activity. It has good selectivity over closely related muscarinic receptor subtypes M2 to M5. It has adequate water solubility, and was found to be orally bioavailable (67%) in rats with good brain penetration and free fraction. SUVN-I6107 reversed the time as well as scopolamine induced memory deficit in the object recognition task. It also potentiated the effects of donepezil and promoted non-amyloidogenic APP processing in rats. SUVN-I6107 also enhanced the cerebral blood flow in rats. At the therapeutically effective dose, SUVN-I6107 potentiated the effects of donepezil on elicited hippocampal theta levels in rats. SUVN-I6107 did not affect the colonic/ gastro-intestinal transit in rats or dogs. No notable changes were observed in the salivation. SUVN-I6107 was found to be safe when tested in hERG patch clamp assay and in early stage animal toxicity studies. SUVN-I6107 demonstrates robust efficacy in animal models without cholinergic side effects

Title: Acute administration of haloperidol increases evoked CBF and BOLD fMRI to the somatosensory stimulation in anesthetized rats

Authors: *Y. KIM¹, K. LEE¹, S. HAN¹, J. SON¹, S.-G. KIM^{1,2} ¹Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci. (IBS), Suwon, Korea, Republic of; ²Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Dopaminergic neurotransmission modulates sensory process, but the effects of the antipsychotics which is known as a dopamine antagonist on the sensory modulation were still controversial. Since the fMRI research in schizophrenia field increases rapidly, it is critical to examine the effect of commonly-used antipsychotics haloperidol to neurovascular coupling and BOLD fMRI. Haloperidol was introduced into rats either acutely (0.2mg/kg, I.V) or chronically (consecutive 21 days 0.2mg/kg per day, I.P), and electrical forepaw stimulation (1.0-1.5mA, 10Hz, 0.1ms, 2-5sec) was performed under isoflurane anesthesia (~1.5%). We measured evoked CBF (cerebral blood flow) response using LDF (laser Doppler flowmetry) in the primary somatosensory cortex (S1), BOLD fMRI to determine blood oxygen level changes. To eliminate the effects of physiological changes due to drug administration, physiological measurements including body temperature, blood pressure, and heart rate were observed carefully during entire experiments. No significant physiological change was detected. Acute haloperidol administration did not change baseline CBF in S1, but increased evoked CBF in S1 to the somatosensory stimulation. Interestingly, evoked CBF response in the chronic group was not increased as much as that in the acute group. Similar observation was detected in the fMRI BOLD experiment. To determine whether the change in vascular responses observed in acute haloperidol administration is related to neural activity, we are currently measuring local field potentials in S1. Our initial results show that the effect on the sensory modulation of dopamine antagonist haloperidol is closely dependent on the frequency of drug usage, as implicated in the previous

electrophysiology studies. BOLD fMRI in schizophrenia should be carefully interpreted in the context of type, dose, and frequency of antipsychotic drugs.

Title: Noradrenergic modulation of neurovascular coupling in awake behaving mice

Authors: *Q. ZHANG¹, K. W. GHERES², P. J. DREW³

¹Ctr. for Neural Engineering, Dept. of Engin. Sci. and Mechanics, ²Grad. Program in Mol. Cell. and Integrative Biosci., ³Dept. of Engin. Sci. and Mechanics, The Pennsylvania State Univ., University Park, PA

Abstract: Hemodynamic signals are widely used to infer neural activity in functional brain imaging techniques (e.g., fMRI). Our previous work (Huo et al., J. Neurosci., 2014) has shown that neural activity in the frontal cortex increases without corresponding changes in hemodynamic signals during locomotion, and we sought to mechanistically understand this decoupling. We hypothesized that neuromodulatory input, specifically a noradrenergic (NA) vasoconstrictory signal, interact with neural activity-driven vasodilation to shape the hemodynamic response. Here, we investigated the NA modulation of neurovascular coupling by measuring hemodynamic responses (intrinsic optical signal imaging) and neural activity (multilaminar linear electrode arrays) to voluntary locomotion in awake, head-fixed mice. Noradrenergic tone was decreased or increased by systemic administration of antagonists of a1-(prazosin) and α 2-adrenoceptors (atipamezole), respectively. Compared to vehicle controls, cerebral blood volume changes during locomotion were increased by prazosin in both the frontal and somatosensory cortices, while atipamezole decreases the amplitude the locomotion-related response in the somatosensory cortex. These results suggest that in addition to local vasodilatory signals released from neurons and astrocytes, changes in neuromodulatory tone (especially noradrenergic tone) play an important vasoconstrictory role in shaping hemodynamic signals during behavior. Furthermore, laminar neural activity distribution in the somatosensory cortex shown that increasing NA tone decreased local spiking in layer II/III, while decreasing NA tone

increased local spiking in layer II/III, both at rest and during locomotion. These results further suggest that the NA modulatory effects on hemodynamic signals are due to a cortical layer-specific modulation of neural activity.

Title: Vasodilation induced by pinacidil are attenuated in early vascular injury after subarachnoid hemorrhage on rat cerebral penetrating arterioles

Authors: *T. MURATA^{1,2}, T. HORIUCHI¹, K. HONGO¹

¹Shinshu Univ. Sch. of Med., Matsumoto, Japan; ²Dept. of Neurosurg., Shinonoi Gen. Hosp., Nagano, Japan

Abstract: Early brain injury (EBI) following subarachnoid hemorrhage (SAH), which refers to the acute injuries to the whole brain before onset of delayed cerebral ischemia, is the most important contributor to poor outcome in patients with SAH. EBI is characterized by a severe reduction in cerebral blood flow suggesting alterations on the level of cerebral small vessels. The early vascular injury in small vessels after SAH demonstrated a rapid change in structure, however, vasoactive dysfunction via potassium channels is unclear. This study was therefore conducted to clarify whether SAH induced immediate potassium channels dysfunction in rat experimental SAH model. The institutional animal ethics committee in Shinshu University School of Medicine approved all experimental protocols for this study. In this study, SAH was induced using a blood injection method into the cisterna magna of male rat, and saline injection models were also made. Sham surgery rats as control received the same surgical procedures except for the injection. Rats were sacrificed at 1 hour after SAH, saline injection and sham surgery. The penetrating arterioles from the middle cerebral artery were isolated, cannulated and pressurized. Vessel diameters were recorded by computer-aided videomicroscopy. After development of vascular tone, to investigate the ATP-dependent potassium channels function, the activator pinacidil was applied. The penetrating arterioles from SAH and saline injection models developed significantly more tone compared with the arterioles from sham. The ATPdependent potassium channels activator significantly dilated the penetrating arterioles from sham surgery rats. The vasodilatory responses to the activator were attenuated in SAH rats but not saline injection rats. In conclusion, ATP-dependent potassium channels may inactivate

immediately after SAH, and the dysfunction may be induced by acute increased intracranial pressure. These results provide a background to understand the early vascular injury after SAH.

Physiol. and Pharmacol., Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract: Intracellular Ca^{2+} ($[Ca^{2+}]_i$) signaling in cerebral artery endothelial cells coordinates smooth muscle cell relaxation facilitating cerebral blood flow. However, studies of endothelial function are limited by the presence of confounding factors (e.g., perivascular nerves, blood flow, hormones) arising from intact blood vessel applications. Also, isolated cells in culture manifest significantly altered morphology and ion channel expression relative to physiological conditions. The aim of the current study was to characterize intact vascular endothelium freshly isolated (≤ 1 hr of being within the animal) from middle and posterior cerebral arteries of Young (4-7 mo), Middle (13-16 mo), and Old (24-27 mo) male and female C57BL/6 mice ($n \ge 5$; continuous superfusion of PSS at pH 7.4 & 37°C). Using Fura-2 photometry (~100 cells), we tested the hypothesis that aging increases the magnitude of cerebral endothelial $[Ca^{2+}]_i$ responses in response to a physiological G-protein coupled receptor agonist (ATP) and the oxidizing agent H₂O₂. A cerebral endothelial tube varied in length from 0.5 to 3 mm, whereby diameter was not significantly altered with age (Young: $108\pm12 \,\mu$ m, Middle: $105\pm7 \,\mu$ m, Old: $120\pm7 \,\mu$ m; mean \pm SEM) or gender. With resting $[Ca^{2+}]_i$ in the range of 100 nM to 300 nM, increases in $[Ca^{2+}]_i$ were typically up to ~500 nM during treatment with the purinergic receptor agonist ATP (100 μ M, 5 min) and highest at μ M concentrations following H₂O₂ (200 μ M, 15 min). With general trends (P>0.05) for greater increases in females vs. males across age groups, Δ [Ca²⁺]_i to ATP and H₂O₂ peaked at middle age (P<0.05; \approx two-fold vs. Young) and decreased by \approx 30% (P>0.05) in Old. These data suggest that middle age sets the stage for enhanced $[Ca^{2+}]_i$ signaling, thereby increasing the Ca²⁺ homeostasis burden of internal organelles (ER and mitochondria). Further, intracellular measurements of V_m during respective treatments demonstrated hyperpolarization of membrane potential (V_m) across groups consistent with activation of small- and intermediate Ca^{2+} -activated K⁺ channels (or SK_{Ca}/IK_{Ca}) with NS309 (ΔV_m of -5 mV to -50 mV from a resting V_m of \approx -30 mV to -40 mV). As $[Ca^{2+}]_i$ and oxidative signaling modulates SK_{Ca}/IK_{Ca} activity and vasodilation, these findings provide insight into endothelial cell regulation of cerebral blood flow with advancing age and the potential development of neurodegenerative disease. This work has been supported by NIH grant *R00AG047198* (EJB).

Title: Uncovering the contribution of cortical interneurons to neurovascular coupling - an optogenetic approach

Authors: *C. HOWARTH, L. LEE, C. CHRISTMAS, N. VAUTRELLE, L. BOORMAN, P. SHARP, E. BRACCI, J. BERWICK Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Neurovascular coupling is a vital brain mechanism ensuring that neuronal energy demands are met by dynamic changes in local blood flow. This mechanism underlies functional neuroimaging techniques such as BOLD fMRI and may be dysfunctional in neurodegenerative diseases.

Inhibitory interneurons have previously been shown to induce vasodilation and constriction in the brain^{1,2,3}, thus making them a potential cellular driver of neurovascular coupling. Furthermore, interneuron dysfunction has been implicated in a number of neurodegenerative diseases^{4,5,6}.

We have combined a cell-specific optogenetic approach with 2-dimensional optical imaging spectroscopy (2D-OIS) and electrophysiology in anaesthetized mice to investigate how two populations of cortical interneurons (those expressing somatostatin or NOS) contribute to neurovascular function. Using transgenic mice expressing channelrhodopsin-2 within these neuronal subpopulations enables neuronal activation by light with high spatial and temporal specificity. Light activation was performed with and without somatosensory stimulation. Evoked

cortical surface haemodynamic changes were measured concurrently with neural activity as a function of cortical depth, allowing us to define the roles of somatostatin-expressing and NOS-expressing interneurons in neurovascular coupling in the healthy brain.

By understanding the influence of these cells on normal network physiology and haemodynamic correlates we can not only begin to decipher how interneurons may contribute to disease processes but also improve our ability to interpret perfusion-based neuroimaging signals. References:

Title: Insights into anti-seizure mechanisms of focal cerebral cooling through multi-modal assessment of the interaction between cortical temperature and neurovascular function

Authors: *L. W. BOORMAN¹, S. S. HARRIS¹, M. PORT², T. H. SCHWARTZ³, J. BERWICK¹

¹Univ. Sheffield, Sheffield, United Kingdom; ²Robotics, Univ. of Sheffield, Sheffield, United Kingdom; ³Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Active manipulation of brain temperature is routinely used for cerebral protection during brain surgery and is being investigated as a therapeutic intervention for various pathologies, such as to reduce the effects of seizures in drug-resistant epilepsy or for the prevention of seizures following traumatic brain injury. However little is known of the effects of temperature changes on brain physiology, especially perfusion-related mechanisms which are often disrupted in neuropathological conditions. To address this research gap, we used a multi-

modal neuroimaging approach to investigate neurovascular coupling in the brain of the urethaneanesthetized rat under normothermia and hypothermia. Intrinsic cortical temperature changes were assessed initially during normothermia, with neural and hemodynamic changes evoked through sensory stimulation (16s, 5Hz, 1.2mA), graded hypercapnia (5 and 10%) and recurrent acute focal neocortical seizures induced by infusion of 4-aminopyridine (4-AP, 15mM, 1µl). Concurrent neural activity was recorded alongside cortical temperature, tissue oxygenation, blood flow and hemoglobin concentration. Cortical temperature was found to increase significantly (p < 0.01) during sensory stimulation (0.19±0.02°C), 5% hypercapnia (0.89±0.11°C), 10% hypercapnia (1.46±0.19°C), and recurrent seizures (1.78±0.08°C). A novel system was developed to accurately manipulate the temperature of the cortical surface via superfusion of fluid across a thinned cranial window overlying the somatosensory cortex. Temperatures were maintained above and below normal physiological levels (6 to 40°C), while simultaneously recording neural and hemodynamic changes. Early findings suggest a complex interplay in stimulus evoked neuro-vascular coupling responses across different temperatures. A slowing of the onset of stimulus evoked functional hyperaemia was observed for smaller reductions in cortical temperature ($\sim 20^{\circ}$ C), with attenuation of neural and hemodynamic responses observed during greater levels of cooling (~10°C). Ongoing work will involve the induction of seizures by infusion of 4-AP, followed by cortical hypothermia at a range of temperatures. These findings uncover both the temperature shifts occurring in response to neurovascular changes and the neurovascular alterations which occur during active temperature manipulation. This offers insight into the route of function of various hypothermic therapies and will be relevant to the interpretation of pre-clinical functional neuroimaging data in health and disease.

Title: Functional connectivity of the pituitary gland associated with body mass index

Authors: *T. IKUTA¹, P. RUCKER²

¹Univ. of Mississippi, Oxford, MS; ²Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: The pituitary gland (PG) plays the central role in the endocrinological function of the central nervous system. The hormones secreted by the PG include somatotrophin (HGH) and oxytocin, which are associated with growth and body weight. However, the relation between

body weight and PG-brain interaction remains unclear. Here, we aimed to isolate the functional connectivities of the PG that are associated with body weight, using resting state functional magnetic imaging (rsfMRI) data. Using enhanced Nathan Kline Institute-Rockland Sample, rsfMRI data from 495 individuals were analyzed to assess functional connectivity of the PG in voxel-wise fashion. The pituitary gland ROI was manually defined in the MNI 2mm space centered approximately at [MNI: 0, 2, -32] (Figure 1: Red). A negative correlation was found between pituitary gland functional connectivity and BMI in eleven different brain regions including posterior thalamus, lingual gyrus, precuneus, right superior temporal gyrus, right middle temporal gyrus, right pallidum, hippocampus, pons, orbitofrontal cortex, left temporal pole, and left inferior frontal gyrus (Figure 1: Blue). Our results show that disconnectivity to these regions is associated with higher BMI, implicating that the connectivity between these regions and PG may regulate body weight maintenance, including feeding behavior and growth, and may contribute to obesity.

Title: Glutamatergic neurons mediate the effects of Brs3 on regulation of energy metabolism

Authors: *C. XIAO¹, *C. XIAO¹, R. A. PINOL², J. CARLIN³, A. SAHA⁴, O. GAVRILOVA³, M. REITMAN⁵

¹NIDDK, Natl. Inst. of Hlth. Office of Intramural, Bethesda, MD; ²NIH, Natl. Inst. of Diabetes and Digestive, Bethesda, MD; ⁴NIDDK, ³NIH, Bethesda, MD; ⁵Diabetes, Endocrinology, and Obesity Br., NIDDK, NIH, Bethesda, MD

Abstract: Great efforts are being made to understand the causal mechanisms of and treatments for obesity. Bombesin-like receptor 3 (BRS3) is an orphan G protein-coupled receptor expressed in multiple hypothalamic regions and a few other sites in the brain and in the periphery. The global Brs3 knockout mouse is obese, with increased food intake and reduced resting metabolic rate, body temperature, and heart rate. To dissect the functions of Brs3, we developed two conditional mouse models, floxed Brs3 and loxTB-Brs3, which allow selective deletion or restoration of Brs3, respectively. These mice were bred with existing mouse lines to investigate the necessity and sufficiency of Brs3 in glutamatergic (Vglut2-Cre expressing) and GABAergic (Vgat-Cre expressing) neurons for regulation of energy homeostasis. Mice with Brs3 ablation in Vglut2, but not Vgat, neurons became obese on high fat diet (HFD), and showed reduced effect of the BRS3 agonist MK-5046 to inhibit food intake and increase metabolic rate. Conversely, mice with selective restoration of Brs3 in Vglut2 neurons had normalized food intake and wildtype levels body weight on the HFD. Restoration of Brs3 in Vgat neurons did not alter the obese phenotype, resembling that of the global knockout. Similarly, restoration of Brs3 in Vglut2, but not Vgat, neurons, recovered the ability of MK-5046 to inhibit food intake and increase resting metabolic rate. The effects of Brs3 deletion and restoration in chow-fed mice were generally consistent with, but milder than those observed in HFD-fed mice. The mice with increased adiposity typically had worse glucose tolerance and insulin resistance, consistent with an effect of the increased fat mass. These data demonstrate that the Brs3 located in Vglut2 neurons is both necessary and sufficient to maintain normal food intake, body weight and adiposity, metabolic rate and insulin sensitivity. In contrast, Brs3 in Vgat neurons (and other places) appears to be neither necessary nor sufficient for regulation of these aspects of energy homeostasis.

Title: Investigating the genetic structure of complex phenotypes in free-ranging rhesus macaques

Authors: *S. MADLON-KAY¹, M. J. MONTAGUE¹, N. SNYDER-MACKLER², J. E. HORVATH³, L. J. N. BRENT⁴, J. SKENE⁵, M. L. PLATT¹ ¹Univ. of Pennsylvania, Philadelphia, PA; ²Univ. of Washington, Seattle, WA; ³North Carolina Central Univ., Durham, NC; ⁴Univ. of Exeter, Exeter, United Kingdom; ⁵Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Free-ranging populations of non-human primates (NHPs), like humans, live in dynamic social environments where managing both resources and relationships is crucial for survival. Because such environments are difficult to reproduce in a laboratory setting, freeranging NHP populations provide a potentially powerful model for understanding how genetic and environmental factors shape complex phenotypes. However, genetic variation in many complex phenotypes is driven by small contributions across many genetic variants, which require large sample sizes to estimate reliably. Free-ranging NHP populations for which genetic information is available may be too small to identify the effects of individual genetic variants using traditional approaches. This poses an obstacle for identifying specific neurobiological genetic pathways that contribute to a particular phenotype. Here we take an alternative approach by using recently developed computational methods that increase statistical power by aggregating effects across large numbers of genetic variants within pathways or gene sets of interest. These methods are sometimes known as "realized relatedness" analyses, as they use genomic data to examine overall genetic similarity between individuals and compare it to phenotypic similarity. By allowing genetic similarity in different regions of the genome to contribute differentially to a phenotype, it is possible to identify specific gene sets or pathways that contribute to the phenotype.

We investigated whether this approach could be used to uncover neurogenetic pathways that contribute to complex phenotypes in a large, free-ranging population of rhesus macaques (*Macaca mulatta*) on Cayo Santiago Island, for which large amounts of genetic, behavioral, and morphological data are readily available. We focused on obesity-related morphological phenotypes, including height, weight, and abdominal and subscapular skinfold thickness, as obesity is a pathology with neurological influences that is highly heritable in humans. In order to measure genome-wide and pathway-specific genetic similarity, we generated whole genome sequences for 217 individuals and identified over 19 million single-nucleotide variants. We assessed overall heritability of these morphological phenotypes as well as the specific contributions of neurobiological gene sets that have been implicated in obesity in humans, namely gene sets involving neurotrophin, hedgehog, and glutamate signaling (Locke et al, 2015). These methods may provide a path towards using free-ranging NHP populations to study the neurobiological basis of complex behaviors such as sociality.

Title: Nicotinic acetylcholine receptors containing the β 2 subunit regulate body weight in mice

Authors: *G. DEZFULI, T. OLSON, B. SIEGARS, N. SAHIBZADA, R. GILLIS, K. J. KELLAR, 20057 Pharmacol. and Physiol., Georgetown Univ., Washington, DC

Abstract: Nicotine, the primary psychoactive component of tobacco smoke, has been well documented to have weight-reducing properties in rats and mice, and similar effects are seen with other drugs that target the nicotinic acetylcholine receptor (nAChR). Moreover, we recently reported that drugs that selectively desensitize the nAChR containing the ß2 subunit, such as Sazetidine-A (SAZ-A) exert robust weight reducing effects in rats and mice (Hussmann et al., 2014; Dezfuli et al., 2016). One purpose of the present study was to further test the involvement of B2-containing nAChRs as a major receptor-mediated mechanism by which nicotine lowers body weight and suppresses feeding. To this end, we investigated whether or not chronic nAChR blockade (functionally akin to chronic receptor desensitization) via the use of the selective $\alpha 4\beta 2$ nAChR competitive antagonist dihydro-beta-erythroidine (DHBE) produces weight-reducing effects similar to SAZ-A. An additional goal of the present study was to test the hypothesis that endogenous tonic activity of nAChRs containing the ß2 subunit drives a state of positive energy balance characterized by weight gain. To test this hypothesis, we characterized the body weight phenotype of 8-week old male mice with conventional knockout of the β 2 subunit (β 2^{-/-}) in comparison to littermate controls ($\beta 2^{+/+}$) over a 7-week monitoring period. Results from the present studies demonstrate: (a) DHBE robustly suppresses weight gain in C57BL6/J mice fed a high fat diet, in comparison to saline treated controls [F (10,150) = 2.26, p<0.05] without any concomitant change in dark-cycle locomotor activity, and (b) 8 week-old male $\beta 2^{-/-}$ mice have significantly reduced weight gain in early adulthood compared to littermate controls [F (2,115) = 6.47, p<0.01]. Together, these findings indicate a potentially prominent role for nAChRs containing the ß2 subunit as intrinsically active regulators of body weight. Furthermore, these studies highlight the nAChR containing the β 2 subunit as a potential new drug target site for obesity pharmacotherapy.

Title: Transient and selective overexpression of dopamine 2 receptors in striatal medium spiny neurons promotes diet-induced obesity

Authors: *M. A. LABOUESSE^{1,2,3}, C. KELLENDONK¹, U. WEBER-STADLBAUER^{2,3} ¹Dept. of Psychiatry, Div. of Mol. Therapeut., Columbia Univ., New York City, NY; ²Physiol. and Behavior Laboratory, ETH Zurich, Schwerzenbach, Switzerland; ³Inst. of Pharmacol. and Toxicology, Univ. of Zurich–Vetsuisse, Zurich, Switzerland

Abstract: Abnormal dopaminergic signaling in the striatum has been repeatedly associated with obesity. Clinical investigations have outlined changes in dopamine 2 receptor (D2R) availability within the striatum in obese individuals, although the direction of such changes remains controversial and may depend on the severity of the obesity phenotype. In addition, numerous animal investigations have shown that obesity and/or high-fat diet (HFD) feeding can cause a reduction in striatal D2R binding and expression. Yet it remains unclear whether preexisting changes in striatal D2R levels can per se promote the development of obesity. Recent work has shown that D2R knock-out in indirect-pathway medium spiny neurons (MSNs) reduces locomotion but does not lead to obesity, nor does it affect food intake or energy expenditure in mice, even when fed HFD. In our study, we made the opposite hypothesis, postulating that an upregulation of D2R in MSNs may increase vulnerability to obesity. This was based on recent clinical work suggesting that genetic propensity for greater dopamine signaling may predict future weight gain in lean or modestly obese individuals. We used a transgenic mouse model where D2R levels were specifically upregulated within the striatum; in all MSNs, but not in cholinergic neurons or interneurons. We showed that D2R-overexpression (D2R-OE) robustly increased body weight gain and body fat when fed high fat diets as compared to control mice. We also identified multiple metabolic impairments in D2R-OE mice in the form of glycemic intolerance, hyperlipidemia and hyperinsulinemia. Because striatal D2Rs have been implicated in abnormal reward behavior and eating, we speculated that obesity vulnerability in D2R-OE mice may be due to increased food intake. Surprisingly, D2R-OE mice were hypophagic. They did, however, demonstrate early reductions in energy expenditure following HFD feeding, which were followed by later decreases in daily locomotor activity, supporting the idea that energy

output, rather than input, was causing obesity. We then wondered whether increased obesity in D2R-OE mice was due to ongoing elevated activity of striatal D2Rs in adulthood or whether it may emerge as a result of developmental overexpression of D2Rs. We therefore restricted overexpression of striatal D2Rs to development, and showed that this manipulation was in fact sufficient to promote obesity. Overall, these findings indicate that striatal D2R upregulation may be causally implicated in the development of obesity, and may do so through developmental mechanisms. This work should provide a better understanding of the clinical observations linking striatal D2Rs and obesity.

Title: Investigating the role of ghsr signalling in the dmh and pmv on energy homeostasis

Authors: *L. M. HYLAND¹, S.-B. PARK¹, A. EDWARDS¹, Y. ABDELAZIZ¹, B. WOODSIDE², A. ABIZAID¹

¹Carleton Univ., Ottawa, ON, Canada; ²Concordia Univ., Montreal, QC, Canada

Abstract: Ghrelin is a gut peptide hormone that increases food intake and adiposity. The orexigenic effects of ghrelin depend on binding to its endogenous receptor, the growth hormone secretagogue receptor (GHSR). The GHSR is highly expressed throughout the peripheral and central nervous system, and in particular within the hypothalamus, a region of the brain important in homeostatic processes. Two regions within the hypothalamus, the dorsomedial hypothalamus (DMH) and ventral premammilary nucleus (PMV), show GHSR expression, yet the effects of ghrelin on these regions remains to be elucidated. The DMH is important for many energy balance processes, such as regulating brown fat thermogenesis, food intake, circadian rhythms, and the generation of the stress response, while the PMV is thought to be an integrative centre, owing to its responsiveness to reproductive, metabolic, and social signals. The current experiments aim to identify how altering GHSR signaling in the DMH, or the PMV, alters metabolic processes in mice. In experiment 1, male C57BL6J mice were equipped with a minipump filled with either saline, the GHSR antagonist JMV 2959 (2 µg/day/28days) or ghrelin (10 µg/day/28days) attached to a cannula aimed at the DMH (AP 1.55mm, ML 0.25mm, and DV 5.25 mm). Following surgery, food intake and body weight was monitored for a week before animals were housed in metabolic chambers for 48 hours to determine differences in metabolism

using indirect calorimetry. They were then allowed a recovery period before being tested for glucose clearance using the glucose tolerance test (GTT). The same design was used in Experiment 2, but this time, cannulae were aimed at the PMV (AP 2.45mm, ML 0.3mm, and DV 5.4mm). Our results show that infusions of ghrelin into the PMV but not the DMH affects fuel utilization, while infusions of ghrelin into the DMH but not the PMV affects body weight and fat accumulation. Overall, these results suggest that while GHSR signaling is important for energy homeostasis in both the DMH and PMV, specific metabolic effects are selectively mediated in a region-specific manner.

Title: p75^{NTR} involvement in metabolic control pathways

Authors: *T. P. REMCHO¹, L. M. SIPE², D.-A. JOHNSON², J. EPHREM², C. DEPPMANN¹ ¹Biol., ²Univ. of Virginia, Charlottesville, VA

Abstract: Obesity levels present an urgent public health challenge. The extensive sympathetic innervation of adipose tissue provides a target for treatment. This innervation regulates energy liberation from adipocytes. We have identified a putative protein, integral in the regulation of lipolytic events, the p75 neurotrophin receptor (p75^{NTR}). This protein is expressed in several tissue types and binds a wide variety of neurotrophins. A lack of p75^{NTR} was previously shown to reduce weight gain in response to a high fat diet by increasing the rate of energy liberation from fat stores. Here, we show that mice deficient in p75^{NTR} lose less weight due to restricted caloric intake. This data suggests p75^{NTR} modulates energy homeostasis and does not solely upregulate lipolysis. We aim to understand the mechanism by which p75^{NTR} maintains energetic homeostasis. To elucidate the cell-specific function of p75^{NTR}, we subjected conditional knockouts of p75^{NTR}, in sympathetic neurons and adipocytes, to caloric restriction and analyzed their weight loss. Additionally, the rate of norepinephrine turnover was shown to differ in mice deficient in p75^{NTR}; this begins to elucidate the mechanistic role of p75^{NTR} in our weight-loss resistant phenotype. The understanding of neural mechanisms underlying energetic homeostasis in adipose tissue suggests the possibility for neuromodulation as an avenue for weight control via alteration to energetic homeostasis.

Title: Selective activation of regionally distinct catecholamine neurons in the ventrolateral medulla is sufficient for elicitation of key glucoregulatory responses in normoglycemic rats

Authors: *S. RITTER, Q. WANG, A.-J. LI

Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Acute glucose deficit is a potentially lethal condition. Hindbrain catecholamine (CA) neurons are required for elicitation of protective responses to acute glucose deficit, as shown by selective immunotoxin lesions, localized gene silencing and localized nanoliter injections of the glucoprivic agent, 5-thioglucose. However, whether selective activation of CA neurons is sufficient to elicit these responses is not known. In addition, questions remain regarding the regional distribution of neurons that mediate specific glucoregulatory responses. To address these questions, we virally transfected a Cre-dependent designer receptor exclusively activated by a designer drug (DREADD) construct, AAV2-DIO-hSyn-hM3D(Gq)-mCherry, at one of 4 rostrocaudal levels of the VLM in Th-Cre transgenic rats: rostral C1 (C1r), middle C1 (C1m), the area of A1 and C1 overlap (A1/C1) and A1. Transfection was highly selective for CA neurons at each injection site. We measured feeding, blood glucose, glucagon and corticosterone (Cort) responses to activation of transfected CA neurons following systemic injection of the DREADD receptor agonist, clozapine-N-oxide (CNO). Glucagon was not significantly elevated by CNO in any transfected rat. Feeding was increased in rats transfected at C1r, C1m or A1/C1 sites. Cort secretion was elicited most effectively in rats transfected at A1/C1 or C1m. Neither feeding nor Cort responses were elicited from A1 transfected rats. Blood glucose was not increased in any of these single-site transfected rats, but was increased in rats transfected simultaneously at two adjacent sites (C1m and C1r). Consistent with the blood glucose results, CNO increased c-Fos expression in the spinal intermediolateral column and adrenal medulla only in rats transfected at both C1m and C1r. These results reveal for the first time that selective activation of C1 CA neurons is sufficient to increase feeding, blood glucose and Cort secretion, even in the absence of glucoprivation. The results also suggest that CA neurons mediating blood glucose responses are

sparsely but widely distributed in rostral half of C1, while those mediating feeding and Cort secretion are continuously distributed along C1, but are concentrated in the caudal and middle C1.

Abstract: Different lines show that the expression of preferences for highly palatable foods depends on the gastrointestinal and/or metabolic effects produced by caloric foods. It remains to be determined how the central nervous system converts the sensing of metabolic signals into behavioral preferences. Previous studies show that the midbrain dopaminergic system is a central mediator of food preference formation, given its critical role in the expression of normal feeding behaviors. It is thus of great interest the identification of the physiological pathways allowing the midbrain dopaminergic system to sense metabolic post-ingestive effects. Our results show that cultured dopaminergic neurons are highly sensitive to glucose levels. Exposing cultured murine mesencephalic neurons to hypoglycemic media, or to the glucose anti-metabolite 2-DG, suppressed dopamine levels. Moreover, we show in adult mice that intraperitoneal injections of glucose, but not of 2-DG, 30 minutes after were sufficient to increase the phosphorylation of tyrosine hydroxylase residues Ser40 (2.4-fold) and Ser31 (1.5-fold), molecular events critical for dopamine synthesis. Finally, increases in Ser40 phosphorylation levels were closely associated with increases in blood glucose levels induced by the intraperitoneal injections. Our results suggest that midbrain dopaminergic regions may be activated by metabolic stimuli such as increased glycemic levels.

Title: Long-term sucrose consumption increases excitability of NPY neurons in the arcuate nucleus of the hypothalamus

Authors: *K. O'CONNELL¹, K. ABREU², W. WEI¹, A. SMITH³, J. H. CARDOSO⁴ ¹The Jackson Lab., Bar Harbor, ME; ²Superior Inst. of Biomed. Sci., State Univ. of Ceara, Fortaleza, Brazil; ³Genetic, Genomics, and Informatics, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; ⁴Univ. Estadual do Ceara, FORTALEZA, Brazil

Abstract: Obesity has been a major world-wide public health problem for the past 40 years associated with co-morbidities such as hypertension, type 2 diabetes, dyslipidemia, heart disease and stroke. Although caused by excessive food intake, obesity is associated with dysfunction of appetite circuits in the brain, especially in the arcuate nucleus of hypothalamus (ARH), that regulate energy balance. We previously demonstrated that high fat diet (HFD) is associated with increased spontaneous firing in ARH NPY neurons, independent of weight gain. High sugar intake is also associated with obesity and diabetes. This study investigated the effect of high sugar intake on both mouse metabolic parameters and the excitability of ARH NPY neurons in acute brain slices using whole cell current clamp. Male hrGFP-NPY mice were maintained on control chow diet, and given either regular drinking water or water containing 10% sucrose (w/v) starting at 6 weeks of age and continuing for 12 weeks (long term) or 2 days (short term). Analysis of food and water intake in the 12 week sucrose cohort revealed that although these mice drank significantly more water, there was no difference in food intake, resulting in an overall increased calorie intake, although this was not associated with a significant increase in body weight. In both the glucose and insulin tolerance tests, the sucrose group had elevated blood glucose compared to controls, consistent with a pre-diabetic state. To determine the impact of increased sucrose consumption on neuronal excitability, we used whole-cell current clamp to assess the electrical properties of ARH NPY neurons. We found that 12 weeks of sucrose water was associated with depolarization of the membrane from -65.82 ± 7.31 mV (control) to $-55.94 \pm$ 1.44 mV (sucrose) with no change in input resistance (995.1 \pm 109.5 M Ω (control) to 917 \pm 157

 $M\Omega$ (sucrose)). Sucrose intake was also associated with an increase in the spontaneous firing frequency from 0.1972 \pm 0.1929 Hz (control) to 1.128 \pm 0.2089 Hz (sucrose), with a corresponding decrease in interspike interval following long term exposure. Unlike HFD, we found that 2d of sucrose water had no impact on resting membrane potential, input resistance, or spontaneous firing rate. Taken together, these data suggest that long term high sugar intake leads to a pre-diabetic state and to a significant increase in spontaneous firing in NPY neurons without obesity.

Title: Estradiol modulates gut microbiome in leptin deficient female mice on a high-fat diet

Authors: X. GAO¹, E. P. BLESS¹, K. D. ACHARYA¹, J. CHEN², *M. J. TETEL¹ ¹Neurosci. Program, Wellesley Col., Wellesley, MA; ²Div. of Biomed. Statistics & Informatics & Ctr. for Individualized Med., Mayo Clin., Rochester, MN

Abstract: Estrogens act in brain and the periphery to mediate a variety of functions, including energy metabolism and reproduction. For example, lower levels of circulating estrogens in postmenopausal women are associated with increased fat weight and risk for developing heart disease and type II diabetes. These anorectic effects of estrogens have also been shown in rodents by our lab and others. Ovariectomized mice become obese when fed a high-fat diet (HFD), while treatment with 17β-Estradiol (E2) prevents this HFD-induced obesity. Leptin, a peptide hormone encoded by the ob gene, is released from adipocytes and acts as a satiety signal in the hypothalamus. Mice with a mutation of the ob gene (ob/ob) do not produce leptin and develop metabolic disorders such as obesity and diabetes. The gut microbiome, which consists of bacteria in the intestines that aid in digestion, has been implicated in obesity and disorders related to the gut-brain axis such as anxiety and depression. The present study tested the hypothesis that E2 and leptin modulate the gut microbiome of female *ob/ob* mice fed a HFD. ob/ob (obese) mice and heterozygote controls (Het; lean) were ovariectomized and implanted with capsules containing E2 (50 µg) or oil (Veh control) to form four groups: 1) *ob/ob* E2, 2) ob/ob Veh, 3) Het E2, and 4) Het Veh. After four days on a standard diet, the mice were switched to a HFD for 31 days. Throughout the study, food intake and weights were measured

and fecal samples were collected. Over the course of the experiment, E2 treated mice weighed less and consumed less food than their Veh counterparts. Additionally, *ob/ob* mice had a lower percent weight gain than Het mice, despite a greater food intake than Het mice. To explore the association between the differences in weight gain and food intake to changes in the gut microbial composition between the groups, fecal samples were sequenced for the 16S rRNA gene. We found that E2 treatment was associated with lower species evenness compared to Veh mice, while the *ob/ob* genotype was associated with lower species richness compared to Het mice. Phylum level analysis showed that *Bacteroidetes* was more abundant in E2-treated mice than Veh mice whereas *Firmicutes* was more abundant in Veh mice compared to E2-treated mice. Genotype also affected relative abundance such that the phylum *Actinobacteria* and the class *Clostridia* (phylum *Firmicutes*) were less abundant in *ob/ob* mice than Het mice. Our results reveal that both E2 treatment and the *ob/ob* genotype influence the gut microbial composition of female mice fed a HFD. Understanding the role of E2 and leptin in modulating the gut microbiota will aid in developing treatments for metabolic disorders including obesity.

Abstract: Epidemiological studies estimate that greater than 60% of the adult US population may be categorized as either overweight or obese. There is a growing appreciation that the complications of obesity extend to the central nervous system (CNS) and result in increased risk for neurological co-morbidities like depressive illness. Given the hypothesized role of serotonin (5-HT) in the pathogenesis of depression, it is possible that decreases in brain 5-HT efflux are a mechanistic mediator of depressive illness in obese patients. We previously demonstrated that rodents with a phenotype that is consistent with features of the metabolic syndrome (MetS) exhibit depressive-like behaviors. To determine whether alteration in 5-HT neurochemistry may provide a potential underlying neurochemical basis for these behavioral changes, we combined two complimentary approaches, namely in vivo microdialysis and in vivo fast-scan cyclic voltammetry, to measure basal levels of 5-HT, increases in hippocampal 5-HT following administration of the selective serotonin reuptake inhibitor (SSRI) fluoxetine and hippocampal serotonin reuptake kinetics in control and obese rats. Neurochemical analyses determined that obese rats exhibited decreased basal 5-HT levels and diminished hippocampal 5-HT efflux following fluoxetine SSRI administration in the hippocampus when compared to control rats. Collectively, these data support the hypothesis that deficits in hippocampal 5-HT neurochemistry are a shared feature between depressive illness and metabolic disorders. Additionally, results identify pharmacological differences that provide a mechanistic basis for the decreased efficacy of SSRIs in the treatment of depressive illness in obese individuals.

Abstract: Obesity, characterized by an excessive amount of body fat, is steadily increasing despite the many diet and exercise programs available today. This is problematic as obesity increases the risk of developing many diseases such as cardiovascular disease, cancer, and diabetes. Here, weight loss was investigated using a contrasting rat model of obesity and leanness: obesity-prone rats (low-capacity runners, LCR) and the more physically active lean rats (high-capacity runners, HCR). Our past studies found that during 50% caloric restriction, lean rats lost proportionally more fat than the obesity-prone rats. An alternative diet strategy was then investigated where 16 male rats (n=8/group) underwent 7 weeks of intermittent fasting (IF), with food being removed every-other day, and an *ad libitum* diet provided on non-fasting days. Body composition was measured weekly, and body weight and food intake were measured daily with minimal disruption of daily sleep/activity cycle. The goal of intermittent fasting was to induce loss of fat in the obesity-prone rats. With IF, the obesity-prone rats lost twice as much fat and body weight compared to the lean rats, with relatively little reduction in lean mass. Results were consistent with previous data from female rats, but contrasted with prior findings where weight loss was induced using 50% calorie restriction. Compared to calorie restriction, IF conserved lean mass while enhancing fat loss. These results suggest that IF may be a potential strategy for reducing weight in the obese and obesity-prone.

London, London, United Kingdom; ⁴Life Sci., Univ. of Westminster, London, United Kingdom

Abstract: Introduction: Obesity and excessive amounts of fat in the liver have been associated with poorer learning, memory and executive functions. The mechanisms by which this effect happens, are not well elucidated. We want to address this problem in young children. This interest lays behind the fact that disorders in initial stages of life affect adulthood. The specific objective of the work presented here was to identify changes in cognitive neuroimaging data obtained with magnetic resonance techniques (resting states and diffusion imaging) and correlate them with blood and urine chemistry as well as psychological testing and fatty liver anatomical measurements. This way the bigger question of the mechanisms underlying poor memory and learning in obese people, might be partially addressed. Materials & Methods: The brain of 160 children (ages from 7 to 9 years old) divided in three groups (normal, over weighted and obese) were studied with MRI. Two neuroimaging techniques were applied (resting states and diffusion weighted imaging). Also, fat measurements of pancreas and liver were added, in which position and amounts of ectopic fat were measured. These measurements were complemented with cognitive testing of each subject (depression, WISC-IV, WCST, Rey-Osterreith and auditory, verbal memory:word from ENI). To all these measurements we addedd blood tests in which standard measurements (cholesterol, glucose, red and white cell counts, etc.) as well as more specific inflammatory particles (cytosines) were obtained. **Results & Discussion:** Preliminary findings showed there were differences in-between children groups for the resting state networks related to reward, as well as the default mode network and the sensorimotor network. Diffusion measurements showed differences in white matter microstructure as shown by changes in fractional anisotropy measurements. As mentioned before, these are preliminary findings. When cognitive as well as blood test data are included we hope to have a broader and more complete description of the mechanisms underlaying poorer learning and memory.

Title: Chronic moderate alcohol drinking alters glucose metabolism but spared behavior on elevated plus maze, sucrose preference and novel object recognition tests

Authors: *N. G. NELSON, F. A. SUHAIDI, W. X. LAW, N.-C. LIANG Neurosci. & Psychology, Univ. of Illinois At Urbana-Champaign, Champaign, IL

Abstract: Obesity poses a great world-wide health care burden due to its associated comorbid health conditions. Health programs aimed to alleviate the menace of obesity tend to promote lifestyle changes that include the adoption of rigorous aerobic exercise regimen, and reduced intake of fatty/sugary foods. Unfortunately, not enough attention has been directed at the contribution of alcoholic beverage to the metabolic syndrome. This stems in part from the conflicting reports in the literature of how alcohol affects appetite, weight maintenance, and diabetes care. We previously reported that dose, administration route, and time course of blood ethanol concentration (BEC) dictate how alcohol affects appetite and body weight in rats. Here, we further probed the link between chronic moderate ethanol consumption, emotional-like and cognitive behaviors, and glucose metabolism in rats. We hypothesized that chronic moderate alcohol consumption will (1) be associated with depression- and anxiety-like behaviors and cognitive deficits during abstinence; and (2) impair glucose metabolism during an oral glucose tolerance test (OGTT). We exposed adolescent male and female rats to 7.5h/day (Mon - Fri) access to saccharin-sweetened 10% ethanol for 8 weeks, followed by intermittent (Mon, Wed, Fri) access to 20% unsweetened ethanol in a 2-bottle choice drinking paradigm for 6 weeks (EtOH). A free-feeding control group received water (CTL). The average body weight of a second control group that received water was matched to that of the EtOH group via mild food restriction (BW Match). During abstinence, all rats were submitted to sucrose preference, elevated plus maze (EPM) and novel object recognition (NOR) tests. BECs were measured from tail blood collected after 1 and 3 h access periods in a separate group of male and female rats given sweetened 10% ethanol. The ethanol intake dose correlated significantly with BEC. Rats attained BEC of ~ 50 mg/dL after 1h ethanol access, and the BEC was maintained around this level at the 3h sampling time point. Furthermore, EtOH rats compensated for calories from ethanol (7 kcal/g) and reduced their chow intake, and their resulting body weight did not differ from that of their respective CTL group. Performance in sucrose preference, EPM and NOR tests did not differ between the EtOH and control groups. Results of the OGTT revealed that EtOH male rats required more insulin to clear blood glucose - a sign of insulin insensitivity. Such effect was not observed in females. This landmark study showed that chronic moderate alcohol consumption can have negative metabolic consequences in the absence of overt behavioral deficits.

Title: Interleukin-1 β contributes to the development of hyperalgesia in overweight ovariectomized rats

Authors: *O. A. JARAMILLO-MORALES¹, J. V. ESPINOSA-JUÁREZ², F. J. LÓPEZ-MUÑOZ²

¹Cinvestav, DF, Mexico; ²Pharmacobiology, Cinvestav-Sede sur, México, Mexico

Abstract: Several studies have reported that menopause causes a greater perception to painful stimuli and an increase in adipose tissue, which promotes a greater body weight gain compared to men. Additionally, it is known that weight gain is related to changes in the perception of pain; however, its mechanism is not clear. **Objective.** The aims of this study were to analyze the behavioral responses of hypoestrogenic overweight Wistar rats to thermal stimuli and to analyze the leptin and interleukin-1 β levels in this population. **Methods**. Animals with hypoestrogenism induced by bilateral ovariectomy were used. Animals received either a hypercaloric diet (30% sucrose) or regular water with standard laboratory food ad libitum for 4 weeks; the thermal nociception and body weight were measured during this period. Four weeks after treatment, the interleukin-1 β and leptin levels and the abdominal fat weight were measured in both groups. Nociception was assessed using the "Plantar test". Results. Overweight ovariectomized Wistar rats displayed significantly higher body weight and abdominal fat weight than did the control group. A hyperalgesic response was observed in animals fed sucrose. Thermal latency was also significantly decreased during the 4th week in these animals compared to that of controls. There were no differences in leptin levels, but the interleukin-1 β levels were altered between groups. Conclusions. Our data indicate that increased body weight, abdominal fat and increases in interleukin-1 β are associated with the hyperalgesic responses observed in ovariectomized overweight female rats.

Title: Characterizing glucose-sensing neurons in the amygdala

Authors: *K. DEVARAKONDA¹, S. STANLEY²

¹Dept. of Neurosci., ²Dept. of Medicine, Div. of Endocrinology, Diabetes and Bone Dis., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Dysfunction of blood glucose produces health problems with profound consequences. In humans, the CNS plays a vital role in glucose metabolism. The medial and basomedial amygdalar nuclei contain neurons that alter their firing in response to physiological changes in glucose concentrations and express glucokinase, an enzyme thought to act as a glucose sensor in the CNS. However, little is known about the anatomy and function of these neurons. To better understand how glucose-sensing neurons in the CNS may contribute to the regulation of metabolic function, we have identified neurochemical markers for amygdala GK neurons, characterized their response to altered glucose, and mapped their circuitry.

Title: Pancreatic projections of glucose sensing CNS neurons

Authors: *A. ALVARSSON, M. BAYNE, S. STANLEY Diabetes, Obesity and Metabolism Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: The central nervous system (CNS) plays a complex role in the control of metabolic functions. CNS glucose-sensing neurons respond to blood glucose levels and orchestrate counterregulatory responses to hypoglycemia. Although several brain regions are known to form synaptic connections with metabolic organs, the specific roles of glucose-sensing neurons in such projections have not yet been established. Glucose-sensing CNS neurons appear to constitute distinct neuronal populations that mediate different physiological functions, but previous studies have been hampered by low expression levels of the glucose sensor glucokinase (GK). However, a recently generated transgenic mouse with cre-recombinase expression in GKexpressing neurons (GK-cre/Rosa-tdTomato mice) allows mapping of GK expression. Here we performed retrograde tracing studies to identify neural pathways involving GK-expressing neurons innervating the pancreas using GK-cre/Rosa-tdTomato mice. A pseudorabies virus (PRV) expressing green fluorescent protein (GFP) was injected (5x100 nl) into the pancreas of GK-cre/Rosa-tdTomato mice via a Hamilton syringe. Four to eight days after PRV-GFP injections the mice were perfused and the brains dissected and sectioned. Immunohistochemistry was performed to amplify the GFP signal of neurons infected by the PRV. Stained brain sections were mounted for quantification using an optical microscope. The numbers of PRV-GFP infected neurons and neurons with overlapping GK and GFP labelling were quantified. GFP labelling was found throughout the hypothalamus, midbrain, hindbrain and cortex. Overlapping labelling between GK-expressing and GFP-expressing neurons identified at different time points revealed that subsets of hypothalamic glucose-sensing neurons, particularly in the lateral hypothalamus and paraventricular nucleus of the hypothalamus, form circuits with synaptic connections that project to the pancreas. These findings suggest that several brain regions, most notably in the hypothalamus, harbor glucose-sensing neurons that are potentially playing roles in the control of pancreatic functions.

Abstract: The median eminence (ME) is a brain structure located at the base of the hypothalamus that is involved in integrating metabolic signals, such as glucose. To perform these functions, the ME cytoarchitecture is modulated and the low affinity glucose transporters, GLUT2 and GLUT6, are expressed. However, no study has addressed the alterations of GLUT expression in the ME caused by aging or acute blood glucose changes. We used confocal microscopy in the spectral 3D rendering mode and laser microdissection combined with qRT-PCR to characterize the cellular distribution of GLUTs in the ME. Ultrastructural modification of the ME in rats subjected to normoglycemic conditions or hyperglycemia was evaluated using transmission electron microscopy (TEM). GLUT2 and GLUT6 were both localized to β2 tanycytes, the main glial cells in the ME. At the ultrastructural level, hyperglycemia increased the arborization of $\beta 2$ tanycyte processes. An increase in vascular projections from subventricular area and the outermost region of the ME, with an increase of vacuolization and formation of blebs was also observed. Furthermore, aging had no effect GLUT2 mRNA expression, but decreased GLUT6 mRNA expression. Taken together, GLUT2 and GLUT6 expression and the structural alterations induced by hyperglycemia and aging in β^2 tanycytes is suggestive of their participation in glucose transference from the blood to the cerebrospinal fluid (CSF).

Title: Obese mice exhibit increased motivation towards palatable food and physiological abnormalities in the ventral pallidum

Authors: *Y. M. KUPCHIK, D. INBAR, K. INBAR, L. LEVY, N. BERNAT, S. MENAHEM Dept. of Med. Neurobio., The Hebrew Univ., Jerusalem, Israel

Abstract: Obesity is a major health challenge in the modern world as obesity levels increase in an alarming rate. Obesity is mostly attributed to the lack of energy balance in the sedentary modern lifestyle but other factors, primarily the irresistible urge to eat highly-palatable energydense food, need to be taken into account. Our and others' few previous studies show that obesity entails abnormalities in the striatum, a part of the reward system, indicating a potential role for pathology in the reward system in obesity. However, it is yet to be found whether other parts of the reward system exhibit abnormalities in obesity as well. Here we used the dietinduced obesity model to induce obesity in C57 male wild-type mice. After 10 weeks of high-fathigh-sugar diet, we compared the motivation to obtain palatable food and the physiology of ventral pallidum neurons between the top third (obesity-prone) and bottom third (obesityresistant) weight gainers. We found that obesity-prone mice consistently consumed more calories compared to obesity-resistant mice. Moreover, after an overnight abstinence from the high-fathigh-sugar diet obesity-prone mice exhibited higher performance in a progressive ratio task to obtain high-fat-high-sugar precision pellets compared to obesity-resistant mice. Lastly, using whole-cell patch clamp electrophysiology we found that ventral pallidum neurons of obesityprone mice are less excitable and receive stronger inhibitory input compared with obesityresistant mice. Overall, our data indicates that the pathology in the reward system of obese mice is more widespread than previously thought and includes also the ventral pallidum. This calls for more reward-system-oriented research in trying to understand the underpinnings of obesity in modern society.

Title: Effects of high fat diet on anxiety-like behaviors and hippocampal-dependent learning: Roles of body weight and sex differences

Authors: *K. CHAN, A. BURDICK, K. RASEFSKE, J. MCGOVERN Hartwick Col., Oneonta, NY

Abstract: Past studies have shown that high fat diets impair hippocampal-dependent learning and reduce anxiety-like behaviors in rats. This experiment extended these findings by testing the effects of high fat diet (20% lard) while controlling for body weight differences across groups. Male and female Sprague-Dawley rats received either a high fat diet or regular chow for ten weeks prior to behavioral tests. Groups were weight matched prior to the experiment and weighed and fed daily throughout the experiment to maintain similar weight gains. Half of the rats were tested in an elevated plus maze for anxiety-like behaviors and the other half received training in a spatial water maze. Subjects on the high fat diet spent a significantly longer amount of time (F(1, 16) = 7.691, p = .014) and made marginally more entries into the open arms (F(1, 16) = 3.932, p = .065) of the elevated plus maze, regardless of sex. On the other hand, a probe test conducted after the water maze training showed a significant Diet x Sex interaction on latency to target (F(1,22)=4.458, p=.046). These results are consistent with the interpretation that effects of high fat diet on anxiety-like behaviors are independent of body weight changes. On the contrary, the impairment in hippocampal-dependent learning might be related to both sex differences and body weight changes associated with the diet.

Title: Energy balance regulation and obesity in mice as a function of individual rearing and western style diet exposure

Authors: L. SCHIPPER^{1,2}, S. VAN HEIJNINGEN², *E. M. VAN DER BEEK^{1,3}, G. VAN DIJK²

¹Danone Nutricia Early Life Nutr., Nutricia Reseach, Utrecht, Netherlands; ²GELIFES, Groningen Inst. for Evolutionary Life Sci., ³Dept. of Pediatrics, Univ. Med. Ctr. Groningen, Univ. of Groningen, Groningen, Netherlands

Abstract: Mice are widely used for the study of obesity and cardiometabolic comorbidities. In general, rodent obesity models rely on elevated baseline activity of the hypothalamo-pituitary adrenal axis and feeding of a western style diet. This condition has been mentioned to be anxiogenic and could underlie anhedonia and depression.

We aimed at investigating the role of rearing condition in these effects by subjecting C57Bl/6J mice after weaning to individual (IND) or social (SOC, n=2 siblings/cage) housing while being kept on a low fat (AIN93G based, 20En% as fat) diet. At postnatal day (P)43, one third of the mice from the IND and SOC groups were sacrificed and the remaining groups were split and exposed to a moderate western-style diet (WSD, 40En% as fat) or kept on low fat control diet until P126. Bodyweight was monitored and energy intake and expenditure were determined using indirect calorimetry during adolescence (P40-42) and adulthood (P105-107). In addition, mice were subjected to a sucrose preference test to assess food reward mechanisms during adulthood (P74-79) and to an elevated plus maze test (EPM) to assess baseline levels of anxiety during adolescence (P39) and adulthood (P92). After dissection plasma adipokines and corticosterone were measured and body composition was determined by carcass analysis. IND mice showed lower body weight gain during adolescence than SOC mice, while energy intake and energy expenditure were increased. At P43 IND mice had reduced lean body mass, but significantly higher white adipose tissue mass compared to SOC mice. In adulthood, bodyweight gain of IND animals exceeded that of SOC mice, with elevations in both energy intake and expenditure. At P126, IND mice showed higher adiposity and a lower plasma adiponectin/leptin ratio. WSD exposure amplified these changes and reduced plasma levels of corticosterone. IND mice exposed to WSD showed the lowest sucrose preference index, indicating that food reward mechanisms were most blunted in this group. Baseline anxiety levels were surprisingly reduced by IND housing and by WSD exposure.

We conclude that individual rearing of male mice results in impaired adolescent lean mass development and an obese phenotype in adulthood. The latter effects are exacerbated by adult exposure to an obesogenic diet. These effects are associated with mild alterations in reward sensitivity and reduced baseline levels of anxiety, without elevated levels of glucocorticoids. These results suggest that individual rearing of mice can be regarded as a model for programmed adult obesity without elevated anxiety and hypercorticoidism.

Title: Effects of a GLP-1 agonist on hippocampal functioning underlying the learning mechanisms associated with energy regulation

Authors: *S. JONES¹, C. H. SAMPLE¹, A. HYDE¹, S. L. HARGRAVE², T. L. DAVIDSON¹ ¹American Univ., Washington, DC; ²Natl. Inst. of Heath, washington, DC

Abstract: The hippocampus is thought to play an important role in the learned control of energy and body regulation by gating inhibitory associations between environmental food cues and postingestive consequences. The hippocampus is able to regulate intake using similar mechanisms to those underlying negative feature cues in a typical serial feature negative discrimination problem. In this problem, a target cue is followed by food reward unless it is preceded by a negative feature cue. In other words, the negative feature cue signals that the target cue will not be rewarded. Previous studies with rats have shown that manipulations which interfere with hippocampal functioning also disrupt serial feature negative discrimination performance. Exposure to Western diets (WD), high in saturated fat and sugar, for as few as 12 days disrupts this discrimination and gives rise to signs of hippocampal pathophysiology (inflammation, reduced glucose transport). In the current study, we assessed the effects of administering the glucagon-like peptide-1 (GLP-1) agonist, Liraglutide, on serial feature negative discrimination performance in male and female rats. Following the achievement of asymptotic discrimination performance, the rats were divided into two dietary conditions: WD- or chow-fed, which were further subdivided into two drug conditions: 10 µg/kg Liraglutide or vehicle control. The ability to maintain discriminative responding by utilizing the negative feature cue was tested in all groups after 4d and 12d of ad lib access to diet and daily intraperitoneal injections of Liraglutide or vehicle. After 12d of diet and drug exposure, Liraglutide significantly enhanced discrimination performance compared to vehicle. This enhancement was the result of increased inhibitory control by the negative feature stimulus. This effect could not be accounted for by any nonspecific inhibitory effect of Liraglutide on performance because responding on trials with the target cue alone did not differ dependent on drug treatment. The effects of Liraglutide did not vary as a function of sex or diet. Furthermore, Liraglutide had no significant effects on body weight. Recent reports indicate that inhibition of feeding and perhaps other behaviors depends on activation of an excitatory pathway originating in the hippocampus (Sweeney and Yang, 2015) and that activation of this pathway depends on GLP-1 signaling (Hsu et al, 2017). The present

findings indicate that administration of a GLP-1 agonist specifically promotes a form of hippocampal-dependent appetitive response inhibition, perhaps by operating on the same circuits.

Title: Psychological symptoms is a determinant of body mass index among patients with musculoskeletal pain: A link to vitamin D and calcium

Authors: *K. K. ABDUL-RAZZAK, M. KASSAB

Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: A high prevalence of psychological symptoms and vitamin D among patients with musculoskeletal pain (MSP) and obesity has been observed. People complaining of anxiety and depression are having frequent weight change compared with those without such symptoms. To date, most of the published studies, examined the co-prevalence of chronic pain, psychological symptoms and weight gain, although the loss of appetite also can occur when anxiety is high. The aim of the current study was to investigate the association between body mass index and psychological symptoms among patients with MSP in relation to vitamin D and calcium. A total of 207 participants with MSP were involved. The Hospital Anxiety and Depression Scale (HADS) were used to assess psychological symptoms. Participants' dietary habits and vitamin D were measured. The relation between their food appetite and anxiety level were recorded. Participants with MSP had a high prevalence of vitamin D deficiency (85.5%), anxiety (52.7%), and depression (39.1%) markedly. There was a significant relation between the pattern of appetite and anxiety (p=0.024), which reflected by significant changes in BMI (p=0.013).BMI tend to fluctuate (increase or decrease) depending on the influence of anxiety on appetite. Spearman correlation analyses show that anxiety is negatively associated with daily calcium intake and age ($r^2 = -0.124$, p=0.038, $r^2 = -0.227$, p=0.001, respectively), and positively associated with depression ($r^2 = -.613$, p = < 0.001).

The result of the current study showed that anxiety which negatively correlated daily calcium intake is a determinant of BMI among patients with Musculoskeletal Pain through its influence

on appetite.

Title: Parasympathetic output contributes to the resolution of uncontrolled diabetic hyperglycemia by vertical sleeve gastrectomy in a murine model of type 1 diabetes

Authors: C. R. BOYCHUK¹, K. C. SMITH², *B. N. SMITH³ ¹Physiol., ²Pysiology, Univ. of Kentucky, Lexington, KY; ³Dept Physiol, Univ. of Kentucky Dept. of Physiol., Lexington, KY

Abstract: Recent evidence supports the emerging hypothesis that brainstem autonomic neurons are affected by and contribute to systemic glucose regulation, particularly after bariatric surgery. Vertical sleeve gastrectomy (VSG) can result in resolution of type 2 diabetes in humans and animal models, but information about effects of VSG on type 1 diabetes is scarce. Extant data does not extend beyond 14 days post-surgery, nor does it directly investigate the contribution of parasympathetic regulation in diabetic remission after VSG. Here, we used the streptozotocin (STZ)-treated mouse model of type 1 diabetes to determine effects of VSG on uncontrolled hyperglycemia, weight, caloric intake, and markers of brainstem and peripheral glucose metabolism to test the general hypothesis that a brain-centered glucose regulatory system contributes to systemic glucose regulation after bariatric surgery. We also tested whether the contribution of autonomic regulatory systems changes at 14, 30, or 60 days after surgery. Uncontrolled hyperglycemia (>300 mg/dl) was maintained for 2 days in STZ-treated mice, at which time VSG or sham surgery was performed. After VSG, blood [glucose] was normalized shortly after surgery (<24 hrs) and could persist for 2 months; elevated blood glucose persisted in sham-operated, STZ-treated mice. Normalization of blood [glucose] in the STZ-treated VSG mice was accompanied by a normalization of food intake, similar to age-matched vehicle-VSG controls. Metabolic testing indicated that glucose tolerance was similar between STZ-treated VSG and vehicle-VSG groups 14 days after surgery. Although the glucose tolerance of the STZ-VSG group was improved compared to the STZ-naïve group, the STZ-VSG groups was less

tolerant of glucose at 2 months compared to vehicle-VSG. Examination of glucose tolerance in the presence of a parasympathetic blocker, methylscopolamine, indicated that parasympathetic output contributes to the early resolution of glucose metabolism (14 days post-VSG), but has less influence at later times (2 months). Interestingly, plasma insulin levels were unaffected by VSG surgery. Correspondingly, we examined molecular and electrophysiological markers of glucose metabolism in the dorsal vagal complex. Short (3.5 hr) exposure to elevated [glucose] in vitro resulted in elevated GLUT4, but not glucokinase (GCK), mRNA expression. After STZ-induced chronic hyperglycemia, glucose-sensitivity was significantly reduced in NTS GABA neurons, and VSG restored glucose responsiveness. These results are consistent with a role for vagal complex control of systemic glucoregulation involving a vagally-mediated gut-brain-axis.

Title: The role of type 3 adenylyl cyclase in neuronal cilia

Authors: *X. CHEN^{1,2}, Y. ZHOU², L. QIU², M. STROBEL², A. STERPKA¹ ¹Dept. of Molecular, Cell. and Biomed. Sci., ²Univ. of New Hampshire, Durham, NH

Abstract: Cilia are rigid, centriole-derived, microtubule-based organelles present in a majority of vertebrate cells including neurons. They are considered the cellular "antennae" attuned for detecting a range of extracellular signals including photons, odorants, morphogens, hormones and mechanical forces. The ciliary microenvironment is distinct from most actin-based subcellular structures such as microvilli or synapses. Numerous G protein-coupled receptors (GPCRs) including odorant receptors, rhodopsin, Smoothened, and type 6 serotonin receptor are found in cilia, suggesting that these tiny processes largely depend on metabotropic receptors and their tuned signals to impact neuronal functions. The type 3 adenylyl cyclase (AC3), widely known as a cilia marker, is highly and predominantly expressed in olfactory sensory cilia and primary cilia throughout the brain. We discovered that ablation of AC3 in mice leads to pleiotropic phenotypes including anosmia, failure to detect mechanical stimulation of airflow, cognitive deficit, obesity, and depression-like behaviors. Multiple lines of human genetic evidence also demonstrate that AC3 is associated with obesity, major depressive disorder (MDD), sarcoidosis, and infertility. Here we present our recent research progress on AC3.

Abstract: Erythropoietin (EPO) is a glycoprotein that is released by the kidneys and liver to facilitate red blood cell production, and therefore, EPO expression is increased in response to hypoxia or blood loss. Recent studies have indicated that EPO administration can reduce or prevent some of the pathological mechanisms of secondary brain injury due to excessive inflammatory responses and oxidative damage. EPO also enhances angiogenesis. In one recent study it has been shown that acetylation of the transcription factor HIF-2a regulates EPO production during pathophysiological stress induced by hypoxia. Acetylation is necessary to recruit this transcription factor to the erythropoietin gene enhancer and increase erythropoietin gene transcription. In earlier studies we have used acetate supplementation with glyceryl triacetate (GTA), which generates acetate and glycerol on hydrolysis in vivo, to improve outcomes after traumatic brain injury (TBI). Oral GTA has been repeatedly proven to increase acetate levels in all tissues. The intracellular acetate becomes available for various metabolic and regulatory reactions through the portal of acyl-CoA short chain synthetase 2 (Acss2), the only known enzyme in the cytoplasm and nucleus of cells that can convert free acetate to acetyl-CoA. Acetate supplementation using GTA decreases expression of anti-inflammatory cytokines such as interleukin-1 β (IL-1 β) via regulating histone acetylation. Based on these earlier findings, we proposed to develop oral acetate supplementation using GTA as a way to augment acetylationbased genetic regulatory mechanisms involved in the response to and recovery from brain injury hemorrhage and hypoxia. We used gene array to begin screening for potential functional associations with Acss2 in the brain by comparing gene expression between Acss2 gene knockout mice and wild type mice. Six groups were compared using Acss2 -/- and wild type mice; normally fed, 48 hr fasted and GTA fed. The greatest number of gene expression changes was observed between 48 hr fasted wild type and Acss2 -/- mice (1579 lower expression, 1320

higher expression). In contrast, very few expression changes were observed between GTA fed wild type and Acss2 -/- mice (88 lower expression, 87 higher expression). Gene expression changes in the brain among the different groups linked Acss2 with a wide network of cellular regulatory processes ranging from signal transduction to regulation of gene expression and immune system function. These findings expand the regulatory functions of Acss2 well beyond its classical role in lipid synthesis.

Title: Impacts of stress on glucocorticoids and energy homeostasis: Interactions between liver glycogen, corticosterone, CBG, and glucose concentrations following inescapable tail shock in rat

Authors: *M. A. CONOSCENTI, N. M. WILLIAMS, T. R. MINOR Psychology, UCLA, Los Angeles, CA

Abstract: An acute traumatic event can lead to life-long changes in stress susceptibility and result in psychiatric disease, such as Post-Traumatic Stress Disorder (PTSD). We have previously shown that access to a concentrated glucose solution for 24 hours beginning immediately after trauma decreased stress-related pathology in the learned helplessness model of PTSD and comorbid major depression. Our recent parametric studies show consistent results with previous research, suggesting a critical window of approximately three hours following trauma in which intervention may be effective in modifying stress-related behaviors. To gain further insight into the mechanism of glucose treatment in mediating stress susceptibility following trauma, we assessed the effects of post-stress glucose administration on blood glucocorticoid response and glucose levels at various timepoints including 24 hours following trauma, and before, during, and after the proposed intervention critical window. We exposed 64 male Sprague-Dawley rats to 100 inescapable tail shocks or simple restraint in the learned helplessness procedure. Rats in each stress condition had access to a 40% glucose solution or water. Animals were tested for freezing and shuttle-escape behavior 24 hours after the acute stress session. In the first experiment, we measured liver glycogen concentrations, as well as

plasma concentrations of glucose, corticosteroid-binding globulin (CBG), free corticosterone and total corticosterone, after exposure to 5 FR-1 shuttle-escape trials. We found no differences in any measure between animals that received glucose or water in the simple restraint condition. However, animals that were given access to glucose after exposure to inescapable shock exhibited decreased free corticosterone, increased CBG, and increased liver glycogen concentrations when compared to their water-drinking counterparts. In the second experiment, we measured plasma concentrations of glucose, CBG, free corticosterone and total corticosterone at four time points: pre-stress, immediately post-stress, three hours post-stress, and six hours post-stress. We hypothesized that there would be a reduction of free corticosterone beginning at three hours post-stress that would persist through six hours post-stress. We expected to see this reduction in free corticosterone correlate to increased CBG and glucose concentrations. These results imply that post-stress glucose consumption reestablishes blood glucose homeostasis, thereby upregulating CBG binding of corticosterone. This data suggest the upregulation of CBG is a mechanism by which glucose exerts its prophylactic effects.

Title: Sub-chronic Oleoylethanolamide treatment differentially afftects body weight, gut microbiota composition and cytokines expression in normal and histamine deficient mice

Authors: *G. PROVENSI¹, M. DI PAOLA¹, E. BONECHI¹, A. COSTA¹, P. BLANDINA¹, G. CLARKE³, C. BALLERINI¹, C. DE FILIPPO⁴, M. B. PASSANI² ¹Dept. di Neuroscienze, Psicologia, Area del Farmaco e Salute del Bambino, ²Dept. di Scienze della Salute, Univ. degli Studi di Firenze, Firenze, Italy; ³Univ. Col. Cork, Cork, Ireland; ⁴Inst. di Biometeorologia, Consiglio Nazionale delle Ricerche, Firenze, Italy

Abstract: Recent evidence suggests that the gut microbiota play a role in energy harvest, storage, and expenditure and its composition was shown to differ in lean and obese humans and animals and to change rapidly in response to dietary factors. Recently we demonstrated that the fat-derived satiety factor oleoylethanolamide (OEA) requires the integrity of the central histaminergic system to fully exert its hypophagic action. Here we evaluate the effects of OEA sub-chronic treatment on food intake, body weight, gut microbiota composition, plasma

tryptophan metabolites and cytokines expression in histidine decarboxylase knock out (HDC-KO) mice and wild type (WT) littermates. Male mice received daily i.p. injections of OEA (10 mg/kg) or vehicle (PEG:Tween80:saline 5/5/90) for 11 days, 1 hr before dark onset. A significant reduction in cumulative food consumption as well as in body weight was observed in OEA-treated WT mice with respect to vehicle-treated animals. Both effects were attenuated in HDC-KO mice. Amplicons containing the V3-V5 region of the bacterial 16S rRNA gene were obtained from DNAs extracted from faecal samples, sequenced on a Roche 454 GS FLX+ platform and then analyzed using bioinformatic tools. In keeping with the decrease of weight, an enrichment of the phylum Bacteroidetes and a reduction of Firmicutes emerged in the group of OEA-treated WT mice. This trend in terms of phyla, is associable to the appearance of a "lean" microbiota instead of an "obese", where the trends of the two phyla are reversed. Moreover, PICRUSt analysis revealed and enrichment of sequences associated with aminoacids metabolism. Consistently, we observed a tendency in increase of tryptophan and kynurenic acid and reduction of kynurenine plasma levels in WT but not in HDC-KO mice. OEA sub-chronic treatment also modulated the expression of cytokines from the Peyer's Patches obtained from WT animals and stimulated with faseolamine: OEA decreased the production of the inflammatory cytokines IFNy, IL-17 and IL-4, IL-6 as well CXCL-1 and CXCL-2, whereas it increases IL-10 production and Bcell activating factor (BAFF). In summary, we observed that OEA repeated administrations reduced food intake and body weight, altered the gut microbiota towards a lean phenotype and modulated the expression of pro-inflammatory cytokines. All these effects seem to require the histaminergic system. We acknowledge the Joint Programming Initiative - A Healthy Diet for a Healthy Life for support of AMBROSIAC project.

Title: Muscarinic acetylcholine receptor antagonism decreases sign-tracking behavior in rats

Authors: *C. J. FITZPATRICK, J. D. MORROW

Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Muscarinic acetylcholine receptors (mAChRs) facilitate dopamine (DA) transmission within the mesolimbic reward system. Our laboratory uses a Pavlovian conditioned approach (PCA) paradigm to investigate this system and addiction vulnerability in rats. Briefly, rats are repeatedly presented with a conditioned stimulus (CS; a lever) followed by the responseindependent presentation of an unconditioned stimulus (US; a food pellet). Over multiple training sessions, two phenotypes can develop: sign-tracking (CS-directed behavior) and goaltracking (US-directed behavior). Sign-trackers (STs) attribute incentive-motivational value to reward-related cues and are more vulnerable to addiction-like behaviors, such as cue-induced reinstatement of drug-seeking. In addition, sign-tracking behavior requires DA transmission within the mesolimbic reward system. Therefore, we hypothesized that mAChR antagonism would attenuate the acquisition and expression of sign-tracking behavior. In agreement with our hypothesis, scopolamine (0.3-3 mg/kg; i.p.), a nonselective mAChR antagonist, decreased the acquisition of sign-tracking behavior (and increased goal-tracking behavior) during nine daily PCA training sessions. Next, during an additional PCA training session, previously vehicletreated rats received scopolamine (3 mg/kg), which reduced the expression of previously learned sign-tracking behavior in rats. Taken together, these results demonstrate that mAChRs modulate sign-tracking behavior and suggest that mAChR antagonism might be a useful component of new treatment strategies for addiction.

Title: The effect of cholingergic interneuron ablation and delta-opioid receptor internalization in the nucleus accumbens shell on cue-guided choice

Authors: *A. K. MORSE¹, V. LAURENT², B. W. BALLEINE² ¹UCLA, Los Angeles, CA; ²Psychology, Univ. of New South Wales, Sydney, Australia **Abstract:** Animals can use information from their environment to guide their choices between actions. This ability can be studied through outcome-specific Pavlovian-instrumental transfer (PIT), in which a cue associated with a particular outcome biases choice between actions towards the response that earned that same outcome. The nucleus accumbens shell (NAc-S) is a neural substrate of particular interest, as it is recruited at the point of transfer, and not in encoding either Pavlovian or instrumental contingencies. Delta-opioid receptor (DOR) signaling within the NAc-S is crucial for specific PIT expression, and a plastic change in DOR expression within the NAc-S occurs during Pavlovian learning that appears to be later recruited for specific PIT. During contingent Pavlovian learning, DOR accumulates at the membrane of NAc-S cholinergic interneurons (CINs), and this accumulation is positively correlated with the magnitude of specific PIT expression.

Here we investigated the respective roles of CINs, and of DOR accumulation, within the NAc-S in specific PIT expression. In our first experiment, we selectively ablated NAc-S CINs using targeted caspase activation in ChAT-cre rats, and found that CIN ablation impaired specific PIT expression. However, incomplete ablation preserved some specific transfer. In our second and third experiments, we investigated the effect of transient reduction of membrane DOR expression in DOR-eGFP mice, and in the NAc-S in rats. SNC80 is a selective DOR agonist that triggers profound DOR internalization, and we have found that this internalization is transient in the NAc-S of trained DOR-eGFP mice. 24 hours after SNC80 exposure, membrane DOR expression was reduced, but not eliminated, on NAc-S CINs. However, 48 hours after SNC80 exposure, DOR expression returned to an accumulated state, indicating that CINs have 'memory' for this plastic change that occurs in Pavlovian learning. We therefore exploited SNC80 to investigate specific PIT expression when DOR expression was reduced, and when recovered to an accumulated state.

When SNC80 was administered systemically in DOR-eGFP mice, or infused directly into the NAc-S in rats, specific PIT expression was impaired at 24 hours, when DOR expression was reduced. Specific transfer recovered at 48 hours, when DOR had recovered to an accumulated state. These experiments, considered together, suggest that DOR accumulation at the membrane of CINs in the NAc-S is critically involved in the ability of reward-predictive cues to bias choice between actions.

Title: Optogenetic probing of ventral pallidal neurons in motivated behaviors

Authors: *C. BRAVO-RIVERA, M. STEPHENSON-JONES, C. FERNANDES-HENRIQUES, B. LI Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Recently, there have been significant advances in the characterization of neuronal circuits that influence motivated behaviors, including aversion and reward-related behaviors. The ventral pallidum (VP) is a corticolimbic-motor interface that has been previously linked to conditioned aversion (Itoga et al 2015) and reward-seeking (Tachibana and Hikosaka 2012). Whereas most neurons in VP are GABAergic, a subpopulation of VP projection neurons is glutamatergic (Root et al 2015). VP neurons project to the lateral habenula (LHb), a key structure mediating reward and aversion encoding and, therefore, these projections likely gate aversion and reward encoding. Here, we aim to characterize whether VP neurons mediate motivation related to reward approach and aversion avoidance. First, we tested whether optogenetic activation or silencing of VP somata or projections to LHb generate real-time place preference in a two-chamber box. Optogenetic activation of VP GABAergic somata or their projections to LHb induced strong place preference for the chamber paired with laser stimulation (p < 0.001). Conversely, optogenetic activation of VP glutamatergic somata or their projections to LHb induced strong place aversion for the chamber paired with laser stimulation (p < 0.001). Silencing VP GABAergic or glutamatergic somata, or their projections to LHb, had no effect on real-time place preference (p > 0.1). We next tested whether VP neurons are necessary for reward approach. We developed a task in which five auditory tones predict different levels of reward (water) in head-fixed, water-deprived mice. To obtain the water reward, mice needed to lick the water spout within a time limit after the cue presentation. We found that silencing of VP GABAergic, but not glutamatergic (p > 0.1), somata or projections to LHb reduced reward attainment by diminishing licking responses (p < 0.05). Conversely, activation of VP GABAergic somata or projections to LHb increased licking responses (p < 0.05). Activation of VP glutamatergic somata decreased licking responses (p < 0.05). Together, these results suggest that VP GABAergic neurons are sufficient and necessary for reward approach, whereas VP glutamatergic neurons antagonize reward approach and generate aversion. Characterization of this VP circuit will broaden our understanding of how motivation is encoded in the basal ganglia.

Title: A direct comparison of neuronal firing in passive aversive and passive appetitive conditioning and extinction in the prelimbic and infralimbic cortices of the mPFC

Authors: *B. KAMINSKA¹, D. E. MOORMAN²

¹Neurosci. and Behavior, Univ. of Massachusetts, Amherst, MA; ²Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Neurons of the rat medial prefrontal cortex (mPFC), specifically those in prelimbic (PL) cortex, are modulated by positive and negative cues and outcomes. Neurons in the infralimbic (IL) mPFC are modulated by previously-informative cues that no longer predict an outcome (i.e., after extinction learning). These dichotomous roles are not observed in all cases of conditioning, indicating that more work is required to understand PL vs. IL function during learning. To address this issue, we recorded from PL and IL during learning and extinction of Pavlovian cue and outcome pairings in both appetitive and aversive conditions. Female and male Wistar rats were surgically implanted with intraoral catheters which allowed a brief delivery of either an aversive or appetitive stimulus (quinine or sucrose). Electromyography wires were implanted into the anterior digastric which allowed the measurement of taste reactivity to the stimulus based on hedonic reaction (licks for appetitive stimuli and gapes for aversive). Drivable tetrode arrays were implanted with 4 tetrodes implanted in PL and 4 tetrodes implanted in IL, allowing simultaneous neuronal recordings. Electrodes were driven down ~500um to access a different population of neurons after every session for a total of 5 sessions. Each recording session consisted of 2 days, and the first day was split into 3 sections. During the first section, 3 auditory stimuli were presented in a random order (habituation). During the second section, each tone presentation was followed by sucrose, quinine, or no liquid delivery (conditioning). During the third section, no outcome was delivered after tone presentation (extinction). On the second day of recording the three tones were played with no outcome following them (extinction recall). Currently we have recorded from 2 rats with two sessions each, totaling 54 neurons. Of these, 32 neurons were located in PL and 22 in IL. In the subset of significantly event-modulated neurons (15 PL and 6 IL), there was no consistent pattern of neuronal activation or inhibition to cue or stimulus deliveries during habituation, conditioning, extinction, and extinction recall. These preliminary results suggest a highly heterogeneous coding structure by mPFC neurons during Pavlovian conditioning and extinction. More recordings and analysis, currently underway, will augment these preliminary data and better define the parameters of mPFC neuronal encoding of learning.

Title: Songbirds implement multiobjective reinforcement learning with action-specific cost functions

Authors: *R. CHEN, D. MURDOCH, J. H. GOLDBERG Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: Standard reinforcement learning (RL) algorithms enable an agent to optimize a single cost function such as reward, but it remains poorly understood how an animal might pursue multiple objectives at once. Multi-objective RL can be implemented in machines by endowing a single agent with multiple sub-agents each tasked with optimizing objective-specific reinforcement. Here we use songbirds to test if two behaviors with distinct objectives - vocalization and navigation - are shaped by objective-specific reinforcers. We demonstrate that strobe light reinforces place preference but not song syllables. Playback of song-like sound reinforces song syllables but not place preference. This double dissociation demonstrates that a single animal can possess distinct action-generating systems shaped by correspondingly distinct cost functions.

Title: Adaptive thermogenesis is increased by long term co-adimistration of central GLP-1 and GIP

Authors: *Y. LEE^{1,2}, D. CHUN^{1,2}, C. NAMKOONG^{1,3}, M. KIM^{1,2}, H. LEE¹, H. CHOI^{1,2,3,4} ¹Seoul Natl. Univ., Seoul, Korea, Republic of; ²BK21Plus Biomed. Sci. Project Team, Seoul, Korea, Republic of; ³Neurosci. Res. Inst., Seoul, Korea, Republic of; ⁴Wide River Inst. of Immunol., Hongcheon, Korea, Republic of

Abstract: The brain network that regulates adaptive thermogenesis receives inputs from temperature- and energy-sensing neurons through hypothalamic and brain stem areas. Glucagonlike peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are both wellknown gut hormones that acts on brain to regulate body weight and food intake. In this study, we investigated the effect of long term co-administration of central GLP-1 and GIP on energy expenditure. We co-administered GLP-1 and/or GIP intracerebroventricularly (ICV) in mice with osmotic mini pumps for 17 days. GLP-1 (3nmol/day), GIP (6nmol/day) or both GLP-1 and GIP were continuously administered during 17 days. Comprehensive Laboratory Animal Monitoring System was used to measure O₂ consumption, CO₂ production, RER, locomotion and energy expenditure. Thermogenic marker, UCP-1 was measured in white adipose tissue and brown adipose tissue. Body weight and food intake were significantly decreased by coadministration of GLP-1 and GIP during the first week. After two weeks, co-administration of GLP-1 and GIP significantly increased energy expenditure without changing locomotion. GLP-1 and GIP co-administrated mice showed significantly higher expression of UCP-1 in white adipose tissue and brown adipose tissue. Therefore, the present results suggest that coadministration of GLP-1 and GIP increases thermogenesis via direct modulation of adipocyte metabolism. Our findings suggest that co-administration of GLP-1 and GIP may have synergistic anti-obesity effect on both food intake and energy expenditure.

Title: Genetically distinct ventral pallidal neurons encode the motivation for reward approach and punishment avoidance

Authors: *M. STEPHENSON-JONES, C. C. BRAVO-RIVERA, C. FERNANDES-HENRIQUES, B. LI

Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Motivated behaviours can be driven by two opposing processes, the desire to obtain a reward or the drive to escape a punishment. The ventral pallidum is critical for attributing motivation salience to cues that predict reward and for invigorating reward seeking behaviour. However, sparse evidence suggests that it may also play a role in motivating avoidance behavior. Here we show that two genetically distinct ventral pallidal populations encode the motivation to approach or avoid. Single-unit recording in the ventral pallidum of mice undergoing conditioned reward and punishment tasks revealed three functional distinct clusters, which encoded 1) incentive salience, 2) aversive salience and 3) general vigor. Optogenetic inhibitory tagging demonstrated that neurons that encoded incentive salience were GABAergic, as were the neurons that encoded general vigor. In a Pavlovian reward task, these incentive salience neurons encode the expected reward value through a phasic increase in neuronal firing. As with dopamine neurons, the response to expected reward diminishes with training; but unlike dopamine neurons, the response to reward cues inverts and is signaled with a decrease in neuronal firing when mice are sated. This suggests that GABAergic ventral pallidal neurons encode a state dependent prediction error signal. These neurons also signal state value on a longer timescale as their baseline firing was modulated by the state depending on block type (reward vs punishment). Taken together GABAergic VP neurons signal the positive motivational state and incentive value to invigorate reward seeking on a short and long timescale. In contrast the Glutamatergic ventral pallidal neurons were phasically excited by the expectation or delivery of punishment. As with GABAergic neurons, the baseline firing was modulated depending on the block condition, indicating that these neurons encode aversive salience on both long and short time scales. Together our data demonstrates that there are two genetically distinct types of ventral pallidal neurons that encode either incentive or aversive salience and are critical for driving reward approach or punishment avoidance.

Title: Effect of paternal obesity on the central nervous system reward circuitry in offspring

Authors: *G. SINDI

Biol. Sci., Ohio Univ., Athens, OH

Abstract: Paternal and maternal diet-induced obesity strongly impact subsequent generations. The endocannabinoid system (ECS) is responsible for appetite, and modulating reward processing and includes cannabinoid receptor type-1 (CB1-R). CB1-R expression is altered due to overeating. Previous studies have focused on the direct effect of CB1-R in mice eating high fat diet (HFD) and not their offspring. Our team studied the effect of paternal obesity on offspring and demonstrated that voluntary physical activity occurred more in male offspring of HFD-fed fathers (Gr 2) at 1.5 months of age than offspring of low fat diet (LFD)-fed fathers (Gr 1). Female offspring ran more than males in three groups: HFD-fed father offspring at 6 and 12 months, and LFD-fed father offspring at 1.5 months. Female offspring from Gr2 showed higher food consumption at 1.5 months than Gr1 females. We hypothesized that alterations within the CNS reward circuitry are related to different levels of physical activity and food preference in offspring of obese HFD-fed fathers versus non-obese LFD-fed fathers. Brain samples from offspring at 1.5, 6, and 12 months of age were used for immunohistochemistry. Sections were incubated in primary polyclonal rabbit anti-CB1-R antibody against the C-terminus of the receptor, and secondary conjugated Horseradish Peroxidase (HRP) goat anti-rabbit secondary antibody. CB1-R were detected using DAB substrate HRP, which generates a brown to black product when cleaved by DAB and quantified using ImagePro. Our results demonstrate the effects of paternal obesity on the CNS reward circuitry in offspring mice. We will discuss the expression of CB1-R depending on age, sex, and paternal diet. This study further clarifies the relationship between paternal obesity, voluntary exercise and food intake and CB1-R expression alterations in the brain and may lead to discovery of new agents for prevention of obesity in offspring of obese parents.

Title: Effects of age, sex, and alcohol access on sign-tracking/goal-tracking and omissioncontingency learning in rats
Authors: A. COOK¹, B. GAEDDERT¹, H. FISHER², *C. L. PICKENS¹ ²Psychological Sci., ¹Kansas State Univ., Manhattan, KS

Abstract: Previous research from our laboratory has found that 6 weeks of chronic intermittent access of alcohol during adolescence and early adulthood (PND 26-66) in male rats leads to long-term behavioral changes that include faster omission contingency learning in a lever-based autoshaping task. Subsequent examinations did not find this pattern if the chronic intermittent access occurred in adult males or adolescent females. However, as the adolescent males consumed more alcohol than the adult males or adolescent females, it is unclear whether this differential effect is due to a heightened sensitivity to the effects of alcohol in adolescent males or merely related to the higher level of alcohol consumed in this group. In order to examine this, we gave adolescent male, adolescent female or adult male rats injections with fixed doses of saline or alcohol to ensure that all rats received the same dose of alcohol. Rats received 0, 0.875 or 1.75 g/kg alcohol injections twice per day on Monday, Wednesday and Friday for 6 weeks. Thus, rats received 0, 1.75, or 3.5 g/kg of alcohol during each injection day. Rats began behavioral training 18 days later. During autoshaping training, extension of two levers signaled food delivery regardless of responding. In the subsequent omission contingency phase, presentation of one lever signaled food delivery regardless of responding and presentation of the other lever predicted reward if the rat did not press the lever, but pressing this lever canceled the reward delivery. When compared with saline treatment, alcohol injections had no effect on behavior during the autoshaping phase. However, when we examined terminal levels of signtracking and goal-tracking behaviors (responses/trial) in the autoshaping phase, we found that rats in the adult male groups made significantly more sign-tracking responses than the adolescent female groups (but not the adolescent male groups), but there were no differences between the groups in goal-tracking behaviors. We will also present our research on the effects of alcohol on behavior in the omission contingency task.

Title: Studying temporal decision making in a free-operant foraging paradigm

Authors: *C. CROUSE, S. NICOLA

Dominick D. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The delay-discounting paradigm is used to study how animals make decisions about how long to wait to receive reward and analyze the brain areas involved. However, results from this paradigm conflict with ecological observations about animal foraging where food is distributed in discrete patches, bringing these conclusions into doubt. We are developing an operant-conditioning paradigm modeled on animal choice in the wild to study foraging behavior. Food-restricted rats are trained to press a lever to receive sugar, but each press increases the wait time before the next lever presentation. Pressing a second lever returns the wait time to its original value after a reset period, modeling the time to travel between patches of food. We have found that increases in the reset time causes animals to wait longer for rewards, suggesting that rats are responsive to the task parameters and validating predictions from foraging theory. Future experiments will create a model of optimal choice and test the role of nucleus accumbens dopamine in this task.

Title: Bariatric surgery reduces effort to obtain a sweet drink

Authors: *H. R. KISSILEFF¹, G. M. PAYNE², J. D. HAMM², M. HERZOG³, J. JANG³, A. SHECHTER³, B. LAFERRERE³, F. X. PI-SUNYER³, J. ALBU⁴ ¹New York Obesity Nutr. Res. Ctr. - Med., ³Med. - Obesity Res., ²Columbia Univ. Med. Ctr., New York, NY; ⁴Med. Endocrinol., Mt. Sinai-St. Luke's Hosp., New York, NY

Abstract: Mechanisms for reduction of food intake after bariatric surgery are not thoroughly understood. Bariatric surgery induces unpleasant after-effects of eating such as plugging and dumping syndromes, which may lead to the commonly reported avoidance of sweets by food-avoidance conditioning. The mechanism underlying the avoidance of sweets is one that requires more attention. Post-surgical patients worked less for a sweet tasting solid snack food (M&Ms)

than before surgery (Am J Clin Nutr 2012;96:467–73.). To determine whether reduction of work for a sweet tasting snack extends to beverages, gastric-bypass and gastric-sleeve bariatric surgery candidates (N = 30, mean BMI = 45 kg/m^2) used a sipometer (Physiol. Behav. 2017: 171, 216– 227), that requires oral sipping pressure, to sham-sip (sip and spit out) non-caloric cherry flavored Kool Aid. The beverages were presented either sweetened with 10% sucrose-equivalent aspartame, or unsweetened, in separate counterbalanced sessions on the same trial day, on both continuous and 3-sec time increment progressive ratio reinforcement schedules. Tests were conducted within 2 to 4 weeks before surgery and again at 3 mo after surgery. Before surgery, cumulative pressure difference exerted between sweetened and unsweetened beverages during trials on the progressive ratio schedule increased significantly with differences in patients' beverage ratings of "liking", "enjoyment" sweetness intensity and "wanting" of the beverage, (all p's <.05). After surgery there were no significant correlations between any of the pressure-rating relationships. Pressure exerted in relation to valuation provides a novel measure of effort and propensity to consume. Reduced propensity to consume sweet beverages could be a contributor to reduced intake and, therefore, to weight loss after bariatric surgery. Further study of neural and hormonal mechanisms for reduction in effort to consume sweets could be used to develop non-surgical treatments for obesity.

Title: Localization of npy/agrp and pome neurons in hypothalamus arcuate nucleus (arc) using ihe and tissue clearing technique: Comparative study of human and mouse

Authors: *K. MIN SUN^{1,2}, H. SONG¹, C. NAMKOONG^{1,3}, Y. LEE^{1,2}, J. OH¹, Y. CHUNG¹, H. CHOI^{1,2,3,4}

¹Seoul Natl. Univ., Seoul, Korea, Republic of; ²BK21Plus Biomed. Sci. Project Team, Seoul, Korea, Republic of; ³Neurosci. Res. Inst., Seoul, Korea, Republic of; ⁴Wide River Inst. of Immunol., HongChun, Korea, Republic of

Abstract: Neuropeptide Y (NPY) / Agouti-related peptide (AgRP) and Pro-opiomelanocortin (POMC) neurons are the major regulators of feeding behavior and body weight. Both populations have different roles on appetite. In a previous study with mouse hypothalamus, AgRP/NPY neurons are located in the medial side of ARC while POMC neurons are located in

the lateral side of ARC. However, only few studies investigated the distribution of AgRP/NPY and POMC neurons in human hypothalamus. We investigated the distribution of AgRP/NPY and POMC neurons throughout the mouse brain and human hypothalamus by immunohistochemistry (IHC) and tissue clearing technique. Tissue clearing technique is a novel technique which enables three-dimensional visualization of immunostained tissue. We found that AgRP/NPY and POMC neurons were distributed in a specific locations as previously reported. We were able to document three-dimensional distribution of POMC neurons using tissue clearing technique. Also in human hypothalamus, AgRP/NPY and POMC neurons were localized in a specific locations throughout the ARC. To elucidate the functional aspects of each neuron, co-localization of GLP-1R (which is the target of anti-obesity drug, GLP-1) was investigated. In mouse brain ARC, GLP-1R was not expressed in NPY neurons. However, about half of POMC neurons expressed GLP-1R (45.9%). The distribution of AgRP/NPY and POMC neurons in human and mouse brain ARC, may facilitate obesity research and anti-obesity drug development.

Title: A novel role for acid sensing ion channels in pavlovian conditioning

Authors: ***A. GHOBBEH**¹, S. M. ALAM², R. FAN³, R. J. TAUGHER⁴, R. T. LALUMIERE⁵, J. A. WEMMIE³

¹Psychiatry, The Univ. of Iowa, Iowa City, IA; ²Psychiatry, Univ. of Iowa Dept. of Psychiatry, Iowa City, IA; ⁴Psychiatry, ⁵Dept Psych, ³Univ. of Iowa, Iowa City, IA

Abstract: Pavlovian conditioning is a fundamental form of learning and memory implicated in a variety of behaviors. Pavlovian conditioning involves learning the association between a neutral, conditional stimulus (CS) paired withand an unconditional stimulus (US), which can be either intrinsically aversive (e.g. foot shock) or rewarding (e.g. food). Our previous studies suggest that Pavlovian conditioning to an aversive US depends on synaptic plasticity in the amygdala via Acid Sensing Ion ChannelsIs (ASICs). Here, we asked whether ASIC1A, a critical ASIC subunit,

is also required for Pavlovian conditioning to a rewarding US. We tested mice expressing ASIC1A versus mice lacking ASIC1A using automated chambers to quantify behavioral responses to 20 pairings per day over multiple days of a CS (tone + light) with a rewarding US (Ensure). Three experiments were performed testing three different CS-US pairing strategies: 1) CS immediately preceded US, 2) CS and co-initiated with US co-initiated simultaneously, and 3) CS explicitly unpaired fromand US explicitly unpaired. In these experiments, multiple ASIC1A-dependent effects were observed. Surprisingly,Together, the results suggest that rather than causing impairment, loss of ASIC1A unexpectedly improved Pavlovian reward conditioning by increasing learning precision and efficiencyenhancing learning and memory. NonethelessTogether, these results suggest a fundamental difference in the effects of ASICs in two opposingtwo forms of Pavlovian learning and memory. They also offer a potential target for differentially manipulating reward and aversion in the context of mental illnesses such as drug

addiction and depression. More work is needed to better understand this unexpected improvement in reward conditioning. Nonetheless, these results suggest a fundamental difference in the effects of ASICs in two forms of Pavlovian learning and memory. They also offer a potential target for differentially manipulating reward and aversion in the context of mental illnesses such as drug addiction and depression.

Title: Calorie information modulates reward and control activation in response to food images

Authors: *A. L. COURTNEY, K. M. RAPUANO, E. K. PECONGA, T. F. HEATHERTON, W. M. KELLEY

Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Obesity is a major public health problem in the United States, with more than two out of three of adults categorized as overweight or obese (NIDDK, 2016). In response, public health departments have moved to mandate that restaurants publish caloric data at the point of purchase, with the hope of biasing consumer purchasing decisions toward lower calorie options (Berman, 2008; Roberto, 2010). However, the efficacy of this approach has not been well understood at the level of value processing and decision-making. The present study sought to interrogate the influence of calorie information on brain responses to food cues. Specifically, we hypothesized

that activation in reward regions—including the nucleus accumbens (NAcc) and orbital frontal cortex (OFC)-would be reduced in the presence of calorie information, but that activation in control regions-including the frontoparietal control network-would increase in the presence of calories. Moreover, because dieters are known to consider calorie content when making food choices, we evaluated dieting status as a moderator of these effects. During an fMRI scan, participants (N= 50) viewed pictures of food in which caloric information was either absent or present in a within-subject design. In the presence of calorie information, reward activation decreased whereas frontoparietal control activation increased. Further, reward activation was sensitive to both caloric information and the dieting status of the participant. A whole-brain searchlight multivariate pattern analysis (MVPA) was performed to identify regions of the brain whose activation patterns were most similar across conditions (calories VS. no calories). A group t-test comparing dieters to non-dieters revealed that dieters produced more similar activation patterns in the OFC for food images presented with calories and food images presented without calories—suggesting that dieters may spontaneously consider caloric information when viewing food cues. Taken together, these findings suggest that calorie information alters brain responses to food cues by simultaneously increasing control system activity and reducing reward system activity.

Title: C. elegans as a model system to identify novel pharmacotherapies for nicotine addiction

Authors: *B. S. NEAL-BELIVEAU¹, K. E. BREDHOLD², K. B. STEAGALL, II², S. N. KATNER³, E. A. ENGLEMAN³ ¹Psychology, ²Neurosci. Program, IUPUI, Indianapolis, IN; ³Psychiatry, IU Sch. of Med., Indianapolis, IN

Abstract: Despite the decrease in tobacco use in the United States since 1973, nicotine continues to be one of the most widely used psychoactive drugs in our society. Although the negative consequences associated with nicotine use via smoking cigarettes are well known, people find it very difficult to successfully quit. In fact, current smoking cessation pharmacotherapies only result in long-term abstinence in about 20% of quit attempts. Thus, there is a need to identify

novel, effective treatments for combating nicotine addiction. The purpose of this study was to examine the appetitive properties of nicotine in an invertebrate model of drug preference. Our laboratory has previously shown that the nematode *Caenorhabditis elegans* (*C. elegans*) demonstrates movement toward and self-exposure to various psychoactive drugs (i.e. cocaine, methamphetamine, morphine, ethanol and caffeine). The eventual goal is to use this invertebrate model to identify potential novel cessation aids at a fraction of the time and cost of many other animal models. Preference tests were performed in 6-well test plates spotted with nicotine (5, 50, 100 or 500 mM) and vehicle (water) in the opposing target zones of each well. Adult, agesynchronized worms (N2 Bristol wild-type) were placed in the center of each well and the number of worms in each target zone was counted 30 min later. Untreated worms showed a concentration-dependent preference for nicotine that was significantly enhanced when the nicotine solutions were titrated to a pH of 7. The worms were not immobilized by self-exposure to nicotine as they were able to move away when the aversive compound nonanone was subsequently added to the target zone. Preference for nicotine was significantly decreased by pretreatment with the opioid receptor antagonist naltrexone. In contrast, pretreatment with naltrexone did not alter preference for food or the known attractant benzaldehyde, suggestive of a specific effect on nicotine preference. Overall, these data suggest that the rewarding properties of nicotine can be studied in this invertebrate model. Furthermore, the ability of naltrexone pretreatment to alter the preference for nicotine lends support for the use of this model to test potential pharmacotherapies for nicotine addiction.

Abstract: The basolateral amygdala (BLA) is a cortical-like structure known to be involved in simple forms of emotional learning such as fear conditioning. It is the main entry site for sensory information to the amygdaloid complex and local plasticity in the BLA is crucial for fear memory formation. BLA principal neurons (PN) excitability is under tight control of different subclasses of inhibitory interneurons (IN). However, the contribution of each subtype of IN to sensory processing and fear learning is still poorly understood.

Using a deep brain calcium imaging approach in freely behaving mice, we aim to understand how different IN subtypes control fear learning. We further apply novel intersectional viral tools and optogenetic approaches, together with rabies-based retrograde trans-synaptic tracing to analyse how different IN subgroups interact with each other, and how this disinhibitory interplay could affect plastic changes of BLA PNs and thus gate memory formation.

Title: Noradrenergic modulation of aversive memory formation - from circuits to molecules

Authors: *B. TAN, J. JOHANSEN RIKEN Brain Sci. Inst., Wakoshi, Japan

Abstract: Noradrenergic neurons in the locus coeruleus play an important role in mood, attention, cognitive processes and learning through their diverse projections throughout the brain. Previously, we showed that noradrenaline in the lateral amygdala (LA) modulates Hebbian

plasticity mechanisms via beta-adrenergic receptors (β -ARs) to facilitate the formation of auditory fear memories, possibly via downstream signaling events that regulate long term memory formation. But it is unclear if locus-coeruleus-noradrenaline (LC-NA) projections to the LA modulate learning, and the intracellular changes that are triggered by NA release and β -AR activation in the LA to facilitate this learning. To understand these questions, we used optogenetic and viral approaches in rats to dissect the functional role of LC-NA projections to the LA during fear learning, and the underlying molecular mechanisms through which these neuromodulatory signals regulate long term memory formation. We injected retrograde canine adenovirus expressing Cre recombinase (CAV2-Cre-GFP) into the LA and adeno-associated virus expressing Cre-dependent ArchaerhodospinT (ArchT-tdtomato) into the LC. This produced expression of ArchT in the cell bodies and nerve terminals of the noradrenergic neurons, making it possible to optogenetically inhibit the LC-NA projections in the LA during auditory fear conditioning. We found that inhibition of LC-NA projections in the LA, specifically during the aversive shock period of fear conditioning, significantly reduced fear memory formation. CREBregulated transcription coactivator-1 (CRTC1) integrates calcium and cAMP signaling pathways synergistically to regulate transcriptional processes and neural plasticity through its nuclear translocation. We next examined the role of CRTC1 activity in the LA neurons during fear conditioning and found that fear learning produced a significant increase in CRTC1 nuclear accumulation in the LA neurons. To examine the function of this CRTC1 nuclear translocation, we virally expressed a dominant-negative CRTC1 (DNCRTC1) or shRNA targeting CRTC1 to reduce CRTC1 activity or expression respectively. Both manipulations reduced long term fear memory formation. These results demonstrate a temporally precise role for the activity of LC-NA projections in the LA during fear memory formation, and implicate CRTC1 as a potential mechanism for transducing noradrenergic signaling in the LA neurons into long term fear memories.

Title: Distinct long-range noradrenaline microcircuits control opposing emotional and flexible learning states

Authors: *A. UEMATSU, B. TAN, J. P. JOHANSEN RIKEN Brain Sci. Inst., Wako, Japan

Abstract: Noradrenaline neurons in the locus coeruleus (LC) play a critical role in many functions including emotional learning and behavioral flexibility. This relatively small population of neurons is traditionally believed to be anatomically and functionally homogeneous with all neurons projecting widely throughout the brain and responding similarly to salient stimuli. However, noradrenaline is important for opposing functions such as fear or extinction learning in different brain regions and some studies have reported specificity in the efferent connectivity of specific LC cell populations. Thus, one mechanism for noradrenergic modulation of opposing behavioral learning states is through distinct LC subcircuits that regulate specific aspects of behavior. We found that LC neurons displayed context-dependent interrelationships, with moderate, discrete activation of distinct cell populations by fear/safety cues and robust, global recruitment of most cells by strong aversive stimuli. Retrograde tracing studies demonstrated that distinct subpopulations of LC-noradrenergic neurons project to amygdala- and medial prefrontal cortex (mPFC) and brain-wide efferent mapping revealed that each neuronal subpopulation maintained specific connectivity with amygdala or mPFC. In a series of optogenetics experiments, we discovered that the amygdala-projecting ensemble promoted fear learning, while the mPFC-projecting cells extinguished aversive responses to enable flexible behavior. Importantly, amygdala projecting cells were more activated during high fear states, while mPFC projecting cells were more engaged during extinction. These results revealed a modular organization of the LC-noradrenaline system assembled from a mosaic of projectionand behavior-specific modules coupled with combinatorial activation modes which enables the adaptive tuning of emotional responding and behavioral flexibility.

Title: The bed nucleus of the stria terminals mediates fear expression to temporally unpredictable threats

Authors: *T. D. GOODE, G. M. ACCA, S. MAREN

Inst. for Neurosci. and Dept. of Psychology, Texas A&M Univ., College Station, TX

Abstract: The bed nucleus of the stria terminalis (BNST) is thought to mediate conditioned fear responses to sustained contextual stimuli but not phasic cues. However, contexts differ from discrete cues not only in terms of their duration, but also in the degree to which they temporally predict the occurrence of aversive outcomes. The current experiments sought to determine whether the temporal predictability of a CS (whether a cue or context), rather than CS duration, is a factor in the recruitment of the BNST. To test this hypothesis, adult male Long-Evans rats were implanted with guide cannulae aimed at the BNST. After a week of recovery, rats were conditioned in a single context with an unsignaled footshock (2 sec, 1 mA) that occurred either 1 min (short-delay; "temporally predictable") or 9 min (long-delay; "temporally unpredictable") after the animal was placed in the context. Each animal received 4 trials over 2 days (2 trials per day) and total exposure to the context was equated for all groups (i.e., all rats remained in the context for 10 min independent of when the shock was delivered); freezing behavior served as the measure of fear expression. After training, the BNST was reversibly inactivated using muscimol (a GABA receptor agonist) or NBQX (an AMPA receptor antagonist) immediately prior to a retrieval session in the conditioned context in the absence of shock. Interestingly, BNST inactivation only disrupted contextual freezing in rats in the long-delay condition, despite the fact that total shock and context exposure was equated among the groups. This reveals that BNST mediates fear expression in unpredictable, but not predictable contexts. Next, we examined whether the BNST mediates fear to discrete CSs that are poor predictors of US onset. We used forward (i.e., CS-then-US) and backward (i.e., US-then-CS) fear conditioning procedures to establish CSs that were either good or poor predictors, respectively, of US onset. Twenty-four hours after conditioning in context A, rats were infused with drug or vehicle into the BNST and tested for fear to the CS alone in context B. Similar to the previous experiment, BNST inactivation attenuated fear to the backward CS, without affecting freezing to the forwardtrained CS. Additional experiments demonstrated increases in Fos-positive neurons in the anteroventral BNST following exposure to a backward CS, but not to a forward CS. Collectively, these results suggest that fear evoked by temporally unpredictable CSs, whether contexts or cues, are mediated by the BNST.

Title: Locus coeruleus modulation of extinction retrieval and fear renewal

Authors: *T. F. GIUSTINO^{1,2}, P. J. FITZGERALD², S. MAREN² ²Dept. of Psychology and Inst. for Neurosci., ¹Texas A&M Univ., College Station, TX

Abstract: After a traumatic incident individuals often undergo exposure therapy or psychological debriefing in an attempt to prevent the development of stress- and trauma-related disorders (e.g., posttraumatic stress disorder, PTSD). These "extinction-like" therapies aimed to reduce fear-related behaviors are context dependent. That is, fear tends to relapse in other settings, which limits the efficacy of such therapies. Past work has demonstrated that the stress hormone norepinephrine (NE), produced by and released from the locus coeruleus (LC), is elevated in individuals with PTSD. Extinction learning and fear relapse can be modeled in the laboratory using Pavlovian fear conditioning procedures in rodents. Here, we used LC-specific DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) to examine how LC-NE contributes to both extinction retrieval (low fear) and fear renewal (high fear). Male rats first received bilateral infusions of either AAV9-PRSx8-hM3Dq-HA or AAV9-PRSx8-hM4Di-HA into the LC. Two weeks after surgery, rats underwent standard auditory fear conditioning and extinction procedures. After extinction learning, rats underwent two dual retrieval-renewal sessions (i.e., each session consisted of consecutive retrieval and renewal procedures using a within-subjects design). Thirty minutes prior to each test session, rats received either vehicle or clozapine N-oxide (CNO; 3 mg/kg, i.p.) injections in a counterbalanced fashion; under these conditions, CNO reliably increased (hM3Dq) or decreased (hM4Di) LC firing rates. In animals expressing the excitatory DREADD, CNO greatly increased freezing to the extinguished CS and strongly attenuated extinction retrieval. In contrast, CNO reduced freezing to the extinguished CS in animals expressing the inhibitory DREADD in the extinction context, but paradoxically increased fear renewal outside the extinction context. This suggests that elevated fear can result from either increases or decreases in LC firing, and presumably NE release in forebrain targets such as the amygdala and prefrontal cortex. Further work is required to understand how bidirectional changes in LC firing differentially regulate the context-dependent expression of extinction.

Title: The nucleus reuniens gates prefrontal-hippocampal modulation of extinction retrieval

Authors: *J. JIN, K. R. RAMANATHAN, S. MAREN

Inst. for Neuroscience; Dept. of Psychology, Texas A&M Univ., College Station, TX

Abstract: Fear extinction is a critical component of behavioral therapies for anxiety- and stressrelated disorders. Considerable work has shown that the amygdala and medial prefrontal cortex (mPFC) are crucial for learning fear extinction, whereas the hippocampus (HPC) regulates the context-dependent expression of fear after extinction. Recent work indicates that interactions between the mPFC and HPC mediate the context-dependent expression of extinction memory. Although direct projections from the HPC to the mPFC have been implicated in fear renewal, it is not known whether indirect projections from the mPFC to the HPC via the thalamic nucleus reuniens (RE) are involved in this process. In the present experiments, we explored the role of the RE and mPFC-RE-HPC circuits in the context-dependent expression of extinction. Male rats underwent standard auditory fear conditioning and extinction procedures followed by retrieval tests in either the extinction context or in an alternate context. Pre-testing pharmacological inactivation of the RE using the GABAA receptor agonist muscimol attenuated extinction retrieval, without affecting fear renewal. Consistent with this, RE inactivation was found to reduce the numbers of Fos-positive neurons in the mPFC and HPC after extinction retrieval testing. Lastly, silencing mPFC neurons projecting to RE produced deficits in extinction retrieval similar to those produced by RE muscimol; ongoing studies are exploring the role of RE projections to the HPC in these effects. Overall, our results indicate that the RE may be a novel hub gating information flow between the mPFC and HPC that is critical for the inhibition of extinguished fear.

Title: Nucleus reuniens mediates the acquisition of fear extinction

Authors: *K. R. RAMANATHAN¹, J. JIN², S. MAREN²

²Inst. for Neurosci. and dept of psychology, ¹Texas A&M Univ., College Station, TX

Abstract: The hippocampus (HPC) and medial prefrontal cortex (mPFC) are two brain areas that have an important role in the extinction of fear memories. Inactivation of the dorsal (Corcoran et al., 2005) or ventral (Sierra-Mercado et al., 2011) hippocampus or the infralimbic cortex (Sierra-Mercado et al., 2011) impairs the acquisition of fear extinction. The anatomy of this circuit suggests that unidirectional, monosynaptic projections from the HPC to the mPFC supports extinction learning. However, the mPFC is positioned to influence information processing in the HPC via indirect projections through the thalamic nucleus reuniens (RE); it is not known how the RE or mPFC->RE->HPC projections contribute to extinction learning. To address these questions, we first examined whether muscimol inactivation of RE would affect extinction learning. Animals were implanted with a single cannula targeting RE. After recover from surgery, rats were subjected to 5 CS (tone) -US (footshock) pairings in context A. Twenty-four hours later, they were infused with either muscimol (GABAA agonist) or saline in RE 10 mins before they received an extinction session wherein they received CS-alone trials in context B. This was then followed a day later by retrieval tests in the extinction context (B) and the conditioning context (A). RE inactivation attenuated both within-session extinction, as well as fear suppression in the extinction context the following day; the renewal of fear in the conditioning context was not affected by RE inactivation. To determine if extinction deficits subsequent to RE inactivation were due to blocking PFC input to the RE (and presumably to the HPC), we performed circuit manipulations using Cre-dependent DREADD's (designer receptor exclusively activated by designer drugs) to silence mPFC->RE and RE->HPC projections. Four weeks after surgery, the rats received the same behavioral protocol described above. We found that silencing RE projectors in the mPFC reproduced the extinction deficits we observed after muscimol inactivation of RE; studies exploring RE projections to the HPC are ongoing. Overall, these results indicate that the RE may be critical for gating information flow between the mPFC and HPC during the acquisition of extinction learning.

Title: Avoidance over-conditioning impairs extinction of fear, induces persistent avoidance, and increases use of safety cues: Implications for OCD

Authors: *F. J. MARTINEZ, M. J. SANCHEZ-NAVARRO, C. D. VELAZQUEZ-DIAZ, G. J. QUIRK

Psychiatry and Anat. & Neurobio., Univ. of Puerto Rico, Med. Sci. Campus, San Juan, PR

Abstract: Obsessive-compulsive disorder (OCD) is characterized by compulsive urges that can resemble avoidance of perceived danger. It is treated with exposure-with-response-prevention (ERP) therapy, in which patients are prevented from carrying out compulsions in response to triggers. Due to their repetitive nature, OCD compulsions are thought to resemble habit formation (Gillan et al., 2015), but little is known about the effects of repetitive avoidance on subsequent extinction. Using a platform-mediated avoidance task (Bravo-Rivera et al., 2014), we recently reported that a minority of rats persist in their avoidance following several days of extinction with a barrier that prevents access to the platform (extinction with response prevention, Ext-RP) (Rodríguez-Romaguera et al., 2016). A possible factor contributing to persistent avoidance after extinction is the development of habits over extended periods of training. Therefore, we trained two groups of rats with either 8 days (8d) or 20 days (20d) of avoidance conditioning, followed by 4 days of Ext-RP and a subsequent test with the barrier removed. Both groups showed similar avoidance conditioning. During Ext-RP, however, the 20d group showed impaired extinction of freezing (RM-ANOVA; $F_{(1,28)} = 57.37$, p<0.001), ending with elevated freezing levels. The following day, 20d rats showed increased avoidance at test compared to the 8d group (t-test; $t_{76} = 4.03$, p<0.001), but did not display differences in freezing. Thus, the ability to re-access the platform eliminated the excessive fear in this group. To assess whether 20d group interpreted the barrier as a safety signal, an additional test session was run with the barrier placed opposite to the platform. Under these conditions, avoidance was reduced in the 20d group (t-test; $t_{29} = 4.05$, p<0.001), suggesting the barrier signaled safety to these rats. We are currently using cFos to compare activity in prefrontal-striatal-amygdala circuits in the 8d and 20d groups. Our results suggest that repeated expression of avoidance-like compulsions may reduce the effectiveness of extinction-based therapies, and increase subjects' reliance on apparent safety cues.

Abstract: Memories are not static in the brain, but shift with the passage of time (Frankland and Bontempi 2005). Previously, we showed that the prelimbic - amygdalar projection (PL-BLA) is necessary to retrieve a 6-hour fear memory, whereas the prelimbic - thalamic projection (PL-PVT) is necessary to retrieve a 7-day fear memory (Do-Monte, et al., 2015). The somas of PL-BLA and PL-PVT neurons are in different layers of PL. What characterizes the activity of both neuronal populations in early vs. late fear retrieval? To address this, we infused separate retrograde tracers into BLA and PVT, exposed rats to auditory fear conditioning, and then assessed early (2 h) fear retrieval. One hour after test, rats were sacrificed and brains were processed for fluorescent labeling of the retrograde tracers, as well as the activity marker c-Fos. Compared to unconditioned controls, early fear retrieval increased activity in PL-BLA neurons (21% vs 5% of PL-BLA neurons expressing c-Fos, p=0.03) but not in PL-PVT neurons (4% vs 5% of PL-PVT neurons expressing c-Fos, p=0.47). To characterize the timing of PL neuronal responses during early and late timepoint, we recorded from 216 individual neurons in different PL layers, using 32 channel silicon probes (NeuroNexus). Neurons in layers 2-5 of PL, which project to BLA but not to PVT, showed conditioned excitatory tone responses during early retrieval (2, 24 h), but not during late retrieval (4 d). In contrast, neurons in layer 6, which project to PVT but not to BLA, showed no excitatory conditioned responses in early or late retrieval, but showed pronounced and long-lasting inhibitory responses during late retrieval. Our findings suggest that, following fear conditioning, the conditioned output of PL shifts with time from increased activity in projections to BLA to decreased activity in projections to PVT. We previously showed that PVT neurons develop excitatory tone responses with the passage of time after conditioning, and optogenetic silencing of PL-PVT fibers induces both excitation and inhibition of PVT neurons (Do-Monte et al., 2015). Thus, PL-PVT inhibition could indirectly increase PVT activity, through disinhibitory circuits.

Title: Hippocampal-prefrontal BDNF in the extinction of active avoidance

Authors: *L. E. ROSAS-VIDAL¹, V. LOZADA-MIRANDA¹, Y. CANTRES-ROSARIO², L. MELÉNDEZ², G. J. QUIRK³

¹Psychiatry and Anat. & Neurobio., ²Microbiology, ³Psychiatry and Neurobio. & Anat., Univ. of Puerto Rico, San Juan, PR

Abstract: The infralimbic prefrontal cortex (IL) is necessary for both extinction of conditioned fear (Do-Monte et al., 2015) and extinction of platform-mediated active avoidance (Bravo-Rivera et al., 2014). Brain-derived neurotrophic factor (BDNF) is critical for learning and memory processes. Blocking extracellular BDNF in IL, but not PL, during extinction of conditioned fear impairs its acquisition and recall (Rosas-Vidal et al., 2014). Here we examined the role of BDNF in extinction of active avoidance. We found that blocking extracellular BDNF in either IL (p<0.05) or PL (p<0.01) during extinction of avoidance impaired its recall but not its acquisition. To determine the possible source of extinction-related BDNF, we combined retrograde tracers in IL or PL with immunohistochemistry. Interestingly, we found that extinction of avoidance increased BDNF expression in ventral-hippocampal (vHPC) neurons projecting to IL or PL (p=0.004 and p=0.010 respectively), but not amygdala or mediodorsal thalamic neurons projecting to IL or PL. To determine whether BDNF produced in vHPC is necessary for extinction of avoidance, we injected lentiviri expressing the CRISPR/Cas9 system targeting the *bdnf* gene. CRISPR-Cas9 was sufficient to impair BDNF expression in vHPC (p= 0.014). Furthermore, BDNF knock-down in vHPC neurons impaired recall of extinction of avoidance (p=0.047 and p=0.019 respectively). Post-traumatic stress disorder is associated with reduced hippocampal volumes (Bremner et al., 2002, Bremner et al., 1995, Chao et al., 2013) and with decreased hippocampal-prefrontal connectivity Admon et al., 2012). Our results suggest that reduced BDNF release by an impaired hippocampal-prefrontal pathway may be associated with increased avoidance behaviors seen in post-traumatic stress disorder.

Title: Chronic social defeat stress impairs the ability to discriminate between threat and safety

Authors: *I. S. GRUNFELD^{1,2}, G. E. SCHAFE^{3,1}, E. LIKHTIK^{2,1}, N. S. BURGHARDT^{3,1} ¹Neurosci. Collaborative, The Grad. Center, City Univ. of New York, New York, NY; ²Dept. of Biol., ³Dept. of Psychology, Hunter Col., New York, NY

Abstract: Numerous psychiatric disorders, including post-traumatic stress disorder (PTSD), are associated with a deficit in the ability to successfully discriminate between conditions of fear and safety. Chronic exposure to adverse stressful experiences may confer susceptibility to PTSD by altering the brain's fear memory system in a way that increases generalization of responses usually reserved for threat to innocuous stimuli that are unrelated to the trauma. To test this hypothesis, we exposed 129Sv/Ev mice (N=10) to social defeat stress or to no stress (N=10) for 10 days and then tested their ability to discriminate threat from safety using a threat discrimination learning paradigm. During discrimination learning, mice were exposed to two different auditory stimuli: one stimulus (CS+) was paired with a mild foot shock (0.5 mA), and the other (CS-) was never paired with a foot shock. Training involved exposing mice to 6 presentations of each CS a day for 3 consecutive days (Likhtik et al., 2014). We then placed the mice in a testing chamber that was distinct from the training context and tested them to both tones in the absence of foot shock. During the test session, we found that the non-stressed control group froze significantly more to the CS+ than the CS-, while our socially defeated group exhibited similar freezing behavior to both tones. We categorized mice as 'generalizers' if they froze similarly to both tones (<10% difference in freezing to CS+ vs. CS-) and 'discriminators' if they showed greater freezing to the CS+ than the CS-. We found that a greater proportion of mice exposed to chronic social defeat stress fit the criteria for generalizers (50%) than those in our non-stressed control group (20%). Our data suggest that chronic stress may increase susceptibility to PTSD by impairing the ability to discriminate threat from safety.

Title: Differential activation of GABAergic and cholinergic basal forebrain neurons during threat and safety

Authors: *M. B. HARNOIS¹, M. LABKOVICH², R. RAVENELLE^{2,5}, I. NAHMOUD³, R. ZHANG⁴, E. LIKHTIK^{2,5}

¹Psychology, New York Univ., New York, NY; ²Biol., ³Chem., ⁴Hunter Col., New York, NY; ⁵Neurosci. Collaborative, The Grad. Center, CUNY, New York, NY

Abstract: The basolateral amygdala (BLA) is an integral structure for rapid signaling about potential threats. Cholinergic afferents from the basal forebrain (BF) to the BLA make an important contribution to its role as a threat detector by potentiating cortical input onto BLA principal neurons and increasing the signal to noise ratio of BLA firing (Jiang et al., 2016; Unal et. al., 2014). Less is known, however, about the role of GABAergic projections from the BF to the BLA, which may serve to inhibit the acetylcholine-mediated signal amplification of threat-related learning in the amygdala. To investigate this question, we trained mice to either associate a conditioned stimulus (CS+, 2 kHz tone) with a shock US (0.5mA) or with a period of safety via explicitly unpairing the US and CS. Neural activity in the BF was analyzed via expression of the immediate early gene cfos in parvalbumin expressing GABAergic cells (PV+) and cholinergic cells expressing choline acetyltransferase (ChAT+). As suggested by previous work, paired threat conditioning led to higher cfos activation of cholinergic cells than unpaired conditioning (cfos:ChAT+ paired 23% vs unpaired 6%, p=0.014 in the substantia innominata (SI), and in the

horizontal limb of the diagonal band (HDB cfos:ChAT+ paired 21% vs unpaired 3%, p=0.0023). However, unpaired safety training led to increased cfos activation in PV+ cells of the HDB relative to the paired conditioning (cfos:PV+ paired, 15% vs. cfos:PV+ unpaired, 41% in p=0.015), as well as suppression of ChAT+ cellular activity across all sampled regions of the BF (ventral pallidum [VP], SI, HDB). In light of these findings, we are currently investigating how PV+ GABAergic inputs from the BF to the BLA impact threat and safety learning. These findings indicate that the BF may constitute an important gate for amygdala output at the time of predictive threat and safety.

Abstract: The medial prefrontal cortex (mPFC) and its projection targets play an important role in learning to discriminate threat from safety. Previous studies have shown that the prelimbic (PL) and infralimbic (IL) sub-regions of the mPFC are critically involved in fear expression and fear suppression, respectively. Investigation into how these two contiguous areas govern opposing behavioral responses has focused on their direct, reciprocal connectivity with the

basolateral amygdala (BLA). This work has shown that the mPFC drives both excitation and inhibition in the BLA, with a prevalence toward inhibition after safety or extinction training. However, the mechanism of mPFC-mediated inhibition in the BLA is not well understood. To address this question, we are investigating indirect connectivity between the mPFC and BLA via the basal forebrain (BF). Collectively, the BF (substantia innominata - SI, ventral pallidum - VP, horizontal limb of the diagonal band - HDB) send GABAergic and cholinergic inputs to the BLA, which are thought to increase the signal to noise strength of BLA firing and enhance fear expression. Thus, we reasoned that mPFC inputs to BLA-projecting cell groups in the BF could provide an indirect mechanism for control over BLA activity and fear expression. To investigate this possibility, we injected retrograde fluorescent beads (RB) in the BLA and an anterograde tracer (AAV8.2-hEF1a-DIO-synaptophysin-mCherry with AAVa - hSyn-Cre-WPRE-hGH) in either the IL (N=4) or PL (N=4) of C57BL6J mice. After a 3 week period for viral and RB expression, the BF region was stained for parvalbumin (PV+) and choline acetyltransferase (ChAT+) to identify GABAergic PV+ and cholinergic cell groups, respectively. Analyses show that the majority of projections from the VP region of the BF (VP-to-BLA) are ChAT+ (13.47%), whereas the majority of projections from the HDB are PV+ (5.72%). Surprisingly, despite the comparatively smaller overall number of PV+ cells in the BF overall, they were the principal target of IL synaptic vesicles in all three examined BF regions. We are investigating whether the PL-BF-BLA network shows similar connectivity patterns and the functional significance of this circuit for BLA activity and fear expression.

Title: Thalamic inputs onto the amygdala regulate fear memory retrieval

Authors: *N. FERRARA, P. K. CULLEN, S. E. PULLINS, F. J. HELMSTETTER Psychology, Univ. of Wisconsin--Milwaukee, Milwaukee, WI

Abstract: Pavlovian fear conditioning provides a way to investigate memory formation and retrieval. During fear conditioning, a conditional stimulus (CS) is paired with an aversive outcome and the CS acquires aversive value over several pairings. The CS may then be presented during a retrieval session where fear responding is measured as an indicator of memory strength.

Retrieval sessions allow for the incorporation of new information into the original memory trace by destabilizing amygdala synapses, which is accompanied by changes in synaptic expression of AMPA receptors. Inhibition of protein synthesis-dependent plasticity in the amygdala immediately following a retrieval experience impairs long-term memory retention and disrupts AMPA receptor synaptic expression. Previous work shows that terminals of auditory thalamic (MgN) neurons onto cells in the lateral amygdala are immediately presynaptic to AMPA receptor subunits, suggesting that MgN input may play a role in amygdala-dependent memory through regulation of AMPA receptor dynamics. However, very little is known about the sensory inputs to the amygdala that regulate fear memory at retrieval. Local inhibition of the MgN activity using pharmacological agents prior to fear conditioning, but not prior to retrieval, can disrupt memory, but pathway specific optogenetic manipulation provides more precise tool that potentially allows for isolation of MgN-LA connections. Recent work has shown that optogenetic terminal stimulation of thalamic and cortical inputs onto the amygdala during conditioning can serve as a CS to simulate auditory fear conditioning when paired with a UCS and that this is dependent on glutamatergic synaptic transmission. Importantly, groups conditioned with optogenetic stimulation as a CS show that terminal stimulation closely resembles auditory fear memory retrieval, suggesting a role for thalamic and cortical terminals in the amygdala during fear memory reactivation. Here groups undergo auditory fear conditioning followed by a brief retrieval session to characterize the role of MgN terminals in the amygdala during recall. We found that silencing MgN terminal activity during CS presentations at retrieval impaired fear responding, suggesting that MgN inputs to the amygdala are necessary for the retrieval of an auditory fear memory. Other experiments address if MgN terminal silencing alters anisomycin-induced amnesia following memory retrieval and synaptic destabilization evidenced by changes in AMPA receptor trafficking in the amygdala.

Title: The effects of methylene blue on trace fear memory and brain proteolytic activity in young and aged rats

Authors: *W. CRUZ¹, S. E. PULLINS¹, J. R. MOYER, JR.¹, F. J. HELMSTETTER² ¹Psychology, ²Deptartment of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Both humans and rats experience an age-related decline in episodic/explicit memory. Along with protein synthesis, protein degradation mediated by the ubiquitin proteasome system is critical for the synaptic plasticity underlying memory formation and retrieval. While a decrease in basal proteasome activity with increasing age is evident across various species, agerelated changes in plasticity dependent proteolysis have not been explored and may underlie the age-related deficit in trace fear conditioning (TFC) previously documented in aged rats. Using TFC to model episodic memory in rats, we attempted to rescue age-related memory decline by upregulating proteasome activity via dietary administration of the compound methylene blue (methylthioninium chloride, MB), since prior work showed that MB increases chymotrypsin-and trypsin-like proteasome activity in 3xTg-AD mice. Two experiments tested the effects of MB on TFC and proteolytic activity in male F344 young (3 months) and aged (18 months) rats. In Experiment 1, 3-month-old rats were administered 50mg of MB per 100g of powdered food for 4 months. While this treatment did not significantly enhance memory, it significantly increased proteasome activity in the retrosplenial cortex (RSC). Since MB treatment is dose dependent, we lowered the dose in Experiment 2, and 3 month and 18-month-old F344 rats were administered 25mg of MB per 100g of powdered food. MB treatment enhanced TFC in young rats, while not affecting TFC in aged rats. However, there was a significant increase in proteasome activity in the RSC for both young and aged rats, as well as a significant increase in proteasome activity in the dorsal hippocampus for young rats. These results suggest a lower dose of MB significantly enhances TFC in young but not aged rats. Therefore, additional research is needed to determine the optimal dose at which MB rescues TFC in aged rats.

Title: Contributions of the retrosplenial cortex to event-related and contextual fear memory formation in trace fear conditioning

Authors: *S. E. PULLINS, P. K. CULLEN, N. C. FERRARA, F. J. HELMSTETTER Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: The ability to form memories for aversive events, as well as for where those events occur, is critical to survival. Recent research suggests a critical role for the retrosplenial cortex (RSC) in the encoding and storage of events and their associated contexts. However, the nature of information processing in the RSC during learning remains unclear due to previous manipulations of the RSC lacking spatial and temporal precision. Our initial immunohistochemical analysis of the RSC following auditory trace fear conditioning, a paradigm used to model declarative memory in rodents, showed increased neuronal activity throughout its longitudinal extent. While these results suggest that the RSC may be functionally homogeneous throughout its rostral-to-caudal expanse, previous lesion and immunohistochemical work implicates differential function between the anterior and posterior segments. We then used optogenetics to examine specific functions of RSC segments during trace fear conditioning. Rats were transfected with ArchT, under control of the neuron-specific promoter CAG, while control rats received a similar viral cassette that lacked the light-sensitive pump. By injecting these viruses into the anterior RSC (aRSC) or the posterior RSC (pRSC), and then mounting LEDs over a thinned skull window immediately above the site of transfection, we can achieve spatially and temporally precise reductions in neuronal excitability. All rats received light delivery during each learning trial of conditioning. The following days, rats were tested for memory to the tone and to the training context. Silencing of aRSC during each tone-shock pairing impairs memory formation for the training tone, whereas pRSC silencing selectively impairs contextual memory formation. These results suggest that the two poles of the RSC may differentially contribute to event-related and contextual memory formation, and that the RSC may normally aid in the final association of these two distinct aspects of the fear memory.

Title: Neural activity in the ventrolateral periaqueductal gray provides a feedback mechanism to modulate fear network activity

Authors: *P. K. CULLEN, N. C. FERRARA, S. E. PULLINS, F. J. HELMSTETTER Psychology, Univ. of Wisconsin, Milwaukee, Milwaukee, WI

Abstract: Decades of research on defensive behaviors supports a model in which the amygdala initially processes emotional responses to threat and coordinates defensive responses via "downstream" structures including the midbrain periaqueductal gray (PAG). While the PAG was initially thought to be the final common pathway for fear expression, recent evidence suggests that the PAG plays a much more integrated role in coordinating defensive responding. Inactivation of the ventrolateral PAG (vlPAG) during fear conditioning or extinction training impairs neural plasticity in both the amygdala and medial prefrontal cortex (mPFC), suggesting that the PAG modulates plasticity in these structures. However, our present understanding of PAG function comes primarily from pharmacological manipulations or lesions that impair PAG activity for an imprecise amount of time following drug administration. To gain a better understanding of the role of the PAG in modulating network activity within the fear/extinction circuit, activity within the vlPAG was optogenetically inhibited using virally-mediated expression of the light-driven proton pump ArchT (AAV-CAG-ArchT-GFP) in a temporally precise manner during auditory CS presentations. Animals were trained with auditory fear conditioning and exposed to either a single 30-second white noise CS/laser presentation and were sacrificed 5-minutes later for Arc fluorescent in situ hybridization, or five 30-sec CS/laser presentations followed by two subsequent CS tests in either the same or shifted context. We found that 1) inactivation of vIPAG during one CS presentation significantly reduced retrievalrelated Arc expression in the amygdala and prelimbic (PL) region of the mPFC; 2) inactivation of vIPAG during 5 CS presentations reduced CS freezing during the retrieval session; 3) the reduction in CS freezing persisted during a laser-free test 24-hours following vIPAG inhibition and was renewed in a shifted context. These results indicate that the PAG modulates fear network activity during fear expression. Furthermore, inhibiting vlPAG activity during CS presentations resulted in a stable reduction in fear responding in the absence of optogenetic inhibition and the renewal of fear suggests that inhibiting vIPAG activity during fear expression may have triggered extinction learning. The current study provides new insight into the role of vlPAG during fear memory retrieval/expression and suggests that the vlPAG may participate in a feedback mechanism to modulate network activity, potentially to signal extinction learning.

Abstract: Although epigenetic mechanisms of gene expression regulation have recently been implicated in memory consolidation and persistence, the role of nucleosome-remodeling is largely unexplored. Recent studies show that the functional loss of BAF53b, a postmitotic neuron-specific subunit of the BAF nucleosome-remodeling complex, results in the deficit of consolidation of hippocampus-dependent memory and cocaine-associated memory in the rodent brain. However, it is unclear whether BAF53b expression is regulated during memory formation and how BAF53b regulates fear memory in the amygdala, a key brain site for fear memory encoding and storage. To address these questions, we used viral vector approaches to either decrease or increase BAF53b function specifically in the lateral amygdala of adult mice in auditory fear conditioning paradigm. Knockdown of *Baf53b* before training disrupted long-term memory formation with no effect on short-term memory, basal synaptic transmission, and spine structures. We observed in our qPCR analysis that BAF53b was induced in the lateral amygdala neurons at the late consolidation phase after fear conditioning. Moreover, transient BAF53b overexpression led to persistently enhanced memory formation, which was accompanied by increase in thin-type spine density. Together, our results provide the evidence that BAF53b is induced after learning, and show that such increase of BAF53b level facilitates memory consolidation likely by regulating learning-related spine structural plasticity.

Title: Ventrolateral periaqueductal gray neurons signal threat probability

Authors: *K. M. WRIGHT¹, M. A. MCDANNALD²

¹Psychology, ²Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: The ventrolateral periaqueductal gray (vlPAG) has long been implicated in Pavlovian fear conditioning. The canonical view is that the vIPAG is critical to fear expression. However, recent studies have failed to find adequate neural correlates in this region linked to fear expression. Using a combination of Pavlovian fear conditioning and single-unit recording, we tested the hypothesis that vIPAG neurons signal threat probability, a signal more consistent with threat prediction, than fear expression. Six, Adult Male Long Evans rats, were presented with three auditory cues, each associated with a different probability of foot shock: Safety, p = 0.00; Uncertainty, p = 0.38; and Danger, p = 1.00. Rats received eight discrimination sessions, then were implanted with drivable, microelectrode bundles aimed at the caudal vlPAG. Following recovery, discrimination sessions resumed with single-unit recording. Across all sessions, rats demonstrated excellent fear discrimination, achieving high fear to the Danger cue, low fear to the Safety cue, and intermediate fear to the Uncertainty cue. Our analysis of vlPAG activity during discrimination revealed a population (29/267) of neurons that showed rapid, phasic increases in firing at cue onset. Interestingly, this population showed graded firing to the three cues which appeared to follow a pattern similar to fear expression: high firing to the Danger cue, low firing to the Safety cue, and intermediate firing to the Uncertainty cue. However, using either population or single-unit analyses, we found that differential firing to each of the three cues was best explained by the probability of foot shock associated with a given cue, not the level of fear expressed. Our analyses also found a similar, but largely separate population of neurons (30/267) that showed a ramping of activity from cue onset to offset. This ramping also scaled with the probability of foot shock: Danger > Uncertainty > Safety. Together, these results suggest that vlPAG neurons signal threat probability, or *threat prediction*, and generate signals which may be critical to organizing an appropriate fear response that are independent of the response itself.

Title: Reactivation-mediated organization of associative memory engram in systems consolidation

Authors: *J.-P. OH, J.-T. KWON, Y. LEE, M. KANG, H.-S. KIM, Y. JEONG, H.-Y. CHO, J.-H. HAN

Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: In rodent studies, it has been shown that memory retrieval circuit changes as memory is consolidated over time, suggesting dynamic regulation of memory engram organization during systems level consolidation. However, how memory is organized within neural circuits over time is poorly understood. Previously, we showed optogenetic stimulation of presynaptic auditory input in lateral amygdala (LA) can serve as a conditioned stimulus (CS) to form associative fear memory. In this study, we observed that the retrieval of such memory, driven by optogenetic CS input activation in the LA, was gradually decreased over time after learning. However, when the CS input was reactivated by optogenetic stimulation 1 day after learning, the memory retrieval through this CS input pathway was maintained. Importantly, the reactivation effect was highly specific such that reactivation of auditory input that was not activated during learning had no effect. Consistent with behavior results, we also found that LTP at CS input and c-Fos induction in the LA neurons during memory retrieval was maintained with the reactivation manipulation. Furthermore, in natural auditory fear memory, we found that prolonged inhibition of auditory brain regions activity for one week, starting from a day after conditioning, impaired memory retrieval at remote time, suggesting the possibility of reactivation-mediated maintenance of CS input as a critical part of retrieval circuit for associative memory.

Title: Dissecting the contribution of auditory cortex to acquisition and expression of auditory fear memory

Authors: *T. DALMAY, E. ABS, R. B. POORTHUIS, J. J. LETZKUS Max Planck Inst. For Brain Res., Frankfurt Am Main, Germany

Abstract: Classical auditory fear conditioning is a powerful model to elucidate many key features of adaptive and maladaptive forms of plasticity underlying learning and memory. In particular, a large body of work demonstrated that neurons in the lateral amygdala (LA) that receive thalamic and cortical afferents conveying auditory and foot-shock information undergo plasticity during learning. The LA has therefore been regarded as the primary site of stimulus convergence and fear memory formation. More recent evidence indicates, however, that auditory cortex (ACx) also exhibits foot-shock-evoked activity, and undergoes plasticity as a result of fear conditioning. How the parallel processing of auditory and foot-shock information via the thalamo-amygdala and thalamo-cortico-amygdala circuits interacts to enable memory formation and expression is therefore a key open question. Furthermore, the role of ACx as a whole has been controversial, with lesion experiments providing evidence both for and against a critical involvement in fear memory acquisition and retrieval. Here, we use acute optogenetic silencing of pyramidal neurons with ArchT in freely-behaving mice during different forms of auditory fear conditioning to determine the conditions under which the ACx (areas A1 and AuV) is strongly required for both fear memory acquisition and expression. We find that optogenetically inhibiting ACx during conditioning leads to a robust reduction in fear responses (freezing) in the subsequent recall session. Similarly, our data indicate a strong and reversible reduction in freezing responses when ACx is inhibited during recall of both recent and remote memory. Control experiments demonstrate that the decrease in auditory stimulus-evoked freezing is not caused by potential off-target effects of ACx inhibition or other side effects of light stimulation. As a next step we are investigating how cortical afferents to the LA influence memory formation and expression, and the extent to which tone-evoked activity in the LA depends upon cortical processing. Together, these experiments enhance our understanding of the brain-wide interactions of distinct areas that enable behavioral functions such as learning and memory.

Title: Ventrolateral periaqueductal gray neurons signal positive aversive prediction errors

Authors: *M. A. MCDANNALD, R. A. ZACHARIAS, K. M. WRIGHT Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: Fear is adaptive when confined to situations of danger, but is maladaptive when the level of fear expressed is inconsistent with a present threat. Generating appropriate fear in situations that threaten harm with uncertainty is particularly challenging. Prediction errors (PEs), discrepancies between predicted and actual outcomes, provide an updating mechanism by which appropriate fear in uncertainty may be achieved. Disrupting ventrolateral periaqueductal gray (vlPAG) activity can alter PE-dependent fear learning, and neural signatures consistent with PEs have been identified in rats (single-unit recording) and humans (fMRI). However, strong evidence for vlPAG single-unit activity as a *de novo* source of PEs is lacking. We implanted six male Long Evans rats with drivable microelectrode bundles aimed at the caudal vIPAG. Following recovery, single-unit activity was recorded during Pavlovian fear discrimination in which three auditory cues predicted different probabilities of foot shock: Danger (p = 1.00), Uncertainty (p = 0.38), or Safety (p = 0.00). Theoretically, positive PEs (+PEs) would be weak or absent to 'predicted' foot shock, on Danger trials, when prediction (1.00) is consistent with actuality (1.00). In contrast, +PEs would be generated to 'surprising' shock delivery on Uncertainty trials, due to the discrepancy between the predicted (0.38) and the actual shock (1.00). Across all trials, rats expressed high fear to Danger and low fear to Safety. Critically, rats expressed intermediate fear to Uncertainty, indicative of appropriate prediction error signaling. We identified a population of shock-responsive neurons (30/267) with phasic increases in firing to surprising and/or predicted foot shock. Despite not selecting for this criterion, population and single-unit activity was biased towards greater firing to the surprising foot shock - consistent with positive +PE signaling. In support of a mechanism for updating fear, single trials in which robust +PE responses were observed, resulted in increased fear to the Uncertainty cue on subsequent trials. In contrast, single trials with weak or anti-PE signaling resulted in decreased fear to the Uncertainty cue on subsequent trials. Combined with optogenetic findings from our lab, the present results suggest that +PE signaling is an intrinsic function of vlPAG neurons, and perhaps a neural source of dysfunction in disorders characterized by excessive fear.

Title: VTA dopamine transients reduce prediction error about aversive outcomes

Authors: *A. MAHMUD¹, M.-P. COSSETTE¹, B. P. LAY², M. D. IORDANOVA¹ ¹Psychology, Concordia Univ., Montreal, QC, Canada; ²Univ. of New South Wales, Sydney, Australia

Abstract: Prediction-error, the discrepancy between real and expected outcomes, drives associative learning as exemplified in the blocking paradigm. In blocking, a cue established as a good predictor of an outcome generates a small error in prediction. Therefore little is learned about the relationship between another, novel cue (e.g., a tone) and the same outcome in the presence of the good predictor. When prediction error is large, however, as in the case when the novel cue is trained in the presence of a poor predictor of the outcome, learning proceeds normally. Dopamine in the ventral tegmental area (VTA) has been implicated in *reward* prediction-error. Whether a similar role can be attributed to VTA dopamine in learning about fear remains unknown. We used the fear blocking paradigm to show that optogenetic activation of tyrosine hydroxylase positive neurons in the VTA at time of expected footshock further hinder learning about the blocked cue, therefore, augmenting the blocking effect in the aversive setting. Our results also indicate that optogenetic activation of dopamine does not modulate learning in a series of behavioural and neural control conditions. Overall, our findings suggest that dopamine transients in the ventral tegmental area reduce prediction error about aversive outcomes and thus modulate associative learning via a valance-specific prediction-error mechanism.

Abstract: Affective memory formation is determined by arousal level as well as by the sensory information flow related to a certain memorable experience. Although the amygdala is considered the main scene for integrating these kinds of information, the cell-type-specific subcortical origins of these inputs are yet to be elucidated.

Hereby we study the calretinin(CR)-positive cell aggregates of the thalamus: the midline and the posterior intralaminar/suprageniculate (PIL/SG) nuclei which have been shown to project to the amygdala nuclei. The question thus arises about their specific role in affective learning.

We investigate the temporal dynamics of CR+ neuronal firing in innate and learned behaviour of CR-Cre mice applying optogenetic techniques along with chronic multichannel electrode recording. Spontaneous and stimulus-evoked electrophysiological characteristics of CR+ cells along the thalamo-amygdala pathways are presented.

Frequency-dependent optogenetic excitation of midline thalamic cells in CR-Cre mice leads to a heightened level of arousal and waking with short latency (see also poster of Komlósi et al.). Concerning the PIL/SG CR+ neurons, bidirectional optogenetic manipulation of their axon terminals in the amygdala shows that they contribute to the transmission of both cue- and context-dependent information in auditory fear learning. Optogenetically tagged single units exhibit diverse and plastic response patterns along the stages of threat conditioning, which are supposed to be shaped by distinctive brainstem input characteristics depicted here. Our results suggest that CR+ thalamic cells are good candidates to provide the amygdala with arousal- and sensory-related information in affective learning.

Title: Activating glutamatergic projections from the perifornical hypothalamus to the basolateral amygdala enhances conditioned fear learning and persistence

Authors: *E. T. DUSTRUDE¹, J. L. LUKKES¹, A. R. R. ABREU¹, A. I. MOLOSH^{1,2}, A. SHEKHAR^{1,2,3}

Abstract: Panic disorder is characterized by recurrent and unexpected panic attacks involving a surge of catastrophic fear accompanied by marked cardiorespiratory responses and is often associated with phobias. Disinhibition of the perifornical hypothalamic region (PeF), a panic generating site, by GABA antagonism produces panic associated responses including escape and anxiety-like behavior and enhancement of fear memory in rat models. Chronic infusion of glutamic acid decarboxylase inhibitor L-Allylglycine (L-AG), to inhibit GABA synthesis, generates rats that are vulnerable to interoceptive stimuli, like sodium lactate. Our laboratory has previously shown that L-AG, panic vulnerable, rats can be protected against panic responses by metabotropic glutamate receptor II agonism that reduces glutamate-mediated excitation. Furthermore, pyramidal neurons in the basolateral amygdala (BLA) of panic vulnerable rats undergo a shift in their membrane properties towards increased excitation. As a key region for fear and anxiety behaviors, the BLA may be a major glutamatergic target for the PeF in fear learning during panic; however, the excitatory PeF-BLA circuit has not been selectively activated to determine its role in panic or fear models. Here, we investigate circuit functions by utilizing Sprague-Dawley male rats and adeno-associated virus to express EYFP or EYFP and channelrhodopsin (ChR2) under calmodulin-kinase II promoter within the PeF. BLA-projecting glutamatergic PeF neurons were activated by optogenetic stimulation of fibers within the BLA region in behavioral and brain slice electrophysiology experiments. Blue light stimulation at 10Hz was bilaterally targeted to the BLA of freely moving animals to excite the PeF-BLA circuit during each of the five minutes preceding acquisition, consolidation, and extinction phases of conditioned fear behavior testing. ChR2 expressing animals exhibited enhanced freezing during acquisition as well as delayed extinction suggesting glutamatergic PeF-BLA circuit modulation of fear learning. Three weeks after stimulation, ChR2 expressing animals exhibited increased spontaneous recovery of fear memory and delayed extinction during reinstatement of fear

conditioning. Whole-cell recordings of BLA neurons were utilized to confirm that blue-light evoked excitatory responses were glutamatergic and inhibited by AMPA/NMDA receptor antagonists. Together, our data suggest that enhanced glutamate release from BLA-projecting PeF neurons is important in phobia development.

Title: Region-specific rearrangement of synapses as a consequence of fear conditioning in zebrafish

Authors: *W. DEMPSEY¹, Z. DU¹, T. V. TRUONG², K. CZAJKOWSKI³, A. ANDREEV², G. G. GROSS¹, C. KESSELMAN³, S. E. FRASER², D. B. ARNOLD¹ ¹Mol. and Computat. Biol., ²Translational Imaging Ctr., ³Informatics Div., USC, Los Angeles, CA

Abstract: Information storage within the brain is thought to be facilitated by changes in the number and relative strength of synaptic connections between neurons. Visualizing these changes over time in vivo would help reveal the rules that govern this process. However, longterm, synapse-scale optical imaging in vivo - especially in structures that are found deep in the mammalian brain - continues to be a significant challenge. To circumvent this problem, we have used larval zebrafish, whose essentially transparent brains are organized such that virtually all areas are located close to the surface, within reach of in vivo imaging techniques. We have established an extensive labeling, behavioral training, imaging, and synapse analysis paradigm to track synaptic changes over time in living zebrafish larvae. FingRs (Fibronectin Intrabodies Generated with mRNA display) fused to fluorescent reporters label either PSD95 or Gephyrin in a mosaic subset of neurons within living fish. Before and after rounds of fear conditioning, we visualize labeled synapses at sub-micron resolution (~0.3x0.3x1.0µm voxel size) using selective plane illumination microscopy (SPIM). We focus mainly on the habenulae and pallia regions of the zebrafish brain, which have been suggested to be integral to fear memory formation. Synapses are classified using a custom analytical software package which allows a 3dimensional map of their positions and strengths to be produced. By comparing the differences between synapse maps obtained from the same fish before and after learning, we can map the

changes that occur in distributions of synapses. We have found that dramatic synaptic rearrangements occur in the brains of fish that have learned, but not in those that have not, suggesting that these rearrangements correlate specifically with learning.

Title: Use of autoshaping measures to predict motivation for sucrose rewards

Authors: Z. E. BOND, M. MCWATERS, E. M. ANDERSON, *L. MATUSZEWICH Dept. of Psychology, Northern Illinois Univ., DeKalb, IL

Abstract: Dysregulation of motivational systems has been implicated in several disorders, including addiction to natural and stimulant rewards (for reviews see DiLeone, Taylor, & Picciotto, 2012; Kalivas & Volkow, 2005). Salient cues are thought to increase the likelihood of the development of addiction and reinstatement after extinction (Flagel, Akil, & Robinson, 2009). In order to better understand the contribution of cue saliency in motivational behavior, individual differences in rats have been characterized using operant procedures (for review, see Flagel & Robinson, 2017). Rats can be categorized as those that exhibit salience toward the reward dispenser ("goal-trackers"), the cue (lever) for reward ("sign-trackers"), or both the reward dispenser and cue equally ("intermediates"; Yagers & Robinson, 2013). These categorizations have been assessed using an autoshaping procedure in rats participating in laboratory experiments to examine individual variance in motivational responding for a sucrose reward and stress-induced reinstatement of responding. A total of 211 adult Sprague-Dawley rats, 101 males and 110 females, were exposed to 25 sucrose pellets in their home cages for one day, received one day of pretraining in the operant box in which 25 sucrose pellets were administered on a variable interval schedule, and then received five days of the autoshaping procedure. During autoshaping, the lever extends into the operant box for 8 seconds, retracts, and the reward is immediately dispensed into the magazine, irrespective of responding. The autoshaping paradigm tracks several behaviors during the session, including lever presses and magazine entries while the lever is either in or out; therefore, assessing each rat's individual tendency to approach either the conditioned stimulus (lever) or the reward dispenser. Across 3 laboratory studies, more subjects attributed salience toward the cue for reward and were therefore categorized as sign-trackers (approximately 77%) than either other category ($\chi^2(2) =$

191.2, p < .01). However, the distribution of goal, intermediate, and sign-trackers was similar between males and females (χ^2 (2) = .71, p = .70) and between studies (χ^2 (4) = 8.73, p = .07). Further analyses will investigate individual differences in approach behaviors within each category (e.g. does one sign tracker differ from another?) that may contribute to results found in measures of motivation and reinstatement behaviors for sucrose rewards.

Title: Influence of juvenile methylphenidate on motivational behavior in adulthood

Authors: *M. MCWATERS, Z. BOND, L. MATUSZEWICH Northern Illinois Univ., Dekalb, IL

Abstract: Methylphenidate (MPH) is a commonly prescribed psychostimulant for attention disorders, particularly in children. There is concern that MPH increases the potential for developing other addictions in adulthood because MPH enhances motivation (Chelonis et al., 2011; Crawford et al., 2007). Importantly, motivation can also be influenced by several individual characteristics, such as sex and the salience toward reward-associated cues. A greater degree of salience toward cues may contribute to drug addiction (Christiansen et al., 2012) and can be quantified in rats using the Pavlovian Conditioned Approach (PCA) Index (Meyer et al., 2012). Although research has investigated the role of juvenile MPH treatment on the rewarding value of substances in rats (Andersen et al., 2002; Carlezon, Mague, & Andersen, 2003; Crawford et al., 2011), the influence of juvenile MPH on reward-associated cues in operant conditioning has not been assessed. The objective of the current study was to investigate whether juvenile MPH exposure altered the salience of reward cues and motivation in adulthood, comparing male and females. Therefore, the current study exposed 40 male and female rats to 0 or 2.0 mg/kg MPH on a cookie from postnatal day (PD) 21-35. At ~ PD 80, rats began the following training and testing procedures in operant chambers: pretraining, 5 days of autoshaping, 5 days of increasing fixed ratio, progressive ratio (PR), 10 days of fixed ratio 1 (lever with light cue), extinction (lever with no light cue), and 1 day of cue-induced reinstatement (lever with light cue). Sex and drug condition did not influence PCA index, although 70% of these animals had heightened salience toward the cue as measured by a high PCA index. During the PR assessment of motivation, there was an interaction between sex and drug condition on active lever pressing [F(1,36)=5.22, p=.03]. Juvenile MPH exposure,
compared to vehicle, increased females' motivation, but decreased males' motivation for sucrose. Males tended to have more inactive lever presses than females overall [F(1,36)=4.02, p=.05]. Surprisingly, active lever pressing in PR did not vary by PCA index (p>.05). Preliminary findings suggest that although all rats exhibited cue-induced reinstatement, the number of active level presses were similar across males and females and drug conditions. Overall, early exposure to MPH appears to differentially affect motivation in adulthood for a sucrose reward in males and female rats, which may have clinical implications for sex differences in motivational disorders (drug/food addiction), regardless of inherent individual differences in the salience of reward-associated cues.

Title: Reward under stress: Striatum involvement in reward processing from early detection to reward delivery

Authors: *C. GAILLARD¹, M. GUILLOD¹, A. FEDERSPIEL², D. SCHOEBI¹, R. RECABARREN¹, X. OUYANG¹, C. MUELLER-PFEIFFER³, A. HORSCH⁴, G. HASLER², C. MARTIN-SOELCH¹

¹Dept. of Psychology, Univ. of Fribourg, Fribourg, Switzerland; ²Univ. Hosp. for Psychiatry and Psychotherapy, Univ. of Bern, Bern, Switzerland; ³Dept. of Psychiatry and Psychotherapy, Univ. Hosp. of Zurich, Zurich, Switzerland; ⁴Dept. of Woman-Mother-Child, Univ. Hosp. of Lausanne, Lausanne, Switzerland

Abstract: Introduction: Stress and reward are two important determinants of motivated behavior (Haber & Knutson, 2009; Ossewaarde et al., 2011). Experimentally induced acute stress affects reward-related neural responses to monetary reward, especially in the dorsal striatum (Porcelli et al., 2012). Striatal regions play a crucial role in reward processing (Hare et al., 2008). However, it remains unclear how the striatum is involved in the different phases of reward processing. Here, we aimed to investigate (1) the effect of acute stress on neural activation elicited by monetary reward and (2) what role striatal regions play regarding early reward detection to reward delivery.

Method: We recorded changes in BOLD signal using a 3 Tesla MRI scanner (EPI pulse sequence, TE: 30ms, TR: 2s, slice thickness: 3 mm) in 23 healthy subjects (age: 23.5 ± 4.3 years;

13 women), while they performed a spatial working memory reward task with two difficulty levels (low and high) and two reinforcement conditions (non-reinforced and reinforced). All functional images were acquired within two scanning sessions, one without stress induction and one with stress induction through the administration of unpredictable mild electric shocks. Data were analyzed using the general linear model for event-related designs in SPM12. Statistical parametric maps of voxel t-values were assessed for the comparison between reinforced and non-reinforced trials during the different phases of reward processing (trial cue, stimulus presentation, decision making, reward expectation, reward delivery).

Results: Results revealed significant activation in two striatal regions, the putamen and the caudate nucleus when comparing reinforced and non-reinforced trials in the absence of stress induction (p<0.05, FDR-corrected). These regions were activated exclusively in the condition without experimental stress induction. The putamen showed a specific reward reactivity during trial cue, whereas caudate nucleus was involved later in reward processing starting at stimulus presentation to reward delivery.

Conclusion: These findings indicate a stress-induced reduction in striatal reactivity to monetary reward and differential reward reactivity in dorsal striatum throughout the different phases of reward processing in healthy subjects. Thus, putamen is important at early detection of reward, whereas caudate nucleus is implicated in later phases of reward processing.

Title: Reward preference induced by optogenetic CeA stimulation persists despite competitive physiological motivation

Authors: *O. M. LOFARO, M. J. F. ROBINSON Wesleyan Univ., Middletown, CT

Abstract: Drug addiction involves compulsive pursuit of a reward that persists even in the face of adverse consequences. The DSM-V draws a distinction between external and internal adverse consequences in its criteria for Substance Use Disorder, where external adverse consequences consist of legal or social problems. In contrast, internal adverse consequences consist of continued drug-seeking and drug consumption despite health problems, aversive drug effects, and unpleasant side effects of withdrawal. Previous research has established that optogenetic

stimulation of the central amygdala (CeA) generates an addiction-like preference for laser-paired reward that persists in the face of external punishment. The present study however aims to examine whether CeA stimulation-induced reward preference is maintained despite internal physiological consequences using sodium depletion and conditioned taste aversion (CTA). To this end, rats infused with light-activated Channelrhodopsin (ChR2) or control virus (EYFP) were trained to press levers for either a sucrose reward paired with CeA laser stimulation, or an unpaired salt pellet. During the sodium depletion experiment, rats developed a strong preference for the sucrose pellet, and were then repeatedly sodium-depleted in order to shift preference towards the salt reward. Here, EYFP rats shifted their behavior while ChR2 rats did not, maintaining a focused preference for the laser-paired reward despite their growing sodium appetite. In the CTA experiment, rats were presented with two novel sugar pellet flavors, one of which was repeatedly paired with the aversive agent lithium chloride. ChR2 and EYFP rats were then given the option to lever press for the aversive reward paired with laser stimulation, or the unpaired alternative flavored reward. Here, EYFP rats demonstrated a stronger avoidance of the aversive pellet and reduction in laser preference compared to ChR2 rats. These results suggest that CeA stimulation produces a powerful compulsion that can overcome intense physiological motivation, which could provide insight into why addicts forego their own health and biological needs to pursue their preferred reward.

Title: The impact of junk-food on 'liking' responses to sucrose, saccharin and salt in obesity-prone and obesity-resistant rats

Authors: ***A. BEN-EZRA**¹, E. HALTER¹, C. FREELAND¹, C. L. POISSON¹, A. WANG¹, C. R. FERRARIO², M. J. F. ROBINSON¹ ¹Psychology, Wesleyan Univ., Middletown, CT; ²Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: Diet-induced obesity is a growing problem influenced by the widespread availability of "junk-foods". However, consumption of these high-fat and high-sugar foods can cause varied weight gain due to genetic predisposition. This is reflected in rodent models, where a junk-food diet causes a weight increase in some Sprague Dawley rats (gainers), but not others (non-gainers). We have recently shown that male gainers experience a blunting of pleasure or 'liking' following prolonged junk-food exposure (Robinson et al, 2015). However, it is unclear whether these effects are the cause or consequence of excessive junk-food consumption. We can explore

this question using selectively-bred obesity-prone (OP) and obesity-resistant (OR) rats to examine hedonic 'liking' and 'disliking' responses both before and after consumption of junkfood. We used male and female OP (n = 20) and OR (n = 20) rats to study hedonic taste reactivity responses to sucrose (1%, 3%, 9%), salt (1%), and saccharin (0.15%) solutions. We found that OP rats showed fewer positive hedonic responses to sucrose and saccharin, both before and after junk-food exposure, as compared to OR rats. We also found that after junk-food exposure OP rats demonstrated reduced hedonic sensitivity towards the different sucrose concentrations, but no overall significant sex differences. Together, these data show that hedonic responses to sweet tastes are lower in obesity-prone rats, suggesting that pleasurable responses to sweetness do not drive over-consumption and that these responses are only mildly reduced by junk-food consumption.Furthermore, after junk-food, we observed that OP, but not OR rats, found salt less aversive, possibly suggesting the development of tolerance for salt overconsumption. Previous research suggests that mu-opioid receptor (MOR) transmission in the ventral and dorsal striatum modulates food intake and the preference for palatable foods, and we have previously shown that male gainers show decreased expression of MOR mRNA in these areas. To explore this in OP and OR rats and its possible relationship to changes in taste reactivity, we tested mu opioid receptors sensitivity via a morphine conditioned place preference paradigm before and after junk-food. Ultimately, our results suggest that animals predisposed to obesity have blunted hedonic responses to sweet solutions, even prior to consumption of a junkfood diet. Coupled with previous research suggesting increased attraction to food cues in obesityprone animals, these findings suggest basal differences and interactions between responses to food, highlighting a possible pre-existing dissociation between 'liking' and 'wanting'.

Title: Effects of nicotine exposure and anxiety on motivation for gambling-like cues

Authors: *T. I. RUSSELL¹, M. J. ROBINSON² ²Psychology, ¹Wesleyan Univ., Middletown, CT

Abstract: More than half of disordered gamblers (60.4%) report comorbid tobacco dependence. Furthermore, 41.3% of disordered gamblers report the diagnosis of an anxiety disorder. The cooccurrence of gambling disorder and tobacco dependence might suggest a common mechanism for their pathology, and anxiety might promote the maintenance of these maladaptive behaviors.

One of the most important characteristics common to all gambling games is the uncertainty associated with the probability of reward delivery and the magnitude of the reward. Evidence suggests that uncertainty may powerfully enhance attraction to cues, such as the flashing lights and celebratory sounds of casino slot machines. However, it is unknown how nicotine or anxiety might contribute to cue-attraction. In the present study, we investigate the effects of nicotine (0.3 mg/kg, s.c.) on the desire for cues associated with uncertain rewards in male and female Sprague-Dawley rats. In an autoshaping task, rats learned to associate lever and tone cues (CS) with the delivery of sucrose pellet rewards (UCS) on either a certain or uncertain reward contingency in the presence of nicotine or saline. In the certain condition, each cue presentation was followed by the delivery of one sucrose pellet (100%-1). In the uncertain condition, only half of the trials were reinforced with either 1, 2, or 3 sucrose pellets (with equal probability) (50%-1-2-3). Subsequently, we tested the ability of gambling-like cues to serve as a conditioned reinforcer, and to promote motivation for the sucrose reward during a progressive ratio task. Finally, the Elevated Plus Maze was used to measure the effects of anxiety and its interaction with nicotine and uncertainty. During the autoshaping task, nicotine enhanced attraction to CS cues under certain conditions, but not for uncertain ones. Conversely, in the progressive ratio task, nicotine enhanced motivation to obtain the reward in uncertain conditions, but not for certain conditions, and this effect was largely driven by females. Lastly, we examined the role of anxiety in moderating cue-directed behaviors. In all, nicotine appears to promote motivated behaviors by increasing incentive salience to cues associated with certain rewards and increasing motivation for rewards associated with uncertainty. Since motivation to obtain rewards appears to be greater in females injected with nicotine, comorbidity rates may be sex specific rather than uniform across both sexes. Future studies should consider nicotine comorbidity and these sexdependent effects when developing successful intervention programs for disordered gambling.

Title: Distinguishing between predictive and incentive value of uncertain gambling-like cues in a Pavlovian autoshaping task

Authors: *A. S. KNES, T. I. RUSSELL, C. CLIBANOFF, J. R. COTE, M. J. F. ROBINSON Psychology, Wesleyan Univ., Middletown, CT

Abstract: Gambling Disorder is a behavioral addiction that affects nearly 1% to 2% of the United States adult population each year. In gambling games, cues such as flashing lights and

celebratory sounds are present during reward delivery, and can attract and motivate an individual to continue playing. Cues that reliably predict reward often become attractive and imbued with incentive properties. However, gambling-like cues are typically associated with uncertainty in the form of reward probability and magnitude. Although the predictive value of uncertain cues is degraded, previous research has shown that these cues become more attractive. Currently, it remains unclear how uncertainty affects the attribution of incentive salience to the predictive versus the incentive property of these cues. Here, we used a novel pavlovian autoshaping approach to investigate the effects of reward uncertainty on the predictive and incentive value of CS cues in Sprague Dawley rats. In this task, we presented a CS1 followed by a CS2, which resulted in the delivery of sucrose pellets. The first CS gains predictive value as it is presented immediately before the second CS and predicts the possibility of sucrose reward delivery. The second CS provides no additional predictive information, and instead primarily holds incentive value as its presentation most closely precedes reward delivery. Rats learned to associate the CS1 and CS2 lever presentations with the delivery of sucrose pellets on either a certain or uncertain reward contingency. In the certain reward condition, one sucrose pellet is delivered immediately after the CS period. In the uncertain reward condition, half of the CS presentations are not reinforced, while the other half are reinforced with either 1, 2, or 3 sucrose pellets. Here, we demonstrate the separation of incentive and predictive value for cues that are associated with the uncertain reward contingency. Our results suggest that the presentation of a CS2, which is more proximal to reward, leads to increased attraction primarily for animals assigned to the uncertain reward contingency. In contrast, under certain reward conditions, rats demonstrate increased attraction to solely the first, predictive CS1. These findings suggests that uncertainty might alter attraction and promote the attribution of greater salience specifically to incentive cues, while leaving the attraction to predictive cues unchanged. Therefore, in gambling games with a high degree of uncertainty, attraction to cues such as lights and sounds might be greater due to the increased incentive value that is attributed to these cues.

Title: Regulation of food reward by female gonadal hormones

Authors: *K. E. YOEST¹, K. E. SHASHLO¹, J. A. CUMMINGS¹, J. B. BECKER^{1,2,3,4} ¹Dept of Psychology, ²Neurosci. Program, ³Mol. and Behavioral Neurosci. Inst., ⁴Dept of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: In female rodents, motivated behaviors are influenced by cyclic changes in levels of gonadal hormones. Induction of sexual receptivity by estradiol and progesterone modulates motivated behavior in response to both natural and drug rewards, and estradiol alone is sufficient to enhance motivation for cocaine (Becker & Hu, 2008, Front. Neurosci. 29(1): 36-47). Here we sought to parse the pharmacological and behavioral mechanism by which changes in circulating gonadal hormones levels over the course of the estrous cycle influences motivation for palatable food reward.

We have previously demonstrated that hormone priming with estradiol and progesterone in a regimen that induces sexual receptivity reduces both food consumption and motivation for food when animals are tested on fixed interval (FI) or progressive ratio (PR) schedules of reinforcement. However, we had not yet verified whether administration of estradiol alone is sufficient to induce changes in motivation for food. Therefore, we tested whether repeated administration of estradiol benzoate could induce the same changes in motivation that were seen after giving estradiol benzoate followed by progesterone. This priming regimen also induces sexual receptivity but may not activate progesterone receptors outside of the hypothalamus. We found that administration of estradiol alone reduced both the total number of rewards received and the average number of responses made on the FI schedule. Estradiol did not reduce breakpoint on the PR, however, suggesting that progesterone is required for the decreased motivation for food on the PR schedule. Interestingly, on the FI schedule there was an increase in the number of intervals initiated but not completed when females were treated with estradiol and progesterone, and not estradiol alone.

These behavioral effects led us to hypothesize that estradiol and progesterone may be acting on different neural circuits to modulate different aspects of food reward during periods of sexual receptivity. While estradiol alone can decrease consumption of rewards and overall responding on a well-trained task, supplementary progesterone is required to reduce perseveration toward a food reward. To investigate if this effect of progesterone on perseverative responding is dependent on the ventral striatum, we implanted ovariectomized female rats with bilateral cannula aimed at the nucleus accumbens. Animals were then hormone primed with and without chronic intracranial administration of the progesterone antagonist, RU486. These findings will further elucidate the mechanism by which induction of sexual receptivity induces changes in feeding behavior and food reward.

Title: Chronic stress impairs reward responsiveness in a rat test of anhedonia

Authors: *S. J. LAMONTAGNE¹, M. C. OLMSTEAD² ¹Psychology, ²Queen's Univ., Kingston, ON, Canada

Abstract: Anhedonia, a severe deficit in reward processing, is an endophenotype of several neuropsychiatric disorders (APA, 2000) and increases susceptibility to depression (Atherton et al., 2015), substance abuse (Hatzigiakoumis et al., 2011), and suicidality (Winer et al., 2016). Recent literature suggests that anhedonia reflects a maladaptive interaction between reward circuitry and stress, the former being mediated by the mesolimbic dopamine (DA) system and the latter by the glucocorticoid system (Vrieze et al., 2013). The role of the DA system in the development and maintenance of anhedonia has been studied extensively, but little is known about the contribution of the glucocorticoid system in this process. The goal of the current study was to investigate the effect of stress on reward processing using a validated rat test of anhedonia, the probabilistic reward task (PRT). In this task, rats learned to discriminate between two ambiguous tones for a sucrose reward. During testing, one lever was programmed to produce three times more reward than the other lever. Similar to healthy humans, rats develop a response bias toward the more frequently reinforced stimulus, regardless of which tone is presented. Consistent with prior literature (Der-Avakian et al., 2013), the response bias was enhanced following administration of a DA agonist, amphetamine, and reduced following administration of a DA antagonist, pramipexole. Additionally, a 28-day chronic mild stress (CMS) regimen attenuated the increase in response bias that normally develops over the test session. Finally, the glucocorticoid antagonist, mifepristone, had no effect on the response bias relative to saline; however, the glucocorticoid agonist, dexamethasone, attenuated the response bias relative to both saline and mifepristone. These results confirm a role of DA in reward processing, and highlight an additional contribution of the glucocorticoid system in the mediation of this effect. Thus, it is plausible that stress directly interferes with normal mesolimbic DA functioning, which leads to an overall impairment in reward responsiveness. Future studies on the etiology of anhedonia should carefully investigate the interaction of these systems in reward processing.

Title: Deletion of Prkar2a, with its exclusive habenular brain expression, confers obesity resistance through decreased hedonic behavior and increased drive for voluntary exercise

Authors: *E. LONDON¹, J. C. WESTER², C. A. STRATAKIS¹ ¹NICHD, Bethesda, MD; ²NIH, Bethesda, MD

Abstract: The cAMP-dependent protein kinase (PKA) system is crucial in regulating energy balance and many other cellular functions as it mediates the effects of numerous hormones, neurotransmitters and catecholamines that bind G-protein coupled receptors. Prkar2a codes for PKA regulatory subunit RIIa, that unlike other PKA subunits, has minimal expression throughout the brain except in the habenula where it is highly expressed. The habenula has been implicated in regulating hedonic state, voluntary exercise, and primary reinforcement. Here we show that RIIa knockout (KO) mice resist diet-induced obesity, and this phenomenon cannot be explained by enhanced metabolic rate. Instead, RIIa KO consistently consumed less palatable high fat (HF) chow than wild type (WT) mice, despite their comparable preference for HF over regular chow. RIIa KO mice also consistently consumed less 10% sucrose solution during a twoweek sucrose preference test. Alternatively, when provided home cage running wheels, RIIa KO mice ran two to three times more than WT littermates. These differences were more profound in females. Pkrar2a colocalizes with Chrna3 and Chrnb3 in the medial habenula, and with Mor1 in the lateral habenula, yet it is not known how it might regulate nicotinic or mu opioid receptor pathways. Enzymatic activity assays showed decreased habenular PKA activity in RIIa KO compared to WT mice; PKA activity was unchanged in striatum, a region that provides input to the habenula. Others have shown that mice with dorsal medial habenula lesions have blunted sucrose preference as well as poor performance in voluntary wheel running. These data combined suggest that Prkar2a has diverse roles in modulating behaviors related to reward reinforcement and motivation for voluntary exercise, likely by affecting downstream targets such as ventral tegmental area or substantia nigra. Ongoing studies involve virus-mediated reexpression of Prkar2a in the habenula and habenula-specific KO of Prkar2a. The study of Prkar2a in brain may serve as a useful model for better understanding the role of the habenula in regulating behaviors involved in obesity, addiction, and depression.

Title: An examination of the effects of D1, D2, and mu-opioid receptors of the nucleus accumbens on appetitive and consummatory motivation in a modified effort-related choice paradigm

Authors: *H. N. CARLSON, C. MURPHY, W. E. PRATT Psychology Wake Forest Univ. Winston Salem NC

Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: The nucleus accumbens (NAcc) is critical for regulating appetitive and consummatory phases of motivated behavior. It is innervated by dopaminergic pathways which promote incentive and effort-inducing properties of stimuli. Additionally, opioid receptor activation of the NAcc increases food consumption, particularly on palatable diets. In these experiments, we compared the impact of dopamine or µ-opioid receptor manipulations of the NAcc core on a modified effort-related choice paradigm in which rats could choose between working for a preferred sugar pellet or consuming freely available rat chow. Male Sprague-Dawley rats (n = 12/group) were food restricted to 90% ad libitum weight and trained on a progressive ratio 2 (PR2) schedule to earn sugar pellets. Following training, food was returned, and rats were surgically implanted with bilateral guide cannulas targeting the NAcc core. Rats were then retrained on the PR-2 task, with rat chow also freely available in the operant chamber. Access to the sugar-associated lever and the food was continuous throughout each 1-hr session. Once behavior had stabilized, separate groups were tested following NAcc D1 receptor stimulation or blockade (with 0, 0.25, and 1.0 µg SKF 38393 or 0, 0.5, and 2.0 µg SCH 23390/side, respectively), D2 receptor stimulation or blockade (with 0, 1.0, and 5.0 µg raclopride or 0, 0.2, and 1.0 μ g quinpirole/side, respectively), or μ -opioid receptor stimulation (with 0, 0.025, and 0.25 µg DAMGO/side). Individual rats in each drug group were tested on all doses of a single drug, and then again in separate sessions following 24-hr food restriction. NAcc blockade of the D1 receptor or stimulation of the D2 receptor dose-dependently reduced the break point for earning sugar pellets, but had no impact on consumption of the freely-available rat chow, regardless of the deprivation condition of the animals. Neither NAcc D1 receptor stimulation nor D2 receptor antagonism impacted progressive ratio performance or chow intake. NAcc µ-opioid receptor stimulation increased intake of the freely-available chow and also reduced break point for the sugar pellets. These data support a role for NAcc dopamine for regulating incentive and effort-related processes of appetitive motivation but not consummatory processes. In contrast, stimulation of µ-opioid receptors shifted rats' behavior away from sugar-seeking and towards food consumption, even when additional effort would yield a preferred food. Future use of this

task may be beneficial in teasing apart the motivational functions of other neurotransmitter systems involved in food-directed motivation.

Title: Fenfluramine and lorcaserin inhibit the binge-like feeding induced by mu-opioid receptor stimulation of the nucleus accumbens in the rat

Authors: *W. E. PRATT, S. BLUMENTHAL

Dept. Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: One cause of the current obesity epidemic is the increased availability of highly palatable diets that engage brain reward circuitry and promote overconsumption of food. Prior experiments have shown that the stimulation of µ-opioid receptors in the nucleus accumbens (NAcc) powerfully increases intake of palatable and high-fat diets. In contrast, serotonin agonists reduce feeding by advancing satiety processes, and several serotonin agonists have been prescribed to promote weight loss. Despite this knowledge, it is unclear if serotonin signaling can modulate the food intake elicited by activation of µ-opioid signaling within reward circuits. These experiments assessed the effects of systemic treatments with the serotonin agonists dfenfluramine and lorcaserin on the binge-like feeding induced by mu-opioid receptor stimulation of the NAcc. Male Sprague-Dawley rats (n = 8/group) were surgically implanted with bilateral guide cannulas targeting the NAcc core. Upon recovery, they were acclimated to 2-hr daily sessions, during which they were given free access to Crisco® and water. On subsequent drug testing days, rats received systemic injections of d-fenfluramine (Experiment 1; at 0, 0.6, or 3.0 mg/kg) or lorcaserin (Experiment 2; at 0, 0.3, or 1.0 mg/kg) prior to injections of vehicle or the mu-opioid receptor agonist DAMGO bilaterally into the NAcc (at 0.025 µg/0.5 µl/side). Each rat randomly received all possible combinations of systemic and intracranial injections across 6 treatment days. Food and water intake, rearing, and ambulatory behavior were monitored throughout each session. Consistent with previous reports, stimulation of NAcc µ-opioid receptors significantly increased consumption of the high-fat vegetable shortening, and systemic treatment with d-fenfluramine and lorcaserin dose-dependently decreased intake. Interestingly, both d-fenfluramine and lorcaserin reversed the binge-like feeding observed following stimulation of NAcc µ-opioid receptors. At 3.0 mg/kg, fenfluramine completely blocked feeding on the vegetable shortening, whereas 1.0 mg/kg of lorcaserin reduced DAMGO-induced feeding to baseline at the conclusion of the 2-hr session. Both serotonergic drugs also reversed the

increases of ambulation observed following DAMGO injections into the NAcc; rearing was inhibited at the highest doses of d-fenfluramine and lorcaserin given. There was no impact of any treatment on water intake. These data demonstrate for the first time that serotonergic systems, in addition to impacting homeostatic regulation of feeding, also can inhibit food intake elicited by activation of mu-opioid receptors within the ventral striatum.

Title: Anterior insula-Locus Coeruleus area inputs and α 1-adrenergic receptors promote compulsion-like alcohol intake

Authors: *K. LEI¹, S. A. WEGNER¹, D. DAREVSKY¹, F. W. HOPF² ¹Neurol., Univ. of California, San Francisco, San Francisco, CA; ²Dept Neurol, UCSF, San Francisco, CA

Abstract: Compulsive alcohol intake, where drinking continues despite negative social, legal and physical consequences, is a major obstacle to treating alcohol use disorders (AUDs) in humans. Our previous work identified an anterior insular (aINS) circuit that is specifically required for promoting compulsive alcohol intake, but with no role in the regular, unpunished alcohol drinking. This was observed when inhibiting aINS-NAcCore or mPFC-NAcCore inputs with optogenetics, and inhibiting non-canonical NMDARs in NAcCore with pharmacology and shRNA. Interestingly, the idea that compulsive drinking would be driven by cortical-subcortical circuits that process conflict has been proposed based on clinical findings (Tiffany and Conklin, 2000; Bechara and Naqvi, 2010). In particular, it is the conflict, where intake persists despite negative consequences that requires the use of specific cortical circuits to successfully maintain compulsive behavior such as drinking despite punishment. For regular drinking, there is no conflict and no need for any of this circuitry, and habit-related circuits are likely involved. In fact, ours is the first and only evidence for this model. In addition, we found that both aINS-NAcCore and mPFC-NAcCore projections are critical for driving compulsive intake regardless of whether the aversive consequence is shock or bad tasting quinine. This is important because the quinine-resistant compulsive drinking model is widely used and technically simple, but the

insula is also related to primary taste, but our results implicate these circuits for compulsive drinking independent from the actual type of punishment. Since compulsion-like drinking also involves aversion, we examined here whether the adaptive stress system, especially the Locus Coeruleus (LC) and its noradrenergic projections, also play a specific and potent role in compulsion-like intake. Inhibition of the α 1-adrenergic receptor with prazosin systemically or in the mPFC significantly and selectively reduced compulsive alcohol intake. Prazosin inhibition of compulsive drinking was not related to basal intake levels, suggesting compulsion and self-administration are separate factors, similar to compulsive drinking, with no role in regular alcohol intake. Thus, adaptive stress responding may be a central part of the mechanism that allows the anterior insula to drive compulsive responding for alcohol, in particular through a feed-forward mechanism whereby aINS drives the LC to activated the mPFC, which is essential for allowing compulsive drinking patterns.

Title: Compulsion-like alcohol drinking involves more automatic licking: Evidence for the head down and push model of compulsive intake

Authors: *F. W. HOPF, D. DAREVSKY, S. WEGNER, K. LEI Dept Neurol, UCSF, San Francisco, CA

Abstract: Alcohol addiction remains a major social, economic and emotional cost. Compulsive drives, where drinking continues even in the face of negative consequences (loss of job, family or freedom), represent a particular and potent obstacle to successful treatment. Our lab's recent findings suggest that compulsive drinking involves conflict between desired intake and feared consequences, which recruits cortical circuits and specific NMDAR subtypes, providing a specific intervention for compulsive drives for alcohol. Thus, we used a lickometer system to examine whether rats exhibited concentrated patterns of intake, and perhaps increased motivation for intoxicating effects, during what has been considered binge-like drinking or compulsion-like. Adult male rats drank alcohol under an intermittent schedule (Monday, Wednesday and Friday

overnights) which is known to strongly escalate drinking, a sign of addictive behavior. After ~ 3 months, rats drank 20 min/day, 5 days/week for ~1 month, and then intake patterns were assessed using lickometers. For each rat (n=14) we analyzed 4 alcohol-only sessions (binge intake) and 4 sessions of alcohol adulterated with bitter quinine (compulsion-like drinking). Different parameters of licking were analyzed using multiple linear regression and other methods. Using the widely used 1 sec cutoff, our results support that both binge and compulsive alcohol drinking (and saccharin intake) are based around a particular response pattern, which may represent an optimum for the central pattern generator for licking. Drinking of alcohol with higher levels of quinine, where intake is reduced, also shows evidence of disrupted bout generation, including slower and shorter bouts, suggesting that the stereotyped aspects of licking do not reflect a floor/ceiling effect in terms of licking. Also, different measures of licking also suggest that both forms of alcohol drinking exhibit high motivation. In addition, analyses suggest that compulsive like drinking is more focused and less variable than binge-like licking, perhaps indicating a process where aversion is acutely experienced and the individual tightens their focus to just get through the punished drinking session, our newly described Head Down and Push model. Thus, concentrated patterns of intake during binge-like or compulsion-like alcohol consumption could imply high motivation for, with a greater focus on lick fidelity that may be something akin to just gritting one's teeth and pushing through to get the desired intake done.

Title: Age-related changes in licking microstructure and motivation for palatable rewards

Authors: *I. A. MENDEZ¹, N. P. MURPHY¹, S. B. OSTLUND², N. T. MAIDMENT¹ ¹Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; ²Dept. of Anesthesiol. and Perioperative Care, UCI Sch. of Med., Irvine, CA

Abstract: While food reward processing in adolescents has been well studied, how it changes as individuals age beyond adolescence is less understood. Analysis of licking microstructures may be used to discern the incentive properties from the hedonic impact of rewards; therefore, licking microstructure for various concentrations of sweetened condensed milk (SCM) was assessed in adult (20 weeks old) and aged (21 months old) rats. Following training in a lickometer, within and between subjects SCM concentration-response curves were established to assess licking

microstructures. Motivation to work for either a low or high concentration of SCM was also examined by studying instrumental responding for SCM under various reinforcement schedules over several days. We found that aged rats showed more bouts of licking compared to adults, but only at lower concentrations of SCM. Additionally, differences between age groups on lever pressing for SCM under high demand schedules also depended on concentration. Our results suggest that age-related changes in licking microstructure and motivation go well beyond adolescence and may depend on the palatability of the orosensory reward being consumed. These findings may help understand healthy and pathological age-related changes in food reward processing and associated diseases.

Title: Response allocation in Pavlovian-to-instrumental transfer

Authors: *A. T. MARSHALL¹, C. N. MUNSON¹, S. B. OSTLUND²

¹Univ. of California - Irvine, Irvine, CA; ²Dept. of Anesthesiol. and Perioperative Care, UCI Sch. of Med., Irvine, CA

Abstract: Individual's actions are influenced by external reward cues, which may promote suboptimal reward-seeking behavior. For example, drug-associated cues appear to motivate drug seeking even when individuals are engaged in other, more adaptive behaviors. The presumed mechanism of this phenomenon is that cues induce a state of heightened incentive motivation for reward (increased desire/wanting). The Pavlovian-to-instrumental transfer (PIT) paradigm is a powerful behavioral tool for studying motivated behavior, and a selective assay of the incentive motivational properties of reward cues. In tests of PIT, Pavlovian reward-predictive cues, presented while an instrumental reward-seeking response (e.g., lever pressing) is available, typically result in an invigoration of reward seeking, even though reward-seeking responses were never reinforced during the cues. Unsurprisingly, cues also elicit conditioned approach behavior directed towards the reward delivery receptacle (goal approach), which can compete with cues' abilities to promote instrumental reward seeking. This Pavlovian-instrumental tradeoff is a fundamental component of various behaviors, but much remains unknown about the conditioning factors that govern how individuals allocate behavior between these two reward-related activities

(i.e., instrumental reward seeking vs. Pavlovian goal approach). Thorough analyses of the neural and behavioral mechanisms of this interaction may provide insight into adaptive decision making and aberrations in behavior control (e.g., compulsive drug seeking, gambling). Here, hungry rats pressed a lever for food and then learned to associate auditory cues with food delivery. Reward delivery frequency during the cues was manipulated. In PIT tests, rats could press the lever in extinction while the cues were intermittently presented. We predicted that cues would invigorate lever pressing, and that the cue associated with random reward delivery during the cue would elicit the greatest increase in lever pressing. Microstructural analyses of response allocation showed that rats' lever pressing was augmented during the cue, and that their distribution of lever pressing in the cues was sensitive to cue-specific predictions of reward, elucidating Pavlovian-instrumental interactions in cue-motivated behaviors. Further analyses investigated reward-magnitude effects when the timing of reward was constant. Planned manipulations of dopamine signaling will characterize the involvement of this modulator in cue-triggered response allocation. Overall, these results shed light on the neural substrates and microstructure of cue-motivated behavior.

CUNY Five-Year Graduate Fellowship

Title: Habit formation does not depend on the correlation between response rates and reward rates

Authors: *E. GARR¹, A. R. DELAMATER² ¹Psychology, City Univ. of New York, Brooklyn, NY; ²Brooklyn Col. CUNY, Brooklyn, NY

Abstract: It is known that an animal's behavior can become insensitive to the value of its goal (i.e. habitual). One important variable in determining this phenomenon is the schedule of reinforcement. Rodents trained to press a lever on a random interval (RI) schedule are more likely to develop habits than rodents trained on a random ratio (RR) schedule (Dickinson et al., 1983; Gremel & Costa, 2013; O'Hare et al., 2016). One long-standing hypothesis is that habits do not form as readily under RR schedules because the animal is able to experience a correlation between the rate of responding and the rate of reward—a correlation which is degraded under an

RI schedule (Dickinson, 1985). We tested this theory by allowing rats to press a lever for pellets under an RI schedule whose mean reinforcement rate either remained constant or became increasingly dense over 10 training sessions. The purpose of the latter manipulation was to effectively induce a positive correlation between response rate and reward rate over sessions because we expected responding to increase with training. In Experiment 1 we found that training with a positive or flat response rate-reward rate correlation resulted in equivalent goaldirected lever pressing (F(1,14) = 5.23, p < .05). In Experiment 2, we adjusted the schedules to make the overall reward rate lower. In that case, rats were habitual regardless of whether they were trained with a positive or flat response rate-reward rate correlation (F(1,16) = 0.46, p > .05). Rather than pointing to a role for the correlation between response rates and reward rates, our findings suggests that schedule density or temporal uncertainty of rewards may play more influential roles in habit formation. In fact, switching habitual rats to a denser and less temporally uncertain schedule resulted in goal-directed lever pressing (F(9,135) = 1.87, p < .05). We are currently in the process of independently examining the role that each of these variables plays in habit formation. Given that the transition to habits is mediated by changes in the striatum and medial prefrontal cortex, these findings will inform theories of cortico-basal ganglia function by implying a more precise role played by these structures in habit formation.

Title: High-fructose corn syrup in alcoholic beverages? A study in laboratory rats

Authors: *S. AYOUB, M. MINHAS, F. LERI Psychology: Neurosci. and Applied Cognitive Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Heavy alcohol use is the third leading risk factor contributing to the global burden of disease (The World Health Organization, 2009) and therefore it is important to identify factors that contribute to excessive consumption. It has been observed that the addition of sweet substances (i.e. sucrose, saccharin) to alcohol solutions drastically increases self-administration of alcohol in rats. High-fructose corn syrup (HFCS) is a calorically-dense corn-based sweetener that is frequently found in alcoholic beverages. In the current study, we used an intraoral alcohol self-administration procedure to determine if the addition of HFCS (25%) to a 5% alcohol solution would increase alcohol intake in male Sprague Dawley rats. In the first experiment, it

was found that the addition of 25% HFCS robustly increased the amount of alcohol selfadministered. A second experiment explored whether this effect could be attributable to the sweet taste or to the caloric value of HFCS. Previously, we established that 0.1% saccharin (a non-caloric sweetener) and 25% HFCS are equally palatable to rats (Levy, 2015). Thus, animals were trained to self-administer 5% alcohol mixed in a 0.1% saccharin solution. It was found that saccharin increases alcohol self-administration, but this increase was much smaller than the increase induced by the addition of HFCS. These results in rats suggest that efforts aimed at reducing the harmful consumption of alcohol may include removal of HFCS from the list of ingredients.

Title: Neural representations of observed appetitive actions encode information about reward

Authors: *K. M. RAPUANO, R. H. HYON, S. A. NASTASE, W. M. KELLEY Psychological and Brain Sci. Dept., Dartmouth Col., Hanover, NH

Abstract: Recent neuroimaging studies have shown that viewing dynamic appetitive cues (e.g., smoking, fast food commercials) engage regions of the action observation network (AON), and that this activity is meaningful for appetitive behavior. However, it is unclear what factors influence the spontaneous simulation of appetitive actions. We hypothesized that the simulation of appetitive actions encodes information about the motivational content of the stimuli. To test this hypothesis, we scanned participants using fMRI during passive viewing of naturalistic video clips depicting appetitive actions (e.g., eating food, drinking alcohol) and non-appetitive actions (e.g., applying chapstick). Appetitive actions included a range of appetizing items in a condition-rich design, and each action was presented from both the first- and third-person perspectives. Outside of the scanner, participants indicated their preferences for each item. A univariate parametric modulation analysis was performed in order to identify brain regions where activity correlated with subjective ratings of food preferences. In addition to reward-related regions (e.g., nucleus accumbens [NAcc]; orbitofrontal cortex [OFC]), activity in somatomotor cortex was greater for items that were more preferred. A similar relationship was observed for univariate

comparisons between high- and low-appetitive items (e.g., alcoholic versus nonalcoholic beverages). Additionally, we examined whether distributed patterns of activity encode motivational content using representational similarity analysis (RSA). In order to investigate whether there was shared information between reward and action observation regions, we examined the similarity of representational geometry between NAcc and somatomotor cortex and observed significant correlations between these regions bilaterally. Further, we performed an exploratory searchlight regression analysis to identify regions where local representational geometry was predicted by a weighted sum of three RDMs: perspective (i.e., first, third), categories (i.e., food, beverages), and preference ratings. Perspective and category were encoded in posterior visual areas, while category was additionally represented in ventral somatomotor cortex. Preferences were represented in lateral occipitotemporal cortex, postcentral gyrus, and ventral premotor cortex—canonical members of the action observation network. Taken together, these results suggest that reward-related information shapes representational geometry in the AON, which may influence the motivation to engage in potentially risky behaviors.

Title: Endocannabinoids but not dopamine mediate the sexual behavior inhibition and drug hypersensitivity induced by copulation to satiety in male rats

Authors: *E. GONZÁLEZ-MORALES, G. RODRIGUEZ-MANZO Pharmacobiology, Cinvestav-Sede Sur, Ciudad de Mexico, Mexico

Abstract: The mesolimbic dopaminergic system is involved in the regulation of the motivational component of male rat sexual behavior and it is activated by copulation. When a male rat is allowed to copulate without restriction with a same sexually receptive female, it will ejaculate repeatedly until becoming sexually exhausted. Copulation to satiety induces the instatement of a long lasting (72h) sexual behavior inhibitory period and, at the same time, these rats exhibit a generalized hypersensitivity to drug actions. Both phenomena suggest the occurrence of copulation-induced brain plasticity. Besides, ventral tegmental area (VTA) dopamine (DA) neurons synthesize and release endocannabinoids (eCN) in response to its continued activation. During copulation to satiety, these neurons are continuously activated, inducing a prolonged

increase in DA release in the nucleus accumbens (NAcc). Previous data showed that eCNs are involved in the induction of the long-term sexual behavior inhibition of satiated rats, but it is not known if they are also involved in the induction of drug hypersensitivity in these animals. Due to the increased levels in the NAcc, DA might also play a role in the induction of both phenomena. To test these hypotheses we administered the CB1 receptor antagonist, AM251, or the DA receptor antagonist, haloperidol, immediately before subjecting male rats to copulation to satiety and tested them 24 or 48h later for sexual behavior and drug hypersensitivity. The latter was measured by the appearance of signs of the 5-HT syndrome in response to low doses of 8-OH-DPAT or by the loss of the sexual facilitative effects of yohimbine, at low doses. Results showed that antagonism of CB1 receptors during copulation to satiety interfered with the establishment of the long-term sexual behavior inhibition and of the hypersensitivity to 8-OH-DPAT and yohimbine in sexually exhausted rats. On the other hand, dopaminergic receptor antagonism did not prevent the occurrence of both phenomena. These results show that eCNs, but not DA participate in the induction of both the long-lasting sexual behavior inhibition and the drug hypersensitivity that characterize sexually satiated rats.

Title: Does reward type matter? Examining differences in reward types in healthy weight vs. overweight adolescents

Authors: *N. ROBERTS, S. ADISE, V. BRITTAIN, K. L. KELLER, C. F. GEIER Human Develop. and Family Studies, The Pennsylvania State Univ., State College, PA

Abstract: Adolescence is a period of development associated with a heightened response to rewards and limitations in cognitive control. The majority of research studying reward response has utilized monetary incentives, and only a limited number of studies have used addition types of incentives (e.g. food). While many of these studies compare incentives to a neutral condition, few studies have examined different types of rewards in the same study paradigm. Furthermore, how the brain responds to rewards (anticipation and receipt) has been linked to weight gain and obesity in adults. However, this relationship has not been examined in adolescence, a period where increases in autonomy, including food choice decisions (e.g. types, amounts), occur. In the present study, we used behavioral and imaging methods to examine differences in reward types

(food, money, no reward). We also examine differences by weight status (healthy weight vs. overweight or obese). Seventy participants (35 healthy weight) completed 8 blocks of an incentivized Go/NoGo task. Prior to each randomized block, participants were instructed if they would win money (3 blocks), food (3 blocks), or no reward (2 blocks) based on performance on that block. Our preliminary results of the Go/NoGo task do not show a significant difference by reward type, however, the data suggest a speed accuracy tradeoff. On average, when participant's reaction times were similar in the rewarded conditions relative to the neutral conditions, participants made more errors in the neutral condition relative to the money and food conditions. This suggests that participants took additional time in the rewarded blocks in order to make less errors. A subset of participants (N=30) performed a card-guessing task, again with 3 reward anticipation conditions (food, money, neutral). We measured BOLD response with fMRI to assess brain activation in a priori defined reward and cognitive control regions. Our preliminary imaging results indicate a differential response to the anticipation of food versus neutral in the striatum and food versus money in healthy weight versus overweight or obese adolescents. In healthy weight adolescents, there was greater activation in anticipation of money vs. neutral in the right medial frontal gyrus (BA10/11). Additional analyses in both tasks will be presented. Understanding the neurobiological risk factors for obesity are crucial for obesity prevention.

Title: The effects of depletion and brain stimulation on motivation

Authors: *S.-B. BELL¹, M. M. YEE²

¹Psychology, 1989, LEXINGTON, KY; ²Univ. of Kentucky, Lexington, KY

Abstract: Transcranial direct current brain stimulation (tDCS) is a novel method of neuromodulation that can be used in humans and non-human animals. Electricity is applied to a targeted area of the brain, making neurons in that part of the brain more likely to fire. In this study, we stimulated a self-control area of the brain called the right ventrolateral prefrontal cortex. 224 college students participated in this study. First, participants completed personality questionnaires. Next, the tDCS was attached to the head and turned on. Half of the participants received real brain stimulation. The other half of the participants received sham brain stimulation, which involved turning on the device but covertly turning it back off before it had

time to start working. While the tDCS was attached, participants completed depletion exercises meant to induce a state of mental fatigue. We hypothesized that the participants who got real brain stimulation would be less fatigued in a subsequent motivation task. After the brain stimulation, the tDCS was removed. Participants were asked how hard they planned to work on the next task on a scale of 1 to 7. Then, they completed a progressive ratio motivation task where they had to press the computer mouse hundreds of times to earn points. When participants only got the sham brain stimulation, how hard they planned to work on the progressive ratio task did not affect performance; everyone clicked the mouse about the same amount of time. This was different for the people who got brain stimulation. When they did not plan to work very hard on the progressive ratio task, they performed about the same as the people who only got the sham brain stimulation. However, when they did plan to work hard on the task, they were actually able to press the mouse significantly more on the task. These findings suggest that brain stimulation can help increase work output, but only in people who are actually motivated to work. Future directions for understanding tDCS will require work in non-human animals to better understand mechanisms of action with this device.

Title: Pde-4 inhibitor, rolipram, partially reverses scopolamine-induces behavioral deficits

Authors: *I. M. WHITE¹, B. K. WARD², S. L. CASE², W. WHITE²

¹Psychology, ²Neurosci. Program, Psychology, Morehead State Univ., Morehead, KY

Abstract: Phosphodiesterase-4 (PDE-4) inhibitors have been implicated in enhancing memory and cognitive function, possibly by regulating amyloid protein and other cellular functions. Previously, we reported that scopolamine given in combination with prefrontal lesions severely impaired simple memory, and that stress augmented the behavioral deficits, outcomes resembling those seen in the aged and in Alzheimer's patients. This study examined the capacity of rolipram, a class of PDE-4 inhibitors, and of nicotine to reverse scopolamine-induced deficits in learning and motivation. Male Wistar rats were shaped to press a lever for a food reward, then were trained on a fixed ratio 20 (FR20), which required of the rats moderate motivation and sustained attention to procure food. Scopolamine (0.25 and 0.5mg) reliably impaired performance in a dose-dependent manner, without affecting consummatory behavior. Rolipram

(0.05mg) and nicotine (0.25mg) partially reversed the scopolamine-induced impairment by decreasing the first response latencies, but failed to affect the time taken to complete the task or to retrieve rewards. Results were similar following a combination of nicotine and scopolamine. Our findings suggest that the muscarinic receptor modulates learning and motivation and that a partial reversal by rolipram and nicotine may reflect common target sites of drug action.

Title: Individual differences in palatable food consumption following GABA-mediated inhibition of the medial prefrontal cortex in female rats

Authors: *E. B. SINCLAIR¹, K. L. KLUMP², C. L. SISK³

¹Neurosci. Program, ²Dept. of Psychology, ³Psychology & Neurosci Prgm, Michigan State Univ., East Lansing, MI

Abstract: Binge eating (BE) is the core, maladaptive symptom that cuts across most sub-types of eating disorders in women, and is defined as the uncontrollable consumption of a large amount of highly palatable food (PF, high-fat/sugar) within a short period of time. To study the neural underpinnings of BE, we use an individual differences model of binge eating that identifies binge eating prone (BEP) and binge eating resistant (BER) rats based on consistently high and low intake of intermittently-presented PF (vanilla frosting), respectively. We previously found that Fos expression during PF consumption was higher in the medial prefrontal cortex (mPFC) of BEP vs. BER female rats, suggesting that mPFC regulation of PF consumption differs between the two behavioral phenotypes. Here we sought to determine the functional significance of the mPFC in binge eating proneness by examining the effect of GABA-mediated inhibition of mPFC neural activity on PF consumption. BEP and BER rats were identified from a group of 50 young adult female Sprague-Dawley rats following two weeks of feeding tests consisting of ad libitum chow and intermittent (4h/day, 3d/week) PF access. Thereafter, bilateral guide cannulae were implanted into the ventral mPFC, and after recovery, BEP (N=9) and BER (N=10) rats underwent additional feeding tests immediately following intra-mPFC infusions of saline, 15ng, or 30ng of the GABA-A receptor agonist muscimol. PF and chow intake after 1 and 4hrs of access were measured and rats were video-recorded for the first hour of access to quantify feeding behavior. One hr PF intake in BEPs increased significantly in response to 30ng of

muscimol vs. saline and 15ng muscimol, yet BERs showed only a small non-significant increase in 1hr PF intake after 15ng and 30ng muscimol vs. saline. Moreover, BEPs showed a substantial increase in 4hr PF intake in response to 30ng muscimol vs. saline (Cohen's d = 0.75), while 4hr intake in BERs was unaffected by muscimol. Quantification of feeding behavior revealed that 30ng muscimol significantly lengthened the average duration of individual episodes of PF consumption in BEPs and BERs as compared to saline. These findings suggest that the mPFC normally functions as a "brake" on PF intake, given that pharmacological inhibition of mPFC activity increased (i.e., disinhibited) PF intake. However, the magnitude of the behavioral change induced by mPFC inhibition (i.e., the amount of PF consumed) was larger in BEPs than in BERs, indicating that normal mPFC inhibition of PF intake is weaker in rats prone to binge eating. Thus, aberrant prefrontal cortical control over PF consumption may contribute to heightened risk for binge eating PFs in women.

Title: The neural mechanism of interaction between intrinsic motivation and external incentives

Authors: *L. QIU

Beijing Normal Univ., Beijing, China

Abstract: Minimum uncertainty and maximum rewards are the goal of human beings. We usually make decisions with uncertainty, and are intrinsically motivated to reduce the internal uncertainty through metacognition. Previous studies have found that dorsal anterior cingulate cortex (dACC) and lateral prefrontal cortex (lPFC) play important roles in metacognition. The activity of ventral striatum (VS) encoding the intrinsic motion modulated the PFC activities in metacognition. Alternatively, metacognition could be driven by external incentives. However, the neural mechanism of interaction between intrinsic motivation and external incentives remains unclear. We here devised a novel "decision-redecision" paradigm to allow participants to make two sequential decisions on the same Sudoku problem. Prior to the secondary decision, the cues were presented to indicate different external incentives (positive, neural and negative) for the second correct answers. Behaviorally, the performance accuracy was not significantly improved under the positive incentives, but was significantly reduced under the negative incentives, in comparison to the neural condition. However, we found that the fMRI activities in the metacognition network gradually increased as the magnitudes of both positive and negative incentives incentives increased, indicating the participants tried hardly to avoid punishments under negative

incentives. Although the metacognition network activities increased in both groups, performance accuracy did not. Physiology-psychological interaction (PPI) analyses showed that VS had significant modulations on the metacognition network, and in turn, the VS activities were modulated by the dopamine neural activities in the midbrain (VTA/SN), which were separately sensitive to the positive and negative incentives. Alternatively, the dopamine neural activities sensitive to the positive incentives also projected to ventromedial PFC (vmPFC). In the participants who were sensitive to external incentives, the vmPFC activities gradually increased as the positive incentives increased, impaired the proper function in metacognition. Alternatively, the vmPFC activities were not altered for insensitive participants. Taken together, our findings show external incentives have both effects to modulate the neural activities in the metacognition network and the default-mode network, the former was driven by intrinsic motivation to improve performance, while the latter was driven by external rewards. Although everyone is motivated to better solve the problems, too sensitivity to the external rewards would paradoxically impair the performance.

Title: Compulsive addiction-like aggressive behavior in mice

Authors: *S. A. GOLDEN, C. HEINS, M. VENNIRO, D. CAPRIOLI, M. ZHANG, D. H. EPSTEIN, Y. SHAHAM Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: Some people are highly motivated to seek aggressive encounters, and among those who have been incarcerated for such behavior, recidivism rates are high. These observations echo two core features of drug addiction: high motivation to seek addictive substances, despite adverse consequences, and high relapse rates. Here we used established rodent models of drug addiction to determine whether they would be sensitive to "addiction-like" features of aggression in CD-1 mice.

Methods: In Exp. 1-2, we trained older CD-1 mice to lever-press for opportunities to attack younger C57BL6/J mice. We then tested them for relapse to aggression seeking after forced abstinence or punishment-induced suppression of aggression self-administration. In Exp. 3, we trained a large cohort of CD-1 mice, and tested them for choice-based voluntary suppression of

aggression seeking, relapse to aggression seeking, progressive ratio responding, and punishmentinduced suppression of aggression self-administration. We then used cluster analysis to identify patterns of individual differences in compulsive "addiction-like" aggressive behavior.

Results: In Exp. 1-2, we observed strong motivation to acquire operant self-administration of opportunities to aggress, and relapse vulnerability during abstinence. In Exp. 3, cluster analysis of the aggression-related measures identified a subset of "addicted" mice (~19%) that exhibited intense operant-reinforced attack behavior, decreased likelihood to select an alternative reinforcer over aggression, heightened relapse vulnerability and progressive ratio responding, and resilience to punishment-induced suppression of aggressive behavior.

Conclusion: Using procedures established to model drug addiction, we showed that a subpopulation of CD-1 mice demonstrate "addiction-like" aggressive behavior, suggesting an evolutionary origin for pathological aggression.

Title: Between-person differences in sensation-seeking: Vulnerabilities for cigarette-smoking and opportunities for intervention

Authors: *D. M. LYDON¹, B. LUNA³, C. F. GEIER²

¹Human Develop. and Family Studies, The Pennsylvania State Univ., University Park, PA; ²The Pennsylvania State Univ., Unviersity Park, PA; ³Dept Psychiatry, Lab. Of Neurocognitive Develop., Pittsburgh, PA

Abstract: Brain-based models of adolescent risk-taking have highlighted the importance of sensation-seeking and its associated neural correlates in explaining vulnerabilities for engagement in risky behaviors, including cigarette smoking. In a series of three studies, we present findings providing insight into the association between sensation-seeking and risky behaviors. Using data from the National Longitudinal Study of Adolescence to Adult Health (Add Health), time-varying effect models (TVEM) were implemented to estimate how the associations between sensation-seeking and impulse control (predictors) and daily smoking (outcome) varied from adolescence into young adulthood (ages 12 to 34). Sensation-seeking was significantly associated with daily smoking during adolescence and in the late 20s and early 30s, although the association was strongest during adolescence. Using resting state data from 43

children, adolescents, and adults, we observed that sensation-seeking was negatively associated with between-network connectivity across salience and both the default mode and central executive networks - suggesting that sensation-seeking is associated with patterns of functional connectivity that have previously been associated with limitations in cognitive control. Finally, in the context of an incentivized, anti-saccade task, we show that, although sensation-seekers are vulnerable for engaging in risky behaviors (study 1) and show evidence for limitations in cognitive control (study 2), they exhibit more accurate anti-saccade performance and greater engagement of key ocolumotor control regions (e.g., frontal eye fields, supplementary eye fields) when motivated with monetary incentives relative to low sensation-seekers.

Title: Effects of binge eating behavior on incentive motivation evaluated with two types of progressive ratio schedule

Authors: *W. ZEPEDA-RUIZ¹, N. V. VÁZQUEZ-HERRERA², D. N. VELAZQUEZ-MARTINEZ²

¹Univ. Nacional Autonoma De Mexico, Mexico, Mexico; ²Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Binge eating behavior is characterized by overconsumption of palatable food without energy deficit and changes in motivation to obtain palatable food. In our laboratory, we trained subjects in an exponential progressive ratio schedule; after binge eating induction with sucrose we did not found the changes in motivation previously reported. The main difference of our study was that we used an exponential progressive ration while other studies used arithmetic progressive ratio. Therefore, the main objective of the present work was: first, evaluate the sensibility of the reinforcement schedule through a replication of the results with haloperidol administration, and second, evaluate if the use exponential or arithmetical progressive ratio schedule may influence the changes in incentive motivation. Thirty-six male Wistar rats were divided in three groups: A) haloperidol, B) exponential and C) arithmetic progressive ratio schedule. Subjects of group A were previously trained in the exponential schedule and three doses of haloperidol (0.01, 0.03 and 0.1 mg/k i.p.) were evaluated after subjects reach stability criteria. Subjects of group B and C were trained in an exponential or arithmetic progressive ratio

schedule, respectively. When all of the subjects reach the stability criteria, binge eating induction started. During binge eating induction, subjects in groups B and C, were subdivided in two groups: control and experimental. In all groups access to water and standard food was *ad libitum*; in the control group access to sucrose was also *ad libitum* while the experimental groups had access to sucrose on Tuesday, Thursday and Saturdays two hours per day. When haloperidol was administrated, there was a decrease in the breakpoint as reported previously; this result suggest that the schedule was sensitive enough. However, we did not found changes in the breakpoint either with the exponential or arithmetic progressive ratio after binge eating induction. It is important to note that other groups reported changes on incentive motivation using vegetable shortening; also, there are differences between strains in the susceptibility to binge eating induction: Wistar rats are less prone to binge and this could have influenced the motivational changes observed since the other group used Sprague-Dawley rats.

Title: Assessment of the corticosterone profile and anxiety-related behaviors in sign-trackers and goal-trackers

Authors: *S. A. LOPEZ¹, P. CAMPUS⁴, M. KLUMPNER², S. B. FLAGEL³ ¹Neurosci., ³Mol. and Behavioral Neurosci. Inst., ²Univ. of Michigan, Ann Arbor, MI; ⁴Psychiatry, Univ. of Michigan Dept. of Psychiatry, Ann Arbor, MI

Abstract: Learning to associate cues in the environment with appetitive and/or aversive stimuli allows organisms to develop a behavioral repertoire fit to obtain valuable resources (e.g. finding food and avoiding predators). Cues, however, can also gain inordinate control and lead to maladaptive behaviors (e.g. relapse in addicts). Using an animal model, we have shown that there is individual variation in the ability of reward cues to control behavior. Rats that undergo Pavlovian conditioned approach (PCA) training, consisting of cue (e.g. lever) presentation followed by the delivery of a food reward, develop either a sign- or goal-tracking conditioned response. For both sign-trackers (ST) and goal-trackers (GT) the cue attains predictive value, but

only for ST does the cue also attain incentive value. The attribution of incentive value to the cue transforms it into a "motivational magnet", rendering it attractive and desirable. The ST/GT model can therefore be exploited to investigate individual variation in the propensity to attribute incentive salience to reward cues and the underlying neurobiological mechanisms. Using this model, we have shown that different neural circuits regulate predictive vs. incentive learning, with the latter dependent on dopamine and subcortical mechanisms. Additionally, relative to GT, ST show greater impulsive action as well as other addiction-like behaviors, indicating the coexistence of other behavioral traits that might contribute to the individual variation in cuereward learning. Interestingly, relative to GT, ST also show higher levels of corticosterone (CORT), the major hormone mediating stress response, after a single session of PCA training. It remains to be determined, however, if preexisting or emerging differences in "stressresponsivity" affect the propensity to attribute incentive salience to reward cues. Here, we assessed whether ST and GT differ in stress-responsivity, using both behavioral and neuroendocrine measures. Currently, we have examined CORT profiles in ST and GT under baseline conditions and following PCA training and anxiety-related behavioral paradigms. There does not appear to be a relationship between the propensity to attribute incentive salience to reward cues and anxiety-related behaviors, based on performance on the elevated plus maze or locomotor response to novelty. However, CORT may play an important role in mediating individual differences in cue-reward learning. These data contribute to our understanding of stress responsivity in sign- and goal-tracking behaviors and prompt future investigations examining the interaction between CORT and dopamine during cue-reward learning.

Title: Effect of different intensities of food deprivation over the preference of sucrose and corn oil intake

Authors: *S. ORTEGA-TINOCO¹, N. V. VÁZQUEZ-HERRERA², W. A. ZEPEDA-RUIZ², D. N. VELAZQUEZ-MARTINEZ² ¹Psicofisiología, UNAM, Ciudad de México, Mexico; ²UNIVERSIDAD NACIONAL AUTÓNOMA DE MÉXICO, MEXICO CITY, Mexico **Abstract:** Food intake is regulated by two systems: homeostatic and hedonic. Homeostatic system makes reference to hormones, peptides and neurotransmitters that are released when subjects are hungry or satiated. On the other hand, the hedonic system is related to the incentive value of food and/or the stimulus related to it. It has been suggested that the incentive value integrates two elements: wanting and liking; wanting is related to the approach to food, effort to obtain it and the consumption sustained by food, while liking is related to the sensorial characteristics of the stimulus and represents the hedonic impact of it. Also, it has been suggested that the physiological state of the subject influences incentive motivation. Therefore, the aim of the present work was to evaluate the effect of different magnitudes of food deprivation in the incentive value (measured as the amount of intake) of sucrose and corn oil. Twenty-four male Wistar rats were employed. Subjects were trained in a two bottle choice test with saline solution and water for 10 days. Then, subjects had access for 30 minutes to sucrose (10%) and corn oil (4.8%, diluted with mineral oil) after 2 h or 22 h of food deprivation, it is important to note that concentrations were isocaloric and the order of deprivation hours varied semirandomly. Body weight, intake of both substances and standard food were registered. In either magnitude of food deprivation, subjects preferred sucrose over corn oil. The intake of sucrose under 22 h of food deprivation was higher than intake of 2 h; however the difference did not reach statistical significance. Corn oil intake was similar under both conditions of food deprivation. Our results (intake during 6 days per condition of food deprivation) are at odds to those of Sclafani (Physiol Behav 1992, 53:1091), who observed that rats had a greater intake of fat when they were food deprived but prefer sucrose when sated. Differences in results may be related to the higher concentrations of sucrose and corn oil used in our study. Also, the differences in rat strain may be relevant: CD-IGS rats are more prone to obesity compared to Wistar rats.

Title: A sucrose preference test modified for evaluation of depression-like behavior in macaque monkeys

Authors: *H. YAMANAKA¹, N. HOSAKA², M. TAKADA¹, H. ONOE^{3,2} ¹Primate Res. Institute, Kyoto Univ., Inuyama, Aichi, Japan; ²RIKEN Ctr. for Life Sci. Technologies, Kobe, Japan; ³Neurosci., Kyoto Univ., Kyoto, Japan

Abstract: Depression is a serious mood disorder with a high prevalence in all developed countries. Because of their close proximity to humans, macaque monkeys have a potential to advance our understanding of the etiology and pathophysiology of major depression. However, there are few experimental paradigms suitable for investigating a depression-like sign of the monkey characterized by anhedonia. The sucrose preference test (SPT) is generally used for analysis of depressive behaviors in rodents, but no reports are so far available on the application to the monkey. In the present study, we made an attempt to improve the SPT for macaque monkeys to delineate a transient or fluctuating sign of anhedonia. For determining the sensitivity to a sucrose solution, nine levels of sucrose concentrations ranging 0 to 3.0% were tested in six monkeys. The result obtained from a concentration-response curve showed a critical preference at higher than 0.25% of the sucrose concentration level. Interestingly, all six monkeys displayed a high value of sucrose preference that is more than 99% when 3.0% sucrose solution was presented. In addition, sucrose consumption increased up to 1.5% in a concentration-dependent manner, and then reached a plateau. The most important issue in disease model research is what concentration of a sucrose solution should be used. If the concentration of 5% is too high, animals might still prefer it even if becoming anhedonia-like condition. Therefore, to establish the procedure for evaluating the effect of three sucrose concentrations (0, 0.25 and 1.0%) within a day, we subsequently examined their test sequence and confirmed that a 0.25-1.0-0% sequence was suitable for anhedonia-targeted analysis. Lipopolysaccharide (LPS) is known to induce neuroinflammatory processes and depression-like behaviors in rodents and also humans. To detect an anhedonia-like sign in LPS-treated monkeys, we administered LPS in seven monkeys and analyzed the sucrose consumption and preference using our improved SPT. Administration of LPS (0.1 and 0.3 mg/kg) resulted in the decreased sucrose consumption in all monkeys, and the decreased sucrose preference in two monkeys. Thus, our improved SPT for macaque monkeys may be possible to detect anhedonia, although further investigations are needed, with special reference to the species-specific response pattern and the dosage of LPS.

Title: Molecular and behavioral mechanisms mediating paclitaxel-induced changes in affect-like behavior in mice

Authors: *J. A. MEADE, W. TOMA, Y. ALKHLAIF, D. E. SELLEY, M. I. DAMAJ Pharmacol. & Toxicology, Virginia Commonwealth Univ. Hlth. Syst., Richmond, VA

Abstract: A common finding in longitudinal studies of cancer survivors is long-term changes in mood, such as dysphoria and emotional deficit, including anhedonia. However, there is no efficacious treatment for chemotherapy-induced depression in survivors who had received paclitaxel, an antineoplastic commonly used in the treatment of breast, pelvic, head and neck, and non-small cell lung cancers. Unfortunately, paclitaxel-induced changes in affect can persist for up to five years or longer following completion of treatment. With the Baby Boomer population approaching peak cancer age, it is dire that the mechanisms behind paclitaxel-induced changes in mood are uncovered so as to improve the quality of life of the projected 19 million cancer survivors in 2024. Therefore, in order to study paclitaxel-induced reward deficit over an extended period, cancer-free male C57BL/6J mice were treated with one cycle of four injections of vehicle or paclitaxel (32mg/kg cumulative) and periodically assessed for anhedonia-like behaviors. Paclitaxel caused significant time-dependent deficits in sucrose preference and morphine-induced conditioned place preference (CPP). These initial results suggested an aversive-like state induced by paclitaxel. We therefore investigated kappa opioid receptor (KOR) signaling as a putative mechanism of paclitaxel-induced anhedonia. The selective KOR antagonist norbinaltorphimine (norBNI) reversed paclitaxel-induced sucrose preference deficit. Because KOR signaling in the nucleus accumbens (NAc) can cause anhedonia via modulation of dopamine (DA) signaling, we used the $[^{35}S]GTP\gamma S$ assay to measure KOR and DA D₂ receptor (D₂R) function in the NAc from paclitaxel-treated mice. Surprisingly, a history of paclitaxel had a trend of reducing both U50,488H and quinelorane -stimulated binding, suggesting decreased function of KOR and D₂R, respectively. Our data suggest that paclitaxel-induced changes in affect-like behavior may be due to time-dependent dysregulation of KOR and D₂R signaling in the limbic system.

Title: Repeated corticosterone alters membrane protein clustering in lymphocytes along the lines seen in patients with depression

Authors: *R. ROMAY-TALLON¹, E. Y. FENTON⁴, M. A. MITCHELL², L. E. KALYNCHUK², H. J. CARUNCHO³

¹Dept. of Pharm. and Nutr., ³Col. of Pharm. and Nutr., ²Univ. of Saskatchewan, Saskatoon, SK, Canada; ⁴Project Search and Evaluation, Ctr. for Drug Res. and Develop., Vancouver, BC, Canada

Abstract: Depression is a serious psychiatric disorder affecting about 16% of the population. In previous studies, we suggested that the pattern of serotonin transporter clustering on cell membranes from peripheral lymphocytes could be a biomarker for diagnosis and treatment responsivity in depression patients. Here we evaluated whether similar alterations are seen in lymphocytes collected from rats subjected to repeated corticosterone (CORT) injections - a well-characterized animal model of depression - and whether altered protein clustering in CORT-treated rats, correlates with measures of depression-like behavior.

Long-Evans male rats received a single daily CORT injection (40 mg/kg) for 21 consecutive days, whereas control rats received vehicle injections. On day 22, depression-like behavior was assessed using the forced swim test and blood samples were drawn by cardiac puncture. Lymphocytes were isolated using the Ficoll-Paque gradient. A panel of membrane proteins were analysed in collected lymphocytes using immunohistochemistry: the serotonin transporter (SERT), serotonin 2A receptor (5-HT2A), beta-2 adrenergic receptor (β -2AR), cellular prion protein (PrPc), N-Methyl-D-Aspartate receptor subunit 2B (NR2B), and dopamine transporter (DAT). After immunolabeling, we measured the size and number of membrane protein clusters in lymphocytes using a computerized image analysis system.

Our results indicated that CORT had significant effects on the size and number of membrane protein clusters for several of the proteins included in the experiment. For example, there was an increase of 13%, 6%, 12%, 11%, and 7% in the size of SERT, 5HT2A, PrPc, NR2B, and DAT protein clusters, respectively. However, we noted a 7% decrease in β -2AR cluster size with CORT treatment. No significant group differences were detected in the number of protein clusters, except for clusters of PrPc proteins, which decreased by 20% after CORT treatment. Importantly, CORT-induced alterations in membrane protein clustering for the SERT, PrPc, NR2B, and DAT were significantly correlated with increased immobility in the forced swim test. These results largely parallel previous findings in depression patients, particularly with respect to the SERT and 5HT2A clusters. In addition, we have identified changes in the clustering of additional proteins (β -2AR, PrPc, NR2B, and DAT) that were not previously studied in human patients. Our next step will be to determine whether these addition proteins are also altered in a patient population.

Title: Long-lasting behavioral & molecular alterations following social isolation during adolescence in rats

Authors: V. BEGNI, L. LONGO, S. ZAMPAR, *M. A. RIVA Dept Pharmacol. and Biomolecular Sci., Univ. of Milan, Milano, Italy

Abstract: The exposure to adverse events early in life is associated with long-lasting neurochemical, structural and behavioural changes that may enhance the vulnerability to mental disorders, such as major depression. The pathologic outcome may depend upon the timing and duration of the adverse experience, possibly due to the differential impact on specific brain regions and circuits. In the present study we aimed to investigate the effects of stress exposure during adolescence, a critical developmental period characterized by intensive neural and behavioural changes and thus highly vulnerable to adverse events. We used social isolation, a well-established paradigm of stress for adolescent rats, in order to investigate the long lasting effects of this manipulation. 60 male and 60 female pups were weaned at PND21 and housed either in group or individually until PND49, followed by re-socialization in groups of 3 rats per cage until adulthood. Animals underwent behavioural tests at PND70-80 and they were killed two weeks later.

In the sucrose preference test, aimed to investigate the presence of a depressive like phenotype, isolated rats, both males and females, show a reduction of sucrose preference, as compared to their group-housed counterpart (p<0.05). However the cognitive performance of isolated rats was not different from control rats, as revealed in the novel object recognition test (p>0.05). The results of the molecular analyses performed in the prefrontal cortex and dorsal hippocampus revealed that social isolation produced a significant reduction of *Bdnf* mRNA levels in female, but not in male, rats (p<0.05). In order to investigate if the stressful experience during adolescence may alter the ability to cope under a challenging condition, a group of rats (control or isolated) were exposed to a 1h-session of immobilization stress immediately before killing. We found that while acute stress produced a significant up-regulation of the activity regulated

genes *Arc* and *Zif 268* (p<0.05) in the prefrontal cortex of group housed as well as of isolated rats, the stress-induced transcriptional profile of other genes was significantly affected as a consequence of isolation rearing during adolescence.

In summary, our results demonstrate that stress exposure during adolescence produce a depressive like phenotype, which is associated with a reduction in the expression of the neuroplastic marker BDNF. Future and on-going analyses will try to establish the pattern of transcriptional and translational changes that may sustain the behavioural impairment, with the aim to delineate sex and anatomical specificity as a consequence of the adverse experience early in life.

Title: Cognitive, emotional and microglial assessments of mice bearing mutations of prepro orphanin FQ/nociceptin (OFQ/N) or its receptor, ORL-1, maintained on C57BL/6 and 129S6 mouse strains: Applicability to chronic stress paradigms of resilience

Authors: *A. W. KUSNECOV¹, J. E. PINTAR³, E. FRILING¹, E. B. UKPONG^{2,4}, L.-J. WU^{2,4}, B. PENG³, M. ANSONOFF³, R. GLASS¹ ¹Psychology, ²Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ; ³Dept Neurosci & Cell Biol, Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; ⁴Neurol., Mayo Clin., Rochester, MN

Abstract: The neuropeptide OFQ/N and its cognate receptor (NOP or ORL-1) have been linked to cognitive, emotional and motivational behaviors, as well as neuroinflammation. Human studies have linked the OFQ/N system to anxiety and depression, which is also associated with inflammatory cytokines. Further, animal models point to an anxiolytic role for OFQ/N, although full consensus has yet to be reached. Here we behaviorally compare prepro OFQ/N and ORL-1 mutations maintained on different background mouse strains (C57BL6/J or 129S6) to test the potential role of OFQ/N or ORL-1 as a resilience mechanism - and a possible anti-inflammatory influence - during chronic stress. Transgenic mice were compared to wild type C57/BL6 or 129S6 mice from the same breeding colonies. Male and female mice of at least 2-3 months of age (N was at least 5/group) were subjected to food-motivated T-maze learning and the elevated plus maze (EPM). For T-Maze learning, mice were trained to locate condensed milk in each of two opposing arms. Subsequent to habituation, alternation was tested for 5 days (4 trials/day). Percent correct choices (choosing the alternate arm, after visiting the baited opposite arm) were calculated for each day, and analyzed by ANOVA. Irrespective of genotype, learning was superior in mice of the C57BL/6 background (p <0.001), with the 129S6 mice displaying poor learning. Despite the superior C57 strain learning, ORL mutation delayed acquisition in male mice compared to the C57 WT mice (Day x Genotype, p = 0.054). Females and the ppOFQ/N KO mice are currently being tested. Among the 129S6 strain, while poor learners overall, the 129/ORL and 129/ppOFQ/N mutant mice were significantly worse (p < 0.05). These genotype effects were due mainly to ORL deletion. EPM: Mice were tested twice on days 1 and 4. Percent time in the open arms did not differ between strains (p<0.001), but ORL mutations in C57 mice did reduce percent open time (p < 0.001 compared to C57/wt), supporting an anxiolytic role for ORL-1. The ORL mutation in 129S6 mice is currently being tested for EPM. Microglial Activity: C57 WT or C57/ORL KO mice were crossed with CX3CR1GFP/+ mice to study microglial activity by 2-photon live imaging subsequent to acute or chronic stress exposure. Preliminary data suggest that basal microglial activity in CX3CR1GFP/+ ORL ko mice does not differ from heterozygous or wildtype CX3CR1GFP/+ mice. Conclusion: Further studies are ongoing to determine the potential protective benefits of ORL signaling on T-maze learning after chronic stress using the C57 background. Moreover, the role of ORL in modulating microglial activity during chronic stress is being investigated.

Title: Mapping brain activity after CMS protocol through cytochrome c oxidase histochemistry

Authors: *K. S. HOMEM¹, A. DE TOLEDO RAMOS², C. M. DOMINGUEZ³, M. M. SOARES³, C. SCAVONE², L. R. P. TRONCONE³ ¹Univ. of São Paulo - IPUSP, Sao Paulo, Brazil; ²Pharmacol., Univ. of Sao Paulo - Inst. of Biomed. Sci., Sao Paulo, Brazil; ³Pharmacol., Inst. Butantan, São Paulo, Brazil

Abstract: Previous studies developed in this lab described relevant differences among types of stressors and HPA axis response. Stressors induce remarkable ACTH secretion, but vasopressin 1b antagonists can inhibit physical stressors like ether vapor inhalation while CRH1 antagonists inhibit psychological stressors such as restraint. Mixed stressor such as forced swimming only had its effects blocked by concomitant use of both antagonists. Continuous Mild Stress (CMS) is an important animal model of depression in which anhedonia is measured by sucrose preference. This model demands a long-term (2-3 weeks) exposure to a variety of stresses and sometimes the protocol results unsuccessful. We hypothesize that different stress modalities, physical or psychological, may be more effective in inducing anhedonia. Brain mapping of metabolic changes induced by stresses may offer clues to the understanding of the ongoing processes. Cytochrome c oxidase activity reflects long-term trends in energy demands allowing for an effective mapping of long-term changes in regional brain activity. We used 3 groups of 6 Wistar rats each that underwent CMS protocols: a control non stressed group (CON), a physical stress group (PHY) and a psychological stress group (PSY) for two weeks. All animals were then decapitated and brains were frozen at -80°C and later sliced at 30 µm in a cryostat. Slices were stained for cytochrome oxidase activity mapping by the DAB/cytochrome c standard method. Regions of interest were marked based on Watson&Paxinos rat brain atlas and measured by optical densitometry. Preliminary results are the following, always in comparison to CON: in PHY, areas that had statistically significant increase (1-way ANOVA) were lateral periaquedutal gray (LPAG), 6%; medial preoptic area (MPA), 9%; anterior paraventricular hypothalamic nucleus (PaAP), 8%; ventral paraventricular hypothalamic nucleus (PaV), 3%; ventral bed nucleus of stria terminalis (STLV), 10%; medial anterior bed nucleus of stria terminalis (STMA), 6,5%; medial ventral bed nucleus of stria terminalis (STMV), 11%. In PSY, the areas were LPAG (4%), MPA (5%), PaV (3%), STLV (4%), STMA (6%) and STMV (4%). There were no significant differences in cytochrome c oxidase activity on the other areas examined (anterior and posterior basolateral amygdaloid nuclei, anterior and posterior basomedial amygdaloid nuclei, central amygdaloid nucleus, dorsomedial periaquedutal gray, substancia nigra compacta dorsal, lateral and reticular). These results are in agreement with expected results for stressed animals. A full comparative approach is envisaged.

Title: Cell-type specific SIRT1 signaling pathways in the nucleus accumbens modulate depression-like behaviors

Authors: *H.-D. KIM, T. CALL, S. CAROTENUTO, R. JOHNSON, M. TANG, D. FERGUSON Basic Med. Sci., The Univ. of Arizona Col. of Med., Phoenix, AZ

Abstract: Major depressive disorder (MDD) is a significant cause of disability and 20% of individuals will suffer from a major onset of clinical depression during their lifetime. Despite the prevalence and considerable impact of depression, its pathophysiology is still elusive. The nucleus accumbens (NAc) in the reward circuitry is a key region which integrates rewarding and aversive information from various brain regions, and thus thought to contribute to the pathophysiology and symptomatology of depression. GABAergic medium spiny neurons (MSNs) are major projection cells in the NAc and two different subtypes expressing D1- or D2type dopamine receptors seem to differentially modulate depression-like behaviors. Recently, we demonstrated that increase of Sirt1, a well-known deacetylase, in D1-MSNs, but not in D2, significantly promotes anxiety- and depression-like behaviors. To further elucidate downstream regulation mechanisms of SIRT1, we performed cell-type specific transcriptomics using MSNssubtype specific Sirt1 knock-out mice expressing RiboTag. Based on our unbiased analysis of transcriptome data, Sirt1 signaling pathways modulate various neuronal physiologies in the MSNs and seem to correspond with electrophysiological and morphological changes of MSNs subpopulations in depressed mice. These evidences demonstrate that Sirt1 signaling differentially regulates depression-like behaviors in a cell-type specific manner, implicating novel antidepressant targets.

Title: The effects of medial prefrontal cortex inhibition on symptoms of depression in long evans rats

Authors: *J. J. CORTRIGHT, A. MILLER, B. PODGORSEK, A. BUTTERBRODT, A. WILLARD

Psychology, Univ. of Wisconsin River Falls, River Falls, WI

Abstract: Self-focus (i.e. the process by which one engages in self-referential processing) is a core issue in the psychopathology of major depression, which affects 350 million people worldwide. Previous studies have used functional neuroimaging to identify that the cortical midline structures, including the medial prefrontal cortex (mPFC), play a key role in selfreferential processing in depressed subjects. The current study investigates the hypothesized link between the mPFC and depression using an animal model of learned helplessness to measure self-referential processing. It is hypothesized that a decrease in symptoms of depression will be seen in animals that have undergone inhibition of the mPFC. This research holds significance in that it builds on previous studies, with conflicting results, that have aimed to link specific patterns of activity to the PFC as mediating symptoms of depression. Further examination of the mPFC is therefore warranted not only as a possible precursor to the implication of its involvement in mediating depression, but also in order to provide support for a theory of dominant pattern of brain activity (inhibition) which interacts with symptoms of depression. The current study utilized female Long Evans rats in order to more accurately generalize findings to the population of women, which make up the majority of depressed individuals in humans. Subjects were exposed to 28 days of randomized stressors during adulthood including forced swim, cage tilt, wet bedding, mild restraint and restriction of food and water. Control animals were housed in pairs, while animals exposed to randomized stress were housed in isolation. Following surgical placement of guide cannula animals were either infused with an inhibitory cocktail (0.3 nmol/0.5µl/side baclofen/0.3 nmol/0.5µl/side muscimol) or sham (artificial cerebrospinal fluid) before being tested for resiliency against learned helplessness. Subjects were tested for latency in a forced swim test and hot plate test, for motivation in a radial arm maze, for lethargy in an open field test, and for anhedonia using sugar pellets. To date, attenuation of learned helplessness symptoms have been found in stress-exposed animals which had undergone inhibition of the mPFC (having also had their self-referential processes inhibited) compared to controls. Collectively, these findings hold significance in that they build on recent research that has aimed to link areas of the PFC to symptoms of depression.

Title: Assessing the antidepressant-like effects of the (R) and (S) isomers of the atypical antipsychotic amisulpride in C57BL/6 mice

Authors: *R. RICE¹, D. SMITH¹, H. NANGUNURI¹, S. RAMAN¹, C. FAIR¹, M. A. FRIAR², T. M. HILLHOUSE³, T. J. DONAHUE¹, J. H. PORTER¹ ¹Psychology, Virginia Commonwealth Univ., Richmond, VA; ²Psychology, American Univ., Washington, DC; ³Psychology & Neurosci., Weber State Univ., Ogden, UT

Abstract: The atypical antidepressant amisulpride is used at low doses for the treatment of mild, chronic depression (dysthymia). Unlike most atypical antipsychotics, it exhibits a selective binding profile displaying high binding affinity to dopamine D_{2/3} receptors and serotonin 5-HT₇ and 5-HT_{2B} receptors. Amisulpride is comprised of a mixture of two optical isomers: (S)amisulpride and (*R*)-amisulpride. The enantiomers bind at dopamine $D_{2/3}$ and α_2 -adrenoceptors in a stereoselective manner with marked differences in affinity: (S)-amisulpride displays high affinity binding at $D_{2/3}$ receptors and is approximately twice as potent as racemic amisulpride and 20-50 times more potent than (R)-amisulpride at these receptors. To assess the antidepressant-like activity of amisulpride and its enantiomers, adult C57BL/6 mice were tested in the differential-reinforcement-of low rate (DRL) 72 sec operant procedure and the Porsolt forced swim test (FST). Amisulpride produced an antidepressant-like profile in the DRL task producing significant increases in reinforcers at 1.78, 32, and 56 mg/kg doses and a significant decrease in responding at 56 mg/kg. In contrast, amisulpride did not produce a significant decrease in immobility in the FST at 0.1, 1.0, or 10 mg/kg. Testing with the (R)- and (S)amisulpride isomers in the DRL task revealed that (S)-amisulpride significantly increased reinforcers at 10 mg/kg without any changes in responses. The (R)-amisulpride isomer did not produce any significant changes in reinforcers or responses. The tricyclic antidepressant imipramine and the NMDA noncompetitive antagonist ketamine served as positive controls and produced antidepressant-like profiles in the DRL procedure and FST. Additional testing is being conducted with the amisulpride isomers in the FST and with ketamine isomers in both tasks. These results demonstrate the importance of using multiple behavioral tasks for assessing the antidepressant-like profile of drugs, as different results may be obtained.

Title: Exploring differences in gene expression and relative cell-type balance in the hippocampus of a selectively bred rat model for internalizing and externalizing psychiatric disorders

Authors: *I. BIRT¹, M. HAGENAUER¹, C. AYDIN¹, P. BLANDINO, Jr.¹, R. THOMPSON¹, S. M. CLINTON², J. STEAD³, H. AKIL¹, S. J. WATSON, Jr.¹ ¹Univ. of Michigan, Ann Arbor, MI; ²Neurosci., Virginia Tech. Univ., Blacksburg, VA; ³Dept. of Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: For many years our laboratory has been exploring hippocampal gene expression differences between selectively-bred high responder (HR) and low responder (LR) rats in order to provide insight into the biology underlying mood and temperament. In total, as part of different experiments run across 53 generations of selective breeding, we have collected eight different microarray or RNA-Seq datasets from samples of the whole hippocampus of HR and LR rats. Recently, we ran a formal meta-analysis to determine which molecular candidates are indicated repeatedly across these different datasets. Using the statistical program R, we reanalyzed six separate HR/LR datasets, and also used the results from previous analyses of an additional two datasets. We included datasets from studies that observed gene expression across

several developmental age groups: P7, P14, P21, and adult. In addition, there was a special focus on observing differences in relative cell type expression across phenotype through the use of a cell type-based matrix deconvolution. For the comprehensive analysis, a meta-analysis of effect sizes using a random effects model was performed on both adult and developmental data. Results indicate major differences in the expression of genes with known relationships to various mood disorders, as well as potential differences in immune activation in the LR rats, supporting the theory of altered immune function in the pathophysiology of internalizing disorders.

Title: Fear extinction as a model of exposure therapy in rats: Developing a sub-maximally effective fear extinction procedure to test adjunct pharmacotherapies

Authors: *D. PAREDES, *D. PAREDES, E. A. FUCICH, D. A. MORILAK Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Adjunct treatment combining psychotherapy and pharmacotherapy can improve symptoms of stress-related psychiatric disorders such as depression and PTSD, and can increase remission rates in patients. Exposure therapy, a form of Cognitive Behavioral Therapy, shares many similarities to fear extinction learning. Our lab has previously shown that fear extinction (i.e. learning that an innocuous cue previously associated with a fearful stimulus no longer predicts that stimulus) can be used to model the effects of exposure therapy on cognitive flexibility that has been compromised in chronically stressed rats. Thus, we will use this model of exposure therapy to investigate the mechanisms underlying adjunct treatment, with the goal of enhancing the efficacy of exposure therapy. The aim of these experiments is to investigate variations of vary the parameters of our standard extinction protocol to produce a sub-maximal therapeutic effect on cognitive flexibility and coping style after chronic stress. In these experiments, we varied two parameters, the strength of initial conditioning and the number of trials in the extinction session. Animals were first fear conditioned by 4 pairings of a tone (20 sec) coinciding with a mild footshock (0.5 sec), varying the shock intensity (0.6, 0.8 or 1.0 mA) to vary the strength of conditioning. They were then subject to 2 weeks Chronic Unpredictable Stress. For extinction treatment, in a different context they received either 8 or 16 tone exposures without shock. Cognitive flexibility, measured using the attentional set-shifting test, or coping style, measured on the shock probe defensive burying test, were assessed 24 hr after extinction. We hypothesized that exposing rats to only 8 tones may constitute sub-maximal extinction, and diminish the therapeutic effects of extinction on stress-compromised behavior. Reducing the shock intensity during fear conditioning may also weaken the fear memory, thereby reducing the magnitude of extinction learning and its subsequent therapeutic effect. Alternatively, increasing the shock intensity during conditioning may make it more difficult to achieve full extinction. Preliminary data suggest that decreasing tone exposure from 16 tones to 8 decreased the effect of fear extinction on coping behavior. Experiments are ongoing to determine how varying the shock intensity affects the therapeutic effect of fear extinction.

Title: Psychiatric effect of MCFA via odorant receptor

Authors: D. KIM¹, J. KIM¹, N. KANG², N. LEE¹, Y. JAE¹, *J. KOO² ¹Dept. of Brain & Cognitive Sciences, DGIST, Daegu, Korea, Republic of; ²Dept. of New Biology, DGIST, Daegu, Korea, Republic of

Abstract: Psychiatric regulations through fatty acid receptors (FFARs) have been extensively studied in a variety of metabolic tissues, including gut and cranial nerve endings. Recent studies on the gut-brain axis support a close relationship between FFAR and the hypothalamic-pituitary-adrenal (HPA) axis, a neuroendocrine system that regulates stress response and mood. However,

the expression and functional studies of FFARs in the HPA axis are poorly understood. Here, we present a specific odorant receptor (OR) that is expressed in pituitary gland responding to medium-chain fatty acid (MCFA). The histological location and cell type were also identified by immunohistochemistry, and it was revealed that OR (+) cells were located in the anterior lobe of the pituitary gland, co-localizing with ACTH. The blood ACTH and corticosterone level were measured after intraperitoneal injection of medium-chain fatty acid (MCFA) followed by acute restraint stress. Interestingly, MCFA injection showed an inhibitory effect on both ACTH and corticosterone releases. Furthermore, anxiety and depression behaviors were assessed under chronic restraint stress condition through MCFA treatment, and decreased anxiety and depression behaviors. Finally, the generation of specific OR-KO mice exhibited abnormal HPA axis activity as well as depression- and anxiety-related behaviors. In conclusion, our study has demonstrated the potential role of OR response to stress through the HPA axis, suggesting that OR may be an important therapeutic target for mood disorders

Title: Excitatory/inhibitory synaptic imbalance of hippcampus in mouse learned helplessness

Authors: *G.-E. CHANG, D. LEE, J. KIM, H. LEE, G. KIM, G. HA, E. CHEONG Yonsei Univ., Seoul, Korea, Republic of

Abstract: Major Depressive Disorder (MDD) is one of mental disorders characterized by disturbed symptoms in emotional states, cognitive functions and physical conditions. Alteration of excitatory and inhibitory (E/I) balance in diverse brain regions such as Nucleus Accumbens (NAc), Ventral Tegmental Area (VTA) and medial Prefrontal Cortex (mPFC) has been reported as a conserved pathophysiological brain structures in depressed patients. However, precise correlation between depressive-like behavior and E/I imbalance is still not well-understood. In present study, we used learned helplessness model from adult male C57BL/6J mice by exposing to a set of random electrical foot shock in inescapable chamber. Shocked-mice were tested to evaluate having negative coping strategies and depressive-like behavior using various behavior

tests. By using whole cell patch clamp and immunohistochemistry, we observed changes of GABAergic synaptic inputs and neuronal activity within hippocampus in learned helplessness mouse. These findings suggest that GABAergic synaptic dysfunction of hippocampus is strongly related to pathophysiology of major depressive disorder.

Title: Role of CaV1-2 calcium channel in hippocampal neurons of animals with depressive likebehaviors

Authors: *C. MORENO NARANJO^{1,2}, P. HARDY¹, T. HERMOSILLA², D. VARELA², P. ROJAS¹

¹Univ. De Santiago De Chile, Santiago, Chile; ²Univ. de Chile, Santiago, Chile

Abstract: Major depression (MD) is the most common mood disorder worldwide, and a serious public health problem in most countries. The biological study of MD has partly elucidated the development of this condition. Hippocampal neurons from patients with MD show a reduced dendritic arborization and dendritic spines, nevertheless, the molecular mechanisms responsible for these changes are still to be defined. Cav1.2 calcium channels are the principal pathway for calcium influx in neuronal soma, and have been associated to several cellular processes such as changes in neuronal morphology and excitation-transcription coupling. Our work is centered in studying the role of Cav1.2 in the changes in morphology and function at hippocampal neuron in animals subjected to chronic restraint stress (CRS), an animal model of depression. Behavioral parameters such as anhedonia, reduction in social interaction and behavioral despair, demonstrated that these animals share characteristics of MD as has been reported for this model previously. The expression level of Cav1.2 in whole hippocampal samples were found significantly increased in CRS animals. This correlates with a higher current density observed in CRS neurons compared to control, suggesting an alteration in intracellular calcium handling and maybe in excitation-transcription coupling. By using immunolocalization techniques we are

currently studying the changes in signaling cascades related to L-type calcium channels to test the hypothesis that they are key playerers in the development of depression.

Title: Modulation of adult neural plasticity sets behavioural response in an animal model of recurrent depression

Authors: *N. D. ALVES, J. CORREIA, P. PATRÍCIO, A. MATEUS-PINHEIRO, A. R. MACHADO-SANTOS, E. LOUREIRO-CAMPOS, M. MORAIS, J. BESSA, N. SOUSA, L. PINTO

Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal

Abstract: Depression is a highly prevalent and recurrent neuropsychiatric disorder associated with alterations in emotional and cognitive domains. Neuroplastic phenomena are increasingly considered central to the etiopathogenesis of and recovery from depression. Nevertheless, a high number of remitted patients experience recurrent episodes of depression, remaining unclear how previous episodes impact on behavior and neuroplasticity and/or whether modulation of neuroplasticity is important to prevent recurrent depression. Through re-exposure to an unpredictable chronic mild stress protocol in rats, we observed the re-appearance of emotional and cognitive deficits. Furthermore, treatment with the antidepressants fluoxetine and imipramine were effective to promote sustained reversion of a depressive-like phenotype, however their differential impact on adult hippocampal neuroplasticity triggered a distinct response to stress re-exposure: while imipramine re-established hippocampal neurogenesis and neuronal dendritic arborization contributing to resilience to recurrent depressive-like behavior, stress re-exposure in fluoxetine-treated animals resulted in an overproduction of adult-born neurons along with neuronal atrophy, accounting for an increased susceptibility to recurrent behavioral changes typical of depression. Strikingly, cell proliferation arrest compromised the behavior resilience induced by imipramine and buffered the susceptibility to recurrent behavioral changes promoted by fluoxetine. This study shows that previous exposure to a depressive-like episode impacts on the behavioral and neuroanatomical changes triggered by subsequent reexposure to similar experimental conditions and reveals that the proper control of adult hippocampal neuroplasticity triggered by antidepressants is essential to counteract recurrent depressive-like episodes.

Title: Wistar Kyoto (WKY) rats exhibit memory deficits in addition to exaggerated depressionlike behavior

Authors: *Y. LI, D. EYERMAN, C. SANCHEZ Biol., Alkermes, Inc., Waltham, MA

Abstract: Wistar Kyoto (WKY) rats exhibit increased depression-like behavior and anxiety-like behavior, as well as neurochemical changes in serotonin, glutamate, and gamma-aminobutyric acid (GABA) systems. As these neurotransmitters are involved in diverse cognitive processes, we assessed adult male WKY rats in different memory tasks and in a test for depression-like behavior. Adult male Sprague-Dawley (SD) rats were included in the study as comparators. In the object placement test, WKY rats exhibited an impaired visuospatial memory, while SD rats exhibited an intact memory. This deficit in WKY rats was not accompanied by any reduction in object exploration. In the Y-maze test for spatial working memory, WKY rats made significantly fewer spontaneous alternations than SD rats. However, the performance of WKY rats in the novel object recognition test was intact, similar to that of SD rats. Consistent with previous studies, immobility in the forced swim test was increased in WKY rats compared to SD rats. In summary, WKY rats exhibited deficits in hippocampal-dependent memories and an exaggerated depression-like behavior. Therefore, we hypothesize that WKY rats may be considered as a rodent model for depression comorbid with memory deficits.

Title: Role of ankyrin 3 in bipolar disorder

Authors: *X. QI, T. PETRYSHEN

Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: Background The Ankyrin 3 gene (ANK3) has been repeatedly implicated by genome-wide association studies as one of the strongest risk genes for bipolar disorder (BD). However, the functional genetic variants in ANK3 have not been identified, and its role in BD is unknown. Our recent RNA sequencing and proteomic studies indicate that Ank3 reduction induces neuronal cytoskeletal instability of microtubules, suggesting that Ank3 may contribute to BD via disturbing microtubule function. The present study therefore examined the role of Ank3 in microtubule functions in mouse, primary neuron, and cellular models.

Method Expression of the microtubule plus-end binding protein 3 (EB3), a marker of microtubule stability, was measured in hippocampus of Ank3 +/+ and Ank3 +/- mice with western blot. The dynamic polymerization and depolymerization of microtubules was directly monitored by tracking the GFP-tagged EB3 puncta movement in primary mouse neuronal axons from Ank3+/- and Ank3+/+ mice using time-lapse live-cell confocal imaging. Activity of the lithium target glycogen synthase kinase 3 (GSK3) and its microtubule-associated substrates collapsin response mediator protein 2 (CRMP-2) and Tau, were measured by western blot in lithium- or vehicle-treated Neuro 2A cells in which brain-specific Ank3 isoforms were suppressed by CRISPR/Cas9 transcriptional repression.

Results EB3 expression was increased in the hippocampus of Ank3+/- mice compared to Ank3+/+ littermates (p<0.05), indicating instability of microtubules. Time-lapse video analysis demonstrated that, compared to Ank3+/+ axons, Ank3+/- axons have fewer anterograde and more retrograde moving EB3 puncta (both p<0.01), suggesting the axonal polarity of microtubules is altered. In addition, EB3 puncta in Ank3+/- axons move a shorter distance at reduced speed compared to Ank3+/+ axons (both p<0.05), suggesting microtubule stability is reduced. CRISPR-Cas9-induced repression of Ank3 in Neuro 2A cells reduced inhibitory GSK3-Ser9 phosphorylation and increased CRMP-2-T514 phosphorylation, indicative of reduced microtubule stability, which was rescued by lithium (both p<0.001). In contrast, Tau-S396 phosphorylation was unchanged by Ank3 repression.

Conclusion Our results suggest that Ank3 suppression reduces microtubule stability through a

GSK3/CRMP-2 dependent pathway and this is related to the treatment mechanism of BD. Future studies will focus on microtubule dynamics using human induced pluripotent stem cells carrying Ankyrin 3 genetic variants associated with BD risk.

Title: 'Spring' births induce anxiety/risk averse behavior in normal female mice, but resilience is seen in mice with reduced dopamine transporter expression

Authors: *M. A. KWIATKOWSKI, Z. A. COPE, L. A. LAVADIA, M. A. GEYER, D. DULCIS, J. W. YOUNG

Dept. of Psychiatry, UCSD, San Diego, CA

Abstract: BACKGROUND: Gestation during short-active (SA) photoperiods in humans (late winter/early spring births) increases psychiatric diagnoses. Previously, we determined that SA photoperiods during gestation resulted in psychiatry-relevant behavioral changes in the forced swim and saccharin preference tests vs. normal-active (NA)-born mice when tested in adulthood. Not every spring birth results in a psychiatric condition, however, indicating an important role of genetic susceptibility. Given a dysfunctional dopamine (DA) system has been implicated in most psychiatric disorders - and genetic polymorphisms of the DA transporter (DAT) are associated with some conditions - we tested whether mice with ~50% reduced expression of DAT (DAT-HY) would exhibit exaggerated psychiatry-related behaviors when born in SA photoperiods. **METHODS:** C57/BL6 dams were placed into either SA (19:5 light:dark (L:D)) or NA (12:12 L:D) photoperiods for 2 weeks, then paired with DAT-HY sires. Resultant DAT-HY and wildtype (WT) littermates were maintained in these conditions until weaning (P21), then placed into a NA photoperiod until tested in the elevated plus maze (EPM, n=120) during the active (dark) phase of the L:D cycle.

RESULTS: A significant sex by genotype by perinatal photoperiod interaction was seen for time spent in EPM open arms ($F_{(1,112)} = 6.0$, p < 0.05). When analyzed separately by sex, females exhibited a trend toward a gene by perinatal photoperiod interaction ($F_{(1,51)} = 3.7$, p = 0.061). SA-

born female WT mice spent significantly less time in open arms vs. NA-born female WT mice $(t_{(29)} = 2.1, p < 0.05)$. Female DAT-HY mice spent equal time in open arms regardless of perinatal photoperiod exposure. SA-born female DAT-HY mice spent significantly more time in open arms vs. SA-born female WT mice $(t_{(26)} = -2.9, p < 0.01)$, whereas no gene effect was observed in NA-born female DAT-HY and WT mice. Males exhibited no main effects or interactions on EPM open arm duration.

DISCUSSION: SA gestation photoperiods induce risk-averse/anxiogenic behavior in female WT mice, an effect not seen in mice with reduced DAT function as evidenced by: 1) female WT mice born in SA photoperiods spend less time in open arms compared with WT mice born in NA photoperiods, and 2) no photoperiod effect was observed in DAT-HY mice, but they did spend significantly more time in open arms vs. WT mice. Separating anxiogenic vs. risk-averse behavioral effects of SA photoperiod gestation remains important. Hence, we will test these mice in the Iowa Gambling Task, specifically designed to assess risk-preference and directly translatable to human/psychiatric populations.

Title: Sex-dependent effects of Cacna1c haploinsufficiency on juvenile social play and 50-kHz ultrasonic vocalizations in rats

Authors: T. M. KISKO¹, M. D. BRAUN¹, M. BARTZ¹, C. HOHMEYER², S. WITT², M. RIETSCHEL², R. K. SCHWARTING¹, *M. WÖHR¹ ¹Philipps-University of Marburg, Marburg, Germany; ²Central Inst. of Mental Hlth., Mannheim, Germany

Abstract: Social play behavior is the earliest form of mammalian social behavior directed at peers and not the mother. Vital to healthy development, play deprivation can result in social and cognitive deficits. Rats have complex behavioral repertoires that include both social play and ultrasonic vocalizations (USV). USV serve as situation-dependent affective signals and fulfill important communicative functions, e.g. positive 50-kHz USV ("rat laughter") as social contact calls. *CACNA1C* is a novel, yet well-established risk gene implicated in numerous

neuropsychiatric disorders, most notably affective disorders, i.e. major depression and bipolar disorder, but also schizophrenia and autism. The gene encodes for the pore-forming alpha1c subunit of the L-type voltage-gated calcium channel Ca_v1.2, mediating depolarization-dependent calcium influx into the cell. In this study, our aim was to explore the role of *Cacnalc* in social behavior, specifically during the critical period of early development. Using a newly developed genetic rat model, we investigated juvenile social play behavior and concomitant 50-kHz USV emission in male and female wildtype (+/+) and heterozygous (+/-) Cacnalc rats. In addition to 50-kHz USV in the sender, we assessed behavioral responses displayed by the recipient exposed to 50-kHz USV playback. Our results indicate that in males there are no genotype effects on social play behavior, but male Cacna1c+/- rats displayed less 50-kHz USV emission compared to Cacnalc+/+ controls across all three play sessions. In females, in contrast, evidence for prominent genotype effects was obtained, with female Cacnalc+/- rats spending more time playing and specifically pinning more than *Cacnalc+/+* controls during the second and third play session. However, increased play behavior did not result in elevated 50-kHz USV rates in female Cacnalc+/- rats and during the first play session, where play levels did not differ, 50kHz USV were reduced. Moreover, *Cacna1c* haploinsufficiency affected the behavioral response in recipient rats exposed to 50-kHz USV playback. Despite that Cacnalc+/+ and Cacnalc+/rats both displayed strong social approach behavior and presumably started to search for a conspecific in response to 50-kHz USV, strong place preference for the area in proximity to 50kHz USV was seen in Cacnalc + /+ but not Cacnalc + /- rats after the playback presentation ended, indicating that only Cacnalc + /+ rats kept searching for a conspecific. Together, our findings suggest that Cacnalc haploinsufficiency leads to behavioral changes in social and communication development with relevance to neuropsychiatric disorders, both in sender and receiver.

Title: Examining the role of cell adhesion molecules in emotional reactivity using the bred high-responder/bred low-responder model

Authors: ***A. V. STEFANOV**¹, K. L. HILDE¹, I. BIRT¹, M. H. HAGENAUER¹, E. K. HEBDA-BAUER¹, S. CLINTON², C. AYDIN¹, P. BLANDINO, Jr.¹, J. STEAD³, R. C. THOMPSON¹, S. J. WATSON, Jr.¹, H. AKIL¹

Abstract: In the United States, over a quarter of adults eighteen years or older are diagnosed with a psychiatric disorder over a twelve-month period, where the most common classes reported are anxiety and mood disorders. Developing treatments for individuals susceptible to depression and anxiety requires a better understanding of the underlying neural and molecular mechanisms. Cell adhesion molecules (CAMs) are essential for the organization and communication of neighboring cells in the nervous system of a developing organism, as they orchestrate growing neurons into neural networks and help develop and maintain the synapses between them. The structures, molecular pathways, and interactions of various CAMs have been extensively studied in neural systems, and individual CAMs have been implicated in psychiatric disease. However, we know very little about the role of this broad class of molecules in the development and fine-tuning of emotional brain circuitry.

To assess how CAMs affect the trajectory of neural circuits implicated in vulnerability to depression, we use a selectively-bred rat model of emotional reactivity: the bred high-responders (bHRs) and the bred low-responders (bLRs). bHRs exhibit higher locomotor activity, show greater sensation-seeking and impulsivity, have a propensity toward addiction, and demonstrate a greater tendency for social interaction. bLRs display lower locomotor activity, exhibit greater anxiety and depression behaviors, are more reactive to stress, and are less socially interactive. In this study, we have examined the developmental pattern of CAM gene expression in the hippocampus, an area critical for learning, memory, stress responsiveness, and the regulation of emotionality.

We will outline the phenotypic and age differences in the expression of various CAMs in the hippocampus of neonate, adolescent, and adult bHRs and bLRs. We will show that CAMs can be expressed strongly at certain time points in development while exhibiting low expression at other times. We will describe the phenotypic specificity of these developmental trajectories. Our findings suggest that emotional reactivity, which contributes to susceptibility to mood disorders, may depend in part on the temporally regulated expression of specific CAMs during development.

Title: Increased diversity in microbial communities after chronic social defeat stress in mice

Authors: *K. MCGAUGHEY¹, D. A. CRUZ², N. ELSAYED², T. YILMAZ-SWENSON², R. RODRIGUIZ², W. WETSEL², M. KRITZER-CHEREN², O. MUELLER³, D. E. WILLIAMSON^{2,4}

²Psychiatry & Behavioral Sci., ³Mol. Genet. & Microbiology, ¹Duke Univ., Durham, NC; ⁴Durham VA Med. Ctr., Durham, NC

Abstract: Abstract:

Modulation of the stress response by the interaction between the hypothalamic-pituitary-adrenal (HPA) axis and gut microbiota has been shown to have implications in major depressive disorder (MDD). Significant shifts in microbial composition can play a critical role in the stress response and the microbiome may serve a modulatory role between stressor exposure and onset of MDD. Chronic social defeat stress in mice is an established preclinical model of MDD and results in subpopulations of defeated mice that are susceptible or resilient to further stress. This study examines the structural and functional shifts in microbial composition as a result of chronic social defeat stress in mice and examines whether these differences in the microbiota map onto susceptible or resilient subpopulations. To produce a defeated phenotype, 36 male C57BL/6J mice were exposed to chronic social defeat conditioning and a social interaction paradigm that enabled profiling for susceptibility and resilience to stress. Fecal samples were collected 24 hours post-social interaction. DNA was isolated from the fecal samples and the gut microbiota was profiled using 16S rRNA metagenomic sequencing on the Illumina miSeq platform. Chronic social defeat induced behavioral changes that were associated with distinct shifts at the level of operational taxonomic units (OTUs) across phyla and families ($t_{34} = 6.28$, p < 0.001) as well as increased richness and diversity of the gut microbial community compared to controls ($t_{34} = 6.02$, p < 0.001). The OTUs that differed between defeated and control mice largely belonged to an unclassified family of Bacteroidetes (S24-7; 68 OTUs) or an uncharacterized phylum (TM7; 3 OTUs), limiting the precision in identifying specific taxa. In examining the role of chronic social defeat in creating subpopulations of susceptible or resilient mice, 10% of mice fell into the resilient category. The OTUs of susceptible and resilient mice were significantly different from controls, but not different from each other. This study indicates that exposure to chronic social stress is associated with complex OTU- level shifts in microbiota. While defeated mice present increases in overall diversity and richness, this diversity might not necessarily confer good health, particularly given evidence implicating the role of S24-7 and TM7 in modulating

inflammatory conditions and the interconnectivity of gut microbiota and macrophage activity. Additional studies would aid in the understanding of the role of microbial diversity in chronic stress paradigms and their contribution to MDD.

Title: Changed endocannabinoid signaling in the medial prefrontal cortex is related to chronic pain induced depression

Authors: *B. PAN¹, Z. ZHANG¹, C. J. HILLARD³, Q. H. HOGAN² ¹Anesthesiol., ²Med. Col. of Wisconsin, Milwaukee, WI; ³Med. Col. Wisconsin, Milwaukee, WI

Abstract: Patients with chronic pain often suffer from depression, but the underlying mechanisms are still unclear. The medial prefrontal cortex (mPFC) is a key brain area regulating depression. There are critical links of mPFC synaptic function to depression, with signaling through the endocannabinoid (eCB) system, whereby eCBs 2-Arachidonoylglycerol (2-AG) and N-arachidonylethanolamide (AEA) pre-synaptically suppress GABAergic inhibitory input to mPFC pyramidal neurons via their receptors (CB1Rs), thereby keeping the mPFC active. Anatomical and electrophysiological studies also show that afferent nociceptive pathways connect to the mPFC. eCB signaling is activity dependent. So, it is possible that noxious stimuli acutely activate and chronically depress eCB signaling in the mPFC, which results in depression. The present study was designed to address this hypothesis. We found that spared nerve injury (SNI) reliably induces neuropathic pain and significantly decreases performance of rats on behavioral tests relevant to depression, including the sucrose preference test, novelty-suppressed feeding test, and forced swimming test. Thus, SNI was followed by development of multiple indicators of a depression phenotype. Levels of 2-AG but not AEA in mPFC were elevated 3 days after SNI surgery, but normalized by 34 days. Electrophysiological recordings showed that CB1Rs in GABAergic presynaptic terminals are desensitized 34 days after SNI surgery, which results in increased inhibitory innervation of mPFC pyramidal neurons. Together, these data indicate that depressed eCB signaling in the mPFC may contribute to chronic pain induced

depression, and that eCB signaling is a potential target for treating depression induced by chronic pain.

Title: Diet purity impacts on the cecum microbiome but not depressive-like behaviors and plasma corticosterone levels in C57Bl/6J mice

Authors: ***A. TOYODA**¹, H. SHIMONISHI¹, M. SATO², K. USUDA⁴, K. NAGAOKA³ ¹Agr., Ibaraki Univ., Ibaraki, Japan; ³Vet. Med., ²Tokyo Univ. of Agr. and Technol., Tokyo, Japan; ⁴Vet. Sci., United Grad. Sch. of Vet. Science, Gifu, Tokyo, Japan

Abstract: (Introduction) For the animal experiments, appropriate diets should be used to obtain the reproducible results, however the information about the suitable diets for neuroscience researches is limited. Recently, we reported that vulnerability in chronic social defeat model of mice is affected by feed qualities (Goto et al., Nutr Neurosci, 2016). The purified diet (AIN-93G) increased susceptibility to chronic social defeat stress compared with non-purified diet (MF). In this study, we observed the effects of chronic feeding with AIN-93G and MF on depressive-like behaviors, plasma corticosterone, and cecum microbiome in mice. (Materials and Methods) C57BI/6J male mice (8 weeks, SLC, Shizuoka, Japan) were divided two groups. Group 1 was fed MF (Oriental Yeast, Tokyo, Japan), and group 2 was fed AIN-93G (Oriental Yeast) for 4 weeks. Homecage activity, food intake, and water intake were constantly measured by "3 Points Meter" (O'hara, Tokyo, Japan). After that, all animals were subjected to behavioral tests including open field, elevated plus maze, tail suspension, and forced swimming. Finally, blood plasma and cecum contents were collected. Cecum microbiome was analyzed using MiSec sequencing technology (illumina, San Diego, CA). Plasma corticosterone was measured by radio immunoassay. (Results and Discussion) Total food intake in group 1 was higher compared with group 2, however there were no significant difference between two groups in total calorie intake, water intake, behavioral tests, and plasma corticosterone. In the cecum microbiome, there were several differences between two groups, especially genus *Allobaculum* was predominant in group 2 compared to group 1. These microbiome differences in the digestive tract may affect brain functions and behaviors under stressful conditions. Actually, our previous study showed that diet quality and chronic social defeat stress affect metabolome in cecum, liver, and plasma (Goto et al., J Proteome Res, 2017). Conclusively, the interaction between diets and behaviors should be comprehensively studied in future. Title: Adult hippocampal neurogenesis increases preference for delayed rewards

Authors: *D. R. SEIB, D. ESPINUEVA, O. PRINCZ-LEBEL, E. CHAHLEY, R. QI YU, S. B. FLORESCO, J. S. SNYDER

Dept. of Psycholgy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: There is growing evidence that reduced adult neurogenesis plays an important role in depression. However, clear proof from animal models is still missing. We combine a novel rat model in which we can specifically block adult neurogenesis (GFAP-TK) and complex behavioral operant testing paradigms to elucidate if characteristics of depressive behaviors can be mimicked by loss of hippocampal neurogenesis, for example assigning less value to a delayed future reward.

We first tested rats on a delay discounting paradigm, where animals must choose between a low

reward lever that delivers 1 sugar pellet immediately and a high reward lever that delivers 4 pellets after a delay. Compared to intact wild types (WT), GFAP-TK rats showed a decreased preference for the high reward option with increasing delay times, indicating that adult neurogenesis increases the subjective value of future rewards. We were able to replicate this finding by ablating adult hippocampal neurogenesis with irradiation in WT rats. On the contrary, increasing neurogenesis by voluntary running for four weeks led to increased preference for delayed high rewards.

Second, we employed a probabilistic reversal learning task where rats have to show optimal behavior in the face of an uncertain reward. Here, we test for behavioral flexibility and sensitivity towards negative feedback, behaviors that are known to be impaired in depression. Third, we performed an effort-based decision-making task, since depression is often associated with reduced energy and motivation. Here, the number of lever presses required to receive the high reward option increases across blocks. We did not find any difference in the performance of WT and GFAP-TK animals in these two other tasks, indicating that functions for neurogenesis in reward-based decision-making are specific for immediate vs. delayed rewards.

Ongoing experiments are investigating cellular mechanisms by which new neurons influence valuation of future rewards. Preliminary results indicate that decreased neuronal activity in the ventral dentate gyrus in the GFAP-TK rat is associated with a lower preference for delayed rewards.

This project combines a novel rat model with complex behavioral tasks to study the impact of reduced neurogenesis on various phenotypes observed in psychiatric disorders with a focus on depression. It suggests that increased neurogenesis, for example by exercise, could benefit depressed patients. Results from this project can also be transferred to other psychiatric disorders, where neurogenesis is affected and similar behavioral phenotypes can be observed, such as addiction, Alzheimer's disease, and schizophrenia.

Title: Reduced enkephalin signaling in the nucleus accumbens D2-MSN circuit regulates depression-like phenotype in social defeat stress

Authors: *H. NAM, R. CHANDRA, T. FRANCIS, M. LOBO Dept. of Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Enkephalins are primary endogenous ligands for delta opioid receptors (DORs) and are highly enriched in D2-medium spiny neurons (MSNs) in the nucleus accumbens (NAc) and dorsal striatum. Enkephalins are highly implicated in depression, as preproenkephalin knockout and DOR knockout mice display anxiety- and depression-like phenotypes. Further, enkephalinase inhibitors can act as antidepressants. However, the specific the role of enkephalins, especially in the D2-MSN microcircuit in NAc - ventral pallidum (VP) pathway, in depression is not fully investigated. To provide insight into enkephalin function in this circuit we use an animal model of depression, the 10-day chronic social defeat stress paradigm. Following the defeat sessions, animals were either categorized as susceptible (displaying depression-like behavior) or resilient to defeat stress based on their performance in a social interaction test. Compared to the control and the resilient animals, the susceptible animals showed reduction in enkephalin levels in the NAc and VP. To determine if the reduced enkephalin levels cause depression-like behavior through disrupted Enk - DOR signaling, we treated the animals that experienced chronic social defeat stress with a DOR agonist SNC80. Our results indicate that SNC80 can reverse the depression-like conditions in susceptible animals. To investigate the mechanisms that reduce levels of enkephalins in the depressed conditions, we analyzed levels of different enzymes that can degrade or produce enkephalins. We demonstrate that the decrease in enkephalin levels may be due to increased levels of enkephalinases, such as angiotensinconverting enzyme (ACE) and analyl aminopeptidase (ANPEP), and decreased levels of proprotein convertase 1 (PC1) in susceptible animals. Overall, our data implicate that depressionlike behavior induced by social defeat stress is caused by reduced DOR signaling resulting from lowered level of enkephalins, which may be mediated through elevated expression of enkephalinases and decreased proprotein convertases.

Abstract: Aging is characterized by a decline in motor, sensory, cognitive, and mood functions which are associated with subtle changes in the Excitation/Inhibition balance of the canonical cortical microcircuitry composing of excitatory: pyramidal and inhibitory: Sst, Pvalb, and Vip positive interneurons. The age-associated long-term changes in these neurons of the microcircuitry we hypothesize are regulated through the transcriptomic changes within and across these neuronal cell types. To address this hypothesis, we first assessed the age-associated changes in anxiety-like behavior using Elevated plus maze and open field tests and cognitive abilities using novel object recognition and Y-maze alternation tests in young (2 months, n=9) and old (22 months, n=12) male mouse. Cell type samples for PYC, *Pvalb*, *Sst*, and *Vip* neurons obtained from the frontal cortex, using laser capture microdissection were sequenced for total RNA and the expression profile of each cell type was correlated with the first three principal components of the principal component analysis performed on all the test results. Using ontological approach we show that (1) Pyramidal neurons, with age, show upregulation of pathways related to energy production which can be associated with high activity and protective thus vulnerable nature of these neurons. There was a prominent downregulation of pathways related to synaptic activity in these neurons (2) VIP neurons have increased transcriptional control whereas SST neurons have increased translational control with age. (3) PV neurons seem to be least vulnerable of the four neurons as suggested by relatively increased photolytic clearance and synaptic activity with age. Together our data suggests that different cell types have a different vulnerability, which has a collective effect towards aging. We propose an order of neuronal vulnerability, which may lead to a dominos like fall of neuronal circuitry components and their functions with normal aging. The order of vulnerability has specific consequences and change in this order may lead to a state of psychiatric disorder.

Title: Linking dynamic GABAergic, astroglial and synaptic dysfunctions to stress-induced depressive-like endophenotype: Importance of astroglial integrity

Authors: *T. D. PREVOT¹, K. A. MISQUITTA^{1,2}, C. J. FEE^{1,2}, D. NEWTON^{1,2}, H. OH^{1,3}, E. SIBILLE^{1,2,3}, M. BANASR^{1,2}

Abstract: Major depressive disorder (MDD) is a severe mental condition affecting multiple cellspecific pathways that interact to produce heterogeneous phenotypes. MDD is associated with molecular changes within GABA cells, astrocytes and synapses in the prefrontal cortex (PFC), and similar changes are reported in stress-based rodent models of depression. Despite their intricate functional roles, the cellular alterations observed have been studied independently, when the pathology is already established. To identify the sequence of events affecting each cell compartment we characterized the time-dependent (i.e. onset and trajectory) cell-specific changes during chronic stress exposure and their correlation with depressive-like behaviors to characterize potential key features in the onset of pathological state. Using the chronic restraint stress (CRS) paradigm (1h restraint stress, 2x day) in male and female C57/BL6 mice, we determined CRS effects on behavior and on the expression of GABAergic, astrocytic and synaptic markers in the PFC at different time points (1 to 5 weeks). We assessed CRS effects on anxiety-like behavior (response to a 1h spotlight stressor in home cage-like setting), anhedonialike deficits (reduced sucrose consumption) and coat deterioration. The GABAergic, astroglial and synaptic alterations induced by CRS were characterized using qPCR and western blot analysis. CRS-exposed mice exhibited increased anxiety-like behavior regardless of the duration of CRS but showed a progressive and significant increase in anhedonia-like behavior starting on the 3rd week of CRS-exposure. Both anxiety- and anhedonia-like phenotypes were observed for the following weeks. At the cellular level, GABAergic marker expression (GAD67 and vGAT) reductions were identified as early as the first week of CRS exposure. Astrocytic marker (GFAP, glutamine synthetase (GS), GLT1) expression levels were altered after 3 weeks of CRS exposure and preceded a decrease in synaptic (PSD-95, Syn1) markers. Interestingly, while anxiety-like behaviors correlated with GABAergic marker expression, astrocytic marker expression profile correlated with both anhedonia- and anxiety-like deficits, suggesting that astroglial dysfunction coincides with the emergence of the maladaptive response to stress. We confirm here that chronic stress is a multiphasic process where time-dependent cell-specific alterations are linked to various behavioral outcomes. Altogether, our results suggest that astroglial dysfunction would be a potential turning-point in the response to stress leading to the pathological state associated with MDD and other stress-related illnesses.

Title: Acute and chronic chemogenetic silencing of somatostatin-expressing GABA interneurons induces rapid, robust, and lasting elevation of depressive- and anxiety-like behaviors

Authors: *C. J. FEE^{1,2}, K. MISQUITTA^{1,2}, R. BRAD¹, T. D. PREVOT¹, M. BANASR¹, E. SIBILLE^{1,2,3}

Abstract: Major depressive disorder (MDD) studies consistently demonstrate reduced level and function of somatostatin (SST)-expressing GABAergic interneurons, pronounced in brain regions that regulate cognitive-emotional functions. Past mouse models, using SST gene deletion or frontal cortex-specific silencing, supported a causal role for SST cell deficits in depressive-like behavior. However, these do not recapitulate key features of human pathology, where SST cell deficits are widespread and potentially include altered GABA function. Here, using a brainwide designer receptors exclusively activated by designer drugs (DREADD) approach, we addressed this issue by developing and characterizing a novel mouse model of chronically inducible, global, and cell-specific SST neuron silencing.

C57BL/6J SST^{Cre} and floxed-hM4Di mice were crossed to generate mice with inhibitory DREADD expression specifically in SST neurons (confirmed by immunohistochemistry). *Acute Silencing:* adult SST^{DREADD} or SST^{Cre} mice were administered veh (0.9% saline) or clozapine-N-oxide (CNO 5mg/kg) i.p.30 min prior to behavioral tests (*n*=12/group; 50% female). Z-scoring summarized changes across tests measuring similar outcomes. While SST^{Cre} (±CNO) and SST^{DREADD} (Veh) groups did not differ significantly across tests, SST^{DREADD} (CNO) mice showed elevated emotionality, indexed by increased Z-scores for anxiety (open field, elevated plus maze, Phenotyper tests) and anhedonia/helplessness (sucrose consumption, forced-swim tests), and decreased Z-cognition (object recognition, Y-maze), compared to all other groups. SST^{DREADD} (CNO) mice showed hypolocomotion and reduced food/water intake, suggesting a potential motivational confound. Measures were excluded (food tests) or adjusted (% line crosses) to account for this. *Chronic Silencing:* mice received water or CNO (~5mg/kg/day) *ad libitum* for 5 weeks and behavioral tests were performed weekly. Compared to all other groups, SST^{DREADD} (CNO) mice showed chronically elevated emotionality, unlike past models of regional SST silencing, but unchanged cognition. Where sex was a significant covariate,

between-group relations were unchanged.

This data supports chronic, global, SST neuron silencing as a model to recapitulate depressivelike behavior. Further cellular/behavioral model validation is underway. This model represents a potentially valuable tool to probe the role of SST pathology in MDD, identify cellular adaptations for target discovery, and screen for novel antidepressants.

Title: Behavioral, inflammatory and neurochemical disturbances in LPS and UCMS-induced mouse models of depression

Authors: *J. MA, K. FAN, X. YANG, G. LIU Anat., Dalian Med. Univ., Liaoning, China

Abstract: The immuno-inflammatory activation triggered by various stresses play an important role in pathophysiology of depression. The immune responses display differential pathological characters in different stresses. However, comparative data and analysis on behavioural, inflammatory and neurochemical changes in different stress-induced depression is limited. To imitate different stressful situations, in this study, mice were subjected to a single injection of LPS (0.5 mg/kg, i.p.) and UCMS (4 week period), respectively. LPS-stressed mice showed more immobility time in FST and TST, as well as more time in periphery in OFT than UCMS-stressed mice. Further, LPS-stressed mice showed more robust expression and release of TNF-a, IL-1β and IL-6 in serum and depression-related brain areas (prefrontal cortex, hippocampus and striatum) as compared to UCMS-stressed mice. The ELISA results showed that IDO expression was significantly increased following LPS and UCMS stresses, but more increased IDO expression was observed in prefrontal cortex and hippocampus of LPS-stressed mice. The decrease of 5-HT and BDNF was detected only in hippocampus of LPS-stressed mice, but in overall all the brain areas assessed in UCMS-stressed mice as compared to control. The data indicate that LPS induced more severe depressive-like behaviours and more robust immune activation than UCMS. Our study strongly imply that hippocampus is probably most vulnerable to acute inflammatory challenge in depression, while chronic psychological stress more likely to

resemble the multidimensional symptoms of clinical depression. Our findings provide more insight into pathophysiology in stress-induced depression.

Title: How the environment shapes our behavior: The role of LSD1 and SRF in adaptation and vulnerability

Authors: *F. S. RUSCONI¹, B. GRILLO², A. LONGARETTI³, C. FORASTIERI³, E. TOFFOLO³, L. GEROSA⁵, M. PASSAFARO⁵, M. POPOLI⁴, E. BATTAGLIOLI² ¹Med. Abstract: In mammals, different forms of stress including psychosocial stress can impact on several aspects of human health, fostering mood and anxiety disorders. However, very little is known about the mechanisms underlying brain physiology of stress response, hindering development of new therapeutic strategies. We uncover a role for transcriptional corepressor Lysine Specific Demethylase-1 (LSD1) and its dominant-negative splicing isoform neuroLSD1, in the modulation of emotional behavior. In mouse hippocampus, LSD1 and neuroLSD1 interacting with transcription factor Serum Response Factor (SRF) and SRF Δ 5 participate as molecular transducers of stress stimuli. Indeed, also SRF is modulated by a dominant negative alternative splicing isoform devoid of transactivation domain. Psychosocial stress acutely decreases neuroLSD1 expression through a splicing-based modulation that entails increasing amount of LSD1, while the relative ratio between SRF and SRF Δ 5 is sensitive to both ASDS and CSDS. Moreover, SRF Δ 5 shows a SUS-restricted downregulation that might contribute to shaping psychosocial stress vulnerability, through interfering with homeostatic mechanisms underlying stress resiliency. All these data suggest involvement of the dual system LSD1/neuroLSD1 and SRF/SRF Δ 5 in adaptive response to stress.

Title: Depression like symptoms associated with acute and prolonged methamphetamine withdrawal in a mouse model for binge methamphetamine intake

Authors: ***S. SHABANI**¹, B. GHIMIRE¹, B. SCHMIDT¹, E. MOJICA¹, S. HOULTON¹, T. PHILLIPS-RICHARDS^{2,3}

Abstract: Binge MA users have higher MA use and depression like symptoms associated with acute withdrawal and lower success rates in abstaining from MA use. Drug acute withdrawal sequela are thought to contribute greatly to this type of compulsive drug use. A genetic animal model for binge MA use has recently been developed, though the strength of MA withdrawal after different time points of abstention from chronic MA intake is missing. We used the selectively bred MA high drinking (MAHDR) line to explore sensitivity to MA withdrawal after chronic binge like MA intake at different abstention time points, as well as the resumption of MA intake after prolonged abstention. For comparison data were also collected on the MAHDR line's progenitor inbred strain DBA/2J (D2). In all studies, a multiple bottle choice procedure that had an access ratio of 3 MA to 1 water tube in home cagetops was used as the method for measuring voluntary MA intake and total fluid intake. MA concentration was increased in 20 mg/l increments every four days from 20 to 80 mg/l and at 80 mg/l was kept for 16 days. In two studies, depression like symptoms in the two strains were measured in a tail suspension test (TST) and a subsequent forced swim test (FST) after acute withdrawal of 6 hour (6h), and 30h from the 28 days of chronic MA intake. Similar study in only the MAHDR line, measured the same depression symptoms after prolonged abstention of 1 week and 2 weeks from chronic MA intake procedure. In addition, MA intake was also measured after 1 and 2 week MA abstention.

The MAHDR and D2 mice had similar escalation of MA intake during gradual increase of MA concentration, however MAHDR mice overall MA intake was substantially higher than D2 mice. Furthermore, MAHDR mice escalated fluid consumption from the MA tubes, but not D2 mice. Depression symptoms in chronic MA intake animals as compared to drug naïve animals was significantly higher after acute withdrawal and was dependent on genotype. MA acute withdrawal was more robust in MAHDR mice than in D2 mice. Depression symptoms in MAHDR mice than in D2 mice. Depression symptoms in MAHDR mice were absent after 1 and 2 week abstention. Similarly, MA intake in these animals after 1 and 2 week abstention also dropped significantly. The absolute MA intake after prolonged abstention however remained robust in MAHDR mice. This genetic mouse model has strong face validity for human binge MA use and withdrawal sequela associated with abstention. Furthermore genetic risk factors associated with MA intake and withdrawal can be teased apart to advance our understanding about the emergence of binge MA use like patterns.

Title: Prescription stimulant misuse in undergraduate students: Prevalence and predictors

Authors: A. JONES-LAVALLÉE, N. VAN DEN BERG, M. LAFOREST, G. GOODING, C. GOLDFARB, S. LINDEN-ANDERSEN, A. MENDREK, *S. HOOD Psychology, Bishop's Univ., Sherbrooke, QC, Canada

Abstract: Evidence suggests that prescription stimulant misuse is increasing in prevalence on college and university campuses in North America (e.g., McCabe et al., 2014). Using an anonymous survey, we assessed prescription stimulant use and misuse in a sample of undergraduate students at a small Canadian university (N = 726, mean age = 21 years \pm 0.15 (S.E.), 66% female). Overall, 12% (87/726) of the sample reported having taking prescription stimulants at least once in the past year. Of students who had ever taken prescription stimulants, the majority (125/179, or 70%) indicated not having a prescription. Previous reports have identified demographic predictors of prescription stimulant misuse in post-secondary students such as male gender, Caucasian ethnicity, having poorer academic standing, and reporting higher levels of stress and depressive symptoms (Benson et al., 2015; Teter et al., 2010; McCabe et al., 2014). In our sample, however, demographic variables including gender, age, year of study, and

self-reported quality of academic performance were not associated with prescription stimulant misuse. Furthermore, students who misused did not report higher levels of anxiety, perceived stress, or depressive symptoms compared with non-misusing students. In contrast, students who misused were more likely to have tried other types of stimulants in the past 12 months, including cocaine or amphetamine (χ^2 (2) = 54.320, p < 0.001, odds ratio [OR] 6.78); caffeinated energy drinks (χ^2 (2) = 19.061, p < 0.001, OR 2.32); and energy shots (χ^2 (2) = 15.906, p < 0.001, OR 3.64), compared with students who did not misuse. Taken together, these results suggest that misuse represents a large proportion of total prescription stimulant consumption in undergraduate students. Students who have taken these drugs without a prescription in the past year are more likely to also have consumed other kinds of stimulants, including illicit drugs such as cocaine or amphetamine. These findings may contribute to understanding the pattern of prescription stimulant use by undergraduate students, and to increasing awareness of potential risks that misusers may face from taking multiple types of stimulants.

Title: Comparison of the potency and efficacy of the novel cathinone α -PPP, α -PVP and pentedrone: Self-administration and locomotor stimulation in male and female rats

Authors: *M. JAVADI PAYDAR, S. VANDEWATER, M. TAFFE Dept. of Neurosci., The Scripps Res. Inst., LA Jolla, CA

Abstract: Cathinone is a close structural relative of amphetamine and a recent proliferation of cathinone derivatives (CATHS) produce varying central stimulant actions and represent a new class of drugs of abuse. The CATHS seem to produce their major effects via release or reuptake inhibition of monamine neurotransmitters with differences in vivo that depend upon the nature of their terminal amine, α substituent and/or aryl substituents. **OBJECTIVES:** This study compared the efficacy and potency of α -PPP, α -PVP, Pentyloneand Pentedrone in rodent models to further determine the role of common substituent moieties. **METHODS:** Groups of

male and female Wistar rats were trained in the intravenous self-administration (IVSA) of α -PVP (0.05 mg/kg/infusion), α -PPP (0.3 mg/kg/infusion), or pentedrone (0.2 mg/kg/infusion) under a fixed-ratio 1 schedule of reinforcement. Subsequent randomized dose substitution (0.025-0.3 mg/kg/infusion) was used to evaluate potency and efficacy of α -PVP, α -PPP, pentylone or pentedrone. Additional groups were assessed for locomotor activity and body temperature responses to noncontingent administration of α -PVP, α -PPP, Pentylone or Pentedrone (0.5-10 mg/kg, i.p.). **RESULTS:** Acquisition of α -PVP, α -PPP, or pentedrone IVSA resulted in a consistent drug intake and discrimination for the drug-paired lever. Dose substitution under a fixed-ratio 1 schedule confirmed that potency and efficacy was higher in rats trained on α -PVP compared to those trained on α -PPP, or pentedrone. Across training groups, potency reflected α -PVP > pentedrone $\approx \alpha$ PPP > Pentylone. Peak locomotor responses to α -PVP were observed after the 1.0 mg/kg, i.p. dose and lasted ~ 2 h; however, maximum activity response to α -PPP, pentylone or pentedrone were recorded following a 10 mg/kg, i.p. dose. Body temperature changes were negligible (<0.5 °C) for these compounds. **CONCLUSIONS:** The potency and efficacy of α -PPP and pentedrone were very similar across multiple assays. Pentylone was comparatively less potent and α -PVP was more potent.

Title: Binge alcohol exposure attenuates both the development and extinction of amphetamine conditioned place preference

Authors: *L. O'LOUGHLIN¹, C. IRVING², L. NORENA², A. PAZMINO², A. SAPERSTEIN², E. WALSH², T. PHAN², R. DUSSAULT³, J. SCHROEDER² ¹Behavioral Neurosci., Connecticut Col., Waterbury, CT; ²Behavioral Neurosci., Connecticut Col., New London, CT; ³Wheeler High Sch., North Stonington, CT

Abstract: The binge use of alcohol and abuse of amphetamine in the form of prescription ADHD medication is on the rise among young adults. According to the gateway hypothesis, repeated exposure to alcohol, particularly binge use of alcohol may predispose individuals to use and become addicted to other drugs of abuse including psychostimulants. Alcohol abuse may also make it more difficult to recover from dependency on other drugs of abuse. This study investigated the effects of binge alcohol pre- and/or post-exposure on the development and extinction of amphetamine conditioned place preference in young adult Sprague-Dawley rats. Animals pre-exposed to alcohol received 6 total alcohol (1.5 g/kg, sc of 20% alcohol in saline)

injections on 2 consecutive days at 48-hour intervals for a 10-day period one week prior to undergoing a 6 day, biased amphetamine conditioned place preference (CPP) paradigm. Contrary to the gateway hypothesis, binge alcohol exposure reduced the development of amphetamine CPP. However, binge alcohol pre-exposure attenuated extinction to amphetamine CPP. Exposure to alcohol following amphetamine CPP (post-exposure) only affected extinction in animals that also underwent alcohol pre-exposure. These results suggest that binge alcohol exposure may dampen the development of the association between amphetamine reward and contextual cues, but may extend the extinction of amphetamine reward behavior. Immunohistochemical evaluation of nucleus accumbens c-Fos expression was performed in a follow-up study in an attempt to correlate activity patterns in brain reward regions with reward behavior.

Title: CNS mechanisms underlying the suppression of stress-induced methamphetamine seeking by oxytocin in female rats

Authors: *C. E. O'NEILL¹, R. J. NEWSOM², J. L. HOPKINS³, V. GRINEVICH⁴, J. F. MCGINTY⁵

¹Inst. of Neurosci., ²Dept. of Neurosciences, ³Neurosci., Med. Univ. of South Carolina, Charleston, SC; ⁴German Cancer Res. Ctr., Heidelberg, Germany; ⁵Neurosci., Med. Univ. South Carolina, Charleston, SC

Abstract: High comorbidity of substance use disorders (SUDs) has been observed in patients with post-traumatic stress disorder (PTSD). Stimulants, such as methamphetamine (METH), are among the most highly abused substances by patients with comorbid PTSD. Previous work from our lab found that male rats exposed to the predator odor, 2,4,5-dihydro-2,5-trimethylthiazoline (TMT), exhibit exacerbated levels of stress-induced reinstatement (RST) and 10 days of systemic oxytocin (OXT) injections prevented this effect (Ferland et al, 2016). We also found that female rats pre-exposed to TMT daily for 5 days showed a similar exacerbation of METH-seeking. However, repeated OXT treatment decreased stress-induced RST regardless of prior stress experience in females. A key question is whether stimulation of CNS OXT neurons is sufficient to suppress stress induced METH-seeking. In this experiment, the paraventricular hypothalamic

nuclei (PVN) of female rats were infused bilaterally with an AAV1/2 vector encoding an excitatory DREADD (hM3Dq) driven by the Oxt promoter. Rats then underwent METH selfadministration and extinction training. Prior to TMT-induced RST, rats were injected with clozapine-N-oxide (CNO, 3 mg/kg, i.p.) or vehicle. CNO-induced activation of PVN OXT neurons suppressed stress-induced RST, indicating that stimulation of the endogenous OXT system in the CNS is sufficient to affect relapse similar to the effects of systemic OXT administration. Another goal of the current study is to further elucidate the neural mechanisms underlying the effects of OXT on stress-induced relapse. Thus, we exposed female rats to TMT or saline for 5 days followed by 10 days of OXT (1.0 mg/kg, i.p.) or saline. Rats then underwent METH self-administration, extinction, and TMT-induced RST. Repeated OXT treatment prevented increased expression of heteronuclear corticotropin-releasing hormone (Crh) mRNA in the PVN and bed nucleus of the stria terminalis as well as prevented a decrease in Oxt mRNA, as revealed by rtPCR in METH-treated female rats following stress-induced RST. Ongoing RNAscope in situ hybridization aims to reveal whether OXT treatment following stress alters cfos mRNA expression in Crh-, Oxt-, or Oxt receptor-expressing neurons of stress-related structures. Together these data suggest that OXT may be considered as a therapeutic agent for reducing relapse susceptibility in patients exhibiting comorbid SUD and PTSD.

Title: Dose-dependent effects of methamphetamine on positive and negative affect in rats

Authors: *B. C. CORTES¹, A. ESCOBEDO², K. A. TRUJILLO³ ¹Biol., California State University- San Marcos, San Marcos, CA; ³Dept. of Psychology, ²California State Univ. San Marcos, San Marcos, CA

Abstract: Methamphetamine is a powerful psychomotor stimulant that is widely abused due to its rewarding and addicting properties. Though there is much research on the effects of methamphetamine, few studies have examined how different doses might produce different affective responses. The present study examined ultrasonic vocalizations (USVs) and locomotor

activity in response to different doses of methamphetamine (METH; 0.3, 1.0 or 3.0 mg/kg) in Sprague-Dawley rats. USVs are indicative of affective states, with 50 kHz USVs reflecting positive affect and 22 kHz USVs reflecting negative affect. Locomotor activity assesses the stimulant response to the drug, which may be indirectly related to the affective response. It was hypothesized that there would be an inverted U-shaped dose response, with the greatest number of reward-related (50 kHz) USVs at 1.0 mg/kg, and a reduction at 3.0 mg/kg due to aversive side-effects of the drug. The results supported our hypothesis: 1.0 mg/kg of METH produced the greatest number of 50 kHz USVs. In addition, there was an increase in aversive (22 kHz) USVs at 3.0 mg/kg (but not lower doses), demonstrating the dysphoric side-effect of METH at this dose. For locomotor activity, we found that the medium and high dose of METH produced a similar locomotor effect. The inverted-U response found with USVs gives insight into the affective responses to METH across doses, and suggests that users will moderate dosing to achieve the greatest reward while avoiding aversive side-effects. A better understanding of dose sensitivity enables for more accurate models for addiction, as addicts strive to achieve the "ideal" high. More research is necessary to develop suitable methods of prevention and treatment.

Title: Does sensitization to the rewarding effects of methamphetamine develop with repeated administration?

Authors: *T. T. TOWNER, V. GUTIERREZ, T. ZAFAR, K. A. TRUJILLO California State Univ. San Marcos, San Marcos, CA

Abstract: Behavioral sensitization is an increase in a behavior after repeat exposure to a stimulus and has been widely studied in regards to administration of drugs of abuse. Research suggests that sensitization may play a significant role in the development of addiction. The current studies examined sensitization to the rewarding effect of methamphetamine (METH). Locomotor behavior is a well-established (albeit indirect) measure of drug reward whereas ultrasonic vocalizations (USVs) are a more direct measure of affect and reward. Two experiments were performed to determine the rewarding effect of METH following a single

injection and sensitization following repeated injections, using USVs and locomotor activity in Sprague-Dawley rats. In Experiment 1, animals were injected with METH (1.0 mg/kg) or saline every other day for six days. In Experiment 2, animals were injected with METH (0.5 mg/kg) or saline once daily for ten consecutive days. Both studies had a METH challenge day at the end in which all animals received METH regardless of previous exposure. Initial exposure to METH induced a locomotor stimulant effect as well as an increase in 50-kHz USVs, showing that METH produces rewarding effects. METH induced successive increases in locomotor behavior and 50-kHz USVs across days of treatment, which is consistent with the development of sensitization. However, when all animals were challenged with METH, saline-pretreated and METH-pretreated animals showed similar increases in locomotor behavior and 50-kHz USVs. The current results suggest that sensitization to the rewarding effects of METH did not occur. Instead, it appears that repeated exposure to the experimental environment led to an increase in the response to METH. The fact that the same results were obtained with two different approaches strengthens the conclusions. These findings point toward the need for a challenge test in drug sensitization studies to rigorously test whether or not sensitization develops with repeated administration.

Title: Differences between adolescents and adults in the behavioral response to amphetamines

Authors: *V. ESPINOZA¹, A. ROCHA², K. A. TRUJILLO² ²Dept. of Psychology, ¹California State Univ. San Marcos, San Marcos, CA

Abstract: Amphetamines are synthetic psychomotor stimulants and common drugs of abuse. According to the 2013 National Survey on Drug Use and Health, nearly 600,000 Americans 12 years of age or older were current users of amphetamines. Initiation of drug use during adolescence has been linked to the formation of drug addiction later in life. However, relatively little is known about the effects of amphetamines in adolescents when compared to adults. Research to date demonstrates mixed results in laboratory animal models, with some studies showing adolescents exhibiting an enhanced behavioral response when compared to adults, and other studies showing a reduced behavioral response. Given these differences, more evidence is necessary to further understand potential differences between adolescents and adults. In this study, the locomotor response to methamphetamine (METH), dextroamphetamine (D-AMPH), and methylphenidate (MPH) were examined in adolescent Sprague Dawley rats at 30 days of age and adult Sprague Dawley rats at 60 days of age. Animals were administered METH (1.0 mg/kg s.c.), D-AMPH (1.0 mg/kg s.c.), or MPH (1.5 mg/kg s.c.) and locomotor activity was assessed with a Kinder Scientific Motor Monitor (a photocell-based system). METH, D-AMPH, and MPH produced an increase in activity in adolescents and adults. Differences between adolescents and adults depended on the specific type of locomotor behavior examined. For example, adults showed a greater response when examining fine movements (indicative of stereotypy), while adolescents showed a greater response when examining ambulations (indicative of forward locomotion). These results show that differences between adolescents and adults in the response to amphetamines are dependent on the specific type of locomotor behavior assessed. Since forward locomotion is associated with drug reward, while stereotypy is associated with aversion, the results suggest a more rewarding response in adolescents. Further studies will explore other behaviors related to METH, D-AMPH, and MPH in adolescents and adults.

Title: Ketamine inhibits methamphetamine-induced ultrasonic vocalizations and locomotor activity in rats

Authors: *A. ESCOBEDO¹, A. ROCHA², C. GARCIA³, K. A. TRUJILLO² ²Dept. of Psychology, ¹California State Univ. San Marcos, San Marcos, CA; ³The Med. Affairs Co., Saint Louis, MO

Abstract: Polydrug abuse is common among drug users. Individuals combine drugs in order to increase the rewarding effects (e.g. "speedball"), to decrease aversive effects (e.g. withdrawal), and/or to experience unique psychoactive effects. A combination that has received little scientific exploration is the combination of a dissociative drug (such as ketamine) with a psychomotor
stimulant (such as methamphetamine). Both classes of drugs are abused in the dance club and rave scene leading to the opportunity for combined use. Additionally, studies have shown that psychomotor stimulants, like methamphetamine (METH), are regularly used simultaneously with dissociative drugs such as ketamine (KET) in these settings. The present study examined the effects of combinations of KET with METH using ultrasonic vocalizations (USVs) and locomotor activity in rats. USVs have been found to reflect affective states, including positive affect (50 kHz USVs) and negative affect (22 kHz USVs). For example, 50 kHz USVs are emitted under the influence of methamphetamine and other drugs of abuse, while 22 kHz USVs are emitted during drug withdrawal. It was hypothesized that the combination of KET with METH would induce a greater rewarding effect compared to either of the drugs alone. The responses to KET (5.0, 10.0 or 30.0 mg/kg s.c.) and METH (0.3 or 1.0 mg/kg s.c.) were assessed alone or in a "cocktail" combination in adult Sprague-Dawley rats. Contrary to our hypothesis, KET inhibited 50 kHz USVs evoked by METH and reduced METH-induced locomotor activity. The results illustrate the complex effects of combinations of KET with METH and raise questions as to why individuals abuse combinations of these drugs.

Title: Prelimbic dopamine facilitates the extinction of amphetamine conditioned place preference

Authors: *E. LATAGLIATA¹, G. CHIACCHIERINI³, F. FIOCCHI³, G. COCCIA³, S. PUGLISI-ALLEGRA^{3,2}

¹Santa Lucia Fndn., Roma, Italy; ²Santa Lucia Fndn., Rome, Italy; ³Dept. di Psicologia and Ctr. Daniel Bovet, Sapienza Univ., Rome, Italy

Abstract: Environmental stimuli or discrete cues paired with addictive drugs are major factors able to trigger drug-seeking and drug-taking behaviors. Repeated and unreinforced re-exposure to cues, to induce the extinction, is a method to decrease the magnitude and the frequency of the conditioned response (CR) induced by them. Dopaminergic transmission in medial prefrontal cortex (mPFC) has been critically involved in the modulation of highly salient memories and in particular in the extinction of the CR induced by them (Abraham et al. Neurobiol Learn Mem. 2014 Feb;108:65-77). Manipulation of dopamine (DA) levels in this area, such as selective depletion produces a delay in the extinction of fear CR (Morrow et al. Neuroscience. 1999;92(2):553-64.). Instead, treatments that increase DA transmission in mPFC or that

stimulate D1 dopaminergic receptors in prelimbic (PL) cortex foster the extinction of drug seeking behavior (Brenhouse et al.Neuroscience. 2010 Aug 25;169(2):628-36; Nesbit et al. Behav Brain Res. 2017 Mar 15;321:223-231). In the present study, we investigated a possible different involvement by D1 and D2 dopaminergic receptors in the PL cortex of C57BL/6J mice, in the extinction of drug associated memories. Thus, we evaluated the effects of a single PL infusion of D1 (SKF38393), D2 (Quinpirole) or both (D1 and D2) dopaminergic agonists on the expression and the extinction of amphetamine-induced conditioned place preference (CPP). Single treatment with D1 or D2 dopaminergic agonists did not alter either the expression or the extinction of the amphetamine CPP, whereas treatment with both D1 and D2 dopaminergic agonists produced an early extinction of the CPP without alter the expression of the CR the day of infusion. These results confirm the involvement of PL DA transmission on the extinction of CR, suggesting that a coordinated activity of D1 and D2 receptors in this area is necessary to promote the extinction.

Title: Effects of a 5-HT1B receptor agonist on the acquisition and Expression of Methamphetamine-conditioned place preference in C57BL/6 MALE mice

Authors: *J. L. NEISEWANDER, T. DER-GHAZARIAN, 85282, D. CHARMCHI, S. NOUDALI, A. MAHMUD Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: We previously reported that the 5-HT_{1B} receptor (5-HT_{1B}R) agonist CP94253 enhances cocaine self-administration and seeking in rats tested during daily self-administration sessions, but inhibits these behaviors when tested after a period of forced abstinence. Interestingly, when we replicated the experiment using methamphetamine (METH) we showed that CP94253 reduced METH intake both before and after an abstinence phase. This study investigated the effect of CP94253 on the expression as well as the acquisition of METH conditioned place preference (CPP) in c57 male mice. Conditioning took place in a 2compartment apparatus. First we assessed baseline preference during a 15-min free-access test, repeated on days 1-3. In the Expression experiment, conditioning occurred on days 4-7 with daily 30-min exposure to one compartment immediately after saline injection, and 5 h later exposure to the other compartment immediately after METH, 1 mg/kg, IP (i.e., total of 4 METH sessions). Subsequently, we verified CPP acquisition from a preference test on day 8, and then we assessed the effects of CP94253 on CPP expression on day 11. On the expression test day, mice were pretreated with either saline or CP94253 (10 mg/kg, IP) and given a preference test 30 min later. The Acquisition experiment followed the same procedure for conditioning and testing, except that only one daily 30-min exposure was given alternating between compartments across days (i.e., total of 2 METH 3 mg/kg, IP sessions). Also on each conditioning day, mice were pretreated with saline or CP94253 (10 mg/kg, IP) 30 min prior to the sessions. We found that CP94253 blocked the expression of METH CPP, but did not significantly alter acquisition. These findings suggest that CP94253 attenuates motivational effects of a METH-associated environment without requiring a period of abstinence and supports the idea that 5-HT_{1B}R agonists may be useful for treating METH dependence.

Title: Integrins and focal adhesion kinase as a signaling pathway for MMP-9 induction of transient synaptic plasticity in cocaine relapse

Authors: *C. GARCIA-KELLER, *C. GARCIA-KELLER, D. NEUHOFER, M. SCOFIELD, A. BOBADILLA, S. SPENCER, S. VARANASI, C. MONFORTON, T. REEVES, P. W. KALIVAS Neurosci., Med. Univ. of South Caroline, Charleston, SC

Abstract: Cocaine use elicits neuroplasticity within the nucleus accumbens core (NAcore) that leads to increased vulnerability to relapse, even after protracted abstinence. Matrix metalloproteinases (MMPs) are inducible endopeptidases that degrade extracellular matrix (ECM) proteins (such as fibronectin, laminin and thrombospondin) as well as non-ECM signaling molecules, and reveal an RGD domain that binds and signals through integrins.

Integrins are heterodimeric receptors composed of $\alpha\beta$ subunits, and their primary signaling kinases are the focal adhesion kinase (FAK) and integrin linked kinase (ILK). Previous results show that $\beta3$ integrin is upregulated after cocaine self-administration and MMP-9 activity is increased during cued-reinstatement of cocaine and promotes transient synaptic plasticity (t-SP: increases in spine head diameter (d_h) and AMPA/NMDA (A/N)). Here we endeavor to understand if $\beta3$ integrin signaling through FAK and cofilin (actin depolymerization factor) is necessary to promote synaptic growth and increased AMPA/NMDA ratio during t-SP produced during drug-seeking.

To study the increases of d_h and A/N induced by MMP activation we use an antisense morpholino to reduce the expression of β 3 Integrin during cued-reinstatement. β 3 Integrin downregulation reduced cued-reinstatement, d_h and A/N compared with scramble morpholino. Additionally, microinjection of a FAK inhibitor into the NAcore blocked cue-reinstated behavior, while ILK inhibitor was without effect on reinstatement. Importantly, neither the FAK inhibitor nor β 3 Integrin morpholino impacted cued sucrose-seeking following intra-NAcore microinjection. Immunohistochemistry on NAcore labeled spines with AAVC2-hSYN-ChR2-YFP virus, revealed increased p-FAK and p-Cofilin localization in dendritic spines of reinstated cocaine animals compared to extinguished and yoked-saline. Moreover, using tissue plasminogen activator (t-PA) that increase MMPs activation, MMP-9 in particular, induced increase cued-reinstatement that was blocked with β 3 Integrin morpholino pre-treatment. These data propose that β 3 Integrin, FAK and Cofilin constitute a signaling pathway downstream of MMPs activation that is involved in promoting transient synaptic growth induced by cocaineconditioned cues that reinstate drug seeking.

Title: The effects of different environmental conditions and abstinence periods on sucrose seeking and glutamate receptors

Authors: *B. A. HUMBURG, E. J. GARCIA, A. N. BEESLEY, M. E. CAIN Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Long periods of abstinence following repeated drug use results in an increase in drug seeking behavior. This increase in drug seeking is termed incubation of drug craving. Grimm et

al. (2008) found that an enrichment intervention after sucrose self-administration decreased sucrose seeking compared to the control rats. Recent data from our laboratory indicate that enrichment throughout the experiment reduces amphetamine seeking but does not change AMPA of mGlur expression. The current experiment examined if continuous enrichment housing could reduce sucrose seeking behavior when compared to isolated housing after 1 day and 40 days of forced abstinence. Additionally, we examined AMPA and metabotropic glutamate receptors (mGur) to determine if they changed in accordance with sucrose seeking in differently reared rats. Male Sprague-Dawley arrived at 21 days of age and reared for 30 days in either an isolated (IC) or an enriched condition (EC). The IC rats were housed in metal cages with one rat per cage and did not get handled during the 30 day rearing period. The EC rats were housed with cohorts and handled every day for about a minute with daily toy changes. After rats came of age they began lever press training with 20% sucrose on an FR-1 schedule. Once the rats reached stable responding, they began sucrose self-administration. They self-administered 20% sucrose for 15 days with 1-hr sessions each day on an FR-1 schedule. After the 15th day of self-administration, rats rested for 1 day or 40 days were then tested for sucrose seeking test. Rats were presented with a cue associated with sucrose reinforcement and active lever presses resulted in a cue but no sucrose. Immediately following each sucrose seeking test the brains were removed and the nucleus accumbens was dissected. A western blot was used to determine if there were any difference in the AMPA subunits (GluA1 and GluA2) and mGluR5 receptor expression. Results indicate that IC rats had more seeking after 1 day when compared to EC rats. After 40 days, sucrose seeking was not different between EC and IC rats. EC and IC rats did not express GluA1 and GluA2 AMPA subunits differently at any time point. After 40 days mGlur5 increased in both EC and IC rats. These results indicate that AMPA subunit plasticity in the nucleus accumbens may be specific to psychomotor stimulants. The mGlur5 expression increase is attributable to reduced reward seeking. Future research will examine different abstinence periods to determine how differential rearing alters seeking and receptor expression across varying abstinence periods.

Title: The effects of differential rearing and abstinence period on amphetamine seeking and glutamate receptors

Authors: *E. J. GARCIA, M. E. CAIN Kansas State Univ., Manhattan, KS

Abstract: Cues associated with drug reinforcement can invigorate drug seeking behavior. The magnitude of invigoration changes depending on abstinence period length. The time-dependent increase in drug seeking is termed the incubation of drug craving. Following cocaine and methamphetamine self-administration and prolonged abstinence, there is also a time-dependent increase in Ca²⁺ permeable AMPA receptors (CP-AMPA). Blocking CP-AMPA receptors or stimulating metabotropic glutamate 1 receptors mitigates cue-induced drug seeking behavior. Environmental enrichment (EC) also decreases cue-induced drug seeking. Enrichment during abstinence can also reduce the incubation of drug craving. However, many of these studies have examined cocaine. In the present study, we used amphetamine (0.1 mg/kg/infusion) and reared rats in the EC or isolated condition (IC) to determine if early life development changes the propensity to show an increased drug seeking response motivated by drug-associated cues. Male Sprague-Dawley rats were housed in an EC or IC condition beginning at postnatal day 21 and remained in their conditions throughout behavioral testing. At day 51, rats were trained to press a lever and a week later, were implanted with indwelling jugular catheters. Rats were allowed to self-administer amphetamine or saline for 1h for 16 sessions. After the last session, rats went through a 1 day abstinence period and were tested in a cue-induced seeking test. The nucleus accumbens (NAc) was dissected from half the rats and prepared for western blot. The other half of rats had a 40-day abstinence period and were tested again in the cue-induced seeking test followed by NAc dissection. GluA1 and GluA2 AMPA subunits and mGlur1 and mGlur5 were quantified using western blot. Results indicated that EC and IC rats had equivalent amphetamine self-administration across the sessions. Following 1 day of abstinence, IC rats had significantly more drug seeking during the cued seeking test. This significant increase in IC rats was also present on day 40, indicating that IC rearing significantly increases drug seeking motivation following short and long abstinence periods. There were not significant differences between any of the glutamate receptors measured, suggesting that amphetamine seeking may not result in similar AMPA receptor and mGlur receptor trafficking as cocaine. In conclusion, our results clearly indicate that EC rearing significantly reduces amphetamine seeking behavior at short and long abstinence intervals, even when baseline amphetamine exposure is equal. Thus, the propensity to show enhanced susceptibility to drug cues is moderated by early life development.

Title: The impact of sex and exercise on methamphetamine preference in a rat animal model

Authors: *M. PURPURA¹, P. VIEIRA³, C. BARKAS², J. ADAMS², T. E. KIPPIN⁴ ¹Psychological and Brain Sci., ²Psychological & Brain Sci., Univ. of California Santa Barbara, Santa Barbara, CA; ³Col. of Natural and Behavioral Sci., California State University, Dominguez Hills, Los Angeles, CA; ⁴Dept Psychololgical and Brain Sci., Univ. California, Santa Barbara, Santa Barbara, CA

Abstract: Methamphetamine (METH) abuse remains an extremely serious problem in the United States. METH has a long duration of action, and therefore leads to prolonged stimulant effects. Currently, there is limited information on the individual differences in vulnerability to substance use disorder (SUD) and how subject factors may impact the selection of METH over a competing reinforcer. To explore factors contributing to addiction vulnerability for METH in an animal model, we compared sex, dose (0.05 and 0.1 mg/kg/inf IV), short (20 s) or long (10min) inter-trial intervals (ITI) and the effects of exercise on the behavioral allocation of effort on drug taking. If the reward for exercise and drug taking have overlapping circuitry, then engaging in exercise may reduce the need for drugs. Rats were allowed voluntary exercise in Whamann wheels (6 hr/day, 4 weeks) followed by assessment of choice between METH (1 mg/kg/inf IV, FI20s) or food (2-3x45 mg, FI20s) reinforcement in standard operant chambers. There was a significant interaction between sex and dose (F,145)=5.765, p=0.021. ITI of 20 s and dose of 0.1 mg/kg/inf was the most preferred combination and females exhibited higher and more plastic (i.e. dose dependent) selection between METH over a competing reinforcer. There was a negative correlation between running wheel rotations/hour and preference for METH, and a significant effect of treatment (exercise versus control) amongst the METH preferring rats F(1,11)=5.133, p=0.045. Thus engagement of voluntary exercise may decrease vulnerability and increase resilience to the development of a SUD amongst a subpopulation that is initially METH preferring. Generally, the results of this study are consistent with the growing body of clinical and preclinical evidence demonstrating that females exhibit higher addiction vulnerability for stimulant drugs of abuse.

Title: Cue-Induced methamphetamine seeking behavior is reduced by disruption of memory reconsolidation through the NMDA receptor antagonist memantine

Authors: *M. HANNA, R. CARPENTER, M. JESKE, C. KEITH, L. RIZKALLA Vanguard Univ., Costa Mesa, CA

Abstract: Relapse rates for those struggling with drug addictions are relatively high due to strong craving induced by exposure to cues that have been previously associated with drug administration. Drug associated memories are formed through the process of consolidation, the conversion of memories from a fragile state to a stable state. Reconsolidation claims that when a stable, long-term memory is reactivated, it undergoes consolidation again in which the memory engram is in an unstable form. It has been shown that consolidation requires the activation of the glutamate receptor NMDAR to initiate cellular processes that leads to stable synapses. In this study we examined whether the NMDA receptor plays a role in the reconsolidation of long-term drug-associated memories. To address this question, rats were injected with the NMDA receptor antagonist memantine in a conditioned place preference paradigm. Multiple injections of memantine immediately after reactivation of drug-paired memories attenuated preference for the drug-associated compartment. Our data also showed that the attenuating effects of memantine on cue-induced methamphetamine seeking behavior lasted for several weeks. Finally, we also show that the time frame for reconsolidation interference with memantine is between 0 to 6 hours. Our data suggest that the reconsolidation of methamphetamine-associated memories are dependent on NMDA receptor activation.

Title: Effects of nicotine exposure on oral methamphetamine self-administration, extinction, and reinstatement in adolescent rats

Authors: *Z. R. HARMONY, E. M. ALDERSON, I. GARCIA, L. D. BITUIN, C. A. CRAWFORD

Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Adolescence is a vulnerable developmental period, especially in regard to the use of addictive drugs. Nicotine is particularly problematic, as there are clinical studies indicating that early nicotine exposure increases the likelihood of later illicit drug use. Recently, we found that adolescent exposure to a low dose of nicotine increased the intake of methamphetamine (METH) in adult male rats. The purpose of the present study was to determine if METH intake during adolescence would also be altered by nicotine exposure. Male and female Sprague-Dawley rats were pretreated with saline or nicotine (0.16 or 0.64 mg/kg, sc) for 10 consecutive days beginning on postnatal day (PD) 25. On PD 35, rats in the 0.16 and 0.64 mg/kg pretreatment conditions were evenly divided and assigned to groups that either received saline or continued to receive the same nicotine dose that they were given as adolescents. Rats that had received saline as adolescents either continued to receive saline or were injected with 0.16 or 0.64 mg/kg nicotine. These late adolescent drug treatments started on PD 35 and continued until the end of the experiment. Thus, there were a total of 7 groups: SAL-SAL, 0.16-0.16, 0.16-SAL, SAL-0.16, 0.64-0.64, 0.64-SAL, SAL-0.64. On PD 35, all rats began nose poke training. Rats were exposed to a METH fade in, sucrose fade out procedure across 5 different METH-sucrose combinations. This procedure resulted in exposure to a 40 mg/l METH solution for 3 consecutive days on a FR2 schedule. Following the last day of METH self-administration, rats were given extinction training. Once the extinction criteria were met, rats were given a priming injection of METH (1.0 mg/kg, ip). Rats given continuous nicotine exposure (0.16-0.16) during self-administration had attenuated METH intake, whereas rats only pre-exposed to nicotine during early adolescence (i.e., the 0.16-SAL group) did not show this effect. Conversely, pre-exposure to a high dose of nicotine (i.e., the 0.64-0.64 and 0.64-SAL groups) augmented METH intake during selfadministration. This enhancement was larger in female rats than males. Lastly, neither dose of

nicotine altered behavior during extinction or reinstatement. These data suggest that exposure to a high dose of nicotine during early adolescence enhances METH intake later in adolescence.

Abstract: Background: The ability to sense time and anticipate events is critical for survival in nature. Not surprisingly, anticipatory behaviors occur prior to availability of numerous reward stimuli, including food, water, sex, and drugs of abuse, such as methamphetamine (MA). When available daily, at a regular time of day, animals exhibit anticipatory behaviors, and waken from sleep hours prior to the availability of rewards such as food. Goal: In the present study we evaluated whether animals that have voluntary daily access to MA in early or late day, would anticipate the availability of the drug. We also analyze c-FOS expression in the brain to identify the neural circuitry associated with anticipation of reward availability. Method: To this end, C57/BL6 mice were given free access to nebulized MA or water, for one hour daily either in the early or late day for 14 days. On day 15, at the usual time of availability of nebulized MA, animals were euthanized, and brains were removed and processed for c-FOS immunoreactivity. **Results**: The results indicate that anticipatory behaviors occur in animals with access to MA, but not water (controls), with more anticipatory activity during the early day than in the late day. In parallel, during the anticipatory interval, prior to exposure to MA, c-FOS expression was greater in the early versus the late day. Importantly, FOS-ir was greater in the MA groups than in controls at both early and late times. The brain regions associated with anticipatory activity have greater expression of FOS in early vs. late day, and in animals having access to MA rather than water. Conclusion: In summary, mice that voluntarily choose to self-administer nebulized MA will anticipate its availability by self-awakening and increasing their locomotor activity. The results also point to the importance of time of day, with substantially more anticipatory behavior early vs late in the day. Finally, this work delineates brain regions implicated in anticipatory behavior.

Title: Co-administration of GABAB receptor agonist baclofen with 5-HT2C receptor agonist Ro 60-0175 has additive effects on the expression of amphetamine-induced locomotor sensitization in rats

Authors: *L. N. CEDILLO ZAVALETA, J. C. JIMENEZ, I. R. RUIZ-GARCIA, A. I. BARRIENTOS-NORIEGA, F. MIRANDA-HERRERA UNAM, FES Iztacala, Estado De México, Mexico

Abstract: Drugs of abuse, such as cocaine, amphetamine (AMPH) and methamphetamine, share the ability to activate the mesolimbic dopamine (DA) system. The behavioral effects of AMPH are largely mediated by increased DA neurotransmission in the nucleus accumbens which is an important locus for regulation of motor function and for rewarding influence of psychostimulants drugs. Recent evidence suggests a potential role for γ -aminobutyric acid B (GABAB) receptor in modulating some of the behavioral effects of psychostimulants. We previously reported that GABAB receptor agonist baclofen (BCF) reduced the discriminative stimulus properties of AMPH and the development and expression of AMPH-induced locomotor sensitization. Although it has also been reported that BCF produces adverse side effects such as musclerelaxant properties, sedative and hypothermic effects, which limit its widespread application as a therapeutic agent in humans and as a tool for behavioral research. On the other hand, several lines of evidence suggest that 5-HT2C receptor ligands modulate the behavioral effects of psychostimulants. For example, it has been reported that 5-HT2C receptor agonist Ro 60-0175 (Ro) reduced the behavioral effects of psychostimulants. One strategy for attempting to overcome the side effects of BCF is to use lower dosages to reduce unwanted effects of the BCF, in combination with 5-HT2C receptor agonist, such as Ro. This study was designed to examine the effects of co-administration of BCF and Ro on the expression of AMPH-induced locomotor sensitization. On development phase rats were treated with AMPH (1 mg/kg, ip, experimental groups) or saline (control group) for 5 days. On the test days (expression phase), separate groups of sensitized rats (n=10 for each dose) were treated with saline or BCF (2.0, 3.0 y 4.0 mg/kg) + AMPH (1.0 mg/kg), Ro (2.0, 3.0 y 4.0 mg/kg) + AMPH (1.0 mg/kg) or the co-administration of BCF (3.0 mg/kg) and Ro (2.0, 3.0 y 4.0 mg/kg) + AMPH (1.0 mg/kg). The results showed that BCF and Ro produced a dose-dependent prevention of the expression of AMPH-induced

locomotor sensitization. Furthermore, Ro increased the effects of a lower dose of BCF on the expression of AMPH-induced locomotor sensitization. These data provide further evidence that GABA-B receptor ligands in combination with 5-HT2C receptors ligand may modulate psychostimulant-induced behaviors.

Title: Methamphetamine exposure and withdrawal impact gut microbiota in rats

Authors: S. FOROUZAN¹, *O. OHIA-NWOKO², T. A. KOSTEN¹ ¹Psychology, ²Dept. of Psychology, Univ. of Houston, Houston, TX

Abstract: Methamphetamine (MA) is one of the most frequently used amphetamine-type stimulants in the United States. Individuals who repeatedly abuse MA can develop MA use disorder (MuD)—a chronic, relapsing condition often triggered by withdrawal symptoms that develop following cessation of use. Given the lack of effective treatments for those with MuD, novel therapeutic targets must be considered. One potential target is the gut microbiome, which has an important influence on brain, behavior, and health as a part of the gut-brain axis. In this study, we evaluated the effects of MA administration (2 mg/kg, s.c.) on withdrawal- induced behaviors and gut bacteria in female Sprague-Dawley rats (n=8). Saline (s.c.) was administered twice daily for 14 days, during which baseline behaviors (elevated plus maze (EPM) for anxietylike behavior; forced swim test (FST) for depressive-like behavior) were assessed. Next, rats were given twice daily injections of MA for 14 days, followed by 4 days of withdrawal, during which performance on the EPM and FST were assessed. Fecal collections for microbiome analyses occurred at baseline (before saline administration), on day 5 of saline administration, day 14 of MA administration, and day 4 of withdrawal. Results indicated that MA withdrawal increased depressive-like behavior, with an increase in immobility time in the FST (p<0.05). Anxiolytic-like behavior was increased during withdrawal, indicated by a decrease in time spent in the closed arms of the EPM (p<0.05). Fecal microbiome analyses revealed MA administration and withdrawal significantly changed the relative abundances of several bacterial phyla including an increase in *Firmicutes* (p<0.05, vs. saline) and *Actinobacteria* (p<0.05, vs. saline) and a decrease in Cyanobacteria (p<0.05, vs. saline). No significant changes in Shannon

diversity were observed. Taken together, our observations indicate MA exposure and withdrawal produce specific and lasting changes in gut bacteria. Such information will guide the choice of target therapeutics for MuD to test in future studies.

Title: Behavioral characterization of outbred mice for amphetamine withdrawal: A GWAS pilot study

Authors: ***J. T. DO**¹, *J. T. DO¹, R. AMBACHEW¹, P. KUMAR¹, E. MASIAS¹, K. SHARIF¹, M. THOMAS¹, K. WILSON¹, J. YUAN², C. C. PARKER³

Abstract: Negative mood states that characterize drug withdrawal are partly under genetic control and have been associated with craving and relapse to drug use in humans. Mice can be used to model aspects of the negative mood states associated with amphetamine (AMP) withdrawal and offer a number of advantages relative to studies in humans. Here, we investigated negative mood states associated with AMP withdrawal using commercially available, outbred CFW mice to evaluate their usefulness as a mapping population for future quantitative trait locus (QTL) studies. Outbred mice are powerful populations for fine mapping of QTLs because each individual possesses a large number of recombinations over the course of many generations of outbreeding. These recombinations break down linkage disequilibrium between the QTL and surrounding markers, allowing high resolution mapping of the variants that influence quantitative traits. Mice were tested in the Elevated Zero Maze (EZM), Porsolt Forced Swim Test (FST), and Sucrose Preference Test to assess changes in anxiety-like behavior, dysphoria, and anhedonia following 14 consecutive days of 2.5 mg/kg AMP administration via intraperitoneal injection. A paired-samples t-test was conducted for each of these assessments. There was a significant increase in FST immobility time from before AMP administration (M = 125.75, SD = 65.46) to after (M = 166.43, SD = 44.34), t (45) = -6.45, p < 0.0001, suggesting the mice exhibited dysphoric behavior due to AMP withdrawal. Interestingly, EZM results showed a significant decrease in the time spent in closed quadrants from baseline (M = 222.08, SD =48.70) to withdrawal (M = 180.13, SD = 76.55), t (45) = 3.42, p < 0.001, suggesting a reduction

in anxiety-like behavior after AMP administration. A significant difference was also found in the animals' corrected sucrose preference from before administration (M = 52.56, SD = 25.10) to after (M = 52.55, SD = 26.40), t (42) = -3.19, p < 0.003, indicating a similarly unexpected reduction in anhedonic behavior. Importantly, we observed tremendous variation in all three traits which enables genetic mapping of naturally occurring genetic variation that is associated with trait variation. We predict that the phenotypic diversity displayed by this highly recombinant population will facilitate the discovery of genes and biological pathways underlying drug use disorders in humans.

Title: Voluntary physical exercise abolishes the development of conditioned hyperactivity and behavioral sensitization in mice

Authors: *A. S. RAUHUT, A. STASIOR

Psychology, Dickinson Col., Carlisle, PA

Abstract: This experiment, using an animal model of drug addiction (i.e. behavioral sensitization), examined the impact of voluntary physical activity (i.e., home-cage wheel running) on the acquisition, extinction and behavioral sensitization in male, Swiss Webster mice. The experiment consisted of 4 phases: initial exercise, acquisition, extinction, and tests for behavioral sensitization. Upon arrival, half of the mice either were given access to home-cage running wheels (runners) or not (sedentary) for 3 weeks prior the start of the acquisition phase. During the acquisition phase, mice received either an injection (subcutaneous, s.c.) of physiological saline (vehicle) or methamphetamine (0.25 or 1.0 mg/kg) immediately prior to 5 daily locomotor activity sessions. During the extinction phase, all mice received daily injections (s.c.) of physiological saline prior to 4 locomotor activity sessions. Locomotor activity sessions were 30 minutes in duration for the acquisition and extinction phases. The tests for sensitization occurred following the extinction phase. At this time, all mice received a once daily injection of methamphetamine according to an escalating drug-dose regimen (0.25, 0.5 and 1.0 mg/kg) and tested for 60 minutes. Distance traveled served as the dependent measure of locomotor activity.

Support: This research was supported financially by Student-Faculty Research funds provided by Dickinson College

The results showed that methamphetamine dose-dependently increased locomotor activity in sedentary mice during acquisition; however, runners showed a blunted hyperactive response to the high methamphetamine dose (1.0 mg/kg) following either acute (Day 1) or repeated (Day 5) methamphetamine administration. During the extinction phase, conditioned hyperactivity was observed initially for the sedentary mice conditioned with either the low or high methamphetamine doses and quickly extinguished. However, the runners did not show conditioned hyperactivity following conditioning with any methamphetamine dose. Finally, sedentary mice showed a dose-dependent sensitized response, with the low and moderate methamphetamine doses inducing greater locomotor activity compared to sedentary vehicle control mice. However, runners did not differ following any methamphetamine challenge dose on the tests for sensitization. These results suggest that voluntary physical exercise may have a neuro-protective effect and blunt the unconditioned, conditioned and sensitized locomotor effects of methamphetamine.

Title: Investigation of the cellular mechanisms of the discriminative stimulus effects and hyperlocomotion induced by methamphetamine using the "On cell" analysis

Authors: *T. MORI, A. KAN, C. IWASAWA, M. SASAKI, M. WATANABE, Y. HAMADA, M. NARITA, N. KUZUMAKI, M. NARITA Hoshi University/Department of Pharmacol., Tokyo, Japan

Abstract: Although the analysis of the behavioral effects induced by methamphetamine could provide evidences for the pharmacological mechanism of its behavioral effect of methamphetamine, specific activated cells and/or cellular interactions following methamphetamine treatment is not fully elucidated yet. In the drug discrimination study, the D₁-receptor agonist SKF82958 fully substituted for the discriminative stimulus effects of methamphetamine in mice, indicating that activation of D₁-receptors is critical for the discriminative stimulus effect of methamphetamine. To pin-down the cellular mechanism of methamphetamine-induced discriminative stimulus effects, we performed the "On cell" analysis. Methamphetamine-induced hyperlocomotion was suppressed by an optical suppression of the nucleus accumbens in cFos-eNpHR mice, which had been exposed by methamphetamine to express eNpHR. Furthermore, the D₁-receptor agonist SKF82958-induced c-fos positive "On cells" in the nucleus accumbens were mostly merged to those induced by methamphetamine. We

are now investigating the cellular identification of methamphetamine-activated "On cells" to produce the methamphetamine-induced discriminative stimulus effects and hyperlocomotion. Investigation of the cellular mechanisms of the behavioral effect of methamphetamine using the "On cell" analysis".

Title: DREADD-mediated modulation of the subthalamic nucleus alters locomotor sensitization to amphetamine in rats

Authors: *K. G. NAKATA^{1,2}, E. YIN³, S. M. FERGUSON^{1,2,4}

¹Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; ²Grad. Program in Neurosci., ³Neurobio., ⁴Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: Addiction to stimulant drugs like amphetamine is a debilitating neuropsychiatric disorder that carries with it substantial medical, social, and monetary costs for both addicted individuals and society. It is well established that the basal ganglia play essential roles in the development and maintenance of addiction-related behavior. However, although the subthalamic nucleus (STN) serves as a significant interface within basal ganglia circuitry and is a critical node of the indirect striatal pathway, its role in addiction behavior has been relatively understudied. In addition, studies to date have reported conflicting findings, likely due to the methods for targeting and disrupting cellular activity within the STN. To address these issues and further characterize the role of the STN and its afferents in addiction to stimulant drugs, we used viral expression of DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) to transiently modulate activity of either STN neurons or cortical afferents to STN (i.e., the hyperdirect pathway) during the development of amphetamine-induced locomotor sensitization in adult male Sprague Dawley rats. Stimulation of STN neurons (via Gq-coupled DREADDs (AAV-hSyn-hM3Dq) and clozapine-N-oxide (CNO)) had no effect on the acute locomotor response to amphetamine; however, this manipulation completely blocked the development and persistence of locomotor sensitization. In addition, repeated STN stimulation induced mild hyperactivity in amphetamine-free DREADD controls. In contrast, inhibition of

STN neurons (via Gi/o-coupled DREADDs (AAV-hSyn-hM4Di) and CNO) enhanced amphetamine-induced locomotor sensitization, though this effect did not persist on an amphetamine challenge following two weeks of drug abstinence. In addition, inhibition of STN neurons had no effect on the acute locomotor response to amphetamine, nor did it alter locomotor activity in controls. Next, we used a Cre-recombinase-dependent dual-virus approach to target DREADDs to STN afferents originating in prelimbic cortex (PL). Preliminary data suggest that although transient inhibition of PL-STN afferents with CNO has no effect on the development of amphetamine sensitization during the induction phase, it does attenuate the persistence of this form of behavioral plasticity. As with STN inhibition, this manipulation in afferents had no effect on the initial locomotor response to amphetamine or on locomotion in controls. These results suggest that the STN and its cortical afferents play important, but complex, roles in the regulation of addiction-related behavior and could be relevant targets for future addiction treatments.

Title: Effects of estradiol and methamphetamine exposure on habit formation in rats

Authors: *H. SCHOENBERG¹, E. SOLA¹, J. MLCUCH¹, A. P. KIRSHENBAUM², D. J. TOUFEXIS¹

¹Psychological Sci., Univ. of Vermont, Burlington, VT; ²Psychology, St. Michael's Col., Colchester, VT

Abstract: One aspect of drug addiction may be an accelerated progression from goal-directed behavior to stimulus-directed (habitual) behavior. The psychostimulant methamphetamine (METH) changes dopaminergic pathways in the dorsolateral striatum (DLS), which mediates habitual motor behavior. It has been previously shown that methamphetamine pre-exposure accelerates habit formation in males, and this was related to increased dopamine availability in the DLS. Data also suggests that changes in estrogen levels across the estrous cycle can also increase dopamine availability in the DLS in females. Thus, we hypothesized that accelerated habit formation would be induced by pre-exposure to METH in ovariectomized (OVX) female rats with cyclic estradiol replacement compared to OVX females with no replacement. We tested habitual nose-poking for sucrose following 8 days of pre-exposure to METH or vehicle and sub-

threshold operant training. The replacement group received bolus injections of proestrus levels of estradiol every four days to mimic naturally cycling estradiol. Following acquisition, one half of each group received five days of reward-devaluation (RD) by pairing lithium chloride (LiCl) with sucrose availability. The remaining rats received five days of LiCl unpaired with sucrose. Rats were then tested in extinction. Our results indicate that, at this low level of training, methamphetamine with or without cycling estrogen was not sufficient to accelerate habit formation, as all animals exhibited sensitivity to devaluation of sucrose. This evidence suggests a potential sex difference in habit formation, since methamphetamine exposure has previously been found to push males into habit at the same degree of operant training.

Figure 1. Within each group, all paired and unpaired animals differed significantly at the .05 level

Title: Environmental enrichment: Role in anxiolysis and resilience to amphetamine

Authors: *S. DONALDSON¹, C. CALHOUN¹, S. FISCHER¹, S. KELSEY¹, B. PLOTKIN² ¹Developmental and Brain Sci., ²Developmental and Brain Sciences, Psychology Dept., Univ. of Massachusetts Boston, Boston, MA

Abstract: Few have examined trait anxiety as a risk factor for amphetamine (AMPH) sensitivity in pre-clinical models or evaluated whether environmental enrichment (EE) impacts this vulnerability. We investigated trait anxiety rats' response to anxiogenic stimuli and AMPH, and measured dendritic arborization. Filial 5 outbred high anxiety (HAn) and low anxiety (LAn) male rats (N=60) were housed in: EE, standard environment (SE) and isolated environment (IE) for 30 days. Anxiogenic responses were measured using the elevated plus maze (EPM) and open field activity (OFA); locomotor (LMA) responses were recorded after saline (0.9% NaCl IP) or AMPH (0.5 mg/kg IP). At the end of testing, all animals were transcardially perfused with saline followed by 8% paraformaldehyde and the brains were extracted, quick-frozen, and stained using the Golgi-Cox protocol for Sholl analysis on six neurons per region (e.g., medial prefrontal cortex, basolateral amygdala, and the paraventricular nucleus of the hypothalamus). Neurons were imaged and analyzed using light microscopy and CellTarget software; both the Branching Index (BI), and Schoenen Ramification Index (SRI) were employed for all analyses. Behavioral results revealed that EE significantly reduced anxiety like behavior (p < 0.001) on the EPM and OFA, and attenuated AMPH hyperactivity (p<0.0001) in HAn lines. Interestingly, EE increased BI and SRI in the BLA of LAn and HAn lines (p<0.05) in the BLA. These findings demonstrate a role for EE in mitigating the effects of trait anxiety on anxiety-like behavior and AMPH sensitivity. EE may exert these benefits, at least in part, as a consequence of promoting neuroplasticity in the BLA.

Title: Diazepam reverses anxiety-like behavior, social anhedonia and dopamine deficit following acute amphetamine withdrawal

Authors: *M. RINCÓN-CORTÉS, A. A. GRACE

Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Psychostimulants, including amphetamine (AMPH), increase dopamine (DA) release from ventral tegmental area (VTA) neurons, which is associated with their acute reinforcing actions. However, this positive state is followed by a negative affective state each time the drug is taken (i.e. opponent process theory). Indeed, AMPH-withdrawal is accompanied by symptoms of anxiety and depression, which are commonly associated with DA system dysfunction in humans and animal models. Importantly, although most studies have focused on the negative affective state after withdrawal from long-term (i.e. chronic) drug administration, this negative affective state appears even after a drug is taken for the first time in both humans and rodents. In male rats, acute AMPH-withdrawal increases FST immobility and decreases the number of spontaneously active VTA DA neurons up to 48 hours post-withdrawal. Here we extended these findings by assessing social anhedonia in the three-chambered social approach test and anxietylike behavior in the elevated plus maze (EPM) following acute AMPH withdrawal within this period. Acute AMPH withdrawal induced social anhedonia (i.e. less sniff time), and increased anxiety-like behavior in the EPM (p<0.05, n=6-9 per group), suggesting a link between increased anxiety and impaired social interaction. Given that benzodiazepines are commonly used to treat anxiety disorder and can treat post-acute amphetamine withdrawal syndrome in humans, we tested the effects of diazepam on anxiety-like and social behaviors and conducted extracellular recordings of VTA DA neurons. We show that an acute (5mg/kg) dose of diazepam circumvents the neurobehavioral effects resulting from acute AMPH-withdrawal, as demonstrated by decreased anxiety-like behavior, normal social behavior and VTA DA activity comparable to controls (i.e. non AMPH-withdrawn rats) (p<0.05, n=6-8 per group). These data suggest that negative affective states resulting from AMPH-withdrawal can be modulated by diazepam administration and a highlight a window of time during which effective treatment may be able to prevent neurobehavioral changes that promote transition into chronic use.

Title: The effects of methamphetamine exposure on anxiety-like behavior and corticosterone levels in adolescent and adult mice

Authors: J. H. WEISS, K. H. STRUNTZ, *J. A. SIEGEL Psychology and Neurosci., The Univ. of St. Thomas, Saint Paul, MN

Abstract: Methamphetamine (MA) has neurotoxic effects on the adult brain that can lead to deficits in behavior and changes in the stress response system. The effects of MA are modulated by age, and while much research has examined the effects of MA in adults, relatively little research has examined the effects of MA in adolescents. As the brain is developing during adolescence, the effects of MA may differ from the effects in adults. Previous research shows that acute MA exposure in adolescence increases anxiety-like behavior while acute MA exposure in adults decreases anxiety-like behavior. Acute MA exposure in adolescence does not alter plasma corticosterone levels while acute MA exposure in adults increases corticosterone levels. Furthermore, age modulates the effects of MA on the brain dopamine system, with adolescent rodents showing relative resistance to the neurotoxic effects of MA on the dopamine system compared to adults. To the best of our knowledge, no study has directly compared the acute effects of MA on anxiety-like behavior and corticosterone levels in both adolescent and adult mice together. In order to assess age differences in the response to MA, this research examines the acute effects of MA exposure during adolescence and adulthood on anxiety-like behavior, plasma corticosterone levels, and the brain dopaminergic system in adolescent and adult male C57BL/6J mice. Current experiments are ongoing to study the effects of adolescent and adult MA exposure on behavior in the open field test to evaluate locomotor activity and anxiety-like behavior. Plasma corticosterone and tyrosine hydroxylase levels will be measured following behavioral testing. Based on previous data, we expect MA to cause an increase in anxiety-like behavior in adolescent mice and a decrease in anxiety-like behavior in adult mice, and to have no effect on plasma corticosterone levels in adolescent mice and increase plasma corticosterone levels in adult mice. Furthermore we predict that MA will have no effect on tyrosine hydroxylase levels in adolescent mice, but will decrease tyrosine hydroxylase levels in adult mice. These findings will contribute to a greater understanding of how MA alters behavior, the stress response system, and the dopamine system and how these effects of MA may differ between adolescent and adult mice.

Title: Acute sleep deprivation accelerates the development of locomotor sensitization to cocaine

Authors: *T. E. BJORNESS^{1,2}, R. W. GREENE^{1,2,3}

¹Psychiatry, Univ. of Texas, Southwestern Med. Ctr., Dallas, TX; ²Res. Service, North Texas VAMC, Dallas, TX; ³Intl. Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan

Abstract: With respect to drugs of abuse, sensitization is a progressive increase in drug effect following repeated drug exposures thought to be due to adaptations in the mesocortical dopamine system. Repeated administration of cocaine results in a conditioned increase in locomotor activity. There is some contradictory evidence that sleep disruption, either REM deprivation or total sleep deprivation, can influence locomotor sensitization to amphetamine. We have preliminary data indicating that acute sleep deprivation increases the acquisition and expression of conditioned place preference (CPP) to cocaine and now we are testing whether acute sleep deprivation increases locomotor sensitization to cocaine.

Adult male C57BL/6 mice underwent a locomotor sensitization procedure in which there were 3-5 saline administration days (habituation phase), 5 cocaine administration days (initiation phase), and 1 additional cocaine administration day a week after the initiation phase (challenge phase). Mice were injected intraperitoneally with saline on the habituation days and cocaine (15mg/kg) on each cocaine administration day. After injection, mice were placed into activity boxes (Med Associates) for 1 hour and activity was assessed by infrared beam breaks. Habituation criteria consisted of a decrease in beam breaks from the first to last habituation days and from the second-to-last to last habituation days. Mice that did not meet these criteria after 5 days were excluded. After habituation, mice were divided into two groups. One group of mice was sleep deprived via the treadmill method of forced, slow walking for 4 hours immediately prior to each cocaine trial, while the other group was undisturbed.

We found that mice that were sleep deprived prior to the cocaine-paired trials showed an increase in sensitization during the initiation phase, but sensitization was similar between groups during the challenge phase. Furthermore, day to day comparisons suggest that the increase in sensitization following sleep deprivation is due to a large increase in activity from the first to second cocaine exposures. These data suggest that sleep deprivation may speed the development of sensitization.

Title: Contribution of sex chromosome complement to sex differences in cocaine induced locomotor sensitization

Authors: *M. MARTINI¹, W. J. LYNCH², E. F. RISSMAN¹

¹NC State Univ., Raleigh, NC; ²Dept. of Psychiatry and Neurobehavioral Sci., Univ. of Virginia, Charlottesville, VA

Abstract: Repeated exposure to drugs of abuse such as cocaine, enhances their motor-stimulant response, a phenomenon termed behavioral sensitization. Females show a greater locomotor response to cocaine and more robust behavioral sensitization than males. This sex difference is attributed to circulating estrogens. In our study, we aim to examine sex differences induced by cocaine from a different perspective. We use a novel mouse model, the four core genotype (FCG) mouse, that has a spontaneous mutation in the sex determining Sry gene and a transgene that replaces its function. By breeding wild type females to males with the mutation and the transgene we obtained four types of offspring: XX-males, XY-males, XX-females, XY-females. This model allows us to separate the actions of gonadal hormones from the potential effects of sex chromosome genes on cocaine induced locomotor sensitization and to test the novel hypothesis that sex chromosome complement underlies sex differences in cocaine effects. Cocaine-HCl (20mg/kg) was dissolved in saline (0.9%) and administered i.p. in a volume of 0.1 ml/10 g body weight (BW). Mice were tested between 60-80 days of age. Sensitization to locomotor responses induced by repeated cocaine treatment was evaluated using Open Field (OF) boxes. For each genotype, Group 1 (n = 7, cocaine group, Coc) received cocaine (20) mg/kg) for 5 days and a single cocaine challenge (20mg/kg) on day 15 after a 10-day drug-free period. Group 2 (n = 7, control group, Sal) received saline for 5 days and a single cocaine challenge (20 mg/kg) on day 15. Mice were routinely habituated to the test cage (OF) for 30 min, then saline and cocaine injections were administered and locomotor activity was recorded for 1 h. The comparison between locomotor activity on day 1 and day 5 after cocaine administration determines the induction phase of behavioral sensitization. The response to cocaine challenge 10 days after discontinuation of saline/cocaine administration (day 15) was compared to i) the response to cocaine on day 5, and ii) the response of saline controls that will receive cocaine challenge for the first time on day 15.

Using the FCG mouse, we are examining the independent contribution of chromosomal sex to

cocaine sensitization. If sex chromosome complement is implicated, this will open up a new source of genetic studies on drug addiction.

Title: Crack cocaine inhalation decreases the threshold for epileptic seizures in rats subjected to a subconvulsive dose of pilocarpine

Authors: *C. D. CAVALCANTE^{1,2}, J. F. SANTOS², A. L. D. PACHECO², I. S. MELO², M. A. COSTA², J. M. SILVA³, S. S. MACHADO³, A. U. BORBELY², O. W. CASTRO² ¹UFAL, Maceió, Brazil; ²Inst. of Biol. Sci. and Hlth., ³Inst. of Chem. and Biotech., Federal Univ. of Alagoas, Maceió, Brazil

Abstract: Propose: Crack cocaine is a powerful addictive stimulant drug. Animal studies have been shown that cholinergic system may play a role in neurotoxicity induced by cocaine or its active metabolites inhalation. Behavioral alterations of using crack cocaine include hyperactivity, depressed mood, and decreased seizure threshold. Here we evaluate the acetylcholinesterase (AChE) activity, behavior and the threshold for epileptic seizures in rats exposed to crack cocaine smoke followed by a subconvulsive dose of pilocarpine. Methods: Experimental procedures were approved by the Ethical Committee for Animal Research of UFAL. Male Wistar rats (n=48 [240-340g]) were submitted to stereotaxic surgery for implantation of a cannula into the hippocampus. Animals received microinjections of subconvulsive pilocarpine (PILO [0.75mg/µL]) or vehicle (VEH [saline 0.9%]). Immediately after PILO administration animals were individually exposed to air (O2 + PILO) or 400 mg of crack cocaine smoke (VEH + CRACK and PILO + CRACK) for 10 minutes. We analyzed, the number of Wet Dog Shakes (WDS), frequency, duration and severity of limbic seizures according to Racine's Scale (1972), during 120 min after crack cocaine exposure. Acetylcholinesterase activity (n=24) was performed after 60 min of crack cocaine exposure in cell-free extracts of brain tissue as described by Ellman et al. (1961) and total contents of the extracts were determined according to the method of Bradford (1976). Results were expressed as mean±SEM, compared by one-way ANOVA followed by post-hoc test Student-Newman-Keuls. Results: Animals subjected to PILO

+ CRACK demonstrated increased severity of limbic seizures (stages 0-4) in comparison to O2 + PILO and VEH + CRACK (stages 0-2). PILO + CRACK (107.7 \pm 24.41) displayed higher seizure frequency than O2 + PILO (24.83 \pm 6.44) and VEH +CRACK (11.43 \pm 2.44). Similarly PILO + CRACK revealed increase in duration of seizures (2138 \pm 723,9) when compared with O2 + PILO (442,0 \pm 198,5) and VEH +CRACK (11.43 \pm 2.44). Nonetheless, number of WDS decreased in CRACK+ VEH (8,00 \pm 2,646) and O2 + PILO (127,3 \pm 52,73) compared to PILO + CRACK (162,79 \pm 45,40). The AChE activity showed reduction in PILO + CRACK (0,0475 \pm 0,0030) when compared to O2 + PILO (0,07827 \pm 0,0019) and VEH +CRACK (0,0697 \pm 0,0021) indicating inhibition of AChE. **Conclusion**: Together, these preliminary data suggest that crack cocaine inhalation decreases the threshold for epileptic seizures in rats submitted to a subconvulsive dose of pilocarpine, supposedly through the inhibition of acetylcholinesterase.

Title: Dopamine transporter knockout rats as a model of dopamine transporter hypofunction

Authors: *M. PARDO¹, S. IZENWASSER², P. ILLIANO¹, R. R. GAINETDINOV³, D. C. MASH¹

²Psychiatry & Behavioral Sci., ¹Univ. of Miami, Miami, FL; ³Inst. of Translational Biomedicine, St. Petersburg State Univ., St. Petersburg, Russian Federation

Abstract: Dysregulated dopamine transporter function contributes to the pathophysiology of many psychiatric disorders, including substance abuse, attention deficit disorder, and bipolar mania. Functional hyperdopaminergia has been characterized in dopamine transporter (DAT) knock-out mice. DAT knock-out mice exhibit extreme phenotypes, including decreased dopamine uptake, hyperactivity, exaggerated responses to psychostimulants and altered parameters of dopamine homeostasis. Rodent models of hyperdopaminergia related to genetic deletion of the DAT have been studied only in mice (Gainetdinov et al., 1999). Here, we report on a novel rat model of functional hyperdopaminergia. Behavioral and neurochemical studies demonstrate a consistent hyperdopaminergic state in DAT knock-out rats. We studied DAT hypofunction rats in early (PND35) and mid adolescence (PND48). Homozygous DAT-KO rats (KO) have increased basal locomotor activity due to increased levels of synaptic dopamine. Basal locomotor activity in heterozygous DAT knock-out rats (HET) was unchanged from wild-

type (WT) rats. However, HET rats showed an exaggerated locomotor response compared to WT rats following acute administration of cocaine (10 and 20 mg/kg). This effect was more robust at early adolescence (PND35) compared to mid adolescence (PND48). Sex differences were observed in HET rats following cocaine administration with acute cocaine treatment producing an earlier time to peak locomotor response in female HET rats at PND35, compared to WT rats. In contrast, male HET rats had a sustained increase in locomotion after acute cocaine treatment that remained elevated for at least 60 minutes. In Homozygous DAT knock-out rats, acute cocaine produced dose dependent changes in locomotor activity, since cocaine increased locomotion at 10mg/kg and reduced locomotion at a higher dose 20mg/kg. However, both doses decreased locomotion in homozygous DAT knock-out female rats. Studies are underway to examine the neuroplastic changes in dopamine homeostasis that occur in DAT knock-out rats with chronic cocaine self-administration. We hypothesize that DAT knock-out heterozygous rats may show exaggerated responses to cocaine that model the loss of transporter function observed in people at risk for cocaine-related excited delirium syndrome. This neuropsychiatric disorder is characterized by dysregulation of dopamine, defective regulation of DAT and a functional state of hyperdopaminergia (Mash et al., 2009). Reverse translational strategies will explore the role of DAT mutation in response to stress and psychostimulants to develop a rodent model of excited delirium syndrome.

Title: Sex differences in cocaine-induced ultrasonic vocalizations are modulated by the medial preoptic area

Authors: *J. R. MARTZ, N. MITTAL, C. L. ROBISON, C. L. DUVAUCHELLE, J. M. DOMINGUEZ

The Univ. of Texas At Austin, Austin, TX

Abstract: Evidence indicates that the medial preoptic area (mPOA) in the hypothalamus plays a modulatory role in the regulation of cocaine response, both neural and behavioral activity, as evidenced by conditioned-place preference and microdialysis experiments. The mPOA is also a major regulator of sex-sensitive behavioral differences across various species and for a variety of

behaviors. In rodents, a commonly employed approach for inferring affective states involves measuring their ultrasonic vocalizations (USVs). In this set of experiments we tested whether the mPOA modulates cocaine-induced changes in USVs and possible sex differences that may occur in response to drug administration. To this end, Sprague-Dawley rats received either a lesion or sham lesion of the mPOA. Baseline USV measures were obtained, over 3-days, followed by subsequent sessions of cocaine administration, and USV recordings. Results indicate that females displayed a greater number of vocalizations compared to males; however, this sex difference disappeared with lesions of the mPOA. Cocaine increased USVs in both males and females, compared to baseline. As with baseline, this increase was greater in females than in males, but also disappeared with lesions of the mPOA. These findings point to the mPOA as a modulator of affective response to cocaine and, moreover, as a modulator of sex differences that manifest after cocaine administration.

Title: The antioxidant Tempol abolished the expression of cocaine conditioned reward

Authors: *T. BEISER, R. NUMA, R. KOHEN, R. YAKA The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Cocaine abuse induces toxic effects in many organs, including the brain. In the last two decades it has been discovered that oxidative stress (OS) is the inducer and augmenter of cocaine toxicity and cocaine-induced addictive behaviors. In order to study the mechanism and find pharmacotherapy to drug addiction, it is essential to understand how cocaine-induced OS interferes with behavior and which pharmacological agent can prevent this interference. In previous studies we demonstrated that acute or chronic administration of cocaine generates substantial OS in main areas of the reward system, such as the pre frontal cortex (PFC) and the nucleus accumbens (NAc). In addition, we found that i.p administration of the antioxidant Tempol prior to cocaine injection attenuated cocaine-induced elevation of OS in these areas. Moreover, we found that administration of Tempol in this manner attenuated cocaine-induced psychomotor sensitization in rats and prevented the increase of OS in the PFC and NAc. In the present study we hypothesized that Tempol negatively affects the rewarding properties of cocaine. Therefore, we aimed at testing the effects of Tempol using conditioned place preference (CPP) paradigm. We found that treatment with Tempol during conditioning decreased cocaine-

induced OS in the PFC and NAc. In addition we found that in rats treated with Tempol, a significant decrease in the expression of CPP was evident. Further, we show that repeated injections of Tempol (7 days) following withdrawal from cocaine CPP abolished the expression of CPP. Finally, we show that the cocaine-induced CPP decreases the phosphorylation of the eukaryotic elongation factor 2 (eEF2) in the NAc which was remarkably restored following Tempol treatment. Taken together, this data suggests that Tempol given during conditioning and following withdrawal can interfere with reward processing in the mesolimbic system in a mechanism that may involve the translation machinery. Further, our results pave the way for the development of new therapy based on reducing OS to prevent cocaine addiction.

Title: Neuropeptide Y blocks the expression of a Pavlovian-conditioned locomotor response in rats with a 3-week history of cocaine exposure

Authors: *M. SUAREZ¹, A. C. THOMPSON²

¹Psychology, Univ. At Buffalo, Buffalo, NY; ²Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY

Abstract: Our lab has been exploring the hypothesis that NPY may be a target for cocaine dependence treatment. We have found that intracerebroventricular (ICV) administration of NPY, in rats with a history of cocaine exposure, decreases the expression of cocaine-induced conditioned place preference (CI-CPP). Furthermore, this decrease is long-lasting; a single ICV NPY injection blocked the expression of CI-CPP on a subsequent test one week later. Here we tested whether the acute and long term effect of ICV NPY on the expression of CI-CPP generalizes to another conditioned response: cocaine-induced Pavlovian conditioned locomotor response (CI-PCLR). We tested the hypothesis that ICV NPY will block the expression of CI-PCLR in rats with a history of cocaine exposure. One week later, rats were then tested again for the expression of CI-PCLR, every other day for 5 days, to determine whether the initial single ICV NPY exposure induces a persistent inhibition of CI-PCLR. Male Long-Evans (hooded) rats were exposed to daily injections of cocaine for 21 days using an escalating cocaine dose regimen (5 to 30 mg/kg, IP). CI-PCLR training occurred over the last 4 days of cocaine treatment and involved 2 conditioning sessions a day: one session with cocaine and one session with saline. We

used an opaque Plexiglas Locomotor Box, (LMB; 39 cm X 39 cm X 30.5 cm) as a unique training context. On training days half of the rats received cocaine in the LMB (i.e. the Paired group) and saline in a familiar context, while the other half received saline in the LMB and cocaine in a familiar context (i.e., the Unpaired group). NPY (0, 0.1, or 1 nmol in 5μ l) was microinjected 30 min before a 30-min, cocaine-free, test session in the LBM (i.e. first CI-PCLR test) 24 h after the last training day. As expected, rats that received cocaine in the LMB demonstrated a robust CI-PCLR, compared to saline controls, and showed extinction with repeated testing. Both doses of NPY treatment attenuated the CI-PCLR at test 1 in the Paired group but had no effect on rate of extinction (i.e. did not produce a persistent effect). NPY had no effect on the locomotor response of the Unpaired group at any dose on any test day. These results support the idea that central administration of NPY decreases the expression of at least two cocaine-induced conditioned behaviors, but that the persistent decrease seen in CI-CPP does not generalize to CI-PCLR. Consideration of the differences in learning and behavioral expression between these two conditioning paradigms may suggest a more specific role of NPY in the treatment of cocaine dependence.

Sci., Sch. of Nursing, Univ. of Pennsylvania, Philadelphia, PA

Abstract: In a 2015 survey, 1.5 million Americans were reported to be using cocaine. Environmental stimuli, including cocaine, produce heritable changes to the genome via epigenetic mechanisms. Studies investigating transgenerational effects of drugs have mostly focused on maternal use and prenatal exposure. Our lab and others have recently focused on paternal phenotype transmission. We used a rat model of paternal cocaine self-administration to examine cocaine-induced behavioral plasticity in male and female offspring of sires with a history of cocaine taking. Additionally, we assessed changes in histone post-translational modifications (PTMs), an epigenetic process that regulates gene expression by controlling the accessibility of genes to transcriptional machinery. Previously, our group found that paternal cocaine exposure reduced the reinforcing effects of cocaine in male, but not female offspring. Here, we examined cocaine-induced locomotor sensitization. Repeated exposure to cocaine produces behavioral sensitization, which is characterized by increased locomotor response to subsequent stimulant challenge injection. We found that male, but not female, progeny show deficits in cocaine sensitization, indicating a resistance in the long-lasting behavioral responses following cocaine exposure. Paternal cocaine experience has been shown to change histone modifications in the hippocampus and prefrontal cortex. Here we used a mass spectrometrybased approach to survey histone PTMs in the nucleus accumbens (NAc), a brain region critical for the rewarding effects of cocaine. Five histone PTMs were found to be consistently different between saline- and cocaine-sired males, suggesting that targeted epigenetic remodeling is responsible for the behavioral effects observed in F1 male progeny. We also examined cocaine self-administration and sensitization in grand-offspring (F2 generation) of cocaine-exposed sires to further investigate the transmission of altered behavioral responses to cocaine. Importantly, no effect of ancestral cocaine experience was found on sensitization or self-administration in the F2 generation. These data suggest that paternal cocaine exposure remodels the epigenome of F1 male progeny, resulting in blunted responses to cocaine.

Title: Fingolimod attenuate cocaine induced locomotor activity by decreasing PKA/DARPP32 signaling in striatal D₁-type medium spiny neurons

Authors: *K. UEMATSU¹, T. SHUTO², N. UCHIMURA¹, A. NISHI² ¹Cognitive and Mol. Res. Inst. of Brain Dis., ²Dept. of Pharmacol., Kurume Univ. Sch. of Med., Kurume, Fukuoka, Japan

Abstract: Fingolimod (FTY720) is an agonist of sphingosine-1-phosphate receptors (S1PRs) and a new oral drug for multiple sclerosis. It has been reported that S1PRs are expressed in many cell types including neurons and glias in the brain. In this study, we investigated the effect of fingolimod on cAMP/PKA signaling in mouse striatal slices by monitoring the phosphorylation states of an intracellular phosphoprotein, dopamine- and cAMP-regulated phosphoprotein of M_r 32 kDa (DARPP-32) at Thr34 (PKA-site). In striatal slices prepared from D₁-DARPP-32-Flag/D₂-DARPP-32-Myc transgenic mice, fingolimod (100 nM) decreased P-Thr34 DARPP-32 in D₁-type/striatonigral neurons at 30 min to 60% of control. The effects of cocaine and a D1 receptor agonist were examined after 30 min of preincubation with fingolimod. The cocaine (100 μ M)- and a dopamine D₁ agonist (±)-SKF-81297 (1.0 μ M)-induced increases in P-Thr34 DARPP-32 were abolished by pre-treatment of slices with fingolimod (100 nM). In behavioral studies, pretreatment with fingolimod (1.0 mg/kg, i.p.) attenuated cocaine (20 mg/kg, i.p.)- and R(+)-SKF-81297 (0.7 mg/kg, i.p.)-induced locomoter activities. Thus, fingolimod inhibits cAMP/PKA signaling in striatonigral neurons, resulting in the suppression of psychostimulant-induced activation of dopamine signaling and behavior.

Title: The long-term effects of repeated cocaine exposure on impulse inhibition

Authors: *N. MACK, M. BLOSSON, C. COWAN, M. CREWE, K. PONDER, S. SEQUERIA, D. HOLT, J. DYCHE James Madison Univ., Harrisonburg, VA

Abstract: The correlation between cocaine use and impulsivity has been well established but the causal relationship remains unclear. Are drug addicts innately more impulsive, or does drug use cause long lasting changes in impulsive behavior? It is established that repeated cocaine use results in long-term deficits to delayed reinforcement, but other facets of impulsivity have not been studied in depth. This experiment analyzes the long-term effects of chronic cocaine

exposure on impulse inhibition using differential reinforcement of low rates of responding (DRL) methodology. Sprag Dawley rats (N=16) were trained in operant chambers on a DRL-20 task and measured on efficiency. Following stabilization, each rat received two daily injections of either 15 mg/kg cocaine HCl or saline solution for 14 days total. Rats were re-tested on the DRL-20 on days 7, 14, and 21 following drug sensitization. A mixed ANOVA revealed no differences in DRL-20 efficiency across the study, f(1,4) = 0.008, p = 0.929. The results suggest that there are no short term nor long term effects on impulse inhibition following repeated cocaine exposure. The results are discussed considering validity of DRL methodology and implications of behavioral therapy for addicts. Future work includes analyzing inter-response time profiles as different measure of impulse inhibition and immunohistochemical analysis of D2 receptor expression in the nucleus accumbens core.

Title: Synaptic zinc modulates the effects of chronic cocaine exposure

Authors: *S. E. THACKRAY, S. S. BRYDEN, N. BIHELEK, R. H. DYCK, V. LOVIC Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Zinc (Zn) is a divalent metal that plays critical roles in many biological processes throughout the body. In the brain, it is packaged into vesicles and released into synapses by a subset of neurons that also release glutamate. Synaptic Zn acts as a potent neurotransmitter/neuromodulator, exerting its action by binding to Zn-specific sites on several neurotransmitter receptors. In addition, Zn can enter post-synaptic cells and affect intracellular signaling cascades. Most zincergic neurons are in the forebrain, almost exclusively in cerebral cortex, hippocampus and amygdala. Although the striatum itself does not house zincergic neurons, it is densely innervated by zincergic afferents. Cortico-striatal circuits are important in learning and control of actions, including responses to drugs of abuse. As a first step to understanding the role of Zn signaling in striatal function, we assessed acute and chronic effects of cocaine exposure in zinc transporter 3 (ZnT3) knockout (KO) mice. ZnT3 is the sole protein responsible for packaging zinc into synaptic vesicles. In normal mice, acute cocaine exposure leads to increased locomotor activity, while repeated administration, additionally, results in

behavioral sensitization and alterations in morphology of medium spiny neurons (MSNs) in the striatum. Locomotor activity was recorded and quantified in female ZnT3 wildtype (WT) and KO mice in response to cocaine administered at 6 doses compared to control animals administered vehicle. Specifically, the mice in cocaine groups were administered 5 mg/kg cocaine i.p. on experimental day (E) 1& 2, 10 mg/kg on E3 & 4, 15 mg/kg on E5, 20 mg/kg on E6 & 7, 25 mg/kg on E8, and 30mg/kg on E9 &10. All mice were left untreated for 14 days, then challenged with a dose of 10mg/kg cocaine to assess sensitization (% change from initial exposure). The recordings were screened for instances of stereotypy. The mice were euthanized and the brains processed for Golgi-Cox staining to examine MSN morphology. All mice exhibited dose-related increases in locomotor activity, however ZnT3 KO mice traversed significantly lower distances at higher doses of cocaine (≥ 20 mg/kg) compared to WT mice. These differences were not attributed to differential expression of non-ambulatory behaviors/stereotypies (eg. grooming, digging, circling). Both ZnT3 WT and KO mice exhibited behavioral sensitization with no genotype by drug interaction. In addition, dendritic length of MSNs in ZnT3 KO and WT mice was increased in the cocaine groups compared to control groups. In conclusion, synaptic zinc is important for modulating cocaine-induced locomotor activity, but does not appear to affect sensitization to cocaine.

Title: Error monitoring deficits in cocaine addicted individuals with high trait anger

Authors: *M. A. PARVAZ, R. Z. GOLDSTEIN, N. ALIA-KLEIN Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Compromised error processing is a hallmark of substance use disorders and of heightened trait anger. However, it is not known whether this deficit is exacerbated in addicted individuals with high trait anger and whether such comorbid symptomology influences drug taking behavior. To fill this knowledge gap, we recruited 33 individuals with cocaine use

disorders (CUD) and 34 healthy controls (HC) who were further stratified into low (LA) and high anger (HA) groups by way of a median split on the State-Trait Anger Expression Inventory trait anger scores with comparable non-verbal IQ and education but significantly different age [HC-LA (n=18; 43.9±6.9 years); HC-HA (n=16; 37.5±9.2 years); CUD-LA (n=16; 50.9±6.8 years); and CUD-HA (n=17; 47.3±7.3 years)]. Drug use severity was assessed using the Severity of Dependence Scale in all CUD. All participants performed a Simon's Flanker Task during the acquisition of event-related potentials (ERPs). The response-locked error-related negativity (ERN; quantifies early subliminal error monitoring), error positivity (Pe; quantifies more conscious error sensitivity) and the total number of errors were used as dependent variables. Although drug use severity did not differ between CUD-LA and CUD-HA, there was a preponderance of comorbid alcohol and other drug use in the CUD-HA (12/18) compared to the CUD-LA (4/16). For dependent variables, a 2 (Cocaine: CUD, HC) \times 2 (Anger: LA, HA) ANOVA, with age as covariate, revealed significant Cocaine (p=.004), and Anger (p=.008) main effects such that the ERN was reduced and number of errors were increased in CUD (vs. HC, p < .014) and in HA (vs. LA, p < .043); there was also a trend for reduced Pe in CUD (vs. HC, p=.074). A follow-up one-way ANOVA across all 4 groups (HC-LA, HC-HA, CUD-LA, and CUD-HA, to explore the additive effect of cocaine use and high anger), also with age as covariate, revealed significant linear effects for all dependent variables. That is, HC-LA showed the highest ERN and Pe amplitudes and least number of errors, CUD-HA showed the most reduced ERN and Pe amplitudes and highest number of errors, while HC-HA and CUD-LA showed comparable effects. Together, these results indicate that while both cocaine use and high trait anger negatively impact error-processing, their comorbid symptomology further worsens these impairments. Because these individuals also present an increased proclivity for using other substance of abuse, results underscore the potential contribution of deficits in error processing and underlying neural underpinnings to the exacerbation of symptoms in addiction, calling for the development of targeted intervention approaches for this subgroup of CUD.

Title: Cannabidiol attenuates expression of cocaine conditioned place preference with a U-shaped dose-response profile

Authors: *G. E. WAGNER¹, G. DE NESS², T. KERR², D. WATRY², A. LAQUE¹, N. SUTO¹, F. WEISS¹

¹Mol. and Cell. Neurosci., The Scripps Res. Inst., San Diego, CA; ²The Scripps Res. Inst., La Jolla, CA

Abstract: Cannabidiol (CBD), the major non-addictive and non-toxic component of cannabis sativa, may have potential for relapse prevention in addiction. Our previous findings demonstrated that a transdermal cannabidiol preparation (tCBD) attenuated both cue- and stressinduced drug seeking. These findings suggested that tCBD may reverse neuroplasticity that underlies perseverative drug seeking. These longitudinal studies included only one dose of tCBD such that no dose-response information was available. However, measures of plasma and brain CBD levels revealed that maximal attenuation of drug seeking occurred before CBD in plasma and brain reaches maximal levels, and that at maximal plasma and brain levels CBD did not further increase the reduction of drug seeking. We therefore sought to characterize the doseresponse profile of tCBD's attenuation of drug seeking by establishing the effects of five tCBD doses on the expression of cocaine conditioned place preference (CPP). Male Wistar rats were initially habituated to a two-chamber CPP apparatus for seven days to measure the animals' inherent bias toward one chamber over the other. The rats then underwent ten daily conditioning sessions, alternating between chambers each day, for a total of five sessions per chamber. Following conditioning, rats entered a 4-day treatment phase during which they received one of five tCBD doses or vehicle (0.0mg/kg, 2.5mg/kg, 5.0mg/kg, 7.5mg/kg, 10.0mg/kg, 15.0mg/kg). Expression of CPP was measured on the fourth day of treatment. Consistent with the hypothesis, tCBD suppressed the expression of CPP along a U-shaped dose-response profile, with maximal efficacy at 7.5 mg/kg. These findings continue to support potential for CBD in the attenuation of drug seeking and relapse prevention. Although CBD's dose effects were U-shaped with significant suppression of drug seeking at intermediate doses, the highest tCBD dose was associated simply with a lack of effect, but not aggravation of CPP (i.e. drug seeking). It is not clear presently whether U-shaped effects apply to other actions of CBD such as amelioration of anxiety or cue- or stress-induced reinstatement of drug seeking, and these questions remain for future research.

Title: Stress-induced cocaine bingeing in rats: Role of mesolimbic dopamine

Authors: *M. Z. LEONARD, M. H. DAWES, J. F. DEBOLD, K. A. MICZEK Tufts Univ., Medford, MA

Abstract: Intermittent exposure to brief episodes of social defeat stress precipitates long-term modulation of mesolimbic dopamine activity in rats. These adaptations are mediated via CRF activity within the VTA, and are associated with an intense cocaine-taking phenotype; whereby rats with a history of social stress exhibit an extended duration of cocaine self-administration under continuous access conditions. Factors that contribute to the maintenance and termination of these binge-like episodes are not well-understood. As mesolimbic DA signaling appears to be critical to the maintenance of self-administration behavior, we aim to determine the extent to which augmented dopaminergic response to cocaine might promote sustained bingeing in stressed rats. To that end, rats were exposed to social defeat stress intermittently over 10 days, or handled (Ctrl). After one week, rats were implanted with microdialysis guide cannulae targeting the NAcSh, and trained to self-administer cocaine on a fixed-ratio (FR5) schedule of reinforcement. In vivo microdialysis was conducted throughout a 24-hour cocaine 'binge' (FR5, 0.3mg/kg), where dialysate was collected in 20 min. fractions and analyzed for DA content. These ongoing experiments gather compelling evidence to suggest a pattern of DA efflux that predicts the maintenance/termination of cocaine bingeing in both stressed, and non-stressed animals. Parallel studies also examine the acute contributions of VTA-CRF as a driver of extended cocaine binges through modulation of DA activity during self-administration. Together, these studies approach a mechanism by which upregulated CRF signaling in the VTA might potentiate binge-like cocaine consumption in individuals with a history of stress exposure.

Title: The emergence of negative affect as motivation for drug taking in rats chronically selfadministering cocaine
Authors: *S. D. KLEIN¹, J. KULIK², N. BEACHER², A. P. PAWLAK¹, M. O. WEST³ ²Behavioral Neurosci., ³Psychology, ¹Rutgers Univ., Piscataway, NJ

Abstract: A large body of work examining ultrasonic vocalizations (USVs) emitted by rats in relation to psychostimulant drug administration has demonstrated that rising drug level leads to an increase in 50-kHz calling (positive affect), while acute withdrawal induces an increase in 22kHz calls (negative affect). In the context of self-administration studies, the role of negative affect as a motivational factor in animal models of drug addiction has been underexplored. The present investigation explored the relationship between the magnitude of affective response, and the quantity of cocaine consumption. Rats underwent a 14-day self-administration (SA) paradigm in which cocaine availability was indicated by the presentation of a 30-second tone cue. 50-kHz calls were measured prior to the introduction of cocaine, during the load-up period of days 1 and 14 of SA, and during an equivalent time period during the first day of abstinence. 22-kHz calls were measured prior to the introduction of cocaine, during the entire first day of abstinence, and a 2-hour window following day 14 of the SA paradigm dubbed "Withdrawal". Experimental results showed a highly statistically significant increase in 50-kHz calling between baseline and the load-up periods of self-administration. Results also showed a highly statistically significant increase in 22-kHz calling between baseline and forced abstinence, but not between baseline and withdrawal. Taken together, the results suggest that negative affect emerges during acute withdrawal when animals are expecting cocaine. Our findings that an increase in negative affect when deprived of drug was directly related to drug intake, while concurrently, the direct relationship of positive affect to drug intake decayed, provides strong empirical evidence from an animal model for the widely hypothesized shift from positive to negative affect as the salient motivational factor in drug addiction as the disease progresses. These observations have implications for understanding the role of hedonic dysregulation in preclinical models of drug addiction.

Title: Environmental enrichment during abstinence from cocaine self-administration alters cocaine-seeking behavior and addiction-related gene expression in female rats

Authors: *G. L. POWELL¹, M. ST. PETER², T. CHAUDHURY², D. ALCAZAR², R. M. BASTLE³, R. J. OLIVER, JR⁴, N. I. PERRONE-BIZZOZERO⁴, J. L. NEISEWANDER² ¹Sch. of Life Sciences, Dept. of Psychology, ²Sch. of Life Sci., Arizona State Univ., Tempe, AZ; ³Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; ⁴Dept. of Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: Our lab found that rats express an increase in cocaine-seeking following abstinence from drug and that this effect can be blunted when the rats are housed in environmental enrichment (EE) during abstinence. Much research has investigated changes in addiction-related genes associated with cocaine-seeking and EE; however, little of this work has been done in female rats, despite preclinical and clinical data suggesting sex differences in cocaine consumption and relapse patterns. Therefore, we aimed to investigate the effects of EE on cocaine-seeking behavior and addiction-related gene expression following abstinence in adult, female Sprague-Dawley rats. The rats were trained to press a lever for cocaine (0.75 mg/kg/infusion i.v., paired with a light + tone cue) during 2-hr sessions with a minimum of 21 sessions, during which they were individually housed. Upon stabilization of cocaine intake, animals were placed into abstinence for 21 days and either remained in isolated housing or were placed into EE chambers that contained 3-6 rats, a running wheel, tubes, toys, and communal food and water. After 21 days of abstinence, all animals returned to their self-administration cages for a 1-hr cue-reactivity test session, where cocaine-paired cues were presented responsecontingently but no cocaine was available. Rats were immediately sacrificed after the session, and brain tissue punches of the nucleus accumbens core (NAcore) and shell (NAshell) were collected and processed for RNA analysis using qRT-PCR. EE significantly blunted cocaineseeking behavior following 21 days of abstinence, comparable to results seen in male rats housed in EE vs. isolation for 21 days of abstinence. Additionally, qRT-PCR analysis of female rats housed in EE vs. isolation demonstrated significant alterations in multiple addiction-related genes: 1) Arc and Camk2a, both plasticity-associated genes, were significantly reduced in the NAcore but not the NAshell, in enriched animals; 2) miR-495, a known regulator of addiction related genes including Arc and Camk2a, demonstrated a trend toward an increase (p<0.06) in NAcore in enriched animals. These results represent the initial stages of discerning sex differences in cocaine-seeking behavior and the mechanisms that potentially modulate that behavior. We are now in the process of comparing gene profile changes in male and female rats using RNAseq with the aim of revealing new potential targets to reduce cocaine-seeking behavior.

Title: Erk1/2 phosphatase (MKP3) expressed in dopaminergic neurons affects cocaine induced conditioned place preference and self-administration

Authors: *S. LEWANDOWSKI¹, D. L. BERNSTEIN², R. A. ESPAÑA², O. V. MORTENSEN¹ ¹Pharmacol. & Physiol., ²Neurobio. and Anat., Drexel Univ., Philadelphia, PA

Abstract: Psychostimulant addiction is a chronic relapsing disorder that is thought to occur in vulnerable individuals and is characterized by compulsive drug use despite consequences. Approximately 2.5 million people abuse cocaine every year, with only 800,000 of them being treated. Cocaine's primary molecular mechanism is to block the dopamine transporter (DAT), leading to excess dopamine (DA) in the synaptic cleft, and thus resulting in the euphoric "high" that is sought after during addiction. There are currently no FDA approved pharmacotherapies for cocaine use disorders, and therefore it is imperative to develop more viable treatment options. The ERK1/2 Map kinase signaling pathway has been implicated in the locomotor stimulant effects of psychostimulants but also cocaine induced psychomotor sensitization and cocaine induced conditioned place preference. However, limitations exist in these previous studies as they were based on systemic or local administration of kinase inhibitors and thus lack the anatomical specificity that is needed for a more detailed investigation of the role of ERK1/2 signaling in specific cell types. This is critical to identify specific downstream targets of this pathway to reveal novel therapeutic targets for treating cocaine use disorders. In this study we describe the modulation of the ERK1/2 pathway in vivo by expressing the ERK1/2 phosphatase MKP3 only in dopaminergic cells. We have generated adeno-associated viral (AAV) vectors with Cre-recombinase (Cre)-dependent expression of MKP3 resulting in a decrease of ERK1/2 signaling in dopaminergic cells in the ventral tegmental area (VTA). This construct was injected into the VTA of Long Evans rats expressing Cre in tyrosine hydroxylase positive cells (Th-Cre rats). We used synaptosomal uptake assays to evaluate the effect of this overexpression on DAT uptake function and sensitivity to cocaine, as well as examined the effects of this overexpression on cocaine induced conditioned place preference, a Pavlovian conditioning paradigm that assesses the rewarding and aversive properties of drugs. Animals underwent a pre-test, three days of saline/cocaine conditioning and a post-test to determine preference. Finally, a different cohort of animals underwent self-administration, an operant model of addictive behavior that

investigates the reinforcing properties of drugs. Results from the present study demonstrate specific relationships between ERK1/2 signaling in DA neurons and cocaine induced behaviors that model human substance abuse. We believe these studies could have potential for identifying novel therapeutic targets for the treatment of cocaine use disorders.

Abstract: Psychiatric disorders including depression and addiction have proven difficult to treat, therefore, novel targets are critical for future development of effective treatments. We previously identified retinoic acid (RA) signaling as a novel regulator of behavior in preclinical models. Our previous transcriptomic identified the RA pathway as a likely mediator of the protective depression and addiction phenotypes conferred by environmental enrichment. In addition, a previous topographic transcriptomic analysis found that several genes in the RA pathway have selectively enhanced expression in the NAc shell (NAcSh). We also previously demonstrated

that manipulation of RA in the NAcSh by in vivo knockdown of cytochrome p450, family 26, subfamily b, polypeptide 1 (CYP26b1), which degrades RA, altered anxiety-like, depressionlike, and addiction-related behaviors. Here we aimed to provide further evidence for the role of RA signaling in the NAcSh by investigating the downstream signaling partners of retinoic acid through patch-clamp electrophysiological analysis of medium spiny neurons (MSNs) as well as behavioral analysis. Cellular retinoic acid binding protein 2 (CRABP2) and fatty acid binding protein 5 (FABP5) both bind RA, delivering RA to one of two downstream signaling pathways, either retinoic acid receptor (through CRABP2) to induce transcription through retinoic acid receptor response elements or peroxisome proliferator receptor beta/delta (through FABP5) to signal through peroxisome proliferator response elements. Knockdown of CRABP2 in the NAcSh decreased action potential threshold and increased the number of evoked action potentials while knockdown of FABP5 decreased the number of action potentials without altering threshold. CRABP2 knockdown also potentiated sEPSC amplitude but neither knockdown altered sEPSC frequency. Evaluation of the effects of acute retinoic acid on medium spiny neurons in the NAcSh are ongoing. In behavioral tests, CRABP2 knockdown decreased depression-like behaviors with no effect on addiction-related behaviors, while FABP5 knockdown decreased cocaine self-administration with no effect on depression-like behaviors. These compelling results are the first demonstration of a role of RA signaling in controlling the input and output strength of MSNs and provides insight into the neurobiological basis of addiction and depression.

Abstract: Cocaine is known to induce synaptic plasticity in the brain reward system. Persistent phosphorylation of protein kinases PKM² mediates late-phase LTP maintenance, and it can be inhibited by the myristoylated PKMzeta inhibitory peptide (ZIP). Using the cocaine behavioral sensitization model, we previously showed that persistence of cocaine evoked long term potentiation (LTP) in the ventral tegmental area (VTA) is necessary for synaptic alterations in the Nucleus Accumbens (NAc), which suggests a temporal sequence of neuroplastic changes in these two areas. However continuous disruption of LTP in VTA had a behavioral effect only after chronic micro-infusions of ZIP. In order to further characterize the role of LTP in cocaine elicited-behavior, we explored if ZIP had an acute effect in cocaine-induced plasticity in the VTA. For this, male Sprague-Dawley rats (250g) were stereotaxically implanted with bilateral cannulas into the VTA. The animals were given a cocaine injection and a ZIP micro-infusion 6 hours later. Whole cell patch clamp recordings of the VTA DA cells and NAc MSN were made 24 hours after ZIP microinjection. Results showed that a single ZIP micro-infusion after an acute cocaine exposure, effectively inhibited VTA LTP. Taken together with our previous results this suggests that initial behavioral response develops independently from VTA plasticity. Moreover this implies a more important role of plasticity during later phases of cocaine sensitization.

Title: Inherent variability in dopamine uptake in the medial dorsal striatum is associated with subsequent motivation for cocaine

Authors: *J. K. SHAW¹, P. ALONSO¹, S. I. LEWANDOWSKI², R. A. ESPAÑA¹ ¹Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; ²Pharmacol. & Physiol., Drexel Univ., Philadelphia, PA

Abstract: Cocaine addiction is a chronic, relapsing brain disease characterized by the heavy use of, aberrant motivation for, and an inability to maintain abstinence from cocaine. Considerable effort has been directed towards understanding the factors underlying the risk for cocaine addiction, however the mechanisms that predispose individuals to develop the disease remain unclear. The mesolimbic dopamine system has been particularly implicated in the reinforcing effects of cocaine, as cocaine enhances extrasynaptic DA in this system primarily by inhibiting DA uptake. Recent evidence suggests that inherent variability in DA neurotransmission may influence the risk for developing cocaine addiction. To determine the relative contributions of DA release and uptake to the vulnerability to use cocaine, we employed a novel application using fast scan cyclic voltammetry in anesthetized male rats to construct a neurochemical profile of DA signaling in the medial dorsal striatum (mDS) and ventral striatum of individual animals under baseline, drug-naïve conditions prior to any behavioral testing. Following recovery, rats were allowed to self-administer cocaine or were induced to develop cocaine conditioned place preference (CPP). Results suggest that there is no significant relationship between DA release or uptake and the acquisition of either CPP or operant self-administration, nor did we identify a significant relationship between DA signaling and the consumption of cocaine. We did, however, identify a strong, linear relationship between DA uptake in the mDS and the motivation for cocaine under both progressive ratio and threshold schedules of reinforcement-implicating DAT function in the risk for aberrant motivation associated with cocaine addiction. Preliminary results in an ex vivo model suggest that variability in DA uptake may be positively associated with sensitivity to the uptake inhibiting effects of low concentrations of cocaine. Examinations of the effects of viral-mediated alterations of DA uptake in the mDS on the motivation for and neurochemical response to cocaine are ongoing. Together, these data suggest that inherent variability in the mesolimbic DA system may underlie behavioral components associated with cocaine abuse.

Title: Role of acid-sensing ion channel-1a in cocaine-induced synaptic plasticity

Authors: *S. C. GUPTA^{1,2}, R. J. TAUGHER², J. A. WEMMIE², R. T. LALUMIERE³ ¹Univ. of Iowa, Iowa, IA; ²Univ. of Iowa, Iowa City, IA; ³Psychological and Brain Sci., Univ. of Iowa, Iowa, IA

Abstract: Acid-sensing ion channel-1A (ASIC1A) is a cation channel expressed in dendritic spines that contributes to synaptic plasticity and is activated by extracellular acidosis. ASIC1A is particularly abundant in the nucleus accumbens (NAc) and genetic disruption of ASIC1A increased cocaine-conditioned place preference and altered cocaine-evoked synaptic plasticity. Loss of ASIC1A increased the ratio of AMPA receptor to NMDA receptor (A/N) at synapses in NAc medium spiny neurons (MSNs) resembling cocaine withdrawal, and like a cocainewithdrawn mice, the change in A/N in Asic1a^{-/-} mice was reversed by a single dose of cocaine. In this study we sought to test whether this cocaine-induced effect on A/N in Asic1a^{-/-} mice is permanent or transient. We administered a single dose of cocaine or saline, and assessed A/N at 6 hours, 24 hours, and 7 days after injection. Although the cocaine-evoked effect was not observed at 6 hours following injection, it was evident by 24 hrs. Moreover, by 7 days the A/N had returned to the elevated baseline state in the $Asic1a^{-/-}$ mice. Together these observations suggest that the cocaine-evoked plasticity in the Asic1a^{-/-} mice is transient and reversible. Next, we sought to determine whether the effect of ASIC1A on the A/N was cell autonomous or might be due to ASIC1A outside of the NAc. We injected AAV2/1-CMV-Cre mixed with AAV2/1-CMV-eGFP (AAV-Cre) into the NAc of Asic1a^{loxP/loxP} mice to disrupt ASIC1A specifically in a subpopulation of neurons in the NAc. Littermates were injected with AAV2/1-CMV-eGFP (AAV-eGFP) as a control. After allowing three weeks for viral transduction, we studied the A/N in both transduced (eGFP+) and non-transduced (eGFP-) NAc MSNs. We found that in the AAV-Cre injected mice, A/N was elevated in transduced cells relative to non-transduced cells. There was no difference in A/N between transduced and non-transduced cells in the AAV-eGFP group. Thus, the ASIC1A-dependent increase in A/N is cell autonomous and NAc specific. Together, these studies help discern when and where the interaction between cocaine and

ASIC1A disruption takes place, and set the stage for further investigation into the cellular mechanisms for the interaction.

Title: Using the intermittent access self-administration procedure to assess sex differences in the motivation for cocaine

Authors: *A. KAWA, T. E. ROBINSON Univ. of Michigan, Ann Arbor, MI

Abstract: Studies assessing addiction-like behaviors in rats using the Intermittent Access (IntA) cocaine self-administration procedure have produced findings suggesting that the temporal pattern of cocaine consumption (in the case of IntA, characterized by intermittent spiking of brain cocaine concentrations) is a critical factor for addiction-like behavior. This pattern of intermittency is suggested to more closely resemble the temporal pattern of cocaine consumption in humans suffering from addiction and thus can serve as an asset in animal models of addictionlike behavior. To this point, studies using the IntA procedure have involved male rats, exclusively. However, work in humans and in animals- using the traditional "Long Access" (LgA) model, has suggested that females may be more susceptible to develop addiction-like behavior. For example, female rats are more likely to acquire self-administration and do so more rapidly than males, and escalate their cocaine intake to a greater degree than male rats. In humans, females more rapidly progress from casual cocaine use to cocaine addiction, suggesting some sex difference that predisposes them to suffer from addiction. Previous work has shown that IntA cocaine experience produces robust incentive-sensitization in male rats, but it is not known if this occurs in female rats. In this study, we directly compared the effects of IntA selfadministration on the motivation to self-administer cocaine in male and female rats measured using behavioral economic metrics. Our results reinforce previous findings regarding addictionlike behavior in males, as males exhibited an escalation in drug consumption, as well as an increase in motivation to self-administer cocaine over the course of the 30 day IntA procedure. In female rats, we observed an even greater escalation in drug consumption as well as stronger

motivation to consume cocaine throughout IntA experience. Finally, a 14-day abstinence period led to greater incentive-sensitization in female rats than male rats.

Title: Relapse depends on the type of cue and the type of brain: A cue that signals cocaine availability reinstates drug-seeking more readily in goal-trackers than sign-trackers, and depends on basal forebrain cholinergic activity

Authors: *K. PITCHERS, K. B. PHILLIPS, J. L. JONES, T. E. ROBINSON, M. SARTER Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The most predictable outcome of a first diagnosis of addiction is a high chance for relapse. When addicts encounter cues previously associated with drug administration, their attention is unduly attracted to such cues, and these cues can evoke motivational states that instigate and maintain drug-seeking behavior. There is, however, considerable variation in the motivational properties of such cues, both as a function of the individual and the nature of the cue. Some individuals (sign-trackers, STs) are especially susceptible to cues paired with reward delivery, perhaps because they are prone to process information via dopamine-dependent, cuedriven, incentive salience systems. Other individuals (goal-trackers, GTs) are better able to incorporate higher-order contextual information, perhaps because they have better executive/attentional control over behavior, which requires frontal cortical cholinergic activity. We hypothesized, therefore, that a cue that 'sets the occasion' for drug-taking (a discriminative stimulus, DS), which shares properties of contextual stimuli, would renew cocaine-seeking more readily in GTs than STs, and that this would require intact cholinergic neurotransmission. To this end, STs and GTs were trained to self-administer cocaine using an Intermittent Access schedule with periods of cocaine availability and unavailability signaled by a DS+ and a DS-, respectively. After this, half the rats received an immunotoxic lesion that destroyed ~50% of basal forebrain cholinergic neurons, and later, after extinction training, tested for the ability of non-contingent presentations of the DS+ to renew cocaine-seeking behavior. The DS+ was much more effective in renewing cocaine-seeking in GTs than STs, and this effect was abolished by the cholinergic lesion, despite the fact that all rats continued to orient to the DS+. While STs were previously demonstrated to exhibit greater relapse vulnerability for localizable Pavlovian drug cues, here we

demonstrate that their counterparts, the GTs, are more vulnerable if drug cues act to signal drug availability, and that the basal forebrain cholinergic system mediates such vulnerability. We conclude that vulnerability to relapse depends on individual cognitive-motivational biases that interact with the form of the drug cue encountered. Given the importance of contextual cues for triggering relapse and the human cognitive-cholinergic capacity for the processing of such cues, GTs model essential aspects of relapse vulnerability.

Title: Motivational-dopaminergic versus cognitive-cholinergic processing of a Pavlovian cocaine cue in sign-versus goal-tracking rats

Authors: *L. F. KANE¹, K. K. PITCHERS², Y. KIM³, T. E. ROBINSON⁴, M. SARTER⁵ ¹Biopsychology, Univ. of Michigan, Baltimore, MD; ²Psychology, ³Univ. of Michigan, Ann Arbor, MI; ⁴Dept Psychol, ⁵Psychol, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI

Abstract: Pavlovian reward cues are known to have greater motivating properties, or acquire greater incentive salience, in some animals (sign trackers; STs) compared to others (goal trackers; GTs). Conversely, GTs have a greater capacity for the processing of more complex contextual cues, reflecting their relatively superior bias for goal-directed cue processing. Prefrontal circuitry is essential for the processing of cues, including for influencing the motivational-attentional processes that determine the efficacy with which cues exert control over behavior. Here we investigated the activity of two major prefrontal neuromodulatory input systems, dopamine (DA) and acetylcholine (ACh), in response to a Pavlovian cue that was previously paired with cocaine administration in STs and GTs. Rats underwent 15 days/sessions of training in which each session consisted of 9 light-cue presentations that were either paired or explicitly unpaired with an intravenous cocaine infusion (0.4 mg/kg/infusion). Consistent with previous findings using similar training conditions, STs and GTs exhibited similar rates of orienting toward the paired cue. Following a 10-day abstinence period, prefrontal, 4-min dialysates were collected in STs and GTs during Pavlovian cue presentations in the absence of cocaine. We used benzoyl chloride derivatization (Song et al., 2011) and HPLC-mass spectrometry to simultaneously measure several neurotransmitters and metabolites from these

collections. In STs, the previously paired cocaine cue significantly increased prefrontal DA levels. DA levels remained elevated over baseline across multiple cue presentation blocks. ACh levels remained unaffected. In contrast, in GTs, presentations of the cocaine cue did not affect DA levels but increased prefrontal ACh levels. In STs, elevated DA levels coincided with the propensity of these rats to approach the previously paired cue. GTs did not exhibit such cue approach behavior and thus elevated ACh levels did not correlate with these rats' behavior during cue presentation. These results suggest that, in STs, dopaminergic modulation of prefrontal circuitry contributes to the expression of the motivational state evoked by the drug cue. In contrast, in GTs, cholinergic modulation of prefrontal circuitry mediates a "colder", or more cognitive, analysis of the stimulus and extinction context, not yielding cue-directed behavior. The attraction of STs to, and the neutrality of GTs toward, a Pavlovian cocaine cue is mediated via dopaminergic versus cholinergic modulation of prefrontal circuitry.

Title: Environmental complexity increases tendency to attribute incentive salience to a food cue, but does not affect cocaine conditioned "cue" preference in Heterogeneous Stock (HS) rats

Authors: ***J. A. TRIPI**¹, A. M. GEORGE², C. D. MARTIN¹, K. ISHIWARI³, A. A. PALMER⁵, J. B. RICHARDS², P. J. MEYER⁴

¹Psychology, Univ. at Buffalo Dept. of Psychology, Buffalo, NY; ²Res. Inst. On Addictions, Buffalo, NY; ³Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY; ⁴Psychologu, Univ. at Buffalo, Buffalo, NB; ⁵Psychiatry, UCSD, La Jolla, CA

Abstract: Environmental complexity produces an array of neurobehavioral effects in preclinical models, including altering responsivity to novel and reward-related stimuli. Studies in outbred rat strains have indicated that environmental complexity may reduce addiction-like behaviors. However, there is limited research addressing the interaction between genetic variability and the environment on responsivity to rewards and their cues. To address this, we used a genetically heterogeneous stock (HS) rats to assess the effects of environmental complexity on response to a food cue using Pavlovian conditioned approach (PavCA) and conditioned reinforcement (CRf), and response to cocaine in conditioned "cue" preference (CCP). Male HS rats (30-40 days

postnatal) were reared in pairs in a standard housed cage (SH; n=100) or in groups of 16 in an environmentally complex cage (EC; n=32) throughout testing. EC housing consisted of a multilevel cage filled with pet toys. Subjects were first tested in PavCA, a task used to assess the attribution of incentive salience to a food cue. Subjects learned to associate a lever cue with the delivery of a food pellet into a food cup. We measured approach to the lever ("sign-tracking") and the food cup ("goal-tracking") over five sessions (25 lever-pellet trials per session). Rats were then tested in CCP, during which a tactile floor (grid or hole) was paired with cocaine (10 mg/kg, *i.p.*) and the opposite floor was paired with saline. After eight conditioning trials rats were tested for their floor preference. Data analysis of PavCA behavior revealed a main effect of housing type on goal-tracking, with EC rats displaying more food cup entries (p < .001). Additionally, EC rats sign-tracked more than SH rats, indicating an increased tendency to attribute incentive salience to the food cue (p < .001). During a conditioned reinforcement test, in which rats could snout-poke into an active port to gain lever access, EC rats produced significantly more active pokes and subsequent lever presses (p < .001). During CCP trials, EC rats had lower levels of injection-induced locomotion (p < .05). However, both groups showed similar preference for the cocaine-paired floor and conditioned locomotion. These studies indicate a robust effect of environmental complexity on reward learning and locomotor sensitivity, but not to Pavlovian drug learning. This suggests that environmental complexity facilitates incentive salience attribution to food but not drug cues. Yet, others have observed contrasting effects of environmental complexity; this may be due to factors including the genetic background of the HS rats and the specificities of the housing conditions.

Title: Effects of environmental complexity on novelty seeking, impulsivity and sustained effortful attention in heterogeneous stock (HS) rats

Authors: *A. M. GEORGE¹, C. D. MARTIN², K. ISHIWARI¹, P. J. MEYER², A. A. PALMER³, J. B. RICHARDS¹ ¹Res. Inst. On Addictions, Buffalo, NY; ²Psychology, Univ. at Buffalo Dept. of Psychology, Buffalo, NY; ³Psychiatry, UCSD, La Jolla, CA **Abstract:** Most laboratories use standard shoebox housing for behavioral studies, despite evidence that complex or enriched environments can profoundly change behavior. We sought to compare the effects of different housing conditions on behavioral measures of novelty seeking, impulsivity and effort. Five-hundred male heterogeneous stock (HS) rats in social housing with standard plastic cages, and sixty-four male HS rats housed in a complex environment were tested on locomotor, light reinforcement and reaction time procedures, to measure individual differences in novelty seeking, impulsivity and sustained effortful attention, respectively. In the locomotor behavior task, fine movements, total distance, and rearing are used to quantify exploration in a novel environment. Standard rats had higher and more variable activity, distance, and rearing scores than the complex housed rats. Complex housed rats habituated more rapidly on all measures, suggesting they were hypoactive with an ability to distinguish an irrelevant novel sensory stimulus.

Using a light reinforcement paradigm, we have previously shown, on average, HS rats demonstrate an initial increase in responding to a novel light stimulus followed by monotonic decrease in responding as the reinforcing effects of the novelty habituate. The rate of habituation for the complex housed rats was more rapid than the standard housed rats. Additionally, some standard housed rats show a sensitization pattern, rather than habituation, while this phenomenon is absent in the complex housed rats.

The number of trials completed in the reaction time task is the primary measure of sustained attention. Standard housed rats were less able to sustain attention than complex housed rats, completing fewer trials throughout the 18-minute test session. Premature responding is considered a measure of motor impulsivity and represents a failure of inhibitory control. Premature responding may be analogous to false alarms in human vigilance tasks. Using this measure, standard housed rats were more impulsive, completing more false alarms per opportunity, than complex housed rats.

Together, these results indicate that the large behavioral differences reflect environmental influences in which genes are differentially expressed as a function of their housing environment. Furthermore, these large effects of housing on behavior in rats may question traditional standard housing conditions and support transitioning towards complex environments to optimize translational validity. Future studies will explore whether genetic effects of these tasks interact linearly or epistatically with differences in housing conditions.

Title: The essential role of DNA methylation and demethylation in cocaine withdrawal

Authors: *K. ANIER¹, M. URB¹, T. MATSALU¹, K. KIPPER¹, K. HERODES¹, T. TIMMUSK², A. ZHARKOVSKY¹, A. KALDA¹ ¹Univ. of Tartu, Tartu, Estonia; ²Tallinn Univ. Technol., Tallinn, Estonia

Abstract: An increasing number of reports have provided crucial evidence that epigenetic modifications, such as DNA methylation, may be involved in initiating and establishing psychostimulant-induced stable changes at the cellular level by coordinating the expression of gene networks, which then manifests as long-term behavioral changes. Recent discoveries suggest that ten-eleven translocation enzymes (TET1-3) participate in the DNA demethylation process and might also play a role in cocaine action. However, to date there are no studies that have focused on the complex role of both DNA methylation and demethylation in the mechanisms of psychostimulant-induced addiction. Our aim of this study was to investigate the effect of non-specific DNMT inhibitor (RG108) and selective Dnmt3a inhibition (AAV-Dnmt3a shRNA) on the expression of cocaine-induced behavioral sensitization in mice. Using the behavioral sensitization model, we evaluated the effect of cocaine withdrawal on the expression and activity levels of Dnmt1, Dnmt3a, Dnmt3b and Tet1-3 in the nucleus accumbens (NAc) of male C57BL/6NTac mice. We also assessed the specificity of these alterations in the NAc with changes in peripheral blood cells. Our qPCR data showed that cocaine withdrawal upregulates mRNA levels of DNA methyltransferases (Dnmts) and downregulates mRNA levels of Tets in the nucleus accumbens (NAc) of mice and that these changes correlate tightly with Dnmts and Tets mRNA levels in peripheral blood cells. Our data show that cocaine withdrawal increases DNMT activity but decreases TET activity in the NAc and that these changes are associated with enhanced global DNA methylation levels. In addition, bilateral intra-NAc injection of a nonspecific inhibitor of DNMT (RG108) during withdrawal from cocaine decreases DNMT activity levels in the NAc and diminishes the expression of cocaine-induced behavioral sensitization. In contrast, long-term selective Dnmt3a silencing in the NAc did not affect DNMT activity levels or the expression of cocaine-induced behavioral sensitization. These data indicate that cocaine withdrawal may disturb the equilibrium between DNA methylation and demethylation processes in the NAc and cause global changes in DNA methylation.

Title: PKMz knockout enhances cocaine self-administration and reinstatement through sex dependent mechanisms

Authors: *A. MCGRATH, J. LENZ, L. BRIAND

Temple Univ., Philadelphia, PA

Abstract: PKM^{\zet} is a constitutively active form of protein kinase C, once believed to be critical for the maintenance of memory. However, PKMζ knockout (KO) mice show no impairments in multiple forms memory or long term potentiation. Although very few behavioral phenotypes have been found in PKM² KO mice, they do exhibit increased alcohol drinking. This suggests that this protein may play a role in addictive behavior. The current study examined the effect of constitutive PKMζ KO on food and cocaine self-administration and cocaine reinstatement. We found that the PKMC KO mice exhibited increased food and cocaine self-administration as well as increased cocaine seeking during cue-induced reinstatement. This enhanced cocaine seeking could not be attributed to an increase in cocaine-induced locomotor activity or an increased preference for novelty. We next examined whether these effects were due to the actions of PKMC in the nucleus accumbens utilizing floxed PKM KO mice. When PKM was knocked down specifically in the nucleus accumbens, we did not see any effects on food self administration. Further, we saw an increase in cocaine self-administration and reinstatement that was only present in the male mice. Ongoing experiments are examining the role of circulating hormones in the sex-specificity of the effect of accumbal PKM² KO. Furthermore, as the constitutive PKM² KO female mice show enhanced cocaine seeking and the accumbens specific PKMC KO females do not; additional studies are underway to determine what brain regions are responsible for the effect seen in the constitutive KO females. Together these data suggest that PKM² plays a role in inhibiting cocaine consumption and seeking. A better understanding of the role of PKM² in addiction could one day lead to novel therapeutic options for people struggling with cocaine addiction.

Title: The effect of prefrontal GRIP deletion on drug-seeking behavior

Authors: *M. M. WICKENS, A. Q. FOSNOCHT, L. A. BRIAND Psychology, Temple Univ., Philadelphia, PA

Abstract: Disrupted glutamatergic signaling is a component in the development and maintenance of addiction. The glutamatergic pathway from the prefrontal cortex (PFC) to the nucleus accumbens plays a critical role in extinction and reinstatement of drug-seeking. The majority of studies examining the trafficking of glutamate receptors have focused on the prefrontal inputs to the nucleus accumbens, rather than changes in the PFC itself. The goal of this work was to examine how disrupted AMPA receptor trafficking in the PFC affects addiction-like behavior. To do this, we utilized mice with an inducible (floxed) deletion of glutamate receptor interacting protein, GRIP, a scaffolding protein necessary for the synaptic localization an aggregation of AMPA receptors. Six weeks prior to any behavioral testing, mice received intracranial viral injections of either Cre recombinase or GFP into the medial prefrontal cortex. Following viral expression and knockdown, all mice were trained on a self-administration procedure. Briefly, mice were taught to perform an operant response to receive sucrose pellets. They next underwent an intravenous catheterization surgery, and after recovery, were allowed to perform the acquired operant response for an infusion of cocaine. We next used a progressive ratio schedule to measure motivation to work for the drug, before the mice entered a period of forced abstinence and the behavior was extinguished. Finally, mice experienced a cue reinstatement trial. Following prefrontal GRIP knockdown, mice exhibited higher breakpoints on a progressive ratio schedule, suggesting that impaired AMPA receptor trafficking in the mPFC increases motivation for drug-seeking behavior. Additionally, prefrontal GRIP KO mice exhibited greater rates of cue-induced reinstatement, indicating that impaired PFC AMPA receptor trafficking increases vulnerability to relapse. Future work aims to examine how disrupting AMPA receptor trafficking in the mPFC affects accumbal physiology. These findings could lead to an improved understanding of the biological alterations associated with addiction and relapse.

Abstract: Recreational stimulant (amphetamine and cocaine) use is a growing concern among young adults, with 16% of individuals who experiment eventually developing stimulant dependence. Despite the importance of understanding how to predict which recreational users will become problem users, little is known about the behavioral or neural indices that can forecast the trajectory of occasional to problematic stimulant use. The present longitudinal study utilized follow-up data from a sample of 110 occasional stimulant users (OSU) three years after baseline functional magnetic resonance imaging (fMRI) and clinical interview sessions were obtained. Baseline fMRI recording during a Risky Gains Task (RGT) was analyzed to determine if preexisting neural activation patterns differentiated individuals who became problem stimulant users (PSU) from those who desisted stimulant use (DSU). The RGT was assessed from two distinct perspectives: (1) decision phase analyses evaluated neural and behavioral differences when individuals made a "risky" versus "safe" decision; and (2) outcome phase analyses assessed differences in response to wins versus losses on "risky" trials. For each voxel, a linear mixed effects (LME) analysis was computed to identify significant regions of percent signal change between PSU and DSU and voxelwise clusters were extracted, correcting for familywise error. Results indicate that compared to DSU, PSU exhibited lower activation in frontal executive control, sensory, and emotional processing regions during decision making as well as greater sensitivity to risky rewards and reduced sensitivity to losses. Findings suggest that PSU and DSU can be differentiated by neural biomarkers in several regions of the brain critical for decision making.

Title: Heterogeneous development of drug abuse: Individual differences and predisposition to addiction

Authors: *N. J. BEACHER¹, J. KULIK¹, J. STAMOS², S. KLEIN¹, D. ESTRIN¹, V. CHEN¹, A. LEONTE¹, A. P. PAWLAK¹, M. O. WEST³ ¹Rutgers The State Univ. of New Jersey, Piscataway, NJ; ²Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; ³Psychology, Rutgers Univ., Piscataway, NJ

Abstract: The ability to identify individual predisposition to drug abuse is important for long term prevention of drug addiction. A particularly troubling component of addiction is subsequent relapse to drugs after a period of abstinence. Studies have shown the vast majority of the addicted population is susceptible to relapse triggered by drug-associated cues. During such episodes, 'drug-craving' can be induced by drug-associated cues which can re-invigorate drugassociations in motivational brain regions such as the nucleus accumbens (Nac). Thus, identifying predispositions to cue reactivity is important for the long term prevention of relapse in drug addiction. Differences in cue reactivity have been explored using an autoshaping test which identifies two distinctive behavioral phenotypes; Sign-trackers (ST) and Goal-trackers (GT). This phenomenon is thought to involve incentive salience, where the "self-rewarding" cue becomes associated with a future reward. Historically, GT animals have been largely ignored in drug addiction modeling and have been overshadowed by a common focus on their ST counterparts. Our study questioned whether individual differences in STGT phenotype would predict differences in drug seeking behavior and Nac firing during a 14-day cocaine selfadministration (SA) paradigm. Male and female Long Evans rats identified as ST, GT, or 'Middle' received 14 days' training (6 hours/day) in a tone discrimination paradigm where cocaine availability was contingent on a nose poke response during a 30 sec tone S^D. Single unit Nac responses to the S^D were compared between groups (core/shell, M/F, ST/GT), at different times (early SA sessions v late SA sessions), and during different behavioral events (hit and missed cocaine opportunities). Finally, Ultrasonic Vocalizations (USVs) were recorded to assess affective state with respect to individual baseline USV emission (prior to day 1 of SA). Results may identify a new model for studying individual differences in vulnerability to drug abuse and advance our understanding of cocaine cue-evoked Nac firing patterns that may contribute to relapse.

Title: Mimicking DBS with optogenetics in rats to identify the specific nucleus accumbens neurocircuits underlying relapse to cocaine

Authors: *S. E. SWINFORD-JACKSON, M. E. HOFMANN, R. C. PIERCE Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Repeated cycles of abstinence and relapse are a signature of cocaine use disorder. The nucleus accumbens (NAc) is fundamentally implicated in relapse to cocaine. We previously demonstrated that deep brain stimulation (DBS) of the NAc shell suppressed reinstatement of cocaine-seeking in rats; however, the mechanisms of DBS which underlie this effect are not well-understood. For example, DBS affects the activity of all cell-types within the targeted region, but it is unclear whether the impact of DBS on specific populations of neurons drive the attenuation of cocaine-seeking. Optogenetic techniques facilitate manipulation of specific cell types and neural pathways in a temporally-precise manner. Additionally, recently-developed transgenic rat lines which express Cre-recombinase in selective populations of neurons permit investigation into the effect of selectively activating or inhibiting neuronal subtypes on complex behaviors, including rat cocaine self-administration and extinction/reinstatement. Combining an optogenetic approach with transgenic rat lines provides an opportunity to investigate the mechanisms underlying the effect of DBS to suppress reinstatement of cocaine-seeking. This study first validated and characterized the use of optogenetic tools in wild type and transgenic rat lines expressing Cre-recombinase in subtypes of neurons. Ubiquitously-expressed or Credependent adeno-associated viral vectors expressing channelrhodopsin and eYFP were injected into the NAc shell or afferent regions to assess inputs and outputs of the NAc shell. Immunofluorescence was used to indicate viral expression and co-localization with subtypespecific markers. Firing properties of eYFP-positive neurons were recorded during 473nm laser stimulation at varied output intensities, pulse widths, and frequencies. Behavioral analyses are ongoing. This study is an initial step toward our goal of using optogenetics within specific pathways and neuronal subtypes to elucidate the mechanisms of DBS which attenuate reinstatement of cocaine-seeking.

Title: Differential regulation of Bdnf and behavior by HDAC and BET inhibition

Authors: *G. C. SARTOR¹, A. M. MALVEZZI¹, H. J. WIEDNER¹, J. M. WASSERMAN¹, C. R. WAHLESTEDT²

²Psychiatry and Behavioral Sci., ¹Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Brain Derived Neurotrophic Factor (BDNF) plays a central role in neuronal development, neuroplasticity, and learning and memory. As growing evidence indicates that altered epigenetic regulation of the BDNF gene may contribute to the pathophysiology of multiple brain disorders, epigenetic-based therapies have recently emerged as an attractive approach to modulate BDNF expression. For example, previous studies have shown that histone deacetylase (HDAC) inhibition increases Bdnf expression and enhances learning and memory in rodents. However, the underlying mechanisms by which HDAC inhibition (HDACi) increases Bdnf expression remain unclear. Previously, we found that inhibition of histone acetyl-lysine readers (BET bromodomains) reduces Bdnf mRNA and protein expression and reward-related learning. Because HDAC inhibition increases histone acetylation at the Bdnf promoter and because BET proteins are readers of histone acetylation, we hypothesized that HDACi-induced increases in Bdnf are mediated, in part, by BET proteins. In in vitro and in vivo studies, we found that the Class I/IIb HDAC inhibitor, SAHA, and HDAC3-specific inhibitor, RGFP966, increased Bdnf expression. Further, this HDACi-induced elevation of Bdnf expression was blocked in a dose- and time-dependent manner by the BET inhibitor JQ1. In additional siRNAmediated knockdown studies, we found that the increased Bdnf expression by HDAC2 and HDAC3 knockdown was blocked by knockdown of the BET protein BRD4. Behaviorally, JQ1 blocked the enhanced learning induced by RGFP966 in novel object recognition and cocaine conditioned place preference tests. Ongoing chromatin and electrophysiological studies will further uncover the interaction between HDACs and BETs in the regulation of Bdnf and neuroplasticity. Together, these studies reveal that BET proteins mediate HDACi-induced increase in Bdnf expression and learning and memory.

Title: Multiple system dysfunction in addiction: Evidence from model-based fMRI

Authors: *J.-C. YU¹, V. G. FIORE², J. S. SPENCE², R. W. BRIGGS³, J. BRAUD⁴, B. ADINOFF^{4,5}, X. GU¹

¹Cognition and neuroscience, ²Sch. of Behavior and Brain Sci., Univ. of Texas At Dallas, Richardson, TX; ³Dept. of Aging and Geriatric Res., Univ. of Florida, Gainesville, FL; ⁴Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; ⁵VA North Texas Hlth. Care Syst., Dallas, TX

Abstract: Existing models of addiction describe it as a shift from goal-oriented substanceseeking to reactive and habitual drug-taking. Under this framework, once addiction is formed, activity of the dorso-lateral sensorimotor cortico-striatal circuit (putamen, sensorimotor cortex) overrides activity of the ventral goal-selection cortico-striatal circuit (nucleus accumbens and ventromedial prefrontal cortex). However, this theory does not account for several important findings such as the altered behavioral and neural responses to non-drug-related rewards; and the abnormal neural activities in the ventral cortico-striatal circuit. In this research, we propose that substance-induced reinforcements alter circuit gain and neural dynamics in multiple corticostriatal circuits concurrently. We test the hypothesis with a probabilistic reward-learning fMRI study where 41 individuals with cocaine use disorders (CUD) and 18 healthy controls performed a task involving non-drug rewards. Our fMRI results demonstrate that cocaine addiction is associated with altered responses, such as enhanced activation and prolonged activity in multiple cortico-striatal circuits. Specifically, CUD participants show increased activation in nucleus accumbens and medial prefrontal cortex (ventral goal-oriented circuit) in association with reward values during the onsets of outcomes. In addition, CUD participants showed an increased activation in caudate (dorso-medial associative circuit) which associated to loss values during the onsets of outcomes. Furthermore, as opposed to the decreasing putamen activity (dorso-lateral habitual circuit) after action selection in healthy controls, the same activity in CUD individuals is maintained for a prolonged time. These findings suggest that in addicted individuals, abnormal neural activities can be observed in multiple cortico-striatal circuits, supporting the hypothesis that addiction is characterized by aberrant circuit gain and impaired information processing in multiple systems. Moreover, with non-drug related cues and rewards involved, the results also allow us to generalize this hypothesis to non-drug-related circumstances. This may explain why patients can fall back to relapse so easily even when they are not exposed to the addicted drug.

Title: Perturbations of the gut microbiome affect drug seeking behaviors

Authors: *D. D. KIRALY¹, E. G. PECK², A. GODINO³, N. L. MERVOSH², E. S. CALIPARI⁴ ¹Psychiatry / Neurosci., ²Icahn Sch. of Med. at Mount Sinai, New York, NY; ³Fishberg Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York City, NY; ⁴Mount Sinai Sch. of Med., New York, NY

Abstract: The resident bacteria of the gastrointestinal tract, collectively dubbed the gut microbiome, have been shown to have profound effects on both brain and behavior. To date, the majority of research into the effects of the gut microbiome in neuropsychiatric pathology has focused on affective and neurodegenerative disorders. However, we recently demonstrated that altering the gut microbiome has a marked effect on the behavioral and neurobiological responses to cocaine. Animals with depleted gut flora exhibited increased locomotor sensitization and a lower threshold for conditioned place preference for cocaine. Additionally, these mice had altered regulation of the genes encoding brain-derived neurotrophic factor, the D1 dopamine receptor, and other important regulators of behavioral response to cocaine. Here, we utilized a cocaine self-administration paradigm and behavioral economics modeling to assess how shifts in the gut microbiome directly affect motivation to seek and take cocaine. As previously published, we depleted the gut microbiome of rats with a cocktail of broad-spectrum non-absorbable antibiotics via their drinking water for two weeks. These animals were then trained to selfadminister cocaine on a fixed-ratio 1 schedule until they were stably administering for five days. Self-administration acquisition rates did not differ between groups. Animals were then assessed using a behavioral economics threshold task, a within-session method used to assess an animal's motivation to self-administer a reinforcer in the face of increasing cost. Microbiome-depleted rats were insensitive to increases in cost (as measured by effort required) for each milligram of cocaine. This insensitivity to increasing drug cost is analogous to insensitivity to cost seen in human drug abusers. When cue and drug were removed, microbiome-depleted rats exhibited

more rapid extinction of lever pressing for cocaine. However, after allowing for an incubation period after completion of extinction, we find that microbiome-depleted rats exhibited enhanced reinstatement for both cue and cocaine stimuli. Taken together, these findings suggest that changes in the gut microbiome can alter motivation to seek drug, and affect how animals update reward contingencies in a complex manner. Molecular studies are currently underway to determine how underlying changes in gene expression and epigenetic regulation lead to this altered behavioral phenotype.

Abstract: There is growing evidence implicating dysregulation of the immune system in the pathophysiology of multiple psychiatric disorders. While cocaine is known to affect immune system function, mechanistic links between altered immune function and pathological substance use behaviors remain poorly understood. To better characterize the effect of cocaine on innate immune function, we performed serum profiling of 32 cytokines, chemokines and growth factors after cocaine treatment. This assay identified multiple innate immune mediators that are regulated by chronic self- or experimenter-administered cocaine in mice. However, only granulocyte colony stimulating factor (G-CSF) was both increased by cocaine exposure and also positively correlated with the extent of both locomotor sensitization and levels of cocaine self-

administration. To interrogate the effect of G-CSF on cocaine-induced neuronal activation, we assayed induction of the immediate early gene *c-Fos* following an acute treatment with systemic G-CSF and/or cocaine in multiple brain regions involved in reward processing. G-CSF potentiated the cocaine-induced increase in neuronal activation specifically in the nucleus accumbens (NAc) and medial prefrontal cortex, while having no effect on its own. To assess effects of G-CSF on cocaine-induced behavioral adaptations, animals were pre-treated with systemic injections of G-CSF during locomotor sensitization and conditioned place preference (CPP) paradigms. G-CSF-treated animals exhibited significantly enhanced locomotor sensitization to 7.5mg/kg of cocaine. Similarly, treatment with systemic G-CSF during place conditioning enhanced the formation of cocaine CPP at lower doses (3.75 & 7.5mg/kg). Conversely, we were able to block the formation of CPP at 7.5mg/kg by infusing a G-CSF neutralizing antibody into the NAc. To better understand how G-CSF alters the motivational properties of cocaine, we utilized a behavioral economics threshold procedure in rats selfadministering cocaine. G-CSF-treated animals were less sensitive to gradual increases in cocaine cost, a measure that is indicative of increased motivation to self-administer cocaine. G-CSF treatment also increased total drug intake in both the threshold task and during FR1 selfadministration. Taken together, these experiments define a mechanistic and causal role for G-CSF in both the neuronal and behavioral responses to cocaine. Additionally, we posit that G-CSF is a putative target for development of pharmacotherapeutics to improve treatment outcomes in cocaine-addicted individuals.

Abstract: A key feature of human and animal behavior is to learn from environmental stimuli to efficiently adapt. The ability to learn about a new environment and to minimize contact with aversive experience is a hallmark of adaptive behavior and recent studies have demonstrated a key role of the ventral tegmental area (VTA) dopamine neurons in this process. Moreover, a critical role in the integration of relevant contextual information is played by the hippocampus, which controls the activity of dopamine neurons in VTA. It is generally recognized that the mesolimbic dopamine pathway originating in the VTA have an important role in the development of addiction. We have recently reported that the ventral subiculum of hippocampus (vSUB) regulate VTA dopamine neurons activity through the Bed nucleus of stria terminalis (BNST), and the potentiation of vSUB-BNST-VTA pathway increase locomotor activity induced by a sub-threshold dose of cocaine given in a novel context. Here we investigate how novelty induced by a switch of context trigger changes in electrophysiological properties of VTA dopamine neurons and the role of novel environment to trigger cocaine-evoked plasticity in dopamine neurons. We combined computational and in vitro/in vivo electrophysiological approaches to uncover the early cellular targets of cocaine in the mesolimbic dopamine system and the consequent adaptations at the circuit and behavioral level. Considering the tight links between stress, arousal and change in social interactions during the exploration of a novel environment, we explore the role of these individual components on cocaine-evoked modifications on integration properties of VTA dopamine neurons. We found that the novelty exposure is necessary for cocaine-induced effects on VTA dopaminergic neurons activity, and that this effect is due to the exploration of a novel environment and is not supported by a stresseffect during novelty exposure. Our study reveals a neuronal circuit encoding behavioural effects of cocaine in rats and the key role of hippocampus to the cocaine-induced effects on VTA dopamine neurons during exposition in a new context.

Title: "I must avert my eyes": Cocaine patients with a heightened brain response to 33 msec subliminal cocaine cues are more likely to "look away" from cocaine cues in an attentional bias task

Authors: *A. R. CHILDRESS¹, K. JAGANNATHAN¹, P. REGIER¹, J. J. SUH¹, R. EHRMAN^{1,2}, Z. MONGE³, S. DARNLEY¹, T. FRANKLIN¹, R. WETHERILL¹, D. D. LANGLEBEN^{1,2}, M. GAWRYSIAK¹, R. SZUCS-REED¹, K. YOUNG¹, K. KAMPMAN^{1,2}, C. P. O'BRIEN¹

¹Psychiatry, Univ. PENN Perelman Sch. Med., Philadelphia, PA; ²VA Med. Ctr., Philadelphia, PA; ³Duke Univ., Durham, NC

Abstract: Aims: A cardinal feature of addiction is the afflicted individual's profound ambivalence toward the abused drug. Even after experiencing repeated negative (even lifethreatening) consequences of drug pursuit, addicted individuals still experience the strong incentive motivational "pull" of drug reminder cues. This "pull" is reflected both in the high rates of relapse and in the triggering of the brain's motivational circuitry by drug reward cues. Using a behavioral task of attention to cocaine (vs. neutral) cues, we tested whether cocaine patients with a greater brain response to cocaine cues would pay greater attention to the drug cues, reflecting the positive attentional "pull" of the cues - or whether they might actually pay less attention to the cocaine cues ("look away"), reflecting ambivalence for the drug. Methods: In a "fast" event-related BOLD fMRI paradigm, treatment-seeking cocaine inpatients (n=27, ongoing) were exposed to cocaine-related (and comparison) cues of 33 msec duration in a backward-masking paradigm; 48 images of each cue type were presented in quasi-random order. Image preprocessing was conducted within a standard SPM 8 pipeline, with pre-planned contrasts (e.g., drug-neutral; first half of task). Subsequent performance (RT_{neutral} - RT_{cocaine}) in a classic "dot-probe" attentional bias task was used to measure differential attention, toward or *away*, from cocaine (vs. neutral) cues. The mean attentional bias score was used as a regressor (covariate of interest) in the drug-neutral contrast. Statistical parametric maps were thresholded (2 < t < 5) for display.

Results: Strikingly, the brain correlation maps revealed a robust and widespread *inverse* correlation between the brain response to 33 msec subliminal cocaine cues and the attentional bias scores to cocaine cues. The inversely correlated brain regions included multiple nodes of both the subcortical motivational circuitry (caudate, putamen, insula, midbrain tegmentum, medial orbitofrontal cortex) and cortical modulatory regions (inferior frontal gryus, anterior cingulate, dorsolateral prefrontal cortex) regions, as well as the cerebellum.

Conclusions: Intriguingly, cocaine patients with the *strongest* brain response to the 33 msec cues were actually more likely to "look away" from the cocaine cues in the attentional bias task. The "I must avert my eyes" response has been observed in clinical disorders where the tested stimulus contains elements of fear and threat (e.g., phobia). Whether the 'look away' response simply reflects a heightened cue sensitivity - thus a greater risk of relapse -- or a potential coping response, will be tested directly in future outcome analyses.

Title: Effect of intra-nucleus accumbens shell infusion of the CB1 receptor antagonist AM251 on reinstatement of cocaine-seeking behavior

Authors: *M. C. KNOUSE, S. E. SWINFORD-JACKSON, M. E. HOFMANN, R. C. PIERCE Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Repeated cycles of abstinence and relapse are a defining feature of cocaine use disorder, and there are currently no FDA-approved pharmacotherapies to prevent relapse to cocaine. Several factors can provoke relapse, including a sensitivity to cocaine-related cues, reexposure to cocaine, and stressful life events. Previous studies have demonstrated a role for the cannabinoid type 1 (CB1) receptor in the reinstatement of cocaine-seeking in rodent models. Systemic administration of CB1 receptor antagonists attenuated reinstatement of cocaine-seeking elicited by cocaine priming injections as well as cocaine-associated cues. Administration of the CB1 receptor antagonist AM251 (10 ug/ul) directly into the nucleus accumbens suppressed cocaine-primed reinstatement (Xi et al., 2006). However, the effect of intra-nucleus accumbens administration of AM251 on reinstatement evoked by other stimuli, including cocaine-associated cues, has not been examined. We tested the hypothesis that an intra-nucleus accumbens shell infusion of AM251 would attenuate both cocaine-induced and cue-induced reinstatement of cocaine-seeking behavior. Rats were trained to lever press for cocaine (0.254 mg/infusion) for 21 days on an FR1-5 schedule. Responding on the active lever resulted in an infusion of cocaine paired with activation of a cue light above the lever; inactive lever presses had no consequences. Rats then underwent extinction training where responses on the active lever produced infusions of saline but no light cues were delivered. Cocaine-seeking behavior was reinstated by noncontingent injection of cocaine (10 mg/kg, i.p.) or delivery of the cocaine-paired light cue in separate groups of rats. Fifteen minutes before each cocaine-primed reinstatement session, rats were pretreated with an intra-nucleus accumbens shell infusion (1 ul/side) of vehicle (25% hydroxypropyl- β -cyclodextrin), 5 µg/µL of AM251, or 10 µg/µL of AM251 in a within-subjects design; rats evaluated for cue-primed reinstatement received only vehicle and the 10 μ g/ μ L dose of AM251 in a within-subjects design. Preliminary data suggest that 10 µg/µL of AM251 attenuates cocaine- and cue-primed reinstatement of cocaine-seeking; additional experiments are

ongoing. These data suggest CB1 receptors in the nucleus accumbens shell may be involved in both cocaine-primed and cue-induced reinstatement. Our results replicate and extend prior findings which support the notion that CB1 receptor antagonists may be a potential pharmacotherapeutic for cocaine craving and relapse.

Title: Ca_v1.2 channels mediate extinction of cocaine-associated memories via its interaction with signaling mechanisms downstream of dopamine D1R activation

Authors: *C. E. BURGDORF^{1,2}, D. FISCHER², A. M. RAJADHYAKSHA^{1,2} ¹Feil Family Brain and Mind Res. Inst., ²Pediatric Neurology, Pediatrics, Weill Cornell Med., New York, NY

Abstract: Cocaine addiction is characterized by a high rate of relapse in response to cocaineassociated cues or contexts despite interventions such as behavioral therapy. Such persistent drug-seeking behavior results in part from established drug-associated contextual memories that are often resistant to extinction learning. Similar to other forms of experience-dependent learning, extinction learning has been proposed to utilize calcium-dependent signaling pathways. We have evidence that extinction of cocaine conditioned place preference (CPP), a commonly employed contextual behavioral model in addiction research, requires Ca_v1.2 within the dorsal hippocampus. In addition, using molecular studies with mice expressing cell-type specific knockout of Cav1.2, we have found that changes in synaptic proteins associated with extinction behavior are also dependent on Cav1.2 channels in dopamine D1 receptor (D1R)-expressing cells. Region-specific studies are investigating whether activity within D1R cells of the hippocampus are required for extinction of cocaine CPP. Activation of D1Rs initiate several signaling cascades, including PKA via interactions with AKAP150, molecules that we find are increased following extinction of cocaine CPP. In addition, PKA and AKAP appear to also regulate the effects of Cav1.2 channel activity, both at the synapse and via changes in gene expression within the nucleus. Ongoing studies are investigating specific Cav1.2-dependent changes in gene expression within D1R-expressing cells of the dorsal hippocampus following

extinction of cocaine CPP. These studies aim to identify the role of $Ca_v 1.2$ in mediating extinction of cocaine-related behaviors.

Title: Cav1.2 channels underlie stress-induced relapse of cocaine-seeking

Authors: *C. C. BAVLEY, R. FETCHO, B. HALL, D. K. FISCHER, C. BURGDORF, C. LISTON, A. M. RAJADHYAKSHA Pediatric Neurol., Weill Cornell Med., New York, NY

Abstract: Cocaine addiction is a large public health concern, and while current treatment methods help reduce drug-taking, they are largely ineffective at preventing relapse. Current evidence supports the diathesis-stress model of substance abuse, which postulates that genetic predisposition alters the response to environmental factors, such as exposure to stressful life events, in order to increase risk for substance abuse and relapse. The gene CACNA1C, which codes for the L-type voltage-gated Ca2+ channel Cav1.2, has been implicated in a multitude of neuropsychiatric disorders, including bipolar disorder, major depressive disorder, and schizophrenia. These disorders show high comorbidity with substance abuse disorders, suggesting that they may share similar etiologies. Additionally, previous studies have identified a role of Cav1.2 in mediating the effects of stress on the brain. However, no studies have examined a role of Cav1.2 in models of stress-induced relapse of cocaine addiction. Preliminary data indicate that heterozygous loss of Cav1.2 or focal knockdown of Cav1.2 within the PL reduce cocaine conditioned place preference (CPP) following exposure to an acute stressor. Current experiments are aimed at identifying the neural circuitry involving the PL that mediates stress-induced reinstatement of cocaine CPP and the role of Cav1.2 channels therein.

Title: Impact of intra-nucleus accumbens MS-275, a class I HDAC inhibitor, on the histone post-translational landscape as well as cocaine reinstatement

Authors: ***A. S. THOMAS**¹, B. FANT¹, S. E. SWINFORD-JACKSON¹, N. V. BHANU², B. A. GARCIA², R. C. PIERCE¹

¹Dept. of Psychiatry, ²Dept. of Biochem. and Biophysics, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Accumulating evidence suggests that cocaine-induced epigenetic modifications, such as histone post translational modifications (PTMs), contribute to addiction and relapse to cocaine. As such, pharmacotherapies targeting PTMs are interesting new candidates for the treatment of cocaine use disorder. For example, certain histone deacetylase (HDAC) inhibitors have been shown to attenuate cocaine-taking and relapse-like behavior in rodent models (Romieu et al. 2008; Romieu et al. 2011). Although pan-HDAC inhibitors have been investigated with mixed results, more specific inhibitors have yet to be extensively evaluated for efficacy in attenuating cocaine-related behaviors. Class I HDACs are a promising inhibitor target given that these enzymes are the most abundant of their kind in the brain and are more catalytically active than other classes of HDACs. Previous studies demonstrated that intra-nucleus accumbens (NAc) infusion of the class I HDAC inhibitor MS-275 attenuated cocaine-induced locomotor sensitization. When paired with repeated administration of non-contingent cocaine, chronic intra-NAc infusion of MS-275 altered both acetylation and methylation patterns in the NAc, suggesting that MS-275 may broadly alter histone PTMs. We hypothesized that MS-275, cocaine, and their combination would differentially alter histone PTMs in the NAc shell, with potential behavioral consequences. Rats received bilateral infusions (2 µl/side) of MS-275 (500 µM) or vehicle (1% DMSO) into the NAc shell. One hour following intracranial infusion, rats were pretreated with saline (1 ml/kg, i.p.) and placed into open field chambers where locomotor activity was recorded for two hours. This procedure was repeated for two additional days except that rats were pretreated with either cocaine (10mg/kg, i.p.) or saline (1ml/kg, i.p.) immediately prior to placement in the locomotor chambers. Tissue punches of the NAc shell were collected immediately following the third locomotor activity session. Histones were extracted from the NAc shell and analyzed via mass spectrometry to identify differences in histone PTMs across treatment groups. Future studies will investigate the effect of intra-NAc shell infusion of MS-275

on rodent models of cocaine-taking and relapse. Identifying epigenetic targets differentially modified by cocaine, HDAC inhibitors, and their interaction may provide insight for future therapeutic development with even finer targeting.

Title: Caveolin-1 involvement in cocaine-induced locomotor sensitization

Authors: *K. R. TONN, J. C. DWORSKY, N. M. STEENROD, M. J. THOMAS, P. G. MERMELSTEIN Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Caveolin-1 (Cav1) is an integral membrane protein that creates functional microdomains of neuronal proteins within lipid rafts. Cav1 regulates a variety of signaling pathways, including mGluR-activated G protein cascades, and is involved in membrane trafficking of proteins such as estrogen and dopamine receptors. Recent studies have shown that altering Cav1 expression influences neuronal plasticity and related behaviors in contexts ranging from learning and memory to chronic injury. Given this relationship between Cav1 and experience-dependent plasticity, we hypothesized that Cav1 expression would also be involved in drug-induced changes in neuronal signaling. We utilized a locomotor sensitization paradigm to test this hypothesis. Wild-type C57Bl6 mice received five days of repeated cocaine or saline exposure, followed by a week of abstinence and a subsequent challenge dose of either cocaine or saline. Animals receiving repeated cocaine displayed behavioral sensitization and greater expression of Cav1 mRNA in the nucleus accumbens when compared to saline-treated controls. Changes were specific to the Cav1 isoform, as no differences were observed in Cav2 or Cav3 mRNA within the nucleus accumbens following cocaine treatment. Additional studies are underway to determine the necessity of Cav1 for the development of cocaine-induced locomotor sensitization. Preliminary results in Cav1 knock-out mice show blunted responses to cocaine and impaired sensitization. Further work will investigate the molecular mechanisms underlying the relationship between Cav1 expression and cocaine-induced signaling.

Title: Escalating, non-contingent cocaine exposure induces persisting changes in synaptic transmission and LTP in the mouse ventral hippocampus

Authors: C. PRESTON¹, *J. J. WAGNER²

¹Physiol. & Pharmacol., ²Dept Physiol. & Pharmacol., Univ. of Georgia, Athens, GA

Abstract: We investigated the actions of a non-contingent cocaine dosing protocol on locomotor sensitization (LMS) and conditioned place preference (CPP). The effects of either cocaine or saline injections were assessed on measures of synaptic transmission and long-term potentiation (LTP) in the ventral hippocampus (vH). Locomotor activity was monitored in C57BL/6J mice that received either saline or cocaine (10 mg/kg i.p.). CPP was established using a modified conditioning protocol similar to the one described by Itzhak & Anderson (2012) that involved cocaine-treated mice receiving an escalating (Esc) dose protocol (4, 8, 16, 24, 16, 24, 32, 32 mg/kg i.p. once daily) on their least preferred side, whereas saline (Sal) mice were treated on each side of the two compartment apparatus. This protocol produced significant CPP and LMS 1 day and 1 week after cocaine conditioning, respectively. Littermates that did not undergo conditioning were handled intermittently to generate a "naïve" control group to establish the baseline LTP magnitude. Slices were prepared from the vH and field EPSPs were recorded in the CA1 region 4 weeks after the final injection day. Following the induction of LTP (100Hz/1sec*3), normalized fEPSP values were increased (1.57 +/- 0.03) in behaviorally naïve mice 60 minutes post-induction. Mice in the Sal group had a significant (p<0.05) increase in LTP (1.69 + - 0.03) as compared to naïve mice whereas the Esc group displayed an elevated but not significant increase in LTP (1.64 +/- 0.04). In order to reduce stress effects related to the behavioral protocol, separate groups of saline- and cocaine-treated mice were pretreated with the κ -opioid antagonist NorBNI (10 mg/kg i.p.) the day prior to initial CPP testing (pretreatment did not alter either LMS or CPP). Compared to naïve animals, the Sal/NorBNI group LTP was no longer significantly elevated (1.62 +/- 0.04). When compared to the Sal/NorBNI group, the Esc/NorBNI group LTP was significantly (p<0.05) decreased (1.52 +/- 0.03). This significant decrease in LTP between the Sal/NorBNI and Esc/NorBNI groups indicates the action of cocaine in the absence of the concomitant effect of stress induced by the behavioral protocol (i.p. injections/novel environment). Interestingly, the Esc/NorBNI treated animals also exhibited a

significant leftward shift in the stimulus sensitivity of their initial baseline fEPSP responses. Together, these findings are consistent with the hypothesis that an enhancement of neurotransmission contributes to a partial occlusion of LTP in the vH of cocaine-exposed mice that persists 4 weeks after the final drug exposure.

Title: Intranasal oxytocin reduces cocaine conditioned locomotion and anxiety-like behaviors: Possible modulation of the endocannabinoid system within the mesolimbic system

Authors: *G. C. MOLINA-CASTRO, A. N. FIGUEROA-GONZALEZ, A. L. LOYOLA-VÉLEZ, A. V. MARTI-MENDOZA, E. TORRES-HERNÁNDEZ, C. S. MALDONADO-VLAAR

Univ. of Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico

Abstract: Oxytocin (OT) is a neuropeptide secreted by the hypothalamic paraventricular nucleus (PVN) and commonly associated with social behaviors, stress responses and drug-addiction. Previous studies have shown that OT has anxiolytic properties associated with cues in a cocaine-conditioning paradigm, but the underlying mechanism remains unknown. This study aims to characterize possible mechanistic interactions between OT and the endocannabinoid system mediating cocaine conditioning and anxiety response, in particular the cannabinoid receptor type 1 (CB1). Rats were exposed to activity chambers after receiving systemic intraperitoneal injections of cocaine (10 mg/kg) or saline 0.9%. during five consecutive days. On the testing session (D7), rats received intranasal infusions of OT (1 $\mu g/\mu L$) or vehicle (saline 0.9%) 30 minutes prior being exposed to the cue-associated environment. Our results showed that OT pretreatment reduced both cocaine-paired conditioned locomotion and anxiety-like behaviors. Preliminary immunohistochemical analysis showed a colocalization of OT receptors and CB1 receptors within the nucleus accumbens (NAc), pre-frontal cortex (PFC) and hippocampus in all treated animals. Further pharmacological role of endocannabinoids and glial involvement is under study. The proposed mechanism includes a cross-talk between OT and endocannabinoid

system within mesolimbic system that might be responsible for the anxiety modulation triggered by cocaine exposure. This data suggests intranasal OT as a novel therapeutic approach of cocaine addiction.

Title: Kainate receptor expression and function in a rat model of cocaine self-administration

Authors: *M. HOFMANN, B. FANT, S. E. SWINFORD-JACKSON, M. C. KNOUSE, A. S. THOMAS, R. C. PIERCE

Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Addiction to cocaine remains a major public health concern in the United States due to its high rate of relapse. Chronic exposure to cocaine causes changes to the expression landscape of a variety receptors in the brain including ionotropic glutamate receptors. The clear majority of research on glutamatergic signaling following cocaine exposure has focused on AMPA and NMDA receptors, while our understanding of the role for kainate receptors in models of cocaine addiction remains limited. There are 5 subtypes of kainate receptors, GluK1-5, which form homo- and heteromeric tetramers for functional receptors. Here, we examined the expression of kainate receptor subtypes using qPCR and kainate receptor function using electrophysiology in the nucleus accumbens (NAc) of rats following 21 days of cocaine selfadministration. Rats were separated into two groups: one group self-administered cocaine and one group was a paired yoked-saline group. Initially, rats self-administered cocaine (0.25 mg/infusion i.v.) over a daily 2-hour session on a fixed ratio (FR) 1 schedule of reinforcement until reaching stable responding. Then, rats transitioned to a FR5 schedule of reinforcement. The yoked-saline rats received a saline infusion (59 µL/infusion i.v.) for every cocaine infusion from their paired cocaine self-administering rat. After 21 days of acquisition, brains were removed and used for either qPCR or electrophysiology to assess changes to kainate receptor expression or function, respectively. Using qPCR on NAc punches, we confirmed previous reports demonstrating that GluK2, GluK3, and GluK5 were the predominant subtypes expressed in the NAc. Compared to yoked saline controls, rats that self-administered cocaine demonstrated a

significant increase in the expression of GluK2 and no changes to GluK3 or GluK5 expression. Next, we wanted to assess whether this increase in GluK2 expression translated into changes to kainate receptor function using whole-cell recordings from medium spiny neurons (MSNs) in NAc slices. Application of 10 μ M kainate caused decreases in the holding current and membrane resistance of MSNs indicative of the activation of postsynaptic kainate receptors. However, there was no significant difference in these effects of kainate when comparing MSN recordings from yoked saline rats vs. cocaine self-administration rats. These results suggest the observed increase in GluK2 mRNA from cocaine exposed rats likely did not translate into increased expression of postsynaptic kainate receptors. Future studies will determine the potential role of kainate receptors following extinction and reinstatement in this cocaine self-administration model.

Title: Role of PT-type cortical neurons in locomotor sensitization, conditioned place preference, and reinstatement of drug-seeking to cocaine

Authors: *A. F. GARCIA^{1,2}, I. G. WEBB¹, S. M. FERGUSON^{1,2,3}

Abstract: Corticostriatal projections play an important role in addictive behaviors, especially in the processing of drug-associated cues. While most studies examine the prefrontal cortex as a homogenous structure, there are distinct cortical cell types that project to striatum. The intratelencephalic-type (IT-type) neurons project to both striatal hemispheres and contralateral cortex whereas pyramidal tract-type (PT-type) neurons project primarily to ipsilateral striatum and the pyramidal tract. These cortical projections to striatum arise from layer V pyramidal cells, and differ in several ways including dendritic arborization pattern, cell morphology, conduction velocity, presence of h-currents, and projection pattern. Notably, it has also been found that IT-type cells preferentially project to direct pathway striatal neurons and PT-type cells preferentially project to indirect pathway striatal neurons. The role these subtypes of cortical neurons play in addiction-related behaviors has not been examined. In order to begin to address this, we used a combinatorial viral vector strategy (retrograde CAV-Cre in pyramidal tract and a Cre-dependent
Gi/o-coupled DREADD into the anterior cingulate) in male Sprague Dawley rats to selectively target DREADD expression to PT neurons. The effect of transient inhibition of these neurons was examined in cocaine-induced locomotor sensitization, a conditioned place preference to cocaine and reinstatement of drug-seeking following cocaine self-administration. We found that DREADD-mediated inhibition of PT neurons significantly enhanced locomotor sensitization. Furthermore, inhibition of PT neurons enhanced the rewarding properties of cocaine, as animals significantly preferred a chamber associated with PT inhibition plus cocaine compared to just cocaine. Interestingly, this effect of PT inhibition was specific to cocaine, as it had no effect on a hedonic food reward-induced CPP, nor did it produce a place preference by itself. Finally, we found that PT inhibition is sufficient to modulate the effects of cocaine when they are concurrent, but not sufficient to alter pre-existing associations.

Abstract: Zinc imbalances are associated with many psychiatric and brain disorders, including depression, autism, ADHD, Alzheimer's Disease, and addiction. As an essential element for sustaining life, zinc homeostasis is vital for proper physiological function of cellular processes throughout the body. However, its role in the brain is poorly understood. Brain zinc exists in two forms: about 90% of it is static and found on metalloproteins, while the remaining labile zinc acts on a variety of biological processes and is predominantly found in zinc-containing glutamatergic neurons, which package zinc and glutamate into the same vesicles and co-release them into the synapse. While in the synapse, zinc is known to bind and modulate the activity of a

variety of receptors (including NMDA, AMPA, and GABA receptors). Zinc can also transverse synapses and regulate transcriptional processes in post-synaptic cells. Here, we examine how a dietary manipulation of zinc alters peripheral physiological measurements of zinc (in blood, hair, and urine) and how that subsequently alters brain zinc. Furthermore, animals with varying zinc diets show differential responses to cocaine, which appear to be linked to brain zinc levels and changes in synaptic plasticity. Our work further expands on the role of zinc-mediated signaling pathways that contribute to changes in synaptic plasticity and its potential relevance to addiction.

Title: Conditioned taste avoidance and conditioned place preference induced by racemic and enantiomer forms of α -pyrrolidinopentiophenone

Authors: *K. H. NELSON¹, B. J. HEMPEL¹, M. M. CLASEN¹, C. J. WOLOSHCHUK¹, K. C. RICE², A. L. RILEY¹ ¹Psychology, American Univ., Washington, DC; ²Chem. Biol Res. Br., NIH, NIDA & NIAAA, Rockville, MD

Abstract: *Background:* The synthetic cathinone, α -pyrrolidinopentiophenone (α -PVP), has been reported to have both rewarding and aversive effects. Given that the balance of these effects mediates abuse vulnerability, it is important to assess the factors that might impact it. One factor is the chemical composition of the drug itself. Specifically, work on α -PVP has been with the racemate, and with other synthetic cathinones there are differences between their enantiomers, e.g., differences in potency, general activity and mechanism of action. To address if the aversive and rewarding effects of the enantiomers of α -PVP differ, the present studies examined the ability of racemic α -PVP and its S(-) and R(+) enantiomers to induce conditioned taste avoidance and conditioned taste preferences, respectively.

Methods: In Experiment 1, adult male Sprague-Dawley rats were exposed to a novel saccharin solution, injected with either 0, 0.3, 1.0 and 3.0 mg/kg racemic α -PVP (IP) and placed on one

side of a place conditioning apparatus. The next day, they were injected with vehicle, given access to water and placed on the other side. Following four cycles, saccharin avoidance and place preferences were assessed. Based on the dose that induced avoidance and preferences (3 mg/kg), Experiment 2 was run under identical procedures assessing the aversive and rewarding effects of either racemic α -PVP, S(-) α -PVP or R(+) α -PVP.

Results: In Experiment 1, α -PVP induced dose-dependent taste avoidance as well as significant increases in time spent on the drug-paired side (although this effect was not dependent on dose). In Experiment 2, both the racemate and the S(-) enantiomer produced significant and comparable taste avoidance, whereas the R(+) enantiomer never significantly differed from vehicle. There was no evidence of place preference conditioning at this single dose of α -PVP.

Conclusions: The effects of the S(-) enantiomer of α -PVP paralleled those of the racemate in taste avoidance (as well as hyperthermia: data not described) suggesting that this enantiomer mediates the effects of α -PVP (similar to that seen with MDPV). The failure to see any effects of the various forms of α -PVP in place preference conditioning is likely due to the limited number of subjects tested at this single dose, given that prior work has reported preferences with the racemate. The rewarding effects should be studied further given the reported abuse potential of α -PVP to determine the relative contribution of the enantiomers to its overall affective properties and use and abuse.

Title: Evaluating the role of mGluR5 in post-cocaine working memory deficits and persistent cocaine-seeking

Authors: *C. M. GOBIN, M. SCHWENDT Psychology, Univ. of Florida, Gainesville, FL

Abstract: Chronic cocaine abuse produces motivational and cognitive deficits that might be rooted in abnormal function of circuitry that includes the medial prefrontal cortex (mPFC). While diminished activity of the PFC during post-cocaine abstinence has been linked to deficits in working memory and cognitive flexibility, over activation of glutamatergic output from the mPFC promotes relapse to drug-seeking. Systemic administration of metabotropic glutamate receptor 5 (mGluR5) antagonists attenuate relapse, but prolonged blockade of mGluR5 might exacerbate post-cocaine PFC dysfunction. Conversely, stimulating mGluR5, while potentially

beneficial for reversing PFC dysfunctions, may increase the risk of relapse. Previously, we showed that chronic cocaine self-administration results in load-dependent impairments in working memory in adult male Sprague-Dawley rats, as assessed with an operant delayed-matchto-sample (DMS) task. Furthermore, we showed that daily systemic administration of the mGluR5 antagonist MTEP (3mg/kg) attenuated cue+context-induced cocaine seeking (after 45-90 d of abstinence) and also impaired working memory performance in the DMS task. Here we wanted to evaluate the effects of prolonged allosteric activation of mGluR5 on post-cocaine working memory performance. After chronic cocaine self-administration, rats trained in the DMS task at short (0-12s) delays followed by testing at the full (0-24s) set of delays for a block of five days. Next, rats received daily systemic injections of a vehicle solution or the mGluR5 positive allosteric modulator CDPPB (30mg/kg) over a block of five days followed by a washout period of five days. Finally, rats underwent a cue+context-induced relapse test with either CDPPB (30mg/kg) or vehicle administered beforehand. mPFC tissue was collected immediately after the test and will be analyzed by quantitative cytochrome oxidase histochemistry to evaluate persistent metabolic activity and by immunoblotting to measure changes in mGluR5-dependent signaling. We predict that (1) CDPPB reverses working memory deficits in rats with a history of cocaine We also predict that (2) metabolic activity within the mPFC will correlate with the magnitude of post-cocaine working memory deficits and (3) activation of mGluR5 signaling will correlate with the 'intensity' of drug-seeking during relapse. Future studies will explore the effects of localized, intra-mPFC interventions targeting mGluR5 for their dual ability to restore post-cocaine cognitive deficits, while reducing cocaine-seeking.

Title: Cocaine self-administration and extinction induces adaptations in NMDA receptormediated currents in the nucleus accumbens core

Authors: M. T. SEPULVEDA-ORENGO¹, K. L. HEALEY², *K. J. REISSNER³ ¹Dept. Psychology and Neurosci., ²Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; ³Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Our lab has previously shown that cocaine self-administration and extinction leads to adaptations in astrocytes from the nucleus accumbens (NAc) core, including decreased surface

area, volume, and synaptic colocalization (Scofield et al, 2016). Because astrocytes are an important source of the NMDA co-agonist D-serine, we hypothesized that the reduction in synaptic colocalization would lead to impaired astrocyte modulation of NMDA receptor function. We previously showed that the stimulus-response relationship of isolated NMDA receptor currents is reduced in medium spiny neurons (MSNs) from cocaine versus saline experienced animals, an effect which is reversed by D-serine augmentation (SFN abstract, 2016). To extend these findings, we have used whole cell patch-clamp recordings to measure the current-voltage relationship of NMDA receptor-mediated currents, as well as the response to Dserine perfusion of NMDA receptor-mediated currents, in MSNs from cocaine versus saline extinguished rats. We have also assessed the contribution of specific NMDA receptor subunits to the cocaine-mediated adaptations in NMDA receptor currents. Preliminary data suggest that NMDA receptor currents are decreased following cocaine self-administration and extinction at both positive and negative holding potentials, an effect which is reversed by D-serine augmentation. In addition, ifenprodil application reduces NMDA receptor currents most effectively in MSNs from cocaine-experienced rats treated with D-serine augmentation, suggesting that restoration of NMDA receptor function by D-serine augmentation occurs at least in part through increased contributions of NR2B receptor subunits. These findings support the existing evidence suggesting that modulation of synaptic transmission by astrocytes in the nucleus accumbens is impaired following cocaine self-administration, an effect which can be ameliorated by systemic administration of D-serine.

Title: Cocaine-induced histone methylation on Egr3 and Nab2 promoters

Authors: B. EVANS¹, R. CHANDRA³, M. MCGLINCY¹, A. CHOW¹, K. K. COVER¹, M. ENGELN³, T. C. FRANCIS⁴, *M. LOBO² ²Anat. and Neurobio., ¹Univ. of Maryland Sch. of Med., Baltimore, MD; ³Anat. and Neurobio., Univ. of Maryland Baltimore, Baltimore, MD; ⁴Dept. of Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Epigenetic modifications plays an important role in transcriptional changes in the nucleus accumbens (NAc) in cocaine addiction. However, there is little information about the

role of histone demethylation in the NAc, after exposure to drugs of abuse. The NAc is a critical brain region, which mediates motivation for drugs of abuse. The NAc is composed of two types of medium spiny neurons (MSNs), which are differentiated by their enrichment of dopamine D1 vs. D2 receptors. We previously demonstrated that the transcription factor, Egr3, is upregulated in D1-MSNs and down-regulated in D2-MSNs after repeated cocaine exposure. It is postulated that Egr3 regulates its co-repressor; Nab2 and they both act together as a feedback mechanism to repress Egr3 transcription. Consistent with this, we observed a reduction of Nab2 in D1-MSNs and an increase of Nab2 in D2-MSNs after repeated cocaine. In order to further investigate the molecular regulation of Egr3 and Nab2 we examined the histone lysine demethylase (Kdm1a) enzyme as well as its demethylation targets H3K4me and H3K9me in NAc after repeated cocaine. We observed an increase in Kdm1a mRNA in D1-MSNs and a reduction in D2-MSNs after repeated cocaine. To further assess if Kdm1a might alter methylation on Egr3 and Nab2 promoters after cocaine we performed chromatin immunoprecipitation (ChIP) for histone marks, H3K4me3 and H3K9me2. Repeated cocaine caused changes in H3K4me3 and H3K9me2 on promoters of Egr3 and Nab2. We further found that Kdm1a is enriched on the Egr3 and Nab2 promoters in the NAc after repeated cocaine. To determine if Kdm1a is responsible for bidirectional induction of Egr3 and Nab2 in D1-MSNs vs. D2-MSNs we are developing a CRISPR-Cas9 approach to target specific methylation sites on the Egr3 and Nab2 promoters. In this approach we will alter methylation on the Egr3 and Nab2 promoters by using light-inducible heterodimerizing proteins CRY2-KDM1A and dCas9-CIB1, along with Egr3 and Nab2 gRNAs. This approach will allow us to understand the precise epigenetic mechanisms regulating expression of Egr3 and Nab2 in MSN subtypes during cocaine-mediated behaviors. Overall our studies will provide new information into the effects of cocaine on histone demethylation and its regulation of Egr3 and Nab2 transcription in MSN subtypes.

Abstract: Altered brain energy homeostasis is a key adaptation occurring in the cocaineaddicted brain. However, the underlying mechanisms that govern these homeostatic adaptations are not clearly defined. One such mechanism, which is a fundamental component of energy homeostasis and has not been addressed in cocaine abuse are mitochondrial dynamics; which can include mitochondrial biogenesis, fission, and fusion. To provide insight into this we assess mitochondrial dynamics in the two nucleus accumbens (NAc) projection medium spiny neuron (MSN) subtypes, those enriched in dopamine D1 vs. D2 receptors in mice that self-administer cocaine. Using a Cre inducible adeno-associated virus (AAV)-double inverted floxed open reading frame (DIO)-mito-dsRed combined with D1-Cre and D2-Cre mouse lines we label mitochondria in MSN subtypes. Cocaine self-administration (SA) caused an increase in the frequency of smaller mitochondria in D1-MSN dendrites, implicating enhanced mitochondrial fission in D1-MSNs. Consistent with our data we observe an increase in mRNA of Dynaminrelated protein 1 (Drp1), a mediator of outer mitochondrial membrane fission, in NAc of rodents that self-administer cocaine and in postmortem NAc of cocaine dependent individuals. Using the RiboTag approach, we observe an upregulation of ribosome-associated mRNA of Drp1in D1-MSNs and a decrease in D2-MSNs after repeated cocaine. Additionally, the activated form of Drp1 protein is increased in NAc of mice after repeated cocaine injections. We next used a small molecule inhibitor of mitochondrial fission, Mdivi-1, which blocks the activated form of Drp1. Mdivi-1 treatment blunted cocaine conditioned place preference, reduced cocaine locomotor sensitization, and blunted cocaine seeking behavior after cocaine SA. Consistent with these findings, adeno-associated virus (AAV) based Cre-inducible knockdown of Drp1 in D1-MSNs caused reduced seeking behavior after cocaine SA. Finally, we generated Cre-inducible Drp1constitutively active (CA) and Drp1-wild-type (WT) AAVs. Overexpression of Drp1-CA in D1-MSNs increased seeking behavior after cocaine abstinence. In addition, our study demonstrated that overexpression of Drp1-CA in D1-MSNs increased the frequency of smaller mitochondria in D1-MSN dendrites. Since these findings occur in D1-MSN dendrites we are currently investigating how blocking fission or altering Drp1 levels can alter synaptic and structural plasticity. Our findings demonstrate a novel role for altered mitochondrial fission in NAc in cocaine abuse and implicate that blockade of mitochondrial fission has potential therapeutic treatment for cocaine addiction.

Title: Cocaine self-administration causes a persistent reduction of Kv7 channel mediate intrinsic inhibition in the prefrontal cortex

Authors: J. PARRILLA-CARRERO, P. GOSWAMEE, W. BUCHTA, *A. C. RIEGEL Neurosciences, Med. Univ. of South Carolina (MUSC), Charleston, SC

Abstract: Conditioned stimuli associated with self-administration (SA) of cocaine, but not natural rewards like sucrose, elicit persistent craving and drug seeking. Although this response appears to require the dopamine mediated recruitment of nucleus accumbens core-projecting glutamate cells in the prefrontal cortex (PFC), the underlying mechanism remains unclear. Here, we tested the hypothesis that the cue-paired recruitment of dopamine signaling during cocaine-SA persistently disrupts Kv7 channel mediated intrinsic inhibition in PFC glutamate cells. To investigate this, we recorded from glutamatergic pyramidal cells in (L5) of the prelimbic PFC in the current and voltage clamp configuration in slices from naïve rats or rats with a history of conditioned cues (light + tone) presented in conjunction with chronic cocaine-SA, sucrose-SA, yoked-cocaine, or yoked-saline. At 24-hours after completion of operant SA training (14d), most cells in tissue from rats receiving yoked-saline or yoked-cocaine during non-contingent cue presentation resembled responses in naïve rat slices and displayed robust spike-frequency adaptation (SFA). However, cells in slices from contingent cued sucrose-SA or cocaine-SA rats typically lacked SFA, suggesting learning-mediated changes in intrinsic inhibition. Following extinction training (14d), SFA normalized in sucrose-SA control slices, but remained reduced in cocaine-SA slices. Re-exposure of cocaine-SA+extinction rats to drug predictive cues further reduced SFA (75% cells) in PFC slices, without altering SFA in yoked-saline controls. In slices from similarly treated transgenic cFos-GFP rats with a history of cocaine-SA, expression of the GFP-transgene correlated with decreased SFA and reduced Kv7 channel currents. Bath applied

dopamine (10 uM) robustly reduced SFA and Kv7 channel currents in controls, but produced no significant reduction in cocaine-SA tissue suggesting a functional desensitization of Kv7 channels. The Kv7 channel stabilizer retigabine restored SFA when applied to slices from cocaine-SA rats and dose dependently attenuated cue-induced reinstatement when injected in vivo into the PL-PFC. These findings shed light on the functional significance of Kv7 channel mediated intrinsic inhibition in mediating cocaine seeking and may offer a drug target by which cocaine seeking behavior can be treated.

Title: Hypothalamic hypocretin/orexin within ventral midbrain of rat

Authors: *S. J. SIMMONS, R. M. MARTORANA, F. H. TRAN, T. A. GENTILE, J. W. MUSCHAMP

Ctr. for Substance Abuse Res., Temple University, Lewis Katz Sch. of Med., Philadelphia, PA

Abstract: Numerous brain circuits underlie rewarding and reinforcing properties of abused drugs. Once conceived as a relatively homogenous production center of dopamine (DA), anatomy and function of ventral tegmental area (VTA) of Tsai has been re-visited in the recent decade. While VTA houses DA-producing neurons, evidence from the late-2000s revealed a neurochemically- and functionally-distinct nucleus in caudal VTA termed the rostromedial tegmentum (RMTg). Comprised dominantly of GABA-producing neurons, the RMTg receives dense input from lateral habenula and provides inhibition to DA-producing neurons of rostral division of ventral midbrain (i.e. to VTA). Habenular input to RMTg functionally brakes reward/signals aversion, and although clear roles of habenular input to RMTg have been revealed, numerous structures including hypothalamus target RMTg. Hypocretin/orexin (hcrt/ox) peptides are produced within hypothalamus and their transmission underlies wakefulness, arousal and motivation to retrieve salient and palatable reinforcers including high-fat food and drugs of abuse. The present study sought to topographically organize hcrt/ox afferents within ventral midbrain and to provide functional assessment of hcrt/ox transmission within distinct ventral midbrain structures in models of substance use disorder. Rats underwent stereotaxic cannulation surgery to target VTA and RMTg, and fluorescent microspheres were microinjected

to label projection neurons via retrograde transport. Hypothalamus-containing tissue was thereafter immunolabeled for hcrt/ox and sub-regional proportions of hcrt/ox afferents within each target structure were measured. The VTA was found to receive slightly greater input (10.9%) relative to RMTg (8.4%) in cases examined, and no pattern of anterior-posterior topography within hcrt/ox field was observed. Ongoing study is evaluating function of hcrt/ox within ventral midbrain in models of substance use disorder as our exploratory mapping study suggests hcrt/ox may additionally signal to GABA-containing RMTg.

Schmidt Col. of Medicine, Florida Atlantic Univer, Florida Atlantic Univ., Jupiter, FL

Abstract: The etiology of multiple brain disorders stems from a dysfunction in dopaminergic and/or glutamatergic signaling, with phenotypes ranging from movement perturbations to drug dependence to cognitive dysfunction. Our lab conducted a forward genetic screen in *C.elegans* looking to uncover novel regulators of dopamine (DA) signaling, resulting in the discovery of the glial expressed gene *swip-10*. Loss of function mutations of *swip-10* result in a hyperdopaminergic phenotype associated with hyper-excitability of DA neurons which evidence indicates is driven by elevated glutamate (Glu) signaling. In a BLAST search for proteins homologous to SWIP-10, we identified the unstudied protein MBLAC1 (Metallo- β -lactamase domain containing protein 1) as the likely SWIP-10 ortholog. Sequence identity between SWIP-10 and MBLAC1 derives largely from a shared metallo- β -lactamase domain that, in prokaryotes, supports hydrolysis and inactivation of β -lactam antibiotic ceftriaxone (Cef), a drug that has shown

to afford neuroprotection in rodent models of Glu dysfunction as well as to alter glial-dependent control of Glu levels. Because of the potential of MBLAC1 as a Cef target, we used the CRIPSR/Cas9 system to introduce mutations in mouse Mblac1 coding sequences, validating loss of MBLAC1 protein expression by immunoblotting. Here, we report on our initial characterization of the resultant KO line. We are taking a three-pronged approach to uncover phenotypes associated with loss of MBLAC1 expression. First, we are using LC-MS/MS to pursue an untargeted metabolomics approach that can identify small molecules in serum distinguishing WT and Mblac1 KO mice. Analysis of these changes indicates enrichment of pathways that feature sulfur containing metabolites including taurine and taurocholic acid. Second, given the connection of SWIP-10 to C. elegans Glu signaling, we examined expression of glial Glu transporters. Based on Western blot analysis, we observed no significant difference in total GLT1 protein expression in the cortex, whereas a reduction was detected in expression of the Cys/Glu exchanger (XC-) subunit xCT. Lastly, we are exploring behavioral changes arising in Mblac1 KO mice. Initial evaluation of growth rates, reproduction and locomotor/sensory alterations reveals no gross phenotypes. Preliminary studies of drug responses indicate no differences in locomotor response to amphetamine, and we are currently studying the effects of acute and chronic cocaine. Future studies will examine biochemical and behavioral responses to Cef. Supported by NIH Award MH095044 (RDB)

Abstract: Drug addiction is a chronic brain disease that develops gradually with compulsive use of psychoactive substances. Cocaine is one of such drugs that progressively alters brain regions associated with reward and motivation, including the nucleus accumbens (NAc). The changes in synaptic and epigenetic plasticity mediate cocaine craving evoked by drug-associated cues, which intensifies during abstinence in human addicts and animal models of addiction, and this incubation of craving may underlie persistent relapse susceptibility. The ubiquitin-proteasome system (UPS), which is responsible for proteasomal-dependent protein degradation, has been shown to be involved in cocaine-induced plasticity. Substrates are polyubiquitinated for degradation via E3 ubiquitin ligases. There are over 600 E3s, which are currently being examined for their therapeutic potential in many neuronal disorders due to their high specificity. However, the role of E3s in regulating cocaine-dependent plasticity and relapse behaviors has not been examined. Here, we examined tripartite motif-containing protein 3 (trim3), which regulates the polyubiquitination of substrates involved in drug-induced adaptations. Following extended-access cocaine self-administration, we found dynamic changes in trim3 expression in NAc subcellular fractions. On withdrawal day (WD)1, trim3 levels were decreased in crude synaptosomal fractions from cocaine-treated rats compared with saline controls. Moreover, the levels of the synaptic regulators Shank and γ -actin, which are substrates of trim3, were increased. By contrast, trim3 was decreased in the nuclear fractions on WD30 in cocaine-treated rats compared with saline controls and INO80, a trim3 substrate that regulates transcription, was increased. We used viral-mediated gene transfer in the NAc to demonstrate that trim3 mediates cue-induced cocaine seeking during withdrawal.

Title: Examination of E3 ubiquitin ligase Smurf1 following abstinence from cocaine self-administration

Authors: *R. VISWANATHAN, C. T. WERNER, Z.-J. WANG, J. A. MARTIN, D. M. DIETZ Dept. of Pharm and Tox; Res. Inst. on Addictions; Program in Neurosci., State Univ. of New York At Buffalo, Buffalo, NY

Abstract: Drug addiction is a disease characterized by episodes of relapse despite periods of abstinence. It is thought that cellular and molecular events in discrete brain areas of the reward pathway, including the nucleus accumbens (NAc), underlie these long-lasting behavioral changes. Recently, we identified members of the Transforming growth factor (TGF)- β pathway as essential mediators of drug addiction-like plasticity and behavior. However, how TGF-β signaling is regulated in drug addiction has not yet been examined. The TGF- β superfamily of proteins regulates a wide variety of cellular responses, including gene expression and cellular plasticity. Some of these proteins are tagged by E3 ubiquitin ligases for degradation through the ubiquitin-proteasome system (UPS). The UPS regulates the expression of a variety of proteins that play significant roles in synaptic plasticity, learning, memory and behavior and has been shown to be involved in cocaine-induced plasticity. After a 7-day abstinence period following short-access cocaine self-administration in rats, we found that the E3 ubiquitin ligase Smurf1 mediates the expression of the TGF- β family member SMAD1 in the NAc. These data suggest that regulation of SMAD1 via E3 ubiquitin ligases may be involved in drug-dependent cellular and behavioral plasticity. Our future experiments aim to determine the functional role of Smurf1 in mediating drug addiction-like behaviors in an effort to determine if these pathways hold potential therapeutic value in the treatment of substance abuse disorder.

Title: Cocaine regulates extracellular vesicle release in mouse midbrain

Authors: *Y. NAKAMURA, S.-Y. A. TSAI, T.-P. SU Cell. Pathobiology Section, Integrative Neurosci. Res. Br., NIDA IRP, Baltimore, MD

Abstract: Cocaine is an agonist of the sigma 1 receptor (Sig1R) which is a receptor chaperone expressed in the ER membrane. We previously showed, by using NG108 cells, that cocaine evokes the extracellular vesicle (EV) release via the Sig1R-ADP ribosylation factor 6 (ARF6) pathway (Nakamura et al., SfN 2015 and 2016). The present study examined the release of EV in mouse midbrain region after an injection of cocaine (15 mg/kg; i.p.). We first confirmed a

method for the brain EV isolation through a series of differential centrifugations to isolate EVs from the extracellular space of mouse brain (Perez-Gonzalez et al., JBC, 2012), and then examined the EV level by quantification of the EV markers including integrin β 1, Alix, and ARF6. The mitocondrial markers cytochrome-c (Cyto.-c) and the dopamine (DA) neuronal marker tyrosine hydroxylase (TH) were also examined. The EV markers could be seen in the EV sample collected from the mouse midbrain. However, the EV didn't contain Cyto.-c. Those data confirmed that the EV samples, but not cellular debris, could be collected from mouse midbrain. In addition, EVs derived from midbrain, but not cortex or hippocampus, contained a lot of TH. Thus, those data suggest that DA neurons in mouse midbrain region can release TH-containing EVs into extracellular space. Furthermore, 30 min, but not 60 min, after an i.p. injection of cocaine significantly increased the amount of extracellular TH in the form of EV in mouse midbrain. Taken together, our results suggested that the cocaine regulates the EV release from mouse DA neurons via previously the proposed Sig1R-ARF6 pathway. (supported by IRP NIDA NIH)

Title: Sigma1 receptor modulates cocaine-induced endocannabinoid signaling in the mouse ventral tegmental area

Authors: *D. I. DRYANOVSKI¹, Y. NAKAMURA², T.-P. SU², C. R. LUPICA¹ ¹Electrophysiology Res. Section, ²Cell. Pathobiology Section, Natl. Inst. On Drug Abuse, NIH, Baltimore, MD

Abstract: Endogenous cannabinoids (eCB) are signaling lipids released from neurons to retrogradely activate cannabinoid CB1 receptors (CB1R) located on axon terminals of presynaptic cells to limit neurotransmitter release. The eCB associated with activity dependent modulation of synapses is 2-arachidonoylglycerol (2-AG). We have shown that cocaine can stimulate 2-AG synthesis in the VTA, resulting in CB1R activation on GABAergic axons targeting dopamine (DA) neurons. Moreover, this disinhibition of dopamine neurons by cocaine-induced 2-AG release is functionally relevant since it elevates DA release in target areas, perhaps contributing to the rewarding and addictive properties of cocaine (Wang et al., Cell Rep., 2015). 2-AG synthesis is triggered by activation of G α /11-coupled metabotropic receptors through

activation of phospholipase C- β (PLC β), which hydrolyzes membrane phospholipids to form 1,2dacylglycerol (DAG) and inositol triphosphate (IP3). DAG is converted to 2-AG via diacylglycerol lipase- α (DGL α), whereas IP3 can elevate cytosolic Ca²⁺ by stimulating its release from endoplasmic reticulum (ER). The sigma1 receptor (σ 1R) resides on the mitochondria-ER interface membrane, serving as a protein chaperone, and conferring a conformation of the IP3 receptor that sustains Ca²⁺ signaling. Under basal conditions, σ 1R is bound to ADP-ribosylation factor 6 (ARF6), however, cocaine can bind to σ 1R and release ARF6. Since the σ 1R is involved in Ca²⁺ signaling and the production of 2-AG by cocaine is Ca²⁺ dependent, we examined a possible interaction between these effectors. We measured cocaine-induced 2-AG activity in VTA DA neurons by monitoring its activation of CB1Rs on GABAergic axon terminals and the inhibition of GABA_B-receptor mediated IPSCs. We find that both σ 1R antagonists and ARF6 inhibitors prevent the cocaine-induced inhibition of IPSCs mediated by 2-AG, implicating this system in eCB signaling in the VTA.

Title: Circadian transcription factor NPAS2 and metabolic redox sensor SIRT1 interact in the mouse nucleus accumbens (NAc) to regulate cocaine reward-related behavior

Authors: *D. D. BECKER-KRAIL¹, P. K. PAREKH¹, R. W. LOGAN¹, J. YOSHINO², C. A. MCCLUNG¹

Abstract: Cocaine addiction is a widely prevalent substance use disorder in the United States. With a lack of successful therapeutic options, it is important to investigate the cellular and molecular level changes following cocaine use, and how these changes establish and/or reinforce addiction. As its mechanism of action, cocaine increases mesolimbic dopaminergic signaling via inhibition of dopamine transporter. This increased activity is energy taxing for the cell and can cause both severe oxidative stress and altered mitochondrial function. Interestingly, metabolic changes associated with cocaine use may directly regulate the circadian molecular clock and its output genes through associated metabolic redox sensors. More specifically, the circadian transcription factors CLOCK/NPAS2 and the NAD+ dependent deacetylase, SIRT1, have all been shown to directly respond to changes in levels of the mitochondrial coenzyme NAD+. Previous work in the lab has shown CLOCK and NPAS2 differentially regulate cocaine reward; e.g. mutations in the *Clock* gene increase cocaine preference and self-administration, while mutations in Npas2 yields an opposite phenotype. Moreover, our data suggest NPAS2 regulates reward through its enriched expression in the nucleus accumbens (NAc). Interestingly, SIRT1 modulators have also been shown to regulate cocaine preference, in that SIRT1 agonists increase cocaine preference and vice versa. In addition to NPAS2 and SIRT1 modulation altering cocaine reward, chronic cocaine exposure has been shown to preferentially alter expression of these proteins in the NAc. Given these observations, we investigated how changes in cellular metabolic state may feed into the circadian molecular clock and alter regulation of cocaine reward, and whether an interaction between NPAS2 and SIRT1 in the NAc mediates this regulation. Through co-immunoprecipitation studies, our preliminary findings suggest that NPAS2 and SIRT1 do interact in a shared complex in the NAc, and chronic cocaine may alter this interaction. Furthermore, utilizing high-performance liquid chromatography to assess NAD+ concentration, we observed a diurnal variation of NAD+ levels in the striatum that is disrupted following chronic cocaine exposure. Finally, in mice with a NAc specific viral-mediated knockdown of NPAS2, we determined NPAS2 to be necessary for the increase in cocaine preference seen with a SIRT1 agonist. Ultimately, our findings highlight a mechanism by which chronic cocaine's metabolic changes can directly alter circadian molecular clock function, and how this interaction, mediated by NPAS2 and SIRT1, may afford regulation of cocaine reward-related behavior.

Title: Regional differences in striatal neuronal ensemble excitability following cocaine and extinction memory retrieval in Fos-GFP mice

Authors: *J. J. ZIMINSKI¹, M. C. SIEBURG², G. MARGETTS-SMITH³, H. S. CROMBAG⁴, E. KOYA¹

Abstract: Learned associations between drugs of abuse and the drug administration environment play an important role in addiction. In rodents, exposure to a drug-associated environment elicits conditioned psychomotor activation, which may be weakened following extinction learning. While widespread drug-induced changes in neuronal excitability have been observed, little is known about specific changes within neuronal ensembles activated during the recall of drugenvironment associations. Using a cocaine conditioned locomotion procedure, the present study assessed the excitability of neuronal ensembles in the nucleus accumbens core and shell (NAc^{core} and NAc^{shell}), and dorsal striatum (DS) following cocaine conditioning and extinction in Fos-GFP mice that express green fluorescent protein (GFP) in activated, GFP+, neurons. During conditioning, mice received repeated cocaine injections (20 mg/kg) paired with a locomotor activity chamber (Paired) or home cage (Unpaired). 7-13 days later both groups were re-exposed to the activity chamber under drug-free conditions, and Paired, but not Unpaired, mice exhibited conditioned locomotion. In a separate group of mice, conditioned locomotion was extinguished by repeatedly exposing mice to the activity chamber under drug-free conditions. Following the expression and extinction of conditioned locomotion, GFP+ neurons in the NAc^{core} (but not NAc^{shell} and DS) displayed greater firing capacity compared to surrounding GFP- neurons. This difference in excitability was due to a generalized decrease in GFP- excitability following conditioned locomotion, and a selective increase in GFP+ excitability following its extinction. These results suggest a role for both widespread and ensemble-specific changes in neuronal excitability following recall of drug-environment associations.

Title: Linking developmentally-regulated genes with drug addiction in the nucleus accumbens of mice overexpressing the RNA-binding protein HuD

Authors: *N. PERRONE-BIZZOZERO, R. J. OLIVER, A. S. GARDINER Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: The neuronal RNA-binding protein (RBP) HuD plays an important role in the posttranscriptional control of gene expression during neuronal development, regeneration, and synaptic plasticity. However, the potential role of HuD in drug addiction is poorly understood. Recent studies in our lab demonstrate that HuD overexpressor (HuD_{OE}) mice display increased cocaine conditioned place preference (CPP) compared to wild type (WT) littermates. In addition, CPP trained HuD_{OE} mice have increased expression of HuD and its validated addiction-related gene targets Camk2a and Bdnf in the nucleus accumbens (NAc), potentially driving this enhanced place preference behavior. To further understand the role of this RBP in drug addiction, we performed RNA-immuno-precipitation and sequencing studies (RIP-seq) of HuDbound RNAs in the striatum of HuD_{OE} mice, using an antibody against myc-tagged HuD. About 1700 coding transcripts showed significant >2 fold enrichment (p<0.05) in the HuD IP vs. WT IP and were defined as putative HuD targets. Importantly, 85.5% of these contained consensus motifs for HuD binding in their 3'UTRs. Comparison of HuD targets and genes in the Knowledgebase of Addiction-related genes database (KARG, http://karg.cbi.pku.edu.cn) revealed that HuD targets represent 17.5% of all the genes in KARG. HuD targets were also significantly enriched in neurogenesis and Wnt signaling pathways, and included many neuronal development-associated genes such as the transcription factors Satb1, Sabtb2, Mef2a, Mef2c, Foxp1, Neurod6, Creb1, Mecp2, Sox5, Sox11 as well as Bdnf, Wnt5a, Jag1, Fz3b, Gs3kb, Dcx, Ndel1, Nlgn3, Nrg1, Nrn1, Nrxn2, Rtn3, Rock2, Stmn3, Sema4d, etc. Given our previous work showing a role for HuD in neurogenesis (Wang et al, PNAS 2015) and our findings that many HuD targets play a role in axonal and dendritic development, we began examining the effect of HuD overexpression on neuronal morphology within the NAc. We found that HuD_{OE} animals have an increased frequency of immature thin spines, with a decrease in intermediate stubby spines but no change in mature mushroom spines within the NAc. This alteration in structural plasticity is similar to changes found in animals trained in CPP, possibly suggesting that these HuD_{OE} animals may be primed for increased drug-reward as determined by their enhanced place preference behavior. Overall, these results are consistent with the notion that some of the plasticity-associated changes during drug addiction not only recapitulate early neuronal development but also recruit similar molecular pathways such as those enriched in HuD targets.

Title: HuD regulation of circRNAs expression and localization during cocaine seeking behaviors

Authors: *M. DELL'ORCO, R. J. OLIVER, N. MELLIOS, N. PERRONE-BIZZOZERO Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: Substance use disorder (SUD) is a chronic disease characterized by compulsive drug seeking and use. SUD is thought to be mediated by aberrant expression of proteins regulating synaptic plasticity in neurons such as RNA-binding proteins (RBPs). Several RBPs have been previously associated with addiction including neuronal HuD. Specifically, HuD regulates the expression of many genes listed in the Knowledgebase of Addiction related genes (KARG) database such as c-FOS, BDNF, GAP43, and CAMK2A. At the molecular level HuD binds to cis-acting elements in RNA molecules governing their processing, subcellular localization, translation and degradation. One such group of RNA molecules that could be regulated by HuD are circular RNAs (circRNAs), a novel category of non-coding RNAs that are derived from the back-splicing and covalent joining of exons. Due to their abundant expression in the brain and their localization at synapses, circRNAs could be of importance to neuronal development and neuroplasticity. Notably, circRNAs contain numerous consensus regulatory sequences for RBPs. Our bioinformatics analyses revealed that 29% of mouse circRNAs bear consensus HuD binding motifs. Thus, we aimed to explore whether HuD interaction with circRNAs may be involved in the control of synaptic plasticity during drug addiction. A subset of circRNAs showed altered expression in the nucleus accumbens (NAc) during cocaine-conditioned place preference (CPP). Within this set, we focused on circRNAs related to genes known to be involved in neuroplasticity. For example, circLmo7 and circHomer1, which are downregulated by CPP, and circTulp4 and circSabt2, which are upregulated. Using RNA immunoprecipitation assays (RIP) followed by qRT-PCR we validated the interaction of HuD with circLmo7, circHomer1 and circTulp4. To assess whether HuD binding can alter target circRNAs localization, we also evaluated circRNAs levels in synaptoneurosomes and found that circHomer1 was significantly enriched in this compartment in HuD overexpressing mice (HuD_{OE}) compared to wild-type (WT) mice. Furthermore, we found that the levels of both cirHomer1 and Homer1 mRNA, which is also a known target of HuD, were increased in the NAc of HuD_{OE}. These results are consistent with previous studies showing changes in Homer1 mRNA and protein levels after cocaine administration. Since HuD levels are increased in CPP and HuD_{OE} show increased cocaine CPP, investigating the role of HuD-circRNAs interactions in cocaine-induced neuroplasticity and behavior may uncover new regulatory processes and molecular targets involved in drug addiction.

Title: Projections from the nucleus accumbens to the ventral mesencephalon collateralize in the ventral pallidum

Authors: *T. PARDO, J. A. HEINSBROEK, P. W. KALIVAS Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: D1-receptor expressing medium spiny neurons (D1-MSN) in the Nucleus Accumbens (NAc) send projections to the Ventral Pallidum (VP) and the Ventral Tegmental Area, as well as the Substantia Nigra (VTA/SN). In the neighboring dorsal striatum, D1-MSNs passing through the Globus Pallidus are known to form branching collaterals in response to hyperactivity of the striatum. As of now, it is unknown whether D1-MSN in the NAc that project to the VTA/SN also collateralize in the VP, and whether other D1-MSN pathways exists that exclusively innervate the VP or VTA/SN. Since accumbens D1-MSNs drive motivated behavior such as social interaction, food consumption, and addictive behavior (drug use and relapse to drug seeking) it is important to dissect the precise anatomy of D1-MSN projections to VP and VTA/SN. Ultimately, investigating the functional relevance of these different pathways may yield novel treatments for addiction and other psychiatric disorders. We hypothesized that the NAc contains D1-MSN pathways that terminally project to the VP and that a subset of VTA projecting neurons collateralize in the VP. To map the projections from D1-MSN in the accumbens, wild-type C57BL/6 and D1-tdTomato reporter mice received unilateral injections of Fluorogold (FG), via iontophoresis, and retrograde latex microspheres (retrobeads), via pump microinjection, into the VP and VTA respectively. After 7 to 10 days of retrograde transport, mice were perfused, and their brains were sliced and immunohistochemically stained for FG, tdTomato, and/or NeuN. Analyses comprised verification of the tracer placement using histochemical stains, and the counting of accumbens neurons that were retrogradely labeled with only FG, only retrobeads, or both. Preliminary results from cell counts suggest that most D1-MSN that project to the VP collateralize into the VTA/SN. Future experiments will assess the role of D1 projections to the VP and VTA/SN in drug seeking behavior.

Title: Cell type specific regulation of cocaine seeking in the ventral pallidum

Authors: *J. A. HEINSBROEK, A.-C. BOBADILLA, D. N. NEUHOFER, P. W. KALIVAS Med. Univ. of South Carolina, Charleston, SC

Abstract: The ventral pallidum (VP) comprises a critical structure in the neural circuit that drives relapse to cocaine seeking in response to drug cues. It receives inputs from the nucleus accumbens, and various other limbic structures, and drives motivated behavior by means of projections to the ventral tegmental area, subthalamic nucleus, habenula and mediodorsal thalamus. GABAergic inputs from nucleus accumbens dopamine D1- and dopamine D2receptor expressing medium spiny neurons converge onto VP neurons, but carry opposing motivational information. How this information is integrated by the VP to encode the motivation to seek and take cocaine remains unknown, but the VP contains both GABAergic and glutamatergic neurons, and these populations may drive different motivational states during relapse. We investigated the efferent and afferent connectivity of VP GABAergic and glutamatergic neurons and found overlapping but distinct innervation and projection patterns. To dissect the functional role of these neurons, we expressed designer receptors exclusively activated by designer drugs (DREADDs, activated by clozapine-N-oxide) in the ventral pallidum of mice to bidirectionally regulate neuronal activity during drug seeking and drug taking tests. Global inhibition of all VP neurons using the Gi coupled DREADD hM4D reduced cue induced reinstatement. In contrast, global activation the VP using the Gq coupled DREADD hM3D strongly augmented cue-induced cocaine seeking, and triggered reinstatement in extinguished mice. Interestingly, selective chemogenetic manipulation of VP glutamatergic neurons using Vglut-IRES-Cre mice revealed effects opposite to global manipulations: Stimulating glutamatergic neurons prevented reinstatement, and reduced breakpoint responding for cocaine during a progressive ratio test. Furthermore, inhibiting glutamatergic neurons increased breakpoint, induced reinstatement in extinguished mice, and induced a trend towards enhanced cue-induced reinstatement. Preliminary results in VGAT-IRES-Cre mice suggest that stimulating VP GABAergic neurons increased breakpoint responding for cocaine and induced reinstatement in extinguished mice. Collectively, these results indicate differential roles for GABAergic and glutamatergic VP neurons in cocaine seeking and cocaine taking behaviors. Ongoing

experiments are set out to record from GABAergic and glutamatergic VP neurons and dissect the specific contribution of their projections to drug seeking.

Title: Nucleus accumbens core group I mGluR signaling after the incubation of methamphetamine craving

Authors: *C. MURRAY, M. MILOVANOVIC, J. A. LOWETH, M. E. WOLF Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: In a rodent model of addiction, cue-induced drug craving intensifies or "incubates" during withdrawal from extended-access drug self-administration. After the incubation of cocaine craving, we have shown that synapses in the nucleus accumbens (NAc) core are strengthened by the accumulation of calcium-permeable AMPA receptors (CP-AMPARs) while group I mGluR-mediated synaptic depression shifts from an mGluR5-dependent mechanism that is expressed presynaptically to an mGluR1-dependent mechanism that is expressed postsynaptically by the removal of CP-AMPARs. After prolonged withdrawal from cocaine selfadministration (withdrawal day 48), we detected a decrease in mGluR5 surface expression and a decrease in its association with Homer scaffolding proteins. These alterations may be related to the loss of mGluR5-medated synaptic depression. In the NAc core of methamphetamine incubated rats, CP-AMPARs similarly accumulate and are removed by mGluR1; however, the status of mGluR5 has not been addressed. To this end, rats self-administered saline or methamphetamine (6 h/d for 10 d) and were killed for biochemical studies after 3, 21, or 48 days of withdrawal. Our biochemical findings reveal no change in surface mGluR5 levels (determined with biotinylation) or in the physical association between mGluR5 and Homer proteins (determined using co-immunoprecipitation) at any of the three withdrawal times, diverging from prior cocaine results that demonstrated decreases in both of these measures. Electrophysiological recordings of NAc medium spiny neurons from methamphetamine-incubated animals will test

mGluR5 function to extend these findings. Support: DA009621, DA038110

Title: Dopamine neuromodulation and the regulation of protein translation in cultured nucleus accumbens neurons

Authors: *M. T. STEFANIK¹, C. MURRAY², M. E. WOLF¹

¹Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; ²Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Protein synthesis is critical for the generation and maintenance of long-lasting synaptic modifications that lead to changes in behavior. Recent work from our lab suggests that, during withdrawal from extended-access cocaine self-administration, adaptations in medium spiny neurons (MSNs) of the nucleus accumbens (NAc) leading to enhanced drug seeking are maintained by dysregulated local translation. In other brain regions, dopaminergic signaling plays a key role in protein synthesis- dependent synaptic plasticity. However, while the NAc receives dopamine (DA) input that is influenced by drugs and DA neurotransmission is involved in both the acute and long-term effects of drugs of abuse, the relationship between DA receptor signaling and protein synthesis in MSNs is not understood. To explore this, we used a co-culture system in which PFC neurons obtained from P1 offspring of homozygous enhanced cyan fluorescent protein (ECFP)-expressing mice were co-cultured with NAc MSNs obtained from P1 Sprague-Dawley rats. PFC neurons restore excitatory inputs to MSNs but can be distinguished by fluorescence. Direct detection of de novo protein synthesis in MSNs was achieved with fluorescent non-canonical amino acid tagging (FUNCAT). Fluorescence immunocytochemistry was used to quantify expression of specific proteins of interest in these cells. Incubation of cultures with the D1R agonist SKF81297 or the D2R agonist quinpirole failed to influence protein translation in MSNs. We re-examined DA receptor effects after increasing excitatory synaptic activity in the cultures using the GABA-A receptor antagonist bicuculline (2 hr). The

D1R antagonist SCH23390, but not the D2R antagonist eticlopride, reduced bicuculline-induced protein synthesis, despite a lack of TH+ neurons in the co-cultures. One potential explanation is that bicuculline-stimulated translation is mediated by glutamate acting at D1R/NMDAR heteromers, which have been reported in other brain regions. Immunofluorescent labeling for D1Rs and the obligatory NMDAR subunit GluN1 suggested the existence of a small population of D1R/NMDAR heteromers on the co-cultured MSNs. We examined signaling of these heteromers by stimulating translation with bicuculline and co-incubating with the NMDAR antagonist APV or APV + SCH23390. Bicuculline- stimulated translation was reversed by either treatment, suggesting that blockade of either receptor in the heteromer may disrupt translation. These results further the understanding of mechanisms controlling local protein synthesis in the NAc and provide evidence for functional cross-talk between D1 and NMDARs in cultured NAc neurons.

Title: Biochemical and electrophysiological studies of NMDA receptors in the rat nucleus accumbens during incubation of methamphetamine craving

Authors: *A. M. WUNSCH, D. T. CHRISTIAN, M. MILOVANOVIC, M. E. WOLF Neurosci., Rosalind Franklin Univ., North Chicago, IL

Abstract: One of the largest problems associated with methamphetamine (METH) addiction is the high rate of relapse, even following long periods of abstinence. While recent studies on incubation of METH craving (a model of cue-induced METH relapse) have focused primarily on behavioral pharmacology or neural circuitry, much less is known about the synaptic mechanisms associated with the incubation of METH craving. Our lab has demonstrated that, during withdrawal from METH, calcium-permeable AMPA receptors accumulate in medium spiny neurons of the nucleus accumbens core within 7 days of withdrawal from METH. However, much less is known about NMDA receptor contributions to incubation of METH craving. Our lab recently found that incubation of cocaine craving is accompanied by time-dependent changes in the subunit composition of NMDA receptors in NAc, involving GluN2B and GluN3 subunits. The main goal of this project is to determine whether NMDA receptor subunit composition and function is altered during incubation of methamphetamine craving. We used biochemical techniques to determine whether levels of GluN1, GluN2A, GluN2B, GluN3A, or GluN3B were altered during METH withdrawal. Rats underwent extended access METH self-administration (6 h/day for 10 days), and tissue from nucleus accumbens core was harvested for surface biotinylation on withdrawal day 21, a time at which incubation of METH craving is maximal. We found no significant changes in either the total or surface expression of any NMDA receptor subunit at this time point. Since functional NMDA receptors are located primarily at the synapse, future studies will assess whether incubation of METH craving is accompanied by changes in expression of NMDA receptor subunits in a synaptic fraction. Lastly, we will use electrophysiological methods to determine whether NMDA receptor function is altered during incubation of METH craving. This work will better define the synaptic mechanisms that contribute to cue-induced relapse following METH self-administration, which may help to identify therapeutic targets for preventing METH relapse.

Title: Effects of cocaine and chronic stress exposure on BLA neuronal activity

Authors: *J. A. LOWETH¹, S. MUNSHI², A. CACCAMISE¹, J. A. ROSENKRANZ², M. E. WOLF¹

¹Neurosci., ²Cell. & Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: A major challenge for treating cocaine addiction is the propensity for abstinent users to relapse. Two important triggers for relapse are cues associated with prior drug use and stressful life events. To study their interaction in promoting relapse during abstinence, we used the incubation model of craving and relapse in which cue-induced drug seeking progressively intensifies ("incubates") during withdrawal from extended-access cocaine self-administration. We have recently shown that exposure to repeated but not acute restraint stress during the first two weeks of withdrawal accelerates the initial rate of incubation of cue-induced cocaine craving, although craving plateaus at the same level observed in controls. These data indicate

that chronic stress exposure during early withdrawal may result in increased vulnerability to cueinduced relapse during this period. Previous studies have shown that chronic stress exposure enhances excitatory drive to the basolateral amygdala (BLA), a region critical for behavioral responses to stress. Given that glutamate projections from the BLA to the NAc are critical for incubation of cocaine craving, we hypothesized that cocaine withdrawal and chronic stress exposure produce a synergistic increase in BLA neuronal activity which accelerates incubated craving. To assess this, we have conducted in vivo extracellular recordings from anesthetized rats to compare neuronal activity in the BLA of rats that self-administer saline or cocaine (6h/day for 10 days) and then either undergo repeated restraint stress or control conditions during the first two weeks of withdrawal. Recording were conducted between weeks 2 and 3 of withdrawal from extended-access cocaine or saline self-administration (0-5 days after the last restraint stress or control session). Our data indicate that cocaine exposure alone enhances neuronal activity within the BLA and that repeated stress exposure during withdrawal from cocaine self-administration may further enhance BLA neuronal excitability, which could contribute to the acceleration of incubation of cocaine craving observed in these animals. These studies may identify potential mechanisms by which chronic stress enhances cue-induced relapse vulnerability in abstinent cocaine addicts.

Title: Extended access cocaine self-administration leads to increased GluN3-containing NMDA receptor function in the rat nucleus accumbens

Authors: *D. T. CHRISTIAN, K. Y. TSENG, M. E. WOLF Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Cue-induced cocaine craving intensifies or incubates during withdrawal from extended-access cocaine self-administration. After ~1 month of withdrawal, levels of GluA2-lacking, Ca2+-permeable AMPARs (CP-AMPARs) increase in the nucleus accumbens (NAc)

and thereafter their activity is required for expression of incubated craving. NMDARs play a major role in Ca2+ signaling, but little is known about whether they are altered during incubation of cocaine craving. However, incorporation of GluN3- and GluN2B-containing NMDARs accompanies increases in CP-AMPAR levels in the ventral tegmental area elicited by a single cocaine injection (Yuan et al., 2013). To determine if NMDAR transmission in the NAc is altered following extended-access cocaine self-administration, we utilized whole-cell patch clamp electrophysiology in NAc medium spiny neurons (MSN) from rats that self-administered saline or cocaine. We measured evoked NMDAR-mediated synaptic responses across various membrane holding potentials (-80 to +40; 40mV steps) and then characterized these responses using antagonists selective for GluN2B- or GluN3-containing receptors. As expected from prior studies, MSN from saline rats exhibited NMDAR currents sensitive to GluN2B- but not GluN3selective antagonists. During the first week of withdrawal, we observed an increase in NMDAR currents at positive potentials in cocaine rats compared to saline controls that was attributable to NMDARs containing GluN2B but not GluN3. Between 2-3 weeks of withdrawal (still prior to detection of elevated CP-AMPAR levels), we observed increased NMDAR currents at both negative (-80 to -40mV) and positive (+40mV) holding potentials. The same results were obtained during a later period of withdrawal (>39 days) when cocaine craving is maximal. Pharmacological studies conducted in late withdrawal indicated that increased NMDAR currents reflected incorporation of NMDARs that contain both GluN2B and GluN3, as well as NMDARs containing GluN2B but not GluN3. Studies are in progress to determine if these sequential changes in NMDAR subunit composition are required for the elevation of CP-AMPAR levels and the incubation of cocaine craving.

Title: Interoception and relapse to cocaine addiction: Lo,g-term disruptions of the amygdalainsula pathway

Authors: *P. BELUJON, A. C. M. SALIN, M. SOLINAS Lab. de Neurosciences Expérimentales et Cliniques, Univ. Poitiers, Poitiers, France

Abstract: The insular cortex integrates and transforms interoceptive stimuli into a general emotional awareness. In drug addiction, peripheral effects combined with the hedonic experience

associated with the drug are integrated by the IC. This bodily experience is a key component in the memorization of drug effects within a specific context. Thus, during abstinence, drug cues could reactivate the memory of the body response and emotion associated with drug use by activation of the IC, initiating the physical sensation of craving reinforcing drug seeking behavior. Functional imaging studies in abstinent users have shown an increased synchronization of the IC and the amygdala, involved in the process of emotional responses. This suggests disruption of functionality in this circuitry that could increase vulnerability to cues associated to drug use. Our hypothesis is that chronic drug exposure induces long-lasting disruption within the amygdala-IC pathway. In particular, exposure to drug cues would activate the amygdala, and through its projection to the IC, would reactivate the representations of the interoceptive effects of the drug leading to intense craving, increasing the risk of relapse. The aim of the present study was to examine the cocaine-induced persistent changes in i) spontaneous activity of the basolateral amygdala (BLA) and the IC and ii) the synaptic plasticity in the BLAOIC pathway. Using in vivo extracellular recordings in anesthetized rats one month after ten 6h-session of cocaine self-administration, we found an increase in the bursting activity and firing rate of BLA putative projection neurons. Although no significant changes were observed in the spontaneous activity of IC neurons, we found that synaptic plasticity in the BLA-evoked activity of IC neurons was disrupted in cocaine abstinent rats. In particular, we found that chronic cocaine leads to an increased long-term potentiation in the IC after high frequency stimulation of the BLA, with a loss of depotentiation after low-frequency stimulation. Therefore, in cocaine rats, the LTP is abnormally persistent and fails to be down-modulated. These data suggest that chronic cocaine use induced disruption of the BLA-IC information flow, which could lead to an increase in drug-seeking behavior.

Title: Cocaine increases permeability of the blood-brain-barrier in the hippocampus: Implications for drug use and abuse

Authors: *M. M. CLASEN, D. N. KEARNS, T. L. DAVIDSON, A. L. RILEY American Univ., Washington, DC

Abstract: Rationale:

Davidson and his colleagues (2014) have recently demonstrated that consumption of a Western diet (WD) high in saturated fats, carbohydrates and sugars increases blood-brain-barrier (BBB)

permeability that results in the infusion of cytokines and microglia that selectively damages the hippocampus (see also Kanoski et al., 2010). Such damage also reduces hippocampal-dependent inhibitory control, as measured by the Pavlovian serial feature negative (sFN) task, thought to further drive WD intake, spurring a vicious cycle eventually resulting in obesity. The present studies applied this same rationale to assess if cocaine use influences BBB integrity and inhibitory functioning in a manner similar to that induced by the consumption of a WD. Methods:

Experiment 1: Sprague-Dawley rats (n = 24) were injected intraperitoneally with cocaine (20 mg/kg) or saline for 18 consecutive days at which point they were anesthetized and injected with the molecular dye sodium fluorescein (NaFl). Brains were immediately removed, and the expression of NaFl was evaluated in the hippocampus, striatum, and cortex to assess changes in BBB permeability.

Experiment 2: Sprague-Dawley rats (n = 24) were trained on a serial feature negative (sFN) discrimination task in which a tone signaled a food pellet and a light followed by a tone signaled the absence of food (all stimuli were 5 sec in duration). Concurrent with this training (and in the same session), subjects were given a simple discrimination in which a clicker or white noise (counterbalanced) was followed by food (CS+) or no food (CS-). Following acquisition of discriminative control, subjects were maintained on the training conditions for 18 days. Following each daily session, they were given an intraperitoneal injection of cocaine (20 mg/kg) or equivolume saline and changes in sFN performance were evaluated. Results:

Cocaine increased BBB permeability as evidenced by increased levels of NaFl in the hippocampus (Experiment 1) and decreased discriminative performance in the sFN task indicative of a loss of inhibitory control of responding (Experiment 2). Conclusions:

Cocaine exposure resulted in a loss of integrity of the BBB (increased permeability) and a decrease in inhibitory control in the sFN discrimination. Such effects may provide a mechanism for escalated drug intake in drug-abusing populations. Specifically, the drug-induced loss of BBB integrity may result in selective damage to the hippocampus that, in turn, results in a loss of inhibitory control of drug intake that causes more damage, less control and further escalation, i.e., a vicious cycle similar to that posed for excessive eating and the resulting obesity.

Title: Cell type- and receptor type-specific mechanisms of cocaine-induced synaptic AMPAR depotentiation in the nucleus accumbens

Authors: *A. E. INGEBRETSON, M. J. THOMAS

Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN

Abstract: The nucleus accumbens (NAc) is a key mesocorticolimbic structure in which drugs of abuse exert rewarding and reinforcing effects. Composed principally of medium spiny neurons (MSNs), the NAc receives converging glutamatergic inputs from cortical and limbic afferents that drive MSN activity and synaptic plasticity. In rodent models of addiction, changes in glutamatergic synaptic strength at NAc MSNs play a central role in drug-seeking behavior. Previous studies from our lab have shown that repeated exposure to cocaine potentiates AMPA receptor (AMPAR)-mediated signaling in the mouse NAc shell during a period of abstinence (10-14 days) from drug exposure. This increase in synaptic strength is reversed ("depotentiated") by a single re-exposure to cocaine or bout of stress, suggesting that this switch in NAc synaptic excitability might act as a trigger for relapse, promoting renewal of drug-seeking. However, the cellular mechanisms underlying this plasticity have not been well characterized. The present study used an ex vivo cocaine challenge model of synaptic AMPAR depotentiation to examine the neuromodulatory roles of dopamine and endocannabinoids (eCBs) in promoting cocaineinduced plasticity. Application of dopamine receptor agonists promoted synaptic depotentiation, while dopamine antagonists prevented the induction of depotentiation, suggesting a critical role for dopamine in gating cocaine-induced AMPAR plasticity at glutamatergic inputs to the NAc. Additionally, cannabinoid type 1 receptors (CB1s), receptors located pre-synaptically that bind to eCBs released from MSNs and decrease the probability of glutamate release, mediated cocaine-induced synaptic depotentiation, demonstrating that both eCBs and dopamine participate in modulating excitatory synaptic strength in the NAc. Current studies are further investigating the contribution of specific dopamine receptor subtypes located on distinct cell subyptes in the NAc. MSNs of the NAc are segregated into two cell subpopulations based on expression of the dopamine receptor type 1 (D1-MSN) or dopamine receptor type 2 (D2-MSN). These subpopulations have divergent projection targets and exert opposite effects on reward-related behavior. We are currently examining cocaine-induced AMPAR depotentiation in specific cell populations of the NAc to investigate the relationship between specific dopamine receptor and CB1 signaling in promoting plasticity. Our findings demonstrate that re-exposure to cocaine coopts multiple signaling pathways in the NAc shell to induce alterations in synaptic strength, identifying mechanisms that may be targeted for potential pharmacotherapies.

Title: Lateral habenular norepinephrine contributes to anxiogenic behaviors in male rats

Authors: *E. M. PURVIS, A. KLEIN, L. COLLINS, A. GUILLEN, B. JAMES, K. LEE, M. MAYES, L. ZHOU, A. ETTENBERG Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Recent research has identified the lateral habenula (LHb) as a brain region playing an important role in the production of stressful and anxiogenic states. Of particular interest for the current project have been the norepinephrine (NE) projections to the LHb emanating from the locus coeruleus (LC). NE has long been known to be involved in arousal, stress and anxiety. The current research was therefore devised to assess the effects of reducing NE release within the LHb on rodent anxiogenic behavior. Male rats were implanted with bilateral guide cannula aimed at the LHb and subsequently treated with intracranial infusions of the selective α_2 adrenergic auto-receptor agonist dexmedetomidine (DEX) prior to behavioral testing. Doses of DEX (0, 0.5, 1.0 µg/side) were delivered in volumes of 0.25 µL over 120-s infusion durations and ambulatory and anxiogenic responses were assessed using tests of spontaneous locomotion, open field behavior, and acoustic startle response. Results demonstrated that DEX administration significantly reduced the overall locomotor behavior of subjects at both doses, indicating that infusion of even small doses of this α_2 agonist into the LHb can have profound effects on the subjects' general levels of alertness and activity. DEX was also found to attenuate anxiety as evidenced by reduced latencies to enter and more time spent in the center regions of the open field as well as a reduction in the magnitude of an acoustic startle response (ASR) to a 110 dB stimulus. Taken together, the results of the locomotor, open field, and startle-response tests support the assertion that reductions in NE release within the LHb produce statistically reliable reductions in both arousal and anxiety. This work was funded by NIDA grant DA-033370 awarded to AE.

Title: Activation of serotonin _{1B} receptors in the lateral habenula attenuates the negative/anxiogenic effects of cocaine

Authors: *A. KLEIN, E. M. PURVIS, K. AYALA, L. COLLINS, A. GUILLEN, B. JAMES, J. KRUG, K. LEE, M. MAYES, L. ZHOU, A. ETTENBERG Psychological and Brain Sci., UC Santa Barbara, Santa Barbara, CA

Abstract: In addition to its initial rewarding effects, cocaine produces a significant "crash" characterized by a state of dysphoria and anxiety. Any full account of a subject's motivation to seek cocaine must therefore consider the relative balance between these positive and negative effects of the drug. While the neurobiology of the reinforcing aspects of cocaine has been well established, less is known about the systems responsible for its negative effects. Cocaine alters many neurotransmitter systems, including serotonin (5-HT), which has been linked to states of anxiety and depression in both human and animal subjects. The Lateral Habenula (LHb) has been recently implicated in mediating aversive/anxiogenic states and expresses a variety of 5-HT receptors. Thus, the present study was therefore devised to test the hypothesis that serotonergic signaling in the LHb contributes to the anxiogenic effects of cocaine. Male albino rats were trained to traverse a straight alley and enter a goal box for an infusion of IV cocaine (1.0mg/kg) on each of 16 single daily trials. The dual positive and negative effects of cocaine were reflected in the animals' development of a unique approach/avoidance conflict about entering the drugpaired environment as it learns the dual effects of the drug. Pretreatment with bilateral intra-LHb infusions of the selective 5-HT_{1B} auto-receptor agonist CP94,253 (0.0µg, 0.1, or 0.25µg/side in 0.5/µl) reduced the frequency of these approach-avoidance "retreat" behaviors while leaving the positive incentive properties of the drug intact (i.e., start latencies were unchanged). This effect of the autoreceptor agonist was then reversed by co-administration with the selective 5-HT_{1B} antagonist, NAS-181. Together these data suggest a role for 5-HT signaling within the LHb in mediating the aversive effects of cocaine.

Title: BDNF controls the ER stress response protein expression after repeated cocaine administration in the rat dorsal striatum

Authors: J. KIM, J. YANG, I. RYU, M. GHANG, S. SON, E. HAN, *E. CHOE Pusan Natl. Univ., Pusan, Korea, Republic of

Abstract: Brain-derived neurotrophic factor (BDNF) is a key molecule involved in the regulation of glutamatergic neurotransmission in response to chronic stimulation of psychostimulants. This study demonstrated that BDNF in the dorsal striatum regulates the endoplasmic reticulum (ER) stress response after repeated exposure to cocaine. The results showed that unilateral intracaudate infusion of BDNF (0.40, 0.75, or 1.50 μ g/ μ L) decreased the repeated cocaine-induced increase in the expression of immunoglobulin heavy chain binding protein (BiP) sensing unfolded or misfolded proteins in a dose-dependent manner. Unilateral intracaudate infusion of BDNF (0.75 μ g/ μ L) also decreased the phosphorylation of c-Jun N-terminal kinase (JNK), which had been initially elevated by seven consecutive daily intraperitoneal injections of cocaine (20 mg/kg/day). These decreases were reversed by unilateral intracaudate infusion of the specific tropomyosin receptor kinase B (TrkB) antagonist, cyclotraxin B (1 ng/ μ L). These findings suggest that BDNF regulates the unfolded protein response via TrkB-linked JNK inactivation in the dorsal striatum after repeated cocaine administration, thus contributing to the restoration of the ER functions.

Title: Effects of cocaine on spontaneous dopamine release varies across striatal regions

Authors: *J. T. YORGASON, C. FINUF, S. STEFFENSEN Brigham Young Univ., Provo, UT

Abstract: The mesostriatal dopamine system originates in the substantia nigra and ventral tegmental area, and projects throughout the striatum including the caudate, putamen, nucleus accumbens core and shell regions. Dopamine release in these regions underlies drug reinforcement learning, and adaptations to psychostimulants in these regions is thought to be responsible for habitual drug seeking behavior. We have recently shown that local striatal cholinergic interneurons can drive dopamine release independent of dopamine cell firing. This occurs through excitatory cholinergic activity onto nicotinic receptors on dopamine terminals. In the nucleus accumbens core, cocaine increases dopamine transient frequency without increasing cholinergic firing. Previous reports have suggested that cholinergic interneurons by region in their sensitivity to dopaminergic drugs. However, it is unknown if this regional heterogeneity contributes to the effects of cocaine on dopamine transmission. Therefore, we examined cocaine's effects on cholinergic-dependent dopamine transients throughout the striatum. In general, cocaine increased dopamine transient frequency and amplitude. However, cocaineinduced increases in dopamine transients differed by region, with greatest increases observed in the accumbens shell. Future studies will compare dopamine transient responses to cocaine in cocaine-naïve and experienced mice across these brain regions to determine what neural adaptions are occurring in prolonged use states.

Title: Altered resting state functional connectivity of the lateral and medial hypothalamus in cocaine dependence

Authors: *S. ZHANG¹, C.-S. R. LI²

¹Yale Univ. Sch. of Med., New Haven, CT; ²Dept Psychiatry, Yale Univ., New Haven, CT

Abstract: Background: The role of dopamine in cocaine misuse has been extensively documented and this literature involves a wide swath of brain regions including the hypothalamus of the mesocorticolimbic circuit. Preclinical work from earlier lesion studies to recent multidisciplinary investigations has suggested that the hypothalamus could be broadly divided into lateral hypothalamus (LH) and medial hypothalamus (MH) each differentially involved in waking/feeding and resting/satiety. However, little is known of the altered resting state functional connectivity (rsFC) of the LH and MH in individuals with cocaine dependence (CD).

Methods: Resting state fMRI data (3T, 10 minutes, eye closed) of 70 CD and 70 age/gender matched healthy controls (HC) were analyzed. We performed linear regressions for individual subjects between the averaged time course of each of the LH and MH seeds and the time courses of each individual voxel of the whole brain. The correlation coefficients were converted to z scores by Fisher's z transform, and a two-sample t-test was applied to the "z maps" to identify altered rsFC of the LH and MH in CD as compared to HC.

Results: Compared to HC, CD showed increased LH functional connectivity with dorsolateral prefrontal cortex (dlPFC) and decreased functional connectivity with the precuneus. Further, CD showed increased MH connectivity with the inferior parietal lobule (IPL) and decreased connectivity with the vmPFC, temporal gyrus, fusiform gyrus, and ventral striatum. These connectivity differences were correlated to clinical measures. For instance, the connectivity strength between LH and dlPFC was positively correlated with total amount of cocaine use in the past month (p = 0.004, r = 0.35) and number of days of cocaine use in the past month (p = 0.03, r = 0.27). The connectivity strength between MH and vmPFC was negatively correlated with number of years of cocaine use (p = 0.03, r = -0.27). The connectivity strength between MH and VS was negatively correlated with cocaine craving as assessed by the Tiffany Cocaine Craving Questionnaire (CCQ) (p = 0.008, r = -0.33).

Conclusions: The findings demonstrated altered functional connectivity patterns in CD for LH and MH and may provide new insight of our understanding of circuit level deficits in cocaine dependence.

Title: Thalamocortical connectivity and intrinsic thalamic connectivity associated with recency of cocaine use

Authors: *A. S. HUANG, R. Z. GOLDSTEIN Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Drug addiction is a complex disorder that is characterized by excessive drug use despite adverse consequences. Current models highlight the importance of the midbrain reward system, and the prefrontal cortex cognitive control network in underlying core symptoms of addiction. Although the thalamus has an important role linking these two networks, its involvement in drug addiction is not well understood. Recent investigations of thalamic function indicate that it has an important role in integrating information across networks (Hwang et al., 2017), suggesting that it has a broader role in cognition. In this study, we collected resting state functional magnetic resonance images from 19 recent cocaine users, 26 abstinent cocaine users and 31 healthy controls. We analyzed functional integration and functional connectivity of the thalamus with three different resting state analysis techniques. Thalamocortical connectivity was analyzed using seed-based correlations from different thalamic regions based on Behrens et al., 2003 parcellation of the thalamus. Intrinsic thalamic connectivity was examined with regional homogeneity analysis (ReHo) and the fractional amplitude of low frequency fluctuations (fALFF). Compared to healthy controls, in the cocaine addicted individuals we expect the mediodorsal region of the thalamus to show increased connectivity with orbitofrontal and medial frontal regions and decreased connectivity with dorsolateral prefrontal regions. We also expect mediodorsal regions of the thalamus to show increased connectivity with striatal regions. Based on literature with other drugs of abuse (Denier et al., 2015), we expect the thalamus to show increased ReHo and fALFF values in recent cocaine users compared to abstinent cocaine users, and for cocaine users to show greater ReHo and fALFF values compared to healthy controls. Our findings will show the effects of recent cocaine use on the thalamocortical system and may highlight new roles for the thalamus in cocaine addiction.

Title: Neuronal sub-type specific translational changes following long-access cocaine selfadministration in mice

Authors: *E. C. ANDRADE, J. ALVAREZ, E. F. SCHMIDT, N. HEINTZ Lab. of Mol. Biol., The Rockefeller Univ., New York, NY

Abstract: Studies aimed at understanding the molecular basis of drug addiction have focused largely on the mesolimbic dopamine system and related structures. From these studies, long-lasting alterations in transcription are a clear consequence of repeated exposure to drugs of abuse. What remain elusive are the specific contributions of neuronal subtypes within these regions to addiction. To better understand the contributions of different cell-types, bacterial artificial chromosome (BAC) transgenic mice which drive the expression of EGFP-tagged ribosomal protein L10a in defined cell populations (known as bacTRAP transgenic lines) were trained to self-administer cocaine. Cell-types of interest include those found in the mesolimbic dopamine system, specifically D1 and D2 medium spiny neurons in dorsal striatum and nucleus accumbens. Following 2.5 weeks of extended cocaine self-administration, polysomal mRNAs were isolated by affinity purification and analyzed by RNA-seq to identify translational profiles of each cell type. Results from these studies provide insight into the neurocircuitry most affected by cocaine use as well as genes and pathways most affected.

Title: Dynamic remodeling of MSN connectivity upon cocaine self-administration

Authors: *M. SALERY, E. S. CALIPARI, A. GODINO, E. G. PECK, E. J. NESTLER Fishberg Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Drug addiction is a chronic neuropsychiatric disorder characterized by pathological motivation to seek and take drugs, persistent drug consumption despite adverse consequences and ultimately high risk of relapse even long after cessation of drug taking. These drug-induced

behavioral alterations are thought to rely on maladaptive changes in brain circuits involved in reward-associative learning. Extensive work has described drug-induced changes at the molecular, cellular and circuit levels and has implicated stable synaptic adaptations along with neuronal network reorganization in the long-lasting effects of drugs of abuse. However, longterm neuronal substrates specific to drug-seeking and their causal role in driving relapse behaviors remain poorly understood. In order to identify neuronal processes involved in such pathological behaviors, we are analyzing the effect of reexposure to cocaine-associated cues on the synaptic architecture in reward circuits with a focus on the nucleus accumbens (NAc). The NAc is predominantly composed of GABAergic medium spiny neurons (MSNs) which play a key role in integrating molecular signals underlying reward learning and addiction. To first assess how exposure to drug-paired cues affects MSN connectivity, we are measuring the morphology and density of dendritic spines within this neuronal population during reinstatement of drug seeking. Further characterization of MSN connectivity involves the identification and functional manipulation of input-specific synaptic morphological changes as well as the cellular processes engaged within MSN spines long after drug use. Together this work will deepen our understanding of the neuronal underpinnings specific to reinstatement, setting the ground for putative therapeutical strategies targeting relapse to drug taking.

Title: Novel approaches to study the role of endogenous Δ FosB in the action of cocaine and morphine within the nucleus accumbens

Authors: *C. K. LARDNER¹, P. J. HAMILTON¹, H. M. CATES², D. M. WALKER¹, E. A. RIBEIRO¹, J. FENG³, E. J. NESTLER¹

¹Fishberg Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY; ²Dept. of Pharmacol., Weill Cornell Med. Sch., New York, NY; ³Dept. of Biol. Sci., Florida State Univ., Tallahassee, FL

Abstract: The onset and persistence of addiction is, in part, mediated by mechanisms of transcription. However, between classes of abusive drugs, little is known about the overlap of common transcriptional mechanisms and how these converge and diverge to effect an addictive

phenotype. One well-characterized transcriptional regulator shared between different classes of abusive substances is Δ FosB, a Fos family transcription factor. Δ FosB is a splice variant of FosB, arising from a truncation which lends it unusual stability due to the loss of N-terminal degron domains. Consequently, Δ FosB accumulates intracellularly following repeated induction of the *Fosb* gene, which has been shown to occur after chronic exposure to many substances, including cocaine and morphine. A stimulant and an opiate, respectively, the pathogenesis of cocaine and morphine abuse both involve the induction of Δ FosB. However, it is unknown to what degree Δ FosB coordinates their unique effects within the nucleus accumbens. We are utilizing two tools to address this gap in knowledge. First, the scope and extent of Δ FosB's transcriptional activity genome-wide has thus far been elusive due to the lack of antibodies suitable for chromatin-immunoprecipitation (ChIP)-seq. To address this, we generated a knockin mouse in which Δ FosB is expressed with a hemagglutinin (HA) tag fused at its N-terminus, which allowed for anti-HA targeting of Δ FosB using ChIP-seq following chronic cocaine or morphine administration. Next, to elucidate how D1- and D2-type medium spiny neurons coordinate the action of cocaine and morphine, we developed novel CRISPR/Cas9 tools to deliver nuclease-dead Cas9 fused to epigenetic modifying moieties to the Fosb locus. We observed how D1-/D2-type MSN-specific manipulation of Δ FosB influences cocaine- and morphine-mediated behavioral and morphological outcomes. Understanding the transcriptional scope and cell type-specific roles of Δ FosB in the effects of cocaine and morphine will not only clarify their mechanisms of action and reveal new avenues for therapeutic development, but also aid in understanding how diverse pharmacological substances converge at the level of transcription to commonly as well as divergently influence the function of the brain's reward system.

Title: Mechanisms of epigenetic priming in the nucleus accumbens underpin cocaine addiction

Authors: *P. MEWS¹, H. KRONMAN², E. S. CALIPARI³, E. J. NESTLER⁴ ¹Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; ²Dept of Neurosci. and Friedman Brain Institute,, Icahn Sch. of Med. At Mount Sinai, Brooklyn, NY; ³Mount Sinai Sch. of Med., New York, NY; ⁴Icahn Sch. Med. At Mount Sinai, New York, NY Abstract: Drug addiction is a debilitating neuropsychiatric disorder with severe health, financial and societal consequences. Recent increases in drug abuse and the lack of efficacy of conventional pharmacotherapy drive the need for advanced mechanistic insight. Drugs of abuse, in addition to their acute effects, cause persistent aberrations in gene expression in the nucleus accumbens (NAc), the key brain region of reward learning. We found that chronic cocaine exposure permanently alters the inducibility of key neuronal genes to future stimuli in the NAc, referred to as gene priming and desensitization. It is hypothesized that drug-induced changes in the epigenetic landscape underlie such latent transcriptional dysregulation in states of addiction. However, epigenetic priming of transcription is virtually unexplored in the context of psychiatric disease and molecular mechanisms remain opaque. Further, the brain is comprised of a number of heterogenous cell-types, making the cell-type specific identification of these changes critical. In the NAc two functionally exclusive types of medium spiny neurons (MSNs), the D1 and D2 dopamine receptor expressing subtypes, comprise 90% of the total neuronal population. Thus, we defined the differential D1 and D2 MSN transcriptional priming caused by chronic cocaine. These novel subtype-specific analyses lay the foundation for mechanistic studies of epigenetic regulation in drug addiction. Next, we investigated the cocaine-induced aberrations in chromatin structure that drive epigenetic priming in the NAc. Using ATAC-seq, we assessed chromatin accessibility in D1 and D2 MSNs genome-wide and differentiate immediate from persistent changes caused by chronic cocaine. An understanding of the epigenetic processes involved will ultimately allow us to identify novel pharmaceutical targets for epigenetic therapies of psychiatric diseases.

Title: History of cocaine self-administration alters transcriptome-wide responses to cocaine reexposure throughout the brain's reward circuitry

Authors: *D. M. WALKER¹, E. S. CALIPARI², H. M. CATES⁴, E. LOH³, I. PURUSHOTHAMAN³, A. GODINO³, P. MEWS¹, E. J. NESTLER⁵ ¹Neurosci., Icahn Sch. of Med. Abstract: Cocaine addiction is a chronic, relapsing disorder involving maladaptive plasticity in brain reward circuits associated with changes in gene expression. The behavioral responses to self-administration withdrawal and re-exposure have been well-defined in rodent models. However, the gene expression changes underlying the observed circuit wide and behavioral dysregulation remains elusive. We hypothesized that chronic cocaine "re-programs" the transcriptome, resulting in sensitization and desensitization of molecular targets upon reexposure to cocaine. To test this hypothesis, we assigned male mice to one of six groups: saline or cocaine self-administration (SA) + 24hr withdrawal (WD) (S24/C24); saline/cocaine SA + 30d WD + acute saline/cocaine + 1hr (SS/SC/CS/CC). Then we conducted RNA-sequencing on 6 interconnected reward associated brain regions (PFC, NAc, DS, BLA, vHIP, VTA) to determine how a history of cocaine SA influences transcriptome-wide responses at baseline and after cocaine re-exposure. We focused on patterns of gene expression that were altered in response to specific stimuli when compared to the same baseline (S24). Genes that were uniquely altered by acute cocaine after cocaine SA+WD (CC) displayed region-specific regulation, with the greatest numbers seen in NAc, DS, and BLA. Further analysis revealed that the transcription factor, Hnf4a, is a predicted upstream regulator in all three regions and associated with genes that control RNA posttranscriptional processes and neurological diseases. In contrast, genes uniquely altered by cocaine SA + acute saline (CS), possibly a reflection of genes exhibiting "craving," were most affected in vHIP and PFC and associated with neuronal branching. Regulation of subsets of these primed, desensitized, and incubating genes correlates with the SA behavior displayed by individual mice. These data provide further insight into the relationship between these correlated brain regions. Further, this is the most comprehensive picture to date of transcriptome-wide regulation by cocaine SA and WD throughout the brain's reward circuitry, and it will guide future studies of the molecular basis of cocaine addiction.

Title: Conditional deletion of the GABAA α 4 subunit in D1 but not D2 expressing Medium Spiny Neurons affects cocaine-induced locomotor activity and associated neural ensembles

Authors: *J. ROBERTSON, T. MACPHERSON, D. N. STEPHENS, S. L. KING Univ. of Sussex, Brighton, United Kingdom

Abstract: GABA_A receptor α 4 subunits partner with δ subunits to form extrasynaptic receptors (α 4-GABA_ARs) which mediate tonic inhibition of neurons. The α 4 subunit is expressed on Medium Spiny Neurons (MSNs) of the striatum, particularly the Nucleus Accumbens (NAc). Deletion of α 4-GABA_ARs makes MSNs more excitable and we have previously demonstrated that α 4-GABA_ARs are involved in conditioned behaviours such as cocaine-conditioned place preference and conditioned reinforcement.

We have extended these studies to behavioural sensitisation. As well as testing α 4-GABA_AR constitutive knockout (α 4-KO) mice, we assessed the role of α 4-GABA_ARs on Dopamine D1R and D2R-containing neurons specifically in mediating cocaine induced locomotor activity and behavioural sensitisation. We generated two conditional knock-out lines by breeding 'floxed' α 4 mice with mice expressing Cre-recombinase under either the Drd1 or Drd2 promoter to conditionally delete *gabra4* in D1 or D2 receptor containing neurons (D1- α 4-KO and D2- α 4-KO mice respectively).

D1- α 4-KO mice and D2- α 4-KO mice were compared to their 'floxed' α 4 littermates (D1- α 4-WT and D2- α 4-WT, respectively (n=16 per group). Genotypes were divided into two groups with half receiving daily IP injections of either cocaine (10mg/kg) or saline (10ml/kg) for 10 days. On day 11 all mice were given a saline injection to examine whether cocaine treated mice exhibited conditioned activity. Locomotor activity was recorded for 60 minutes post injection. No genotype showed any differences in baseline locomotor activity and administration of cocaine increased locomotion in all genotypes. However in Session 1 D1- α 4-KO mice showed greater cocaine-potentiated activity compared to D1- α 4-WT's. Interestingly cocaine treated D1- α 4-KO's also showed a greater level of conditioned activity on the saline test day. No phenotypic differences were seen with α 4 KO mice (compared to WTs) or the D2- α 4-KO mice. Our results indicate that deletion of α 4 in D1 neurons results in an increased acute response to cocaine and greater conditioned activity but does not affect end-point behavioural sensitisation.

behaviours. Experimental groups were divided with half administered cocaine (20mg/kg) and half saline, and their brains perfused after 90 minutes. We observed increased cFos in the NAc core and shell following acute cocaine and this was further increased in sensitised animals. α 4 KO and D1- α 4-KO's displayed greater cocaine induced cFos in the NAc core following acute cocaine and greater cocaine induced cFos in the NAc core *and* Shell post sensitisation.

Title: Effect of social isolation during adolescence on behavior in adult mice

Authors: *M. NOBACK, N. WHITE, G. ZHANG, J. BARROW, G. CARR Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Social isolation (SI) during adolescence is a risk factor for several psychiatric disorders, including schizophrenia, anxiety, and depression, but the mechanisms by which it contributes to the development of these disorders is unknown. In mammals, adolescence is a critical period in which social interaction with peers is essential for normal brain development. SI is associated with increased neuroinflammation, and altered brain structure and neurochemistry. These SI-mediated effects may underlie SI-associated risk, but the pathologically relevant effects of SI are not clear. We have established a model of SI during adolescence (postnatal day 21-35) in mice that evokes significant behavioral changes. Specifically, male mice exposed to SI during adolescence are hyperactive in a novel open field and display an abnormal exploration pattern suggesting altered attentional processes. Moving the SI mice to group housing (postnatal day 35 on) does not alter their phenotype, suggesting the behavioral changes result from altered neurodevelopmental during a critical period. One possible cause of the abnormal development in SI mice is the lack of opportunity to engage in social play during the postnatal day 21-35 period when normal play behavior peaks. Here we show the effects of intermittent social play behavior (1 hour/day) on the SI phenotype and highlight potential prophylactic measures for SI-induced abnormalities. Along with identifying mechanisms relevant for prevention, these studies identify potential substrates amenable to treatment in adulthood.

Title: Layer dependent attentional modulation of broad and narrow spiking cells in primate V1

Authors: A. THIELE¹, D. FERRO³, M. BOYD², *S. PANZERI³

¹Newcastle Univ., Newcastle upon Tyne, United Kingdom; ²Newcastle Univ., Newcastle Upon Tyne, United Kingdom; ³ISTITUTO ITALIANO DI TECNOLOGIA, Genova, Italy

Abstract: Attention is critical to high level cognition and it improves perceptual abilities. Many studies have delineated how attention affects neuronal firing rates, rate variability, and neuronal correlations, but a detailed understanding how this differs between cortical layers and different cell types is only just emerging[1, 2].

We investigated how attention affects neuronal firing rates, rate variability, and neuronal correlations in broad and narrow spiking cells[3] in macaque V1, while animals performed a top down cued spatial attention task. Recordings were performed with 16 contact laminar silicone probes (150 um intercontact distance) inserted normal to the V1 surface. Layer location was assignment based on current source density and latency analysis, with the earliest current sink and visual responses assigned to layer $4c\alpha$. Layer assignment of sufficiently active cells (>3Hz) was possible for 325/364 broad spiking cells and 224/262 narrow spiking cells. Sustained neuronal activity (following the initial transient after stimulus onset) was higher in supra and infragranular than in granular layers in both cell types. Narrow spiking cells showed a trend towards higher firing rates than broad spiking cells. Attention induced firing rate changes were quantified using Area Under the Receiver Operating Characteristics (AUROC). Braod and narrow spiking cell AUROC distributions did not significantly differ (p=0.72, rank-sum test). AUROCs were largest (p<0.05, rank sum test) in supragranular layers and smallest in granular

layers. Rate variability was assessed using spike count based Fano Factors (FF), and gain variance. Both FFs and gain variance were significantly larger in narrow than broad spiking cells (p=0.004, rank sum test). Across both cell types, FF and gain variance was largest in supragranular layers, intermediate in granular, and smallest in infragranular layers (all pairwise comparisons p<0.05, rank sum test). Attention did not affect FF in either cell type or layer. However, gain variance was reduced by attention in both cell types. The attention induced reduction in gain variance was largest in supragranular layers, and smallest in infragranular layers (latter comparison p=0.029, rank sum test).

Title: Effects of medial prefrontal cortical administration of the orexin-2 receptor antagonist, TCS-Ox2-29, on attentional performance in rats

Authors: *A. TAPP, E. B. MANESS, J. A. BURK Col. of William and Mary, Williamsburg, VA

Abstract: Orexins are excitatory neuropeptides that come in two isoforms, Orexin A and Orexin B, and serve as ligands for the G-protein coupled orexin 1 and orexin 2 receptors (Ox1R and Ox2R, respectively). Changes in orexinergic transmission are thought to contribute to attentional processing. While several studies have examined the role of Ox1Rs in attention, less research has assessed the contribution of Ox2Rs. Moreover, several lines of evidence suggest that the right medial prefrontal cortex is particularly critical for visual attentional performance. Taking all of this into consideration, the goal of the present experiment was to test the effects of Ox2R blockade, via administration of TCS-OX2-29, in the left or right medial prefrontal cortex on visual attention. The results suggest that low dose administration of TCS-OX2-29 into the right, but not into the left, medial prefrontal cortex enhanced attentional performance. We speculate that relatively mild antagonism of Ox2Rs may have increased the sensitivity of these receptors to subsequent orexin transmission, thereby enhancing attentional performance. Ongoing projects in our laboratory are assessing whether these effects are observed when TCS-OX2-29 is infused into other brain regions known to be critical for attentional performance.

Title: The role of basal forebrain orexin-2-receptors in attentional performance in rattus norvegicus

Authors: *J. A. BURK¹, A. P. VIJ¹, E. B. MANESS¹, J. R. FADEL² ¹Psychology, Col. of William and Mary, Williamsburg, VA; ²Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Changes in homeostatic function, including sleep patterns and energy balance, are often predictive of age-related neurocognitive disorders such as Alzheimer's and Parkinson's disease. The basal forebrain has been implicated in both attentional processing and responses to homeostatic cues, suggesting a possible link between the significantly impaired attention task performance of Alzheimer's and Parkinson's patients and shifts in their homeostatic regulation. Recent research suggests a possible mechanism: the basal forebrain receives input from hypothalamic neurons that release the excitatory neuropeptides, orexin-A and orexin-B (orexins). Orexins bind with varying affinities to orexin-1- and orexin-2-receptors on cholinergic neurons in the basal forebrain and increase the rate at which they fire action potentials in response to attentional demands and regulation of homeostasis. Degeneration of these cholinergic projections to the cortex is a hallmark of Alzheimer's and Parkinson's, but it is currently unknown if impairment is due solely to loss of these projections, or if the decline can be attributed to loss of particular receptors on these neurons. In order to evaluate the necessity of orexin-2-receptors for attentional performance, TCS-OX2-29, an orexin-2-receptor selective, non-peptide antagonist was administered via bilateral infusion into the basal forebrain of Rattus norvegicus prior to completion of an attention task with a distracter present. The findings suggest a dose and block dependent decline in correct rejections at the 40 nm TCS-OX2-29 infusion into the basal forebrain on the sustained attention task with distracter compared to saline administration. An exploratory analysis revealed improvements in relative hits at 2 nm and 20 nm TCS-OX2-29 infusions into the basal forebrain. Combined, these findings suggest that the orexin-2-receptor is involved in attentional performance, and that blocking the orexin-2-receptor with TCS-OX2-29 may, at high doses, result in a decline in correct rejections, while lower doses of 2 nm and 20 nm may be involved in sensitization of the orexin-2-receptor, making it more likely to respond to binding of orexin A and orexin B.

Abstract: Visual spatial attention facilitates the processing of information in a specific location of space. According to Posner and Peterson (1990), it is divided into three functional components, subserved by specific neural networks and neuromodulators. Alerting serves to maintain high sensitivity to incoming stimuli, orienting serves to select an information in space and executive control serves to resolve conflict due to limited capacity of the attention system. In this model the locus cœruleus-noradrenaline system (LC-NA) is proposed to specifically modulate the alerting process. However, accumulating evidence suggests a broader role of the LC-NA system in spatial attention (Aston-Jones & Cohen 2005). The objective of the present study was to reexamine its role in spatial attention.

We tested the effect of injections of a NA-reuptake inhibitor (Atomoxetine, ATX), which enhances NA transmission, in seven monkeys performing a task derived from the Posner spatial cueing paradigm (Fan et al. 2002). Monkeys had to saccade to a target in one side of the screen (10° eccentricity). For 80 % of the trials, a cue accurately predicted the upcoming target location ('valid cue'). For the remaining 20%, the cue was either absent ('no cue') or presented on the opposite side of target location ('invalid cue') or two cues were simultaneously presented ('neutral cue'). In addition, a distractor could appear simultaneously with the target onset, randomly either in the same oreaction timesr in the opposite hemifield of the target. Our results showed that ATX increased the number of initiated trials and/or the number of correct trials. Following ATX injections, reaction times in valid trials were reduced leading to an improvement of attentional orienting. The other attentional processes, i.e. alerting and executive control, were also affected by ATX injections but results across monkeys were more mitigated. In conclusion, enhancing NA transmission mainly modulated the orienting process within a highly predictive context. These results suggest that NA influences different facets of spatial attention and that this effect might depend on the context.

Title: Neural coding of social gaze in the amygdala

Authors: *S. GILARDEAU, M. JAZAYERI, S. PINÈDE, S. WIRTH, J.-R. DUHAMEL Inst. Des Sci. Cognitives, Bron Cedex, France

Abstract: Primates have a highly structured and developed social life. To achieve such complexity, appropriate communication between individuals is required. Much of this communication is achieved through the exchange of visual information. Indeed the eyes provide information about an individual to its conspecifics depending on its status, disposition and emotional state, especially thanks to the different gaze interactions they engage in. Despite the importance of social gaze in the behavioral repertoire of primates (Ballesta and Duhamel, 2015, Dal Monte et al, 2016), the neural substrates that support this behavior are still little known. The macaque amygdala has been shown to contain neurons that respond selectively to different part of faces, bodies and, notably to eye gaze and direct eye contact while viewing videos of conspecifics (Mosher et al. 2014). In the present study, we investigated the neural correlates of gaze behavior during live interactions between two macaque monkeys, sitting face to face, both while they engaged in spontaneous visual interactions and as they performed a structured social decision task.

We report that monkeys actively seek to interact with one another through gaze, notably by showing longer fixations during mutual than averted gaze and more frequent social gaze initiation by dominant than subordinate monkeys. Single unit recordings in the amygdala revealed different types of neuronal responses. Neurons responded to the eye region of the partner monkey, and some of these responded selectively to mutual gaze. Interestingly neurons could respond with short (<60ms) or long (>150ms) latency, suggesting two possible routes for visual input to the amygdala. We further observed cells responding to a more complex type of gaze interaction, namely joint attention. Such activity was characterized by increases in firing rate when the two monkeys jointly gazed at the workspace, and by a striking enhancement of the neuronal responses when the recorded animal was following the partner's gaze shift to that location. To conclude, our results confirm the role of the primate amygdala in social gaze and extend its involvement to joint attention mechanisms. References:

Title: The claustrum enables resilience to distraction through gain control of cortical sensory processing

Authors: *G. ATLAN¹, A. TEREM², N. PERETZ-RIVLIN¹, G. POZNER², K. SEHRAWAT¹, B. J. GONZALES², G.-I. TASAKA¹, Y. GOLL², R. REFAELI^{1,2}, O. ZVIRAN², B. LIM³, M. GROYSMAN¹, I. GOSHEN¹, A. Sci., UCSD, La Jolla, CA; ⁴Canadian Inst. for Advanced Res., Toronto, ON, Canada

Abstract: The claustrum is a thin neuronal structure, located deep in the mammalian brain. Enclosed between the insular cortex and the striatum, it has been shown to be reciprocally interconnected with sensory cortices, frontal regions, and subcortical nuclei. We have recently proposed that by regulating cortical gain, the claustrum may suppress task-irrelevant sensory

stimuli and support attention (Goll et al. 2015). However, the delicate anatomy of the claustrum has greatly limited functional studies. We identified a genetic marker that is locally selective for claustrum neurons. A transgenic mouse line allows the utilization of CRE-dependent viral vectors to drive specific expression in a subpopulation of claustral neurons. Using these as starter cells, we conducted brain-wide anterograde tracing and rabies-based retrograde tracing experiments, and verified that these cells display the characteristic reciprocal connectivity of the claustrum (Atlan et al. 2016). To address our hypothesis regarding the involvement of the claustrum in attention, we assessed the impact of claustral activation on sensory responses in the auditory cortex of anesthetized mice. Specifically, we played an array of logarithmically spaced pure tones (3-70 kHz), and optogenetically activated claustrum neurons or processes while performing loose-patch recordings or bulk calcium photometry, respectively. We observed that the firing of the majority of affected single cells was reduced selectively at their preferred frequency. Population calcium activity, however, revealed that claustral activation drives divisive normalization at the circuit level; demonstrating that the claustrum is capable of broadly desensitizing cortical responses, while maintaining their baseline tuning. Finally, we established that the claustrum is important for performing attentional tasks by silencing its activity during operant and naturalistic behaviors. In both assays, mice displayed increased sensitivity to auditory distraction during claustral suppression. Our work serves as the first functional perturbation of the claustrum, demonstrating that it can regulate cortical excitability, and impact resilience to distraction. Therefore, the claustrum could be a novel target for medical treatment of disorders in which perception and attention are impaired, such as autism, schizophrenia, and ADHD.

Title: Serotonergic efficiency underlies causal effect of 5-HTP on attention allocation

Authors: *H. B. WEINBERG-WOLF¹, N. FAGAN², O. DAL MONTE³, M. TRINGIDES⁴, G. ANDERSON⁴, S. W. CHANG⁴

¹Psychology, Yale Univ., New Haven, CT; ²Yale Univ., New Haven, NY; ³Dept. of Psychology, ⁴Yale Univ., New Haven, CT

Abstract: Serotonergic transmission, measured via cerebrospinal fluid (CSF) concentrations of the serotonin metabolite 5-hydroxyindoleacetic Acid (5-HIAA), is linked to psychiatric disorders, particularly depression (Sharp and Cowen, 2011). Impaired serotonergic transmission is also linked to poor impulse control, impaired social functioning, extreme aggression, and even mortality in human and non-human primates (Higley & Linnoila, 1997; Westergaard, 1999). Diversity in serotonergic transmission is often independent from central concentrations of serotonergic compounds. In fact, when scientists modulate central serotonin to examine its effects on behaviors associated with depression, they often report inconsistent results. It is likely that this is in part due to individuals' diversity in central serotonergic transmission efficiency, a characteristic usually overlooked in these studies.

Previously (Weinberg-Wolf et. al, 2016, SfN abstract), we reported that systemically administering the serotonin precursor I-5-hydroxytryptophan (5-HTP) results in robust bidirectional modulation of attention in rhesus macaques, whereby 5-HTP increased looking duration in animals with low baseline attention (Attend+ group) but decreased looking duration in animals with high baseline attention (Attend- group).

Here, we elucidate the biochemical mechanisms underlying this causal effect of serotonin on attentional allocation by examining central serotonergic efficiency. While central concentrations of 5-HTP and serotonin at baseline positively predicted the direction in which, and magnitude by which, 5-HTP modulated attention, CSF analyses also confirmed that 5-HTP increased central concentrations of 5-HTP and serotonin in *both* groups. Previous literature indicates that the ratio of 5-HIAA to serotonin is the best representation of serotonergic efficiency (Roy and Linnoila, 1988). We found that the 5-HIAA to serotonin ratio indeed predicted both looking duration at baseline and also the percent change from baseline in looking duration following 5-HTP administrations. Attend+ animals exhibited lower baseline 5-HIAA to serotonin ratios, and thus poorer serotonergic efficiency, looked for shorter periods of time at baseline and exhibited more positive changes in looking duration due to 5-HTP than their Attend- counterparts. Our results suggest that differences in central serotonergic efficiency underlie diversity in how serotonergic manipulations causally influence attention. These findings may inform treatment plans for serotonergic interventions in disorders like depression and anxiety.

Title: Attentional control in young and aged rats following chemogenetic inhibition of prefrontal projection neurons

Authors: *S. JOSHI, M. DUGGAN, J. STRUPP, V. PARIKH Psychology and Neurosci., Temple Univ., Philadelphia, PA

Abstract: The prefrontal cortex (PFC) governs top-down control of attention and is known to be vulnerable in aging. However, increased recruitment of PFC in aging is hypothesized to reflect an adaptive reorganization process that might compensate for declining bottom-up sensory processing and ensuing attentional capacitates. Therefore, we hypothesized that reduced activity of PFC efferents would exert differential effects on attentional capacities between young and aged subjects, with the latter exhibiting a more robust decline in performance. Wistar rats (young: 3 months and aged: 22 months) were trained in an operant attention task that consists of a random sequence of signal (central panel light of different durations; 500 ms, 50ms, 25ms) and non-signal trials, divided into 3 blocks. We utilized a chemogenetic approach involving DREADD (Designer Receptors Exclusively Activated by Designer Drugs) to silence projection neurons in the PFC. Animals trained to criterion (\geq 70% correct responses), received bilateral infusions of AAV vector expressing hM4D(Gi) under the control CaMKIIa promoter into the medial PFC. Subjects were kept on task for 4-weeks post-surgery after which their performance was evaluated under an attention-taxing condition, a behavioral testing session consisting of the presentation of visual distractors (flashing house light) in the 2nd block. Clozapine-N-oxide (CNO; 1mg/kg i.p.) was administered to suppress the activity of prefrontal projection neurons by activating engineered Gi-coupled receptors 1-hr prior to this testing session. For control conditions, animals received an injection of vehicle. As expected, the ability to discern signal from non-signal events was reduced during the distractor presentation, while this deficit completely recovered in the post-distractor block in vehicle-injected young rats. CNO injection worsened the performance of young animals during the pre-distractor (CNO: 0.27±0.06; vehicle: 0.45±0.05) and post-distractor (CNO: 0.35±0.09; vehicle: 0.63±0.06) blocks, respectively. In general, aged rats performed less accurately on signal trials with shorter signal durations. Contrary to our predictions, CNO-mediated Gi inhibition in the PFC did not affect attentional performance in these animals. Lack of sensitivity to the suppression of PFC output neurons in aging might indicate that restricted modulation of PFC efferents is not sufficient to compensate for age-related decline in attentional capacities. It is possible that other cortical regions involving the frontoparietal networks are also involved in this adaptive process.

Title: Neuronal activity in primate area FST during covert spatial attention

Authors: *A. R. BOGADHI, L. N. KATZ, A. BOLLIMUNTA, R. J. KRAUZLIS Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Inactivation of the superior Colliculus (SC) leads to attention deficits in covert spatial attention tasks, but the circuits through which SC inactivation leads to attention deficits are not known. Using fMRI in a block design, we recently identified area FST in superior temporal sulcus as one of the areas that is significantly affected by SC inactivation in a covert spatial attention task. Because of the limitations of the fMRI study, we do not know which aspects of the task modulate neuronal activity in area FST or how they might be affected by SC inactivation. Here we report neuronal recordings (single and multi-unit combined and hereafter referred to as units) from area FST in a covert spatial attention task. The task consisted of 4 stimulus conditions: Baseline (B), Foveal Attention (FA), Single Peripheral Stimulus (SPA) and Peripheral Attention (PA) blocks. Each condition was blocked and presented in a randomly interleaved order. In B trials, the relevant stimulus was a central fixation point that dimmed at randomized times. FA trials were similar to B trials but added 2 peripheral motion-change stimuli as irrelevant distracters. In PA trials, the fixation point did not dim and the 2 peripheral motion-change stimuli were relevant. SPA trials were similar to PA trials except there was only one peripheral motion-change stimulus. The task of the monkey was to maintain central fixation and report the relevant stimulus change (fixation dimming in B & FA blocks, peripheral motion change in SPA & PA blocks) by releasing a lever to get a juice reward. We have recorded 312 units in area FST of 2 monkeys using single electrodes and 24-contact vprobes. Most units (n = 186) were responsive to the peripheral motion stimulus in PA trials and showed a significant onset response or significant delay period activity to the peripheral stimulus. Units in FST (n = 146) also showed a significant attention-related modulation (comparing PA and FA conditions) with a median modulation index of 0.1, and more than onethird of the units (n = 124) were significantly modulated by the peripheral motion-change. Our preliminary results suggest that units in area FST not only show a significant attentionrelated modulation but also report the peripheral change event. Further experiments will address how the above-mentioned modulations in FST units are affected by SC inactivation in a covert spatial attention task.

Title: Exogenous and endogenous control of visuospatial attention in freely behaving mice

Authors: *W.-K. YOU¹, S. P. MYSORE^{1,2}

¹Neurosci., The Johns Hopkins Univ., Baltimore, MD; ²Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Spatial attention, the ability to select and preferentially process the most important stimulus location in the environment at any instant, is critical for adaptive behavior. To uncover the neural circuit mechanisms underlying spatial attention control, we wish to exploit the power offered by the mouse system for genetically based approaches for the measurement and perturbation of cell-type specific neural activity. As a first step in this endeavor, we develop parameterized paradigms for visuospatial attention in mice using a touchscreen-based operant set-up. Here, we study, explicitly, exogenous as well as endogenous control of visuospatial attention in unrestrained mice using, respectively, a flanker task and a spatial expectation task. Our results reveal systematic changes in behavioral performance and perceptual sensitivity driven either by stimulus salience (exogenous influence) or learned expectation (endogenous influence), consistent with results from similar primate studies. Taken together, we demonstrate that mice exhibit behavioral signatures of visuospatial attention similar to that of humans and monkeys. We propose that mice can serve as a viable model for studying the neural mechanisms of spatial attention.

Title: Signatures of competition in an inhibitory nucleus in the midbrain attention network

Authors: *H. M. SCHRYVER, S. P. MYSORE

Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Attention involves selecting the most behaviorally relevant ("highest priority") stimulus in the environment to guide behavior. The brain mechanisms underlying this function rely on circuitry in the midbrain, specifically the superior colliculus (SC, in mammals, or optic tectum, OT, in birds). Past work has established a causal role for the SC in selecting a target amongst competing distractors. This specific role for the SC in stimulus selection has been shown to be mediated by competitive response suppression provided by a nearby inhibitory nucleus, the Imc (isthmi pars magnocellularis). However, the functional properties of the inhibitory Imc, specifically, how it encodes stimulus competition, are not well understood. Here, with electrophysiological experiments in the barn owl, we will examine signatures of competition in the Imc. Specifically, by contrasting them with those in the OT, we will determine the degree to which the Imc actively performs the computations underlying selection. In addition, with paired recordings in the OT and Imc, we will directly compare the temporal dynamics of competition to determine where competition is first resolved in this circuit. Results from this work will inform us of how this midbrain circuitry that is required for stimulus selection operates, mechanistically.

Title: Neural mechanisms underlying categorization for stimulus selection

Authors: *N. R. MAHAJAN, S. P. MYSORE Johns Hopkins Univ., Baltimore, MD

Abstract: The selection of the most behaviorally relevant stimulus among multiple competing stimuli is critical for the control of gaze and spatial attention. The superior colliculus (SC), a

midbrain sensorimotor hub, is known to play a key role in this selection. Previous work in the barn owl has revealed that the optic tectum (OT, avian analog of the SC) explicitly categorizes competing stimuli into two categories, "highest priority" and "others". In addition, a GABAergic satellite nucleus to the OT, called the isthmi pars magnocellularis (Imc), generates the competitive inhibition that is necessary for this categorization. However, the functional pattern of inhibition from the Imc to the OT is not known. Anatomically, the Imc is known to receive focal input from the topographic OT space map, and to send inhibition back broadly to all regions of the OT space map except the region from which it receives input, i.e., a "donut-like" pattern of connectivity. In addition to directly inhibiting the OT, the Imc also inhibits it indirectly by suppressing a powerful cholinergic amplifier of OT representations called the Ipc. Because the pattern of inhibition from the Imc to the Ipc is not clear, it is unknown whether the net inhibition from the Imc onto the OT, through the direct as well as indirect pathways, is actually donut-like. Computationally, such a donut-like pattern of inhibition could substantially enhance categorical selection among competing stimuli in the OT. Here, we will directly examine the spatial pattern of net functional inhibition from the Imc to the OT in the barn owl using in vivo extracellular recordings, iontophoretic inactivation and computational modeling. Results can reveal the neural circuit implementation of key computations underlying stimulus selection.

Title: Different patterns of neuronal infection in the rodent thalamus and temporal cortex revealed by retrograde transport of pseudorabies virus injected into the dorsal and ventral prefrontal cortex

Authors: *M. PERKINS, K. F. MESSANVI, Y. CHUDASAMA Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: The mammalian prefrontal cortex plays a critical role in complex executive behaviors by enabling several cognitive operations such as attention, working memory, response control and decision-making. Lesions to different regions of the rodent PFC cause specific cognitive impairments. For example, ablating the dorsal part of the PFC (dPFC), which comprises the dorsal anterior cingulate cortex, and the dorsal extent of the prelimbic cortex affects aspects of attention and working memory. In contrast, the ventral part of the PFC (vPFC) which includes

the infralimbic cortex, orbitofrontal cortex, and the rostral and ventral extent of the prelimbic cortex, is implicated in behavioral control and flexibility (Chudasama, 2011, Beh Neurosci. 125:327-343). This differentiation in behavior prompted us to map the organization of direct and indirect inputs to the dPFC and vPFC, and establish how these anatomical pathways might influence different cognitive functions.

We injected a GFP-expressing transsynaptic Pseudorabies virus (PRV-152) and an mRFPexpressing Pseudorabies virus (PRV-614) directly into the dPFC and vPFC respectively using stereotaxic procedures. First-order projections were determined at 48hrs post-inoculation. Retrogradely-infected neurons were found in the ventral hippocampus and the amygdala following vPFC injection, but not following dPFC injection. In addition, while animals with vPFC injections showed infected neurons in several midline thalamic nuclei including the reuniens and rhomboid, the dPFC-injected animals showed a pattern of infection that was sparse but restricted to the dorsal midline thalamus, namely the paratenial and paraventricular nuclei. In the temporal cortex, neurons projecting to the vPFC were abundant in the perirhinal and entorhinal cortex, while the presence of neurons projecting to the dPFC was moderate and mainly located in the perirhinal cortex.

Title: Specific projections of the non-specific midline thalamus

Authors: *G. LARYEA, M. B. LEVENTHAL, Y. CHUDASAMA Section on Behavioral Neurosci., NIMH, Bethesda, MD

Abstract: The midline thalamic group of nuclei are generally divided into a dorsal group comprising the paraventricular, paratenial, and intermediodorsal nuclei, and a ventral group which include the rhomboid and reuniens nuclei. This midline thalamic complex is viewed as the non-specific thalamus because the nuclei project broadly to the cortical mantel and receive diffuse input from the brain stem. Unlike the sensory, motor and associative thalamic nuclei which are well defined in terms of their functions, significantly less is known about the functional anatomy of the midline thalamic structures. Recent studies implicate midline thalamus in diverse behavioral functions including learning and cognition (Prasad et al., 2017, Neurosci. 345:77-88), spatial navigation (Hembrook and Mair, 2011. Hippocampus. 21:815-826), and fear-

related memory (Penzo et al., 2015. Nature. 519:455-459). This functional heterogeneity is likely due to the distinct connections of these nuclei with different cortical and subcortical structures. In this study, we explore the anatomical organization of the dorsal and ventral midline thalamic nuclei using a retrograde viral tracer called Pseudorabies virus (PRV). Single or double injections of the PRV with either a GFP tag (PRV-152) or a dTomato Red tag (PRV-614) were injected into dorsal or ventral midline thalamic nuclei of Long Evans rats. After immunofluorescent processing of serial sections, fluorescent imaging was used to identify the distribution of cells labelled with GFP or dTomato Red. Our preliminary evidence indicates that the dorsal midline thalamus receive first order input from preoptic areas, piriform cortex, the most caudal extent of the dentate gyrus, and the caudal dorsal entorhinal field. Unfortunately, our ventral thalamic injections did not accurately target the reuniens and rhomboid nuclei. However, one preliminary case in which the injection was centered on the caudal reuniens revealed the main source of input coming from the medial and lateral septum and the ventral entorhinal field. Further analyses of both first order and second order neuronal projections will enable a better understanding of the organization of midline thalamic circuits and their contribution to behavior.

Title: The neuropeptide galanin in the ventral medial prefrontal cortex modulates impulse control

Authors: *K. MESSANVI, M. PERKINS, J. DU HOFFMANN, Y. CHUDASAMA NIMH / Section on Behavioral Neurosci., NIH, Bethesda, MD

Abstract: The locus coeruleus (LC), the primary source of noradrenaline in the brain, also synthesizes and co-releases several peptides such as galanin, neuropeptide Y and brain-derived neurotrophic factor (BDNF). Galanin is expressed in ~80% of LC neurons in rat brain, and the LC constitutes the only source of galanin to cortex and hippocampus (Hökfelt et al., 1998, Ann. NY Acad. Sci., 863, 252-263). Consequently, galanin has been implicated in cortex- and hippocampus-dependent functions, and is thought to play a role Alzheimer's Disease, addiction, depression, stress and anxiety disorders (Weinshenker and Holmes, 2016, Brain Research 1641, 320-337). Specifically, cortical galanin receptor 1 (Gal-1) is thought to mediate cognitive functions, whereas galanin receptor 2 (Gal-2) is thought to play a role in mood and anxiety.

In this study, we explore whether galanin is involved in cognitive-executive function. Given the role of LC-derived noradrenaline in attentional processing, and the high expression levels of galanin receptors in the ventral prefrontal cortex (vPFC), we examined the contribution of Gal-1 receptor activation to performance in the 5-Choice task using a touchscreen platform. In this task, rats were trained to reach a high level of accuracy (> 80%) and low levels of omission (< 20%). We then implanted bilateral cannulae targeting the vPFC. Next, trained rats received counterbalanced infusions of either 3 nmol or 5 nmol of the Gal-1 receptor agonist M617 or saline. Rats with local infusions of saline or 3 nmol of M617 showed normal levels of performance with respect to target accuracy, behavioral control and speed of response. In contrast, rats infused with 5 nmol of M617 showed a selective increase in the number of premature responses (mean premature responses \pm SEM: 5nmol = 30 \pm 7.5; 3nmol = 20.8 \pm 4.4; Saline = 15 ± 8.4), with no concomitant change in attention, motor or motivational status. These rats were also sensitive to temporal unpredictability of the visual stimulus. Together, these data implicate vPFC Gal-1-mediated neurotransmission in impulse control mechanisms. Future studies will examine the relationship between Gal-1 and Gal-2 receptors to evaluate whether they mediate similar or unique cognitive processes.

Title: Single-neuron correlates of spatial attention and choice in auditory and prefrontal cortex

Authors: *C. R. CAMALIER¹, M. MISHKIN¹, B. B. AVERBECK² ¹Lab. of Neuropsychology, NIH, Bethesda, MD; ²NIMH/NIH, Bethesda, MD

Abstract: Auditory spatial attention describes our effortless ability to listen to sound from one location while suppressing distracting sounds from other locations. Two key areas implicated in this ability are auditory cortex and prefrontal cortex, but a detailed understanding of how sound is spatially filtered has been hampered by the lack of a robust animal model, particularly one that shares key similarities with humans. To address this, we have developed a novel spatial auditory selective attention task for macaques, based closely on human directed listening paradigms. In this task, a macaque monkey is cued to a particular side and must report the presence of a difficult-to-detect auditory target (embedded in noise) only if it appears on the cued side. If it

appears on the uncued side, he must ignore it.

We collected single neuron data from prefrontal cortex (caudal principal sulcus; n=948) and caudal auditory cortex (primarily A1; n=847) in two monkeys during this task. In both areas, direction of cued side significantly affected responses in about 20% of the neurons. A comparison of patterns between PFC and AC indicated that AC was earlier than PFC in signaling the sensory stimulus (ipsi/contra), but PFC was earlier than AC in signaling the decision made (release/ignore). We applied a classification approach on firing rates of the responsive populations to analyze patterns of firing rates related to error (e.g. misses) vs correct trials, This indicated that the first location to exhibit patterns of activity that classified significantly lower than correct was in AC during the masking noise period. Thus, at least some errors are due to an inability to suppress noise at the level of sensory cortex. These results add insight into the cortical dynamics of auditory decision making during effortful listening.

Title: Impaired NRG1/ErbB4 signaling decreases the vHPC-mPFC synchrony and causes attention deficit

Authors: *Z. TAN¹, H. ROBINSON¹, Y. LIU¹, F. LIU¹, D. YIN², H. WANG¹, T. LIN¹, G. XING¹, W. XIONG¹, L. MEI¹ ¹Dept. of Neurosci. & Regenerative Med., Augusta Univ., Augusta, GA; ²East China Normal Univ., Shanghai, China

Abstract: Top-down attention which is thought to be controlled by prefrontal cortex (PFC) is essential for daily life. Accumulating evidence have shown that hippocampus is involved in the process of attention. However, the underlying mechanism is rarely investigated. Here we show that the synchrony between ventral hippocampus (vHPC) and medial prefrontal cortex (mPFC) is increased in delta and theta band when mice performing correct trials compared with error trials in a 5-choices serial reaction time task (5CSRTT). Interestedly, the ErbB4 mutant mouse which is a schizophrenia mouse model, also shows impaired vHPC-mPFC synchrony and attention deficit. While specifically block NRG1/ErbB4 signaling or optogenetically inhibit ErbB4+ interneurons excitability in vHPC reduces vHPC-mPFC synchrony, slows down processing speed, and causes attention deficit. The same operations in mPFC have no effect on vHPC-mPFC

synchrony and processing speed but still causes attention deficit, which may through a different mechanism. Thus, NRG1/ErbB4 signaling modulates vHPC-mPFC synchrony, which is critical for top-down attention.

Title: Selective modulation of dopamine D3 receptors and norepinephrine transporters enhances sustained attention without the risk for abuse

Authors: *C. MARSHALL¹, Z. BRODNIK¹, D. BERNSTEIN¹, O. MORTENSEN¹, M. REITH², J. SHUMSKY¹, N. SNYDER¹, B. WATERHOUSE^{1,3}, R. ESPAÑA¹, S. KORTAGERE¹

¹Drexel Univ., Philadelphia, PA; ²New York Univ. Sch. of Med., New York, NY; ³Rowan Univ., Glassboro, NJ

Abstract: Dopamine (DA) and norepinephrine (NE) have long been studied as modulators of prefrontal cortex (PFC)-mediated cognitive tasks including sustained attention. However, most catecholaminergic agents such as methylphenidate pose a risk of being abused due to their non-selective effects on DA transporters (DAT), thereby limiting their therapeutic effects. In this study, we have developed a novel pharmacological strategy to selectively combine the agonist effects on a DA D3 receptor (D3R) with the inhibitory effects on a NE transporter (NET) to improve sustained attention without promoting DAT effects. Our recently designed SK609 - a selective D3R agonist - was further characterized for monoamine transporter activity. Our results demonstrate that SK609 not only selectively inhibits the NET at an IC₅₀ value of ~500nM but also behaves as a substrate of NET. Systemic dosing of SK609 in naïve rats led to a 300% and 150% increase in NE and DA levels respectively in the PFC as measured by microdialysis. In naïve, male rats trained to perform to criteria in an operant visual stimulus task of sustained attention, SK609 produced a typical inverted-U dose response when tested between 2-20mg/kg doses with a peak effect at 4mg/kg. The peak effect produced by SK609 was blocked by a pre-

treatment with either 0.05mg/kg of raclopride - a D2/D3R antagonist or 0.25mg/kg of prazosin, an alpha-1 adrenergic receptor antagonist, confirming that the improvement was indeed due to both DA and NE modulation in the PFC. In addition, SK609's effect on improving sustained attention was more prominent among low performing animals. The peak dose of 4mg/kg of SK609 did not produce any increase in locomotor effects and was not self- administered suggesting a lack of psychostimulant effects. These results demonstrate that SK609 has the potential to treat PFC-mediated cognitive deficits without abuse liability which distinguishes SK609 from amphetamines and methylphenidate.

Title: The effects of atomoxetine on distribution skew in a two choice reaction time task in the rat

Authors: *Z. V. REDDING, P. CHAWLA, K. E. SABOL Psychology, Univ. of Mississippi, University, MS

Abstract: *RATIONALE* Norepinephrine (NE) is integral to cognitive processes such as attention (Arnsten et al., 2005, J. of Clin Neurosci (67), 7-12). The NE reuptake inhibitor, atomoxetine (ATX), has been used to treat attention-deficit/hyperactivity disorder. When evaluating reaction time (RT) distributions, ATX decreased RT variability (Kratz et al., 2012, Prog in Neuro-Psychopharm & Biol Psych (37), 81-89), or had no effect (Bedard et al., 2015, J. of Child Psychol & Psychiatry (56), 40-48; Nandam et al., 2011, Biol Psychiatry (69), 902-904). Using the ex-Gaussian model, Ni et al (2016, J. of Psychopharm (30), 459-467) found a decrease in distribution skew, which is thought to reflect attentional lapses (Leth-Steensen et al., 2000, Acta Psychologica (104), 167-190). This study explores the effects of ATX on performance in a two-choice reaction time task (2CRTT) in rats. RT is broken down into initiation time (IT) and movement time to isolate effects on attention. IT is the time from stimulus presentation until the rat first reacts to the stimulus. Measures are derived from the shape of the distribution of ITs, a

distinct peak and a rightward skew. The peak (mode) represents sensorimotor processing when rats are attentive. The skew (measured by subtracting mode from mean, devmode) is caused by slow ITs (Sabol et al., 2003, Behav Pharm (7), 489-500). It was hypothesized that ATX would dose-dependently decrease IT devmode, with no effect on IT mode. METHODS Twenty male Sprague-Dawley rats were trained on the 2CRTT for eight weeks. To perform the 2CRTT the rat placed its nose into a central aperture for a randomly varied foreperiod. After the foreperiod, a stimulus light came on above an aperture to the left or right of the rat. The rat then removed its nose from the central aperture (IT) and entered the aperture underneath the illuminated light. A water drop was given for correct responses. The rat began trials by entering the central aperture. Beginning in the ninth week, ATX was administered thirty minutes before testing, twice a week. Doses were assigned via the Latin square procedure and included saline, 0.1, 0.5, and 1.0 mg/kg. Each rat received each drug dose two times. RESULTS There was a main effect of ATX on IT devmode [F(3,57) = 7.411, p < .001]. Post-hoc analyses showed that 0.5 and 1.0 mg/kg were decreased compared to saline. ATX did not affect IT mode. DISCUSSION ATX's effects on lapses in attention were likely due to increased NE availability in cortical areas that control attention during ongoing tasks (Corbetta & Shulman, 2002, Nat Rev Neuro (3), 201-215). The effect of ATX on devmode (lapses in attention) in our model reflects the reduction in RT variability reported in some human studies.

Title: The role of the intralaminar thalamic nuclei in attention and orienting

Authors: *G. D. WATSON, H. H. YIN

Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: The parafascicular (Pf) and centromedian (CM) nuclei of the intralaminar thalamic complex receive multimodal inputs from multiple brainstem regions. Considered a part of the reticular activating system, these nuclei send diffuse projections throughout the striatum. However, the specific role of these thalamic nuclei in attention, as well as the functional significance of their efferent and afferent projections, is not well understood. To visualize input and output connectivity differences between Pf and CM, canine adenovirus type 2 engineered to express Cre recombinase (CAV2-Cre) was injected into Ai14-tdtomato mice. To examine their contributions toward behavior, Pf and CM were pharmacologically inactivated with muscimol during free field exploration. 3D motion capture was then combined with optogenetic activation

and inhibition to precisely quantity movement. In separate experiments, terminal stimulation of projections from the superior colliculus and locus coeruleus was performed. Finally, attention was assessed during the presentation of stimuli while optogenetically manipulating activity in these nuclei. Our results collectively show that Pf and CM have unique connectivity patterns that underlie different aspects of attention and behavior.

Title: Effects of 5-HT1B antagonists on behavior in dopamine transporter knockout mice

Authors: *Y. H. SABER¹, F. HALL¹, R. ELHAG², F. RESENDIZ² ¹Pharmacol. and experimental therapeutics, Univesity of Toledo, Pharm. Col. and Pharmace, Toledo, OH; ²the university of toledo, TOLEDO, OH

Abstract: Background. Genetic deletion of the dopamine transporter in mice (DAT KO) induces a syndrome of behavioral effects that are characteristic of ADHD, that include locomotor hyperactivity, and impairments in prepulse inhibition of acoustic startle (PPI) and the cliff avoidance reaction. Moreover, many of these effects can be ameliorated by treatments that are effective in treating ADHD in humans. The most commonly used medications to treat ADHD are psychomotor stimulants. The use of these drugs present several problems that would be alleviated by a non-stimulant alternative. Atomoxetine was produced as an alternative but it also has drawbacks. We have recently shown that DAT KO-induced hyperactivity can be reduced by the 5-HT1B antagonist SB 224289. Here we report further studies with this drug and an exploration of behavioral deficits in male and female mice. Methods. Locomotor activity, PPI and CAR were examined in male and female DAT +/+ and DAT -/- mice. The effects of SB 224289 on the PPI and CAR deficits observed in DAT KO mice were examined, as well as upon DAT KO-induced locomotor hyperactivity. Results. In the current studies, the effects of DAT KO were found to be sex dependent (the effect of sex has not been previously examined), with greater effects observed in female mice. Effects of SB 224289 were found for all 3 tests, although the effects were most robust in the CAR and locomotor tests. Conclusions. In the present studies the effects of DAT KO on behavior were found to be sex-dependent, with greater effects in females. These findings will require confirmation in subsequent studies. Moreover, we have found additional evidence that antagonism of the 5-HT1B receptor may reverse some deficits in DAT KO mice, encouraging further investigation of this potential novel target for the treatment of ADHD.

Title: Single neuron correlates of ERP changes linked to spatial attentional shifts in behaving monkeys

Authors: *C. LOCKWOOD¹, W. VAUGHN², C. J. DUFFY³

¹Univ. of Rochester, Fairport, NY; ²Univ. of Rochester, Rochester, NY; ³Univ. Of Rochester Med. Ctr., Rochester, NY

Abstract: Cued shifts of spatial attention modulate behavioral responses to visual stimuli, with spatially valid cues yielding faster responses and invalid cues yielding slower responses (Posner, 1980). These behavioral effects have been linked to changes in cognitive ERPs in both humans (Woodman and Luck, 1999) and monkeys (Woodman, et al., 2007). We previously studied cue validity effects on human ERPs, finding spatial attentional task effects on a variety of response components (CNVs, N200s, N2PCs, and P300s). We have now extended those studies using monkey ERPs, LFPs, and single neuron recordings to identify neuronal correlates of the attentional effects seen in human ERPs. We trained two Rhesus monkeys to maintain search coil or IOG monitored centered visual fixation during the exogenous spatial cueing of optic flow discrimination. Left or right side flashed spots preceded left or right optic flow foci-of-expansion (FOEs). The monkeys then pressed a button to indicate the side of the FOE. The cue was valid (same side as the subsequent FOE) in 75% of the trials, invalid (opposite side of the FOE) in 25%. We recorded ERPs from 32 transcranial electrodes permanently implanted in the monkeys' skull. The first 18 months of recording was devoted to obtaining behavioral and ERP data across a variety of stimulus and task parameters. We then implanted a posterior parietal microelectrode recording chamber over one hemisphere, preserving most ipsilateral, and all contralateral, ERP electrodes. Microelectrodes were inserted daily into cortical area MST for LFP and SU recordings in the task. In monkeys, as in humans, validly cued trials yield faster push button RTs than invalidly cued trials. Monkey ERPs recorded during these trials showed the same component structure seen in humans, with very similar timing but larger amplitude and broader bandwidth than seen in human scalp recordings. MST neurons showed FOE selective firing rate changes in response to optic flow onset. These responses were greatly modulated by the cued location of spatial attention, often reversing Lt/Rt FOE selectivity. Spatial attention modulates ERPs and single neuron activity, often altering fundamental neuronal response properties. Our

findings suggest that posterior cortical neurons are under continuous attentional control focusing signal processing on behaviorally relevant stimulus characteristics.

Title: The prevalence of ON and OFF cortical states in macaque visual cortex

Authors: *N. KHARAS¹, S. R. DEBES², A. R. ANDREI³, V. DRAGOI⁴ ¹Neurobio. and Anat., Uthouston Med. School-Md Anderson Cancer Ctr., Houston, TX; ²Neurobio. and Anat., Univ. of Texas At Houston, Houston, TX; ³Neurobio. & Anat., McGovern Med. Sch., Houston, TX; ⁴Dept Neurobiol/Anat, Univ. of Texas at Houston Dept. of Neurobio. and Anat., Houston, TX

Abstract: Fluctuations in neuronal firing are observed to the order of milliseconds. Traditionally, oscillatory synchronous activity was previously characterized as on and off states during rest and sleep whereas desynchronized activity was a hallmark of wakefulness. Recent studies indicate that on and off states are present in wakefulness but the abundance of these states remains unclear. To investigate whether the fluctuations in on and off states in different behavioral states, such as wakefulness and rest, are ubiquitous we recorded single and multi-unit activity along a cortical column in primary visual cortex (V1) and mid-level visual cortex (V4) of Rhesus macaques. We subsequently employed unsupervised machine learning to identify on and off states in neuronal populations and measured the frequency of transitions between the two states to examine how commonly a cortical column switches between two states. The number of transitions per second between states was significantly greater in rest than in wakefulness. The occurrence of on and off states in wakefulness was rarely observed. Furthermore, the trial-bytrial frequency of transitions weakly correlated with global brain state measures of local field potential (LFP) and changes in pupil size. Our findings indicate that on and off states are not ubiquitous during wakefulness, an increase in prevalence of on and off states and transitions between them arise during rest, and local state in a visual cortical column dynamically mirrors the global brain state. Defining the presence of distinct states and the propensity of neuronal populations to transition between states aids in understanding the influence of endogenous activity in cortical processing.

Title: Phase-relationships of High-Threshold bursting Thalamocortical neurons and their role in modulating Alpha oscillations

Authors: *P. RAMAKRISHNA, R. SHARMA, S. NADKARNI Biol. department, IISER Pune, Pune, India

Abstract: A subclass of Thalamocortical neurons called High-Threshold bursting Thalamocortical (HTC) neurons have been implicated as the potential source of Alpha oscillations in the Thalamus. These neurons have inherent channel properties that ensure that each cell fires at approximately 10 Hz even when the cell is disconnected from the rest of the network. It has also been found that acetylcholine and network inputs can modulate this intrinsic rhythm. These HTCs are coupled via gap junctions allowing them to synchronize. Extant data suggests a connectivity profile of these cells wherein at most 4 cells are seen to be directly coupled to a single cell. Robust alpha oscillations as seen in the thalamus keenly constrains the strength of these connections. Based on these observations, we propose a network motif of HTC cells that includes a biophysically realistic description of ion channels that orchestrate the individual rhythms. This allows for a large population of HTC neurons to be entrained to produce the characteristic 10 Hz oscillation. Separately it has been observed in experiments that injecting external current introduces phase differences while maintaining phase locking. Our model, with the predicted network motif accurately reproduces these phase relationships in response to current injection. Furthermore, we propose that ambient acetylcholine levels could modulate the phases of individual cells leading to a modified spectral behavior of this network. A transition from a single peak at 10 Hz to dual peaks at 10 Hz and 20 Hz within a few hundred milliseconds is seen in EEG recordings in behavioral tasks requiring attention. The rate at which the switching of frequency bands take place suggests that intrinsic channel properties of HTCs alone cannot orchestrate the change. Our model provides a biophysical basis for this surprisingly rapid transition without disrupting the intrinsic rhythm of individual cells.

Title: Modulation of neural activity in the parafascicular thalamic nucleus alters beta oscillations in the basal ganglia-cortical motor circuits and modifies motor function in hemiparkinsonian rats

Authors: E. BRAZHNIK, N. NOVIKOV, A. J. MCCOY, *J. R. WALTERS Neurophys/Pharmacol Sec, NIH NINDS, Bethesda, MD

Abstract: Excessive synchronization of local field potential (LFP) activity in the 15-35 Hz range in the basal ganglia (BG) of Parkinson's disease (PD) patients and in rodent models of PD is thought to contribute to motor dysfunction in PD. Recently we presented evidence that synchronized activity in BG output (substantia nigra pars reticulata, SNpr) in hemiparkinsonian rats entrains activity in the ventromedial thalamus (VM) and supports transmission of 25-35 Hz oscillatory activity throughout the BG-thalamocortical circuits (Brazhnik et al., J. Neurosci. 2016). The parafascicular thalamic nucleus (Pf) receives inhibitory input from BG and provides output to the striatum and subthalamic nucleus. It has been suggested that activity in the PF also contributes to the expression of exaggerated beta oscillations in the BG and may therefore play a role in supporting PD motor symptoms. However, our recent observations have shown that unlike the VM, exaggerated beta oscillations are not evident in LFP recordings from the PF thalamic nucleus in the hemiparkinsonian awake behaving rat model (Brazhnik et al., SFN Abst. 2015).

This study uses the awake behaving hemiparkisonian rat with 6-OHDA-induced unilateral dopamine cell lesion to gain further insight into the potential role of the Pf nucleus in supporting expression of beta oscillations in the BG-motor circuits. Electrodes were implanted in the SNpr, dorsal striatum and motor cortex (MCx), and a cannula was inserted into the Pf to allow modification of Pf activity via local infusion of muscimol, a GABA-A agonist, or picrotoxin, a GABA-A antagonist. After unilateral dopamine cell lesion, the hemiparkinsonian rats can walk on a circular treadmill in the direction ipsiversive to the unilateral lesion, with their affected paws on the outside of the circular path, and have considerable difficulty walking in the opposite direction, contraversive to the lesion. Microinfusion of muscimol into the Pf substantially reduced beta LFP power in MCx and SNpr and MCx- SNpr coherence (by ~50-58% of baseline at 1h post-infusion) while temporarily restoring contraversive walking (up to 3 h). The effect of picrotoxin infusion into the Pf on MCx and SNpr LFP power and coherence and on contraversive walking in dopamine cell-lesioned and control rats is currently being assessed.

These data support the view that following substantial loss of dopamine, manipulations that induce tonic inhibition of the Pf activity improve motor function.

Title: The cognitive role of theta, beta, and gamma band oscillatory activity in the basal gangliathalamocortical circuit in the awake, behaving hemiparkinsonian rat

Authors: *A. R. WEISS, E. BRAZHNIK, N. NOVIKOV, M. J. PRESTON, J. R. WALTERS Neurophysiological Pharmacol. Section, NINDS, Bethesda, MD

Abstract: The motor symptoms of Parkinson's disease (PD) have been linked to the emergence of exaggerated oscillatory activity in the 13 - 35 Hz beta range in local field potentials (LFP) recorded in the subthalamic nucleus (STN), substantia nigra pars reticulata, and motor cortex of PD patients and animal models. PD patients and parkinsonian animal models are also known to express dopamine-dependent cognitive impairments, implying effects of dopamine loss on prefrontal cortex function. The electrophysiological correlates of these cognitive symptoms are not well understood. The anterior cingulate cortex (ACC) is a cortical area known to be involved in set-switching and executive function. Previous studies in human ACC have shown modulation of 3 - 8 Hz theta band activity in response to expected and unexpected outcome valences (Weiss AR et al., SFN 2015 abstract). Here, we investigate the involvement of basal gangliathalamocortical circuits in dopamine-impaired and healthy rats in response to salient cues predicting the onset of expected or unexpected treadmill-induced walking. This study used awake, behaving 6-OHDA-lesioned hemiparkinsonian rats performing a circular treadmill walking task to compare synchronized activity in the ACC, STN, and ventral medial thalamus (VM). Electrode bundles were implanted in the ACC, STN, and VM of rats with either unilateral dopamine cell lesions or saline-controls. Rats were trained to expect epochs of treadmill walking after a tone, with subsequent epochs manipulating expectancy through tone-towalk and tone-to-no-walk epochs. LFPs and spiking activity were recorded during epochs surrounding auditory stimuli and treadmill walking in control animals and 7, 14, and 21 days after dopamine cell lesion. Beta band activity with a peak of 30 - 35 Hz was shown to be coherent between the ACC, STN, and VM of dopamine-lesioned animals with increasing spectral power, peak frequency, and coherence with increasing alertness from a rest state to

walking. The temporal properties of theta, beta, and gamma oscillatory band event related potentials were modified by expected and unexpected treadmill-walking trials. Both control and dopamine-lesioned groups exhibited a robust theta frequency response to unexpected trials. Phase amplitude coupling is being assessed.

This study suggests that prefrontal cortex functions associated with dopamine-modulated executive function may be altered in PD and parkinsonian conditions. Our results provide further insight into the significance of excessive oscillatory activity in PD and its influence on cognitive systems.

Title: Arrangement of multisynaptic inputs from the basal ganglia to the dorsal and ventral premotor cortical areas in macaques: retrograde transneuronal double labeling with fluorescent rabies viral vectors

Authors: *K.-I. INOUE¹, M. FUJIWARA¹, S. UEZONO¹, S. TANABE¹, H. ISHIDA², E. HOSHI², M. TAKADA¹ ¹Primate Res. Institute, Kyoto Univ., Inuyama, Japan; ²Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Transneuronal labeling with neurotropic viruses is a powerful technique for analyzing the architecture of a neural network playing a particular functional role. Among such viruses, the challenge virus standard (CVS) strain of rabies virus (RV) is quite useful, because it is taken up exclusively by axon terminals and moves in the retrograde direction to cross individual synapses in a time-dependent manner. Here, we report a newly-developed RV vector based on the CVS strain of which genome was manipulated to provide the ability to express foreign genes efficiently. We confirmed that this vector retains the infectious property of the parental CVS strain though its propagation rate is slightly decreased and exhibits brilliant labeling of infected neurons. Then, we employed retrograde transneuronal double labeling with RV vectors expressing GFP and RFP to examine the cellular origins of multisynaptic projections from the

basal ganglia to the dorsal and ventral premotor cortical areas (PMd, PMv). These motor-related areas are known to be involved in distinct aspects of motor control, and such functional specializations may be ascribable to differential neuronal connectivities. For elucidating the organization of multisynaptic inputs responsible for forelimb movements, we injected the two RV vectors separately into the forelimb regions of the PMd, and PMv of macaque monkeys, and compared the distribution patterns within the basal ganglia of neurons retrogradely and transsynaptically labeled from the injection sites. We found that the distributions of GFP- and RFP-labeled neurons were generally segregated with only partial overlap. We also observed that there were some neurons double-labeled with the two vectors, which indicates that these neurons simultaneously innervate both the PMd and the PMv by way of axon collaterals in a multisynaptic fashion. The present results indicate that the newly developed fluorescent RV vectors that enable us to perform multicolored retrograde transneuronal tracing provide powerful tool to advance the understanding of the organization of complex neural networks in the primate brain.

Abstract: Neuronal synchrony and coherence are observed throughout neuronal networks, but the significance of these signals is unclear as there are no tools to directly probe them. Here, we used a closed loop control to target an optogenetic manipulation of particular phases of on-going oscillations during interval timing. We calculated the phases of ongoing rhythm by Morlet wavelet transformation. We were able to optogenetically stimulate in < 10ms roundtrip time from on-going LFP to light output. Offline analysis with no phase delay showed that stimulation were targeted accurately smaller than 1 radian standard deviation. We tested these tools in two paradigms. First, we have shown that frontal delta oscillations (1-4 Hz) are critical for interval timing. We stimulated in or out of phase in mice and examined stimulation effects on behavior. Second, striatal beta oscillations (12-25 Hz) are markedly enhanced in movement. We stimulated

basal ganglia nuclein in or out of phase with this oscillation and observed effects on movement. These data could be helpful in developing adaptive, phase-response brain stimulation for many applications.

Title: Striatal D1-medium spiny neurons in levodopa-induced dyskinesias

Authors: *S. L. ALBERICO¹, Y.-C. KIM², N. S. NARAYANAN³ ²Neurol., ¹Univ. of Iowa, Iowa City, IA; ³Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: A major limitation in treating Parkinson's disease (PD) is the development of L-Dopainduced dyskinesias (LID), which are disruptive involuntary movements that lead to a decreased quality of life in PD patients. Prior research demonstrates that mice lacking the D1-dopamine receptor (D1DR) do not develop LID. Here, we investigate the role of D1DRs and D2DRs in LIDs in the striatum of a 6-OHDA PD mouse model. We injected the D1DR antagonist SCH23390 (.1 mg/kg, ip) and the D2DR antagonist sulpiride (1mg/kg) and investigated changes in neuronal activity. We found that administration of SCH23390 and sulpiride modulated striatal activity but only SCH23390 decreased some subtypes of LIDs. We further studied the role of the D1DR in D1-Cre mice by optogenetically inhibiting or stimulating D1DR expressing neurons in the striatum while simultaneously recording striatal activity. We found that stimulating D1neurons drives dyskinesias. These results may elucidate how D1DR expressing neurons in the striatum dysfunction during LID and further the understanding of the mechanism underlying LID.

Title: The effect of alpha-synuclein overexpression on dendritic spines of the prefrontal cortex in a mouse model of Dementia with Lewy Bodies

Authors: *G. M. ALDRIDGE¹, C. S. LALONDE², Q. ZHANG¹, N. S. NARAYANAN² ¹Neurol., Univ. of Iowa, Iowa City, IA; ²Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: Lewy Body dementias, which include Parkinson's disease dementia (PDD) and Dementia with Lewy Bodies (DLB), are characterized by abnormal accumulation of synuclein aggregates in the cortex. Furthermore, overexpression of synuclein in patients with genetic abnormalities is associated with these diseases. It is not known whether synuclein exerts a direct or indirect pathological effect in the prefrontal cortex, where many of the symptoms of these diseases localize. In this study, we utilize an alpha-synuclein overexpression model of Lewy Body Dementias to determine if overexpression of synuclein in the prefrontal cortex alone can alter dendritic spines and neurite anatomy. Dendritic spines are the post-synaptic connections that facilitate communication between neurons, and abnormalities in these structures are associated with most types of dementia. By utilizing an AAV-6 viral vector coding for full length human alpha-synuclein we were able to induce targeted overexpression of this protein bilaterally in the prefrontal cortex of adult mice. After 3 months, the brain was processed either for immunohistochemistry or golgi-cox impregnation for dendritic spine structure. Staining for synuclein revealed overexpression of the protein within medial prefrontal cortex, with a punctate pattern of staining of neurites in this region. Preliminary analysis of dendritic spines in these animals shows a trend towards decreased dendritic spine density in basilar dendrites from layer 2 and 3 pyramidal cells. This finding would be in line with recently published data using transgenic mice and fibrils, which suggests alpha-synuclein overexpression leads to decreased dendritic spine density in cortex (Blumenstock et al., 2017). Our work extends these findings into a viral vector model that allows examination of the local effect of alpha-synuclein overexpression in prefrontal cortex. Further immunochemistry studies will examine colocalization to determine which neurite types (axonal or dendritic) are accumulating alphasynuclein in this model.

Abstract: The subthalamic nucleus (STN) is a key site controlling motor function in humans, and deep-brain stimulation (DBS) of the STN can improve motor function in Parkinson's disease. STN DBS can have cognitive side-effects; however, the reason for this is unclear. Here, we show that in humans the STN is monosynaptically connected with cognitive brain areas such as the prefrontal cortex. We discovered that STN single neurons and field potentials are modulated during cognitive processing, and coherent with 4 Hz prefrontal cognitive control signals. These data predict that low-frequency DBS might compensate for cognitive impairments in PD patients; accordingly, we found that STN DBS at 4 Hz improved cognitive performance. These data provide the first functional evidence of a human hyperdirect pathway in cognitive control.

Title: Frontostriatal ensembles learn during interval timing

Authors: *E. EMMONS, B. DE CORTE, N. NARAYANAN Univ. of Iowa, Iowa City, IA

Abstract: Interval timing refers to temporal processing on the scale of seconds to minutes. The prefrontal cortex and striatum are both critical to adequate interval timing and share a prominent projection. However, the manner in which they shape the neural representation of temporal information is unknown. Here we investigated the dynamics of temporal processing in the medial frontal cortex (MFC) and dorsomedial striatum (DMS) in an interval-timing task in rats. This elementary cognitive task involves working memory and attention. First, we trained rats on an interval-timing task with a 12-second delay (FI12). Following training, animals were implanted with microwire electrode arrays unilaterally in the MFC and DMS. After recovery, animals were retrained on the FI12 interval-timing task. Neural activity was recorded from the MFC and DMS during the FI12 task. The next day, a second interval of 3-second delay (FI3) was added to the task such that trials pseudorandomly alternated between FI12 and FI3 delays. Behavior and neural recordings were assessed over three days of the two-interval timing task. Animals learned the FI3 trial within the first session but improved over each successive day. MFC and DMS recordings revealed that neural changes accompanied the learning of the two-interval task. Single-neuron and single-trial analyses revealed shifting representations of neural activity and behavior. Gradual changes in neural firing rate over time, or "ramping" activity patterns, were found in MFC and DMS neurons during interval-timing behavior. These patterns of "ramping" activity changed as the animals learned the two-interval task. This observation suggests that ramping activity in frontostriatal circuits is fundamentally related to temporal processing. These data demonstrate the importance of frontostriatal circuits in basic cognitive tasks and suggest strategies for further elucidation of cognition.

Title: ORY-2001, a dual LSD1/MAOB inhibitor in development for neurodegenerative diseases, normalizes aggressive behavior in SAMP-8 mice and social avoidance in isolated rats

Authors: D. ROTLLANT¹, M. LUFINO¹, C. MASCARÓ¹, C. GRIÑAN², M. PALLÀS², R. NADAL³, A. ARMARIO⁴, *T. MAES¹

¹R&D, ORYZON GENOMICS S.A., Cornella de Llobregat, Spain; ²Fac. of Pharm. and Food Sci., Univ. of Barcelona, Barcelona, Spain; ³Psychobiology Unit, Sch. of Psychology, Bellaterra, Spain; ⁴Inst. de Neurociències, Univ. Autònoma de Barcelona, Bellaterra, Spain

Abstract: The aging of the population is increasing the incidence of neurodegenerative disease and the corresponding impact on families and on governmental budgets. While cognitive decline is a hallmark of Alzheimer's disease (AD), the behavioral and psychiatric symptoms that often accompany the disease probably pose the heaviest burden on immediate family and caretakers, and ultimately lead to the patients' internalization in special care units. ORY-2001, an orally bioavailable and brain penetrant dual LSD1-MAOB inhibitor in development for the treatment of CNS disease, is currently finalizing a First-in-Human clinical trial to assess safety, tolerability and pharmacokinetics. We previously reported that ORY-2001 restores the cognitive deficit in SAMP-8 mice, a model for accelerated aging and Alzheimer's disease. Preliminary observations revealed that untreated, but not ORY-2001-treated male SAMP-8 mice housed in groups, presented skin lesions initially considered to be a consequence of the accelerated aging phenotype, but ultimately attributed to increased fighting. These early findings induced us to evaluate the effect of ORY-2001 on social behavior. Individually-housed male mice were treated for 5 weeks with vehicle (SAMP-8 and SAMR1) or ORY-2001 at 0.32 or 0.96 mg/kg/d (SAMP-8) from 5 months of age. The effect on behavior was evaluated using the resident intruder (RI) test. Social exploration parameters in the RI test were similar for the SAMP-8 and SAMR1 strain, but clear differences were observed in the aggression parameters. The number of clinch attacks was significantly higher in SAMP-8 than in SAMR1 mice (p<0.01); but reduced to SAMR1 control levels by ORY-2001 treatment at both doses (p<0.001). Gene expression analysis of the prefrontal cortex of stressed versus non stressed vehicle-treated SAMR1 mice and vehicle- or ORY-2001-treated SAMP-8 mice showed that SAMP-8 mice presented a modified stress response capacity that was partially restored by ORY-2001 treatment. ORY-2001 was further studied in the rat isolation rearing model. Isolated adult Sprague Dawly rats were treated at PND61 with vehicle or ORY-2001 (0.16 or 0.48 mg/kg/d) for ~1 month. Isolation did not produce any significant effect on anxiety or locomotor activity tested in the elevated plus maze (EPM). However, social avoidance was greatly increased in isolated rats (p<0.001) in the RI test, and restored to non-isolated rat levels by treatment with ORY-2001 (p<0.05). These data illustrate the potential of ORY-2001 for the treatment of behavior disturbances in a variety of neuropsychiatric disorders in addition to neurodegenerative diseases.

Title: Towards a computational account of theta band (4-8 Hz) power modulation in the subthalamic nucleus under response conflict

Authors: *P. MOOLCHAND¹, S. R. JONES¹, M. J. FRANK² ¹Dept. of Neurosci., Brown Univ., Providence, RI; ²Brown Univ., Brown Inst. for Brain Sci., Providence, RI

Abstract: The Subthalamic Nucleus (STN) plays a fundamental role in arresting automated responses during response conflict. It prevents premature activation of the output of the Basal Ganglia (BG) to buy the Executive Control (EC) system in prefrontal cortex (PFC) time to resolve the conflict and elicit more appropriate behaviors. Experiments in primates have shown that theta band (4-8 Hz) power in the Local Field Potential (LFP) and spike rates in the STN increase commensurate with the level of conflict. Moreover, recent lines of evidence suggest that the STN can act as a conflict detector by integrating competing motor signals to prevent

impulsive responses. Adapting prior cellular models of STN and Globus Pallidus externus (GPe), we have built a novel large-scale biophysically constrained and reciprocally coupled subthalamopallidal (STN-GPe) network. We perturb the network with simulated cortical signals representing competing motor actions to understand the electrophysiological basis of the STN signal modulations and how cortico-STN topography impact these computations. Our results show a balance between intrinsic behaviors of the STN-GPe network and specific patterns of cortical drive is necessary for theta band expression in the network. We conjecture that theta dependent increased spiking in the STN network is the key component for "braking" unwanted impulsive responses.

Title: Distribution and morphology of transplanted human neural stem cells in rats with penetrating ballistic-like brain injury

Authors: *S. GAJAVELLI¹, S. W. LEE¹, M. S. SPURLOCK¹, Z. HU¹, K. N. RIVERA¹, L. QUESADA¹, *G. R. GAJAVELLI¹, *C. J. ALVAREZ¹, A. MAHAVADI², D. A. SHEAR³, T. G. HAZEL⁴, R. M. BULLOCK¹

¹Miami Proj Cure Paral, Univ. Miami, Miami, FL; ²Neurosurg., Univ. of Miami, Miami, FL; ³Walter Reed Army Inst. of Res., Silver Spring, MD; ⁴Neuralstem, Inc, Germantown, MD

Abstract: Severe penetrating traumatic brain injury (PTBI) is associated with the worst outcomes in terms of high mortality and severe disability among survivors. Loss of cells combined with incomplete endogenous repair mechanisms may be an underlying cause of disability. Currently no treatment strategies are available. Using a fetal human neural stem cell line (hNSC; Neuralstem Inc.) that has been approved by FDA for use in clinical trials we have previously shown durable engraftment in a rat model of penetrating ballistic-like brain injury (PBBI). However, the best transplant location to rebuild lost circuitry is unknown. Here we describe follow-on studies wherein cells were transplanted either in the lesion core or in the penumbra in PBBI animals. 12 weeks post-transplantation we assessed graft survival and lesion volume by histology.

PBBI was induced in anesthetized rats. At one-week post-PBBI, immuno-suppressed rats

Support: Support: Funded by The Department of Defense W81XWH-16-2-0008, BA150111 CDMRP JPC-6.

received stereotactic injections of green fluorescent protein (GFP) expressing hNSCs (1 million/rat) into the lesion core (Intralesional; n=10) or lesion penumbra (Perilesional; n=10). An additional group of uninjured rats received hNSC transplant as controls (n=10). 12 weeks post-transplant brain sections were stained to assess (1) axonal damage, (2) lesion volume, and (3) distribution of transplant-derived projections.

Results of lesion volume measurements at 12-weeks post-transplantation revealed significant reductions in lesion volume following both perilesional and intralesional engraftment of hNSCs (p < .05 vs. PBBI+Vehicle). PBBI-injured animals that received perilesional hNSC engraftments showed a significant reduction in lesion volume compared to animals that received intralesional hNSC transplants. Silver staining revealed significant damage to the intratelenchephalic and corticostriatal white matter. GFP+ hNSC survival was significantly greater in PBBI animals compared to Sham animals. However, no differences in hNSC transplant survival were detected between groups. The transplant derived projections traversed corticofugal subcerebellar pathways akin to layer 5 cortical neurons.

These results suggest the PBBI milieu at one-week post injury supports hNSC engraftment independent of transplant location. Integration of transplanted hNSCs into the host may provide therapeutic benefit by salvaging endogenous tissue destined for secondary damage. The distribution of the transplant derived projections in the corticofugal subcerebellar motor pathway suggests a potential role for graft-derived cells in amelioration of motor deficits.

Title: Primary motor cortex modulation during reactive and proactive response inhibition

Authors: *W. D. BYBLOW^{1,2}, M. J. COWIE¹, J. CIRILLO^{1,2}, H. J. MACDONALD³ ¹Dept. of Exercise Sci., ²Ctr. for Brain Res., Univ. of Auckland, Auckland, New Zealand; ³Sport, Exercise and Rehabil. Sci., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: A central component of effective motor control is the ability to cancel a pre-planned movement, termed response inhibition. When stopping is unexpected, response inhibition is reactive and associated with a non-selectively reduction in motor excitability. If stopping is forewarned, response inhibition can be proactive and excitability may be selectively decreased. The modulation of GABA-ergic inhibitory networks within the primary motor cortex during

proactive versus reactive response inhibition is unclear. The present study investigated the modulation of long and short-interval intracortical inhibition using paired-pulse TMS in eighteen right-handed participants performing reactive and proactive response inhibition tasks. Measures of long and short latency intracortical inhibition (LICI and SICI respectively) were obtained from motor evoked potentials in task-relevant and task-irrelevant intrinsic hand muscles. When only a subcomponent of the response required stopping the remaining response was delayed, with the extent of delay greater in reactive versus proactively cued trials. LICI was reduced in both muscles during all types of response inhibition task compared with pre-task baseline. Additionally, on reactive trials task-relevant LICI positively correlated with behavioral response times of the right hand when responses were inhibited on the left side. Task-relevant SICI was reduced when proactive cues indicated responding was highly likely but was unchanged when response conditions were uncertain. These novel findings indicate that GABA_B receptor mediated pathways may be involved in setting inhibitory tone according to task expectations whereas GABA_A receptor mediated pathways may be recruited proactively with response certainty.

Title: Modulation of putative dopamine neuron firing in rat ventral tegmental area during performance of a stop-change task

Authors: *S. TENNYSON¹, D. BRYDEN², N. WOYTOWITZ¹, N. HRICZ¹, M. R. ROESCH³ ¹Univ. of Maryland, College Park, MD; ²Univ. of Maryland Col. Park, College Park, MD; ³Univ. of Maryland at Col. Park, College Park, MD

Abstract: Inhibiting unwanted actions is essential for decision-making and executive control. Attention disorders such as addiction, attention deficit hyperactivity disorder (ADHD), schizophrenia, and obsessive-compulsive disorder (OCD), are marked by an inability to control inappropriate behaviors. The midbrain dopamine system plays a critical role in controlling behavioral impulses and encoding the value of reward. Numerous lines of evidence demonstrate that dopamine (DA) firing is modulated by reward, shown by an increase in firing to unexpected reward and a decrease in firing to reward omission. However, very little is known about how the

activity of single DA neurons are modulated by tasks that require response inhibition and induce response conflict when two opposing behaviors compete with one another. To answer this question, we recorded single neuron activity in the rat ventral tegmental area (VTA) while subjects performed a stop signal reward task. In this task, rats are trained to respond to a 'GO' cue on 80% of the trials. On 20% of the trials, rats are given an unexpected 'STOP' cue, where they must inhibit the ongoing GO response and respond in the opposite direction. Putative DA neurons were isolated based on waveform characteristics and analyzed using peri event time histograms. Data suggests that DA neurons exhibit similar firing on correct STOP and GO trials during cues and responses. However, DA firing was reduced after the STOP cue on error trials, prior to completion of the behavioral response. Further, firing to reward was slightly stronger during reward delivery on correct STOP trials compared to GO trials, possibly reflecting the uncertainty with obtaining reward on STOP trials. Together, these results suggest that DA neurons are not modulated during successful response inhibition when two responses are in competition with each other. In the context of this task, DA likely encodes the predicted value of cues that predict reward and missed reward during correct and incorrect trials, as well as the uncertainty of receiving reward on difficult trials.

Title: Clonidine mildly reduces impulsive behavior at sub-sedating doses that also impair sustained attention in male rats

Authors: *P. J. MCLAUGHLIN, M. C. NORMANN, J. E. JAGIELO-MILLER, T. M. PROPER, R. M. HARDY Dept. of Psychology, Edinboro Univ. of Pennsylvania, Edinboro, PA

Abstract: Clonidine is a nonselective noradrenergic $\alpha 2$ agonist that is approved as a nonstimulant therapy for Attention Deficit Hyperactivity Disorder (ADHD). Relative to psychostimulants, it is less efficacious in treating attention symptoms, and has even been found to reduce accuracy in preclinical models of attention. These counterintuitive findings may be better understood with a fuller investigation into the different behavioral processes that may be involved in clonidine's effects. It was therefore proposed that clonidine would ameliorate impulsive behavior, and impair sustained attention, in two models of different types of ADHD symptoms. Adult male Sprague Dawley rats were trained on a variable consecutive number task

with a discriminative stimulus (VCN-S_D), which requires a chain of paced responses on one lever, until a stimulus tone signals the availability of reinforcement following a response on a second lever. Premature responding on the second lever results in a timeout and reset of the count. A different group of animals performed a fixed-lever, variable ratio 15 (VR15) auditory signal detection task incorporating features of human sustained attention assessments, including minimal feedback, and infrequent, unpredictable signals, relative to frequent irrelevant stimuli. At up to 0.03 mg/kg, clonidine modestly improved percentage of completed chains in the VCN-S_D model of impulsivity. As a positive control, the 5HT_{1A} agonist 8-OH-DPAT produced stronger, biphasic effects: more impulsive behavior at a low dose, followed by less impulsivity at higher doses, relative to vehicle control. In the sustained attention task, clonidine dosedependently impaired sensitivity (d'), without altering bias (c), replicating previous findings. However, when comparing only the first lever press of each trial, clonidine reduced bias, and overall, reduced no-signal lever responding to a greater degree than signal lever responding. Doses of clonidine used in these tasks were just below those that significantly altered observational ratings of sedation. It is concluded that clonidine may have clinical efficacy in ADHD more via reductions in impulsivity than via direct enhancement of attention. Impairments on the attention task appear to have been mitigated somewhat by a slight reduction in bias; we speculate that this may have been due to motor slowing reducing behavioral momentum, an effect not seen in the impulsivity assay.

Title: Involvement of hippocampal, orbitofrontal and subthalamic oscillations in behavioural inhibition in the stop signal task in rats

Authors: *A. BANSTOLA, C. K. YOUNG, N. MCNAUGHTON Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: Rhythmicity allows communication between distributed brain regions to occur in a specific frequency band, potentially binding structures into a functional circuit. Local field potential (LFP) oscillations represent synchronous activity of thousands of neurons and so can assess circuit involvement in behavioural and cognitive functions. Frontal-subthalamic and

frontal-hippocampal circuits have been separately implicated in behavioural inhibition; but their possible interactions have not been assessed. We implanted four adult Long-Evans rats to record LFPs simultaneously from the hippocampus (HPC), orbitofrontal cortex (OFC) and subthalamic nucleus (STN) during a Stop Signal Task (SST). We found increase of beta band coherence across all recording areas when rats inhibit their responses, with correct stopping associated with lower (~20 Hz) beta frequencies compared to failed stopping (~30 Hz). In addition, we observe a decrease in theta and alpha coherence between the HPC and OFC following failed stopping, which coincide with an increase of theta and alpha coherence between the OFC and STN. These observations support the notion that the HPC also receives pro-stopping signals through beta oscillations communicated between OFC and STN. We speculate changes in theta/alpha coherence across the structures may be involved in error-monitoring processes.

Title: A cross-species neurophysiological assay of cognitive control: Development of a touchscreen-based rodent analog of the Flanker Task

Authors: *M. A. ROBBLE¹, S. NICKELS², L. WOOLDRIDGE², S. PERLO², E. CÁRDENAS², B. KANGAS², J. BERGMAN², W. A. CARLEZON, Jr², D. A. PIZZAGALLI² ¹Behavioral Genet. Lab., McLean Hospital, Harvard Univ. Med. Sch., Somerville, MA; ²McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: Deficits in cognitive function, such as reward sensitivity and cognitive control, are a common feature of virtually all neuropsychiatric disorders. While perturbations in cognitive control have been studied extensively in humans, it has been more challenging to examine these complex processes in model organisms. Stagnation in the development of animal-based tasks to assess these processes has coincided with a decline in the development of effective therapeutics for neuropsychiatric disorders. As part of a larger effort to create reliable and valid cross-species assays of cognitive function, we have begun developing a rodent version of the Eriksen Flanker Task to assess cognitive control.

Using fading and correction procedures combined with touchscreen-based response technology, Sprague Dawley rats were trained to discriminate between several distinct pairs of visual stimuli. These stimuli included arrows (</>) and letters (H/S), as well as colored stripes and more detailed pictures (cherries/leaf). While rats did not meet the required criteria of 80% response accuracy for arrow or letter stimuli, successful discrimination was observed using the red/green stripes and cherry/leaf pictures.

Following training, rats were presented with flanker probe trials. Intriguingly, when increasing the number of flanked trials in a session from initially 20% to 100%, performance remained high and the Flanker interference effect of lower reduced accuracy for incongruent stimuli was confirmed. Notably, a response bias on incongruent trial types was observed in which performance on trials with a red target was reduced, regardless of stimulus type. Presently, efforts are underway to reduce this bias by altering the intensity of the green stimulus in each condition. In addition, other color schemes that may be more advantageous for visual discrimination in the rat are also being tested. Following these design modifications, EEG data will be collected during the rodent Flanker Task and the relevant ERPs will be compared to those observed in human studies.

In parallel, 45 EEG data sets were collected from human subjects using the cherry/leaf stimuli and the more traditional arrow stimuli. Relevant outcome measures such as the N200 component, theta power, and the error-related negativity (ERN) were comparable across stimuli, raising confidence that the stimuli ultimately found suitable for rodents will also be appropriate for studies in humans. Cross-species behavioral and neurophysiological correspondence will serve to validate the rodent task and provide the predictive power to screen potential therapeutics for numerous neuropsychiatric conditions.

Title: Neuronal correlates of motivated inhibition in monkey motor cortices

Authors: *M. GIAMUNDO^{1,2}, F. GIARROCCO¹, E. BRUNAMONTI¹, M. MATTIA³, P. PANI¹, S. FERRAINA¹

¹Dept. of Physiol. and Pharmacol., Sapienza Univ., Roma, Italy; ²'PhD Program in Behavioral Neuroscience, Sapienza Univ. of Rome, Rome, Italy; ³Inst. Superiore Sanità, Roma, Italy

Abstract: The ability to rapidly inhibit actions is critical to the effective and flexible interactions with the environment, and it has been widely studied by using the countermanding (stop-signal) task. An open question is how this ability can be affected by other cognitive functions, such as

motivation, and relatedly, which are the neural correlates of this influence. To address this question we designed a combined countermanding/motivation task intended to modulate the motivation to stop and to move by using the reward prospect, and we recorded the Multi-Unit Activity (MUA) by means of Utah arrays (2x48 channels) from the dorsal premotor cortex (PMd) and the primary motor cortex (M1) of a macaque monkey while engaged in the task. Indeed previous data have shown that motor cortices neuronal activity signals both movement inhibition (Mattia et al., 2013) and reward (Roesch and Olson, 2004), but it is unclear whether and how these phenomena are combined.

In the countermanding/motivation task, the monkey was instructed to reach to a target after a go signal (no-stop trials) but to withhold his response when a stop-signal followed after a variable delay (stop trials). In every trial, one out of three possible reward cues (RC) was presented 1 sec before the go signal to inform about the amount of reward that would have been delivered if a correct response had been produced. RC conditions were: Go+Stop- with a higher reward for nostop trials compared to the stop trials; Go-Stop+, with reversed reward amounts; and Go Stop with equal amounts delivered. We found that the monkey strategically adapted his behavior to the different reward prospects: reaction times (RTs) diminished and the probability of errors in the stop trials increased from Go-Stop+, to Go Stop and then to Go+Stop- conditions.Recorded MUA in both PMd and M1 was modulated by task conditions. In some channels (22/96), MUA was significantly modulated before go signal by the RC value. Of these channels, 41% showed a progressive increase of MUA after the RC presentation until movement onset; this activity was progressively higher for Go-Stop+, Go Stop and Go+Stop-. Fifty-five percent showed a decrease during the RT epoch and a further increase of MUA just before or after movement onset. Others channels (48/96) showed RC related modulations around movement onset and/or after reaching the final target but not before go signal. Interestingly, in correct stop trials, some of the channels showed an early stop-signal response which magnitude was affected by the RC value. These results suggest that motor cortices can signal and integrate motivational aspects into movement control and inhibition.

Title: Study of global and selective inhibition of upper and lower limb by a stop signal task

Authors: *E. BRUNAMONTI, P. DE SIMONE, M. PAOLONI, P. PANI, S. FERRAINA Sapienza Univ., Rome, Italy

Abstract: The stop signal task and the related horse race model have been widely used to study the processes underlying motor inhibition of the eyes and of several segments of the upper limb (finger, wrist or arm), while it is poorly investigated whether and how comparable principals account for inhibition of the lower limb segments. Indeed, we count on the control of lower limbs to accomplish many of our daily actions. In addition, we usually engage a complex coordination between the upper and lower limbs that often requires the selective inhibition of only one of the effectors. For example, during driving, one can be required to suppress the command on the gas pedal but to keep acting on the wheel to avoid an obstacle that suddenly appears on the road. In the present work, we used different variants of the stop signal task, presented in experimental contexts of different complexity, to study the inhibition of lower limbs and its mutual interaction with the inhibition of the upper limbs, during actions in which their movement is associated. Specifically, we investigated: 1) whether the inhibition of the foot fitted the predictions of the race model, as described for other motor effectors; 2) whether these predictions were kept, when it was required either a selective or a combined inhibition of the two effectors; 3) if the complexity of the context influenced the selective inhibition of each of the two different effectors. Ten participants were tested in separate blocks in a conditional stop signal task requiring always to lift both their index finger and their foot in response to a go signal (70% of trials), but to suppress the movement of both (global inhibitory block), or only one of the two effectors (either foot or finger selective inhibitory block), when a conditional stop signal was unpredictably presented in 30% of the trials. In an additional block, all the inhibitory conditions were randomly presented (and the effector cue instructed) to test whether the occurrence of an unpredictable stopping condition affected inhibition. Our results revealed that the race model correctly accounted for the selective inhibitory performance of both effectors, when tested in the unmixed conditions, but that it failed its predictions, when the selective inhibition of the effectors was required in the more complex mixed block condition. On the contrary, inhibition in global condition accomplished the model predictions in the mixed block and was significantly more efficient than in selective conditions. The present results are in line with the hypothesis that when the selective inhibitory system is engaged in a complex context the go process interferes with the efficiency of the stop process.

Title: Premotor neuronal correlates of voluntary limb movement initiation

Authors: *P. PANI, F. GIARROCCO, M. GIAMUNDO, E. BRUNAMONTI, S. FERRAINA Sapienza Rome Univ., Roma, Italy

Abstract: In reaction time tasks, when a signal instructing to move (Go) is presented the movement is generated after a variable latency (reaction time; RT). Typically the RT varies across trials with identical instruction conditions, and this variability has been explained within the general framework of accumulator models. These models posit that the movement occurs after a signal, that represents the evidence for the type of movement to perform, has accumulated to a response threshold. These models can account for RT variability in terms of four basic parameters: starting point (initial state of the accumulating signal); encoding time (time necessary to perform sensory and perceptual processing before evidence starts to accumulate); drift rate (mean rate of evidence accumulation), and threshold (level of accumulation). The variability of each of these parameters can explain the RT variability. For example, in the variable threshold account, RT will be shorter when the threshold is lower and longer when the threshold is higher. Neurophysiological studies have linked the evidence accumulation to the dynamic of firing rates of single cortical neurons recorded while monkeys were performing RT tasks. The above parameters have been translated respectively into the mean level of activity before Go (starting point); into initial rising of neural activity after Go signal (the encoding time); into slope of neural activity growth (the drift rate); and, finally, into the level of activity just before movement generation (threshold). This approach has been useful in finding that saccades are initiated when in frontal eye fields (FEF) movement neurons reached a fixed threshold and that the saccadic RT variability is due to a variable drift rate across trials (Hanes and Schall 1996). By using a similar approach we studied single neurons recorded from the dorsal premotor cortex (PMd) while 3 monkeys performed a countermanding task, that required in most trials reaching movement towards peripheral targets, and in some of the trials in try to refrain from moving after a stop signal. This task is able to generate wide RT distributions. We found that in PMd different neural dynamics, and thus different accumulator accounts, are at play when analyzing single unit activity. After the Go signal, we found that different subsets of neurons showed different profiles, i.e. different accumulator instantiations, thus corroborating the idea that RT variability cannot be explained exclusively by a single neural dynamic. Indeed RT variability correlates with different features at the same time, thus showing that in PMd movement initiation is related to diverse dynamic contributions from single neurons

Title: The nigrostriatal dopamine pathway transmits a stop signal during the performance of a saccadic countermanding task in monkeys

Authors: *T. OGASAWARA^{1,3}, M. TAKADA³, M. MATSUMOTO^{2,1}

¹Grad. school of Comprehensive Human Sci., ²Fac. of Med., Univ. of Tsukuba, Tsukuba-Shi, Japan; ³Primate Res. Institute, Kyoto Univ., Inuyama, Aichi, Japan

Abstract: Response inhibition is the ability to withhold planned or ongoing motor actions that would lead to unwanted outcomes. Although previous studies have shown that the prefrontal cortex plays a crucial role in response inhibition, the basal ganglia might also contribute to this ability because they form loop circuits with the prefrontal cortex that regulate body movements not only in a facilitative but also in a suppressive manner. To investigate whether and how the nigrostriatal dopamine pathway, an important component of the basal ganglia circuitry, might contribute to response inhibition, we recorded single-unit activity from projection neurons in the caudate nucleus and dopamine neurons in the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA) in monkeys performing a saccadic countermanding task. While the monkey was gazing a central fixation point, the point disappeared and a saccadic target was presented on the right or left side of the point. In 70% of the trials, the monkey was required to make a saccade to the target. In the remaining 30%, the fixation point reappeared as a "stop signal" with a random delay after the onset of the target. The monkey was then required to cancel a planned saccade to the target. We recorded the activity of 200 striatal projection neurons, and found that 59 of the neurons showed a significant excitation to the stop signal while 72 of them exhibited a significant inhibition. We further recorded the activity of 70 dopamine neurons, and found that 28 of the neurons showed a significant excitation to the stop signal whereas no neurons displayed a significant inhibition. Notably, the dopamine neurons excited by the stop signal were observed mainly in the SNc, but not in the VTA, that send massive projections to the caudate nucleus. These results suggest that dopamine neurons in the SNc transmit a signal that could inhibit saccadic eye movements to the caudate nucleus. To test the causal relationship between the capacity of response inhibition and nigrostriatal dopamine signaling, we injected SCH23390, a dopamine D1 receptor antagonist, or haloperidol, a dopamine D2 receptor antagonist, into the caudate nucleus. We found that the monkey often failed to cancel a saccade not only after the SCH23390 but also after the haloperidol injection. The overall data indicate

that the nigrostriatal dopamine pathway plays an important role in suppressing a planned saccade in the saccadic countermanding paradigm.

Title: Insular cortex activity is implicated in appetitive inhibitory conditioning

Authors: *K. R. LIGHT¹, Z. TEK¹, R. BOWLER², V. WINIGER², A. WANAR¹, B. COTTEN¹, M. R. BAILEY², A. KALMBACH¹, E. H. SIMPSON², P. D. BALSAM¹ ¹Barnard Col., New York, NY; ²Columbia Univ., New York, NY

Abstract: While a great deal is understood about the mechanisms involved in excitatory conditioning both for aversive and appetitive stimuli, far less is known about the neural underpinnings of inhibitory conditioning. Inhibitory conditioning is the process of learning to inhibit a behavior when a signal is presented that indicates that behavior will not produce a previously expected outcome. Rodent research on inhibitory conditioning has suggested a possible involvement of the prelimbic (PL), and infralimbic (IL) subregions of the medial prefrontal cortex (mPFC) as well as the insular cortex. In two parallel experiments we investigated the neural activity in PL, IL, and insular cortex related to conditioned inhibition and tested the functional requirement of PL and IL in appetitive inhibitory learning. To examine the neural activity related to conditioned inhibition, we measured *c-fos* immunoreactivity during initial learning (after 3 days of training) and when learning was asymptotic (after 15 days of training). Behavior and neural activity specific to inhibitory learning about a tone that signaled the non-availability of reward was identified by comparing inhibitory learning groups to control groups in which tones had no consistent relationship to reward or non-reward. One control group received an equivalent number of tone and reward presentations and one received an equivalent rate of tone and reward presentations. Analysis of behavior showed clear inhibitory learning in only the inhibition group. Further, the inhibitory learning group demonstrated far more inhibition on Day 15 than Day 3. Neural activity of the insular cortex as measured by *c-fos* expression did not differ between groups on Day 3 but by day 15 it was significantly elevated in the inhibitory training group relative to controls. Further, *c-fos* expression was significantly higher on Day 15 than Day 3 in the conditioned inhibition group. No significant differences in neural activity were observed in PL or IL at either time point. The results of the neural activity experiment suggest

that the insular cortex is involved in the learning and/or performance of inhibitory learning. In a parallel experiment, we explored the functional role of the PL and IL in appetitive inhibitory conditioning. Specifically, we selectively inactivated these structures with the inhibitory DREADD hM4Di and injected CNO before each daily training session.

Neither inactivation of PL or IL affected the acquisition of inhibitory learning. Together, these data suggest that the circuit required for inhibitory learning in our appetitive conditioning task includes the insular but not medial prefrontal cortex.

Title: Two forms of circadian disruption impact response inhibition and attention in adult longevans rats

Authors: *R. C. BALACHANDRAN¹, M. L. SIEG², K. M. HATCHER², M. M. MAHONEY¹, P. A. EUBIG¹

¹Comparative Biosci., Univ. of Illinois At Urbana Champaign, Urbana, IL; ²Neurosci. Program, Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: Circadian rhythms, which are endogenous rhythms that synchronize behavior and physiology, can be disrupted by external factors, such as alterations in the ambient light cycle. Common forms of circadian disruption in human populations include working outside of the regular hours of '9 to 5' (shift work) or untimely exposure to light at night (artificial light-at-night). We are studying the effects of two models of circadian disruption on attention and response inhibition using a 5-choice serial reaction time task (5- CSRTT). Adult Long-Evans rats of both sexes were maintained on a 12h:12h light:dark cycle and tested under three circadian conditions: 4h into the dark phase with no exposure to a pulse of light for 1h at the time of testing (a model of light-at-night), and 4h into the light phase (a model of shift work). We hypothesized that rats tested under the two models of circadian disruption would be less attentive

and have reduced response inhibition (i.e., be more impulsive) than controls. Our preliminary results reveal that rats tested under both circadian disruption conditions were equally less attentive (had a reduced percent accuracy in responding to visual cues) than control rats. Furthermore, there was a differential effect of circadian disruption on response inhibition. Darkphase tested rats that experienced a pulse of light had significantly greater premature responding on 5-CSRTT than light-phase tested rats, and both groups were significantly more impulsive compared to control rats. Sex-related differences in behavior were not detected. To summarize, our findings demonstrate that different forms of circadian disruption can affect attention and differentially affect response inhibition, the latter being an effect not previously reported. While acetylcholine (ACh) is an important modulator of circadian rhythms and attention, dopamine is a key modulator of response inhibition. Thus, as we begin to investigate underlying mechanisms responsible for our findings, we hypothesize that an interaction between ACh and dopamine systems is important in the relationship between circadian rhythmicity and cognitive functions such as attention and response inhibition, particularly in the prefrontal cortex, where nicotinic ACh receptors (nAChRs) modulate dopamine release. We will also present early results from pharmacologic challenges examining the response to combinations of ACh and dopamine agonists and antagonists on 5-CSRTT performance as we proceed to examine the hypothesized ACh-dopamine interaction.

Title: Microcircuitry of agranular frontal cortex: Laminar organization of saccade performance monitoring signals in supplementary eye field

Authors: *A. SAJAD, J. D. SCHALL Psychological Sci., Vanderbilt Univ., Nashville, TN

Abstract: To effectively interact with the environment, it is essential to monitor the consequences of our visually guided behavior and make appropriate adjustments. Despite much

investigation on this topic the mesoscopic circuit mechanisms accomplishing these processes remain poorly understood. To investigate this, we sampled neural activity from primate supplementary eye field (SEF), an agranular cortical area that contains neural signals related to error and reinforcement, using linear electrode arrays. During recordings monkeys performed a countermanding saccade paradigm where on~50% of trials they made saccadic eye movement towards a visual stimulus (correct; rewarded) but on a proportion of trials (~25%) made erroneous saccades despite an instruction to stop (error; unrewarded). After a short delay following the saccade an auditory tone was presented which indicated the absence or presence of an upcoming juice reward. Spiking activity (N = 293 units), field potentials, and current source density from 16 sessions with perpendicular electrode penetrations into the gray matter (three sites in two monkeys) were analyzed to determine the laminar structure of three signal types: visual, error, and reinforcement. Our analyses revealed that task-related visual signals were largely confined to L2/3 and L5. Error signals had the shortest latency in intermediate layers (lower L3 and upper L5) with a later appearance in upper (L2/3) and lower layers (L6). Reinforcement-related signals were observed throughout cortical depth but exhibited different spatial profile during different task epochs. Entirely predictive units (modulated following the tone but before juice) were mainly concentrated in depths spanning lower L3 to L6b while those that also modulated following juice delivery were mainly observed in upper layers L2/3 and L5. Furthermore, reinforcement units that were positively modulated for reward (L5 and upper L6) showed a complementary (and inverse) distribution to those that were negatively modulated (L2/3 and lower L6). Overall, these data are inconsistent with a general canonical cortical microcircuit derived from sensory areas, and they contribute to understanding the contributions of laminar-specific cortical and subcortical as well as feedforward and feedback processes, and to constraining circuit-level models of executive control.

Title: Dynamic striatal and medial temporal lobe interactions are mediated by varying demands on pattern separation

Authors: *A. FRITHSEN¹, S. M. STARK³, S. NIKOLOVA⁴, C. E. STARK² ¹Neurobio. & Behavior, Univ. of California Irvine, Orange, CA; ²Univ. of California Irvine, Irvine, CA; ³Neurobio. & Behavior, ⁴Univ. of California, Irvine, Irvine, CA

Abstract: Our theoretical framework for understanding striatal responses and striatal-medial temporal lobe (MTL) interactions during conditional motor associative learning is that motor learning proceeds in a gradual transition between two parallel but cooperative phases within the striatum. In the early, more flexible phase, spatial sequences are coded in visuospatial coordinates that is subserved by a cortical-striatal loop involving the associative striatum. The MTL constitutes a parallel and cooperative learning pathway for conditional motor associative learning that is primarily involved in the "flexible" early phase of learning and specializes in learning new associations between arbitrary elements in memory. This framework predicts that early in new associative learning the striatum together with the MTL provide different kinds of parallel and cooperative learning signals: we predict the strongest interaction in the form of coordinated activity and strong functional correlations will be seen between the MTL and both the limbic striatum and the associative striatum. In contrast, we predict little or no interaction between the MTL and the sensorimotor divisions of the striatum. Young adults performed an associative learning task using kaleidoscopic images in two conditions: 1) images with high perceptual similarity and 2) images with low perceptual similarity. Participants learned to associate an arbitrary response pairing with each image, resulting in a continuous probability correct measure across learning: a learning slope that reflects memory strength. We found robust hippocampal and nucleus accumbens (a core part of the striatum) activity that varied across memory strength, regardless of high vs. low similarity. In order to evaluate the functional relationship between the hippocampus and MTL with the limbic, associative, and sensorimotor striatal systems, we performed a seed-based functional connectivity analysis in both the low and high similarity conditions. Interestingly, we found that functional connectivity between the hippocampus and MTL with the associative striatal system was modulated by high vs low similarity, bilaterally. These data suggest that the interactions between memory systems are very dynamic and may reflect competition between memory systems, which may be exacerbated when pattern separation demands are high.

Title: Dynamics of sharp wave/ripple-triggered cortical and subcortical high frequency local field potential in humans

Authors: *I. SKELIN^{1,2}, J. ZHENG³, B. L. MCNAUGHTON^{1,2}, J. J. LIN⁴ ¹Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; ²Neurobio. and Behavior, ³Biomed. Engin., ⁴Neurol., Univ. of California Irvine, Irvine, CA

Abstract: Sharp wave/ripples (SWRs) are brief high frequency events (<100 msec; 80-150 Hz in humans), occurring in hippocampus during non-REM sleep and quiet wakefulness. SWRs are considered to represent the temporal windows for efficient hippocampal-cortical communication during memory reactivation, potentially orchestrating activity of anatomically disparate brain structures, which store different aspects of recent and consolidated memory. Therefore, information on the dynamics of SWR-triggered activity throughout the human brain would improve understanding of the role of SWRs in memory consolidation. Functional magnetic resonance imaging (fMRI) revealed SWR-triggered increases in hemodynamic signal throughout cortex (Logothetis et al., 2012). The patterns of SWR-triggered cortical hemodynamic responses also depend on the SWR waveform signature and phase coupling to hippocampal delta or sharp waves (Ramirez-Villegas et al., 2015). However, the more precise interpretation of these results was hampered by the relatively slow temporal resolution of fMRI. The high frequency (300-900 Hz) local field potential (HF-LFP) represents a reliable indirect measure of neuronal spiking activity (Wilber, Skelin et al., unpublished). Taking advantage of excellent spatiotemporal resolution of electrophysiological recordings, as well as the ability to simultaneously record from large number of subcortical and cortical structures in human epileptic patients undergoing presurgical evaluation, we recorded hippocampal SWRs and SWR-triggered HF-LFP in the amygdala, frontal, cingulate, temporal and parietal cortices from 4 patients, during 8 overnight sleep sessions. The HF-LFP power in amygdala, temporal and parietal cortices was increased around the time of SWRs, with the ipsilateral increases present both before and after SWRs and contralateral increases following SWRs. We also observe delta-phase dependent SWR-triggered effects on HF-LFP power in cingulate cortex. In addition, we observed that the relative proportions of SWRs locked to different delta or sharp wave phases are stable across multiple days, but differ between the hippocampal locations. The present data reveals hemispheric differences in SWR-triggered cortical activity, as well as hippocampal location-dependent patterns of SWR phase locking to delta or sharp waves.

Title: Interaction between the hippocampus and neocortical regions during associative memory formation: An fMRI study

Authors: *T. ISHII, T. ASO, K. NAKAMURA

Human Brain Res. Center, Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan

Abstract: The case report of patient H.M. and a series of subsequent works have revealed that the medial temporal robe (MTL) including hippocampus is critical for forming memory. Meanwhile, many animal studies have uncovered that memory trace is stored in cortical regions which are responsible for processing specific information. However, how the MTL and each cortex interact to form new memory remains to be elucidated especially in human. We aimed to investigate interaction between the MTL and cortical regions during associative memory formation in human using fMRI (functional magnetic resonance imaging). We scanned thirteen healthy participants with a 3 tesla MRI scanner while they performed a face-name association task. During encoding blocks, participants viewed serially presented unknown faces which were paired with names. They were instructed to commit pairs to memory. In recall blocks, participants viewed the faces only and attempted to answer the associated names. To prevent rote rehearsal between encoding and recall blocks, we used the Odd/Even Digit task in which participants were shown single digits and asked to indicate whether the digit was odd or even. We performed PPI (psycho-physiological interaction) analysis to see the effect of memory formation process on the functional connectivity between the MTL and related cortices. The result showed that functional connectivity between the hippocampus and fusiform gyrus, which is thought to be specialized for the perception of faces, was enhanced during both encoding and recall sessions although activation of the hippocampus decreased with repetition of the same pair. The present result lend support to the view that the hippocampus and neocortical regions which engage in processing specific information interact dynamically and wire together to form new associative memory.

Title: Resting-state medial temporal connectivity with reward centers predicts how motivation impacts learning

Authors: *L. FRANK¹, A. R. PRESTON³, D. ZEITHAMOVA² ¹Psychology Dept., ²Univ. of Oregon, Eugene, OR; ³The Univ. of Texas At Austin, Austin, TX

Abstract: Memory is influenced by motivation, such as a promise of future monetary reward for remembering an event. Reward-based memory modulation has been shown to rely on interactions between brain structures sensitive to reward, such as the midbrain, and those supporting episodic memory, such as the medial temporal lobe (MTL), during motivated encoding. Here, we tested whether intrinsic connectivity between the memory-related (MTL) and reward-related (midbrain, striatum, orbitofrontal cortex) regions during rest can predict reward modulation and if these connections increase as a function of motivated encoding. Subjects underwent resting-state functional MRI before and after a monetary incentive encoding task in which a potential monetary reward cue (penny, dime, or dollar) was followed by a pair of objects to be remembered. The associated monetary value was awarded to the subject for each correctly recalled object pair. Resting-state fMRI revealed that MTL connectivity with reward regions significantly increased from pre- to post-learning, specifically driven by MTL-midbrain and hippocampus-striatum connectivity. These findings suggest that interactions between reward and memory systems can be upregulated in response to a motivated encoding task. Intrinsic connectivity further tracked individual differences in reward modulation, such that subjects who demonstrated greater sensitivity to reward also showed significantly greater intrinsic MTLorbitofrontal connectivity when collapsed across the pre- and post-learning scans. These results suggest that intrinsic connectivity between reward- and memory-related regions underlies individual differences in reward modulation and highlight the dynamic interactions between these systems that extend beyond the period of learning.

Title: Changes in memory representations are related to features in prior night's sleep

Authors: *E. COWAN¹, A. A. LIU², S. KOTHARE², O. DEVINSKY², L. DAVACHI³ ¹Ctr. For Neural Science/ New York Univ., New York, NY; ²New York Univ. Sch. of Med., New York, NY; ³Dept Psychology, NYU, New York, NY

Abstract: Theories of systems memory consolidation posit that memories are stabilized as they become more distributed throughout the cortex. Sleep has been linked with successful memory consolidation, and evidence suggests particular features in the architecture of sleep may relate to sleep-dependent memory enhancements. Recent evidence suggests a 24-hour delay promotes more distributed memory traces, as measured by greater hippocampal-cortical functional connectivity, in a manner predictive of subsequent behavioral resistance to forgetting, indicating a specific role in memory stabilization. However, it remains unknown how aspects of sleep architecture might be related to the representation of memory traces the next day, and how this relates to behavioral measures of memory. To investigate this relationship, we designed a threeday experiment utilizing overnight polysomnography recordings, fMRI, and behavior. Subjects encoded two lists of word-image pairs twice, either with an intervening period of overnight sleep (Sleep List), or a brief wakeful period (New List), such that the lists differed in the opportunity for consolidation processes. During the re-study session, subjects were presented with the previously seen word-image pairs, and a new list of pairs (Single Study List) while in the scanner. Cued source recall was probed immediately following the scan and after a 24-hour delay, providing a measure of memory stability over time. Univariate analyses revealed that for the Sleep List in particular, time spent in NREM sleep is positively related to greater activation in the hippocampus. Using multivariate pattern similarity analysis, we examined the representations of trials from each encoding list. Within the anterior hippocampus, later remembered Sleep List pairs were represented more distinctly compared to those later forgotten, while in posterior hippocampus, remembered pairs were more similar compared to forgotten. This significant interaction was not observed in either of other encoding lists, indicating a potential dissociation along the long-axis of the hippocampus that develops with sleep.

Title: Measuring neural activity in the MTL using simultaneous BOLD and functional MR spectroscopy

Authors: *C. E. STARK¹, S. NIKOLOVA², S. M. STARK²

¹Univ. of California Irvine, Irvine, CA; ²Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: We have used BOLD fMRI extensively to characterize behavioral and neural (structural and functional) profiles of neurocognitive aging in the context of the medial temporal lobe (MTL) memory system. However, the spatial and temporal limitations of BOLD are well known and appreciated, as are the limitations imposed by the fact that it is fundamentally a contrastive measure (e.g., Condition X vs. Y vs Z). The effect of this contrastive nature of BOLD is magnified greatly by the fact that factors clearly outside of cognitive or neural changes can alter the BOLD signal. Here, we investigated a functional variant on magnetic resonance imaging spectroscopy (fMRS) that collects metabolite data while participants engage in various cognitive tasks, dynamically measuring excitatory transmission during a memory task by quantifying a composite measure of glutamate and glutamine (Glx) while simultaneously measuring BOLD fMRI at the same location. We scanned 20 young adults during 30 second blocks of 4 conditions: 1) viewing novel images of scenes, 2) viewing familiar images of scenes, and 3) a perceptual baseline task, and 4) unconstrained rest. We collected both BOLD and MRS data from two large voxels: one in the right parahippocampal cortex (PHC) (~12mL) and one in the right hippocampus (~3.75mL). Consistent with previous findings from standard BOLD fMRI, we observed greater BOLD activity for novel images than for familiar ones (i.e. the repetition suppression effect) in both the hippocampus and PHC. Likewise, we found decreased BOLD signal for the perceptual baseline task and a modest decline for rest. Thus, our proxy for BOLD is consistent with prior results using more typical BOLD fMRI scans. NAA and Cr concentrations served as negative controls and, as expected, showed no task modulation, but Glx concentrations showed clear task modulations, demonstrating a reliable functional MRS signal. In both regions, novel and familiar pictures elicited higher levels of Glx than rest. In the hippocampus, the perceptual baseline was associated with very low levels of Glx while in the parahippocampal cortex, Glx levels were elevated. Thus, in both BOLD and Glx, novel and familiar pictures elevated their respective measures of activity. Yet, clear differences emerged. In particular, our two control conditions (simple rest and perceptual baseline) differed dramatically in the parahippocampal cortex (highest levels of Glx vs. lowest levels of BOLD). Therefore, even in a healthy, young population, there are both clear points of contact between these two measures of activity and clear points of departure, providing us with an interesting new tool for evaluating neural activity.

Title: Functional connectivity segregation along the long-axis of the hippocampus

Authors: *A. MENDELSOHN¹, S. GABAY²

¹Dept. of Neurobio., ²Psychology, Univ. of Haifa, Haifa, Israel

Abstract: In primates and humans, the development of the hippocampus and surrounding cortex facilitated an axial change which resulted with an elongated, longitudinal shape whose posteriorto-anterior axis corresponds to the dorsal-to-ventral axis of the rodent hippocampus. Despite its distinct uniform structure, the hippocampus may not, in fact, function as such, but rather consists of distinct sub-structures along its long axis. Given the apparent diversity of sub-hippocampal functionality, the computational principles of the hippocampus as a whole remain to be elucidated. Here we suggest two anatomically-guided functional connectivity methods aimed at delineating cortical and sub-cortical networks that are specifically co-active with discrete subhippocampal areas. These methods were run on resting-state blood-oxygenated-level-dependent (BOLD) data of 31 healthy volunteers from the publicly available NKI Enhanced dataset. Following the parceling of the anatomical MRI datasets using FreeSurfer (http://surfer.nmr.mgh.harvard.edu), each participant's hippocampi were delineated for further analysis. Next, BOLD signal time-courses were extracted for each and every voxel of the entire brain, and Pearson correlations were computed between the time-courses of each voxel in the brain and the time-courses of each and every voxel in the hippocampi. Finally, each brain voxel was assigned the relative location along the anterior-to-posterior hippocampal axis with which it was maximally correlated. Results of this analysis demonstrate that distinct brain networks coactivate with distinct hippocampal regions, such that posterior hippocampus highly co-activates with primary sensory and motor regions (including primary visual, auditory, and taste cortices), the anterior hippocampus is preferably connected with amygdala, temporal poles, and ventromedial prefrontal cortex, whereas the middle hippocampus is highly correlated with core regions of the default-mode network (DMN). Corroborated by converging findings using an anatomically-guided seed-based general linear model approach, these results provide direct evidence as to the distinct cortical and sub-cortical networks that converge into subcompartments of the hippocampus, arguing in favor of a functional segregation along the long axis of the hippocampus.

Title: Travelling waves along the long-axis of the hippocampus

Authors: *M. YEBRA¹, O. JENSEN², N. AXMACHER³, B. A. STRANGE^{1,4} ¹CTB, Madrid, Spain; ²Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; ³Neuropsychology, Inst. of Cognitive Neurosci., Bochum, Germany; ⁴Dept. of Neuroimaging, Alzheimer's Dis. Res. Centre, Reina Sofia-CIEN Fndn., Madrid, Spain

Abstract: Travelling waves are present in different brain structures at different frequency ranges and in different species. The relationship of the phase of the traveling waves with neuronal firing or other oscillations is thought to represent a mechanism to code information by means of the expression of different phases along the same structure or between structures at the same time. Traveling waves have been shown in the theta range in the hippocampal formation of rodents traveling along the long-axis (Lubenov & Siapas, 2009; Patel et al., 2012). Similar patterns were found in humans . We report iEEG recordings along the long-axis of the hippocampus from epilepsy patients. We used a version of the Von Restorff paradigm. Participants studied pictures of faces and houses shown in grayscale against a red or green background. While the majority of items came from *expected* category, a small proportion belongs to *unexpected* category. We used a fine grained analysis, including the traditional convention in humans for different delta, theta, alpha and beta frequency ranges. We confirm the existence of theta traveling waves along the long-axis of the hippocampus and go beyond previous work by showing that this frequency range extends to the alpha band. We did not see a modulation of the travelling wave patterns by novelty processing suggesting that hippocampal activity shows similar anterior to posterior phase differences regardless of unexpectancy. If encoding is more likely to occur at the peak of the theta signal and retrieval at the trough and if the place field size increases from posterior to anterior hippocampus in humans - as has been shown in rodents -, the existence of a theta traveling wave suggests that while the tail is experiencing a peak (representing small place field size -details- and encoding state) the head is experiencing a trough (representing big place field size -context- and retrieval state) and vice versa. This suggests that the hippocampus puts details into context and contextualizes details every ~200ms.

Figure 1. Theta and alpha travelling wave pattern for one representative patient A) Theta and alpha traveling waves across neighbouring electrodes. Displayed filtered signals in theta (4-8Hz) alpha (8-13Hz) locked to the peaks of the most anterior hipocampal electrode and averaged across trials for expected and unexpected conditions. B) Polar histogram across trials for the theta (upper row) and alpha (lower row) phase difference between the most anterior electrode as a reference channel and each electrode along the longitudinal axis of the hippocampus for expected and unexpected conditions.

Title: Preferential viewing of old scenes reflects conscious memory for which scenes are old or new and is impaired after medial temporal lobe damage

Authors: *C. N. SMITH^{1,2}, Z. URGOLITES^{1,2}, L. R. SQUIRE^{1,2,3,4} ¹Veterans Affairs San Diego Healthcare Syst., San Diego, CA; ²Dept. of Psychiatry,

³Neurosciences, ⁴Psychology, Univ. of California San Diego, San Diego, CA

Abstract: When individuals try to select the recently studied (and familiar) item during a multiple-choice memory test, they direct a greater proportion of viewing time towards the selected item when their choice is correct than when their choice is incorrect. Thus, for both correct and incorrect choices, individuals indicate that the chosen item is old, but viewing time differentiates between old and new items. What kind of memory supports this preferential viewing effect? One possibility is that automatic, hippocampus-independent memory supports this effect because viewing time differentiates old items from new items independently of overt behavioral choice. Alternatively, conscious, hippocampus-dependent memory might support this effect. If so, the preferential viewing effect should be related to established measures of declarative memory (i.e., accuracy scores, confidence ratings, and response times). In two experiments, we tested whether the preferential viewing effect reflects conscious memory or unconscious memory (Experiment 1, 30 young adults) and whether the effect is dependent on the medial temporal lobe (Experiment 2, 5 patients with damage limited to the hippocampus or limited to the medial temporal lobe and 6 age-matched, older controls). In Experiment 1, participants made three-alternative, forced-choice, recognition memory judgments for targets (200 photographs of scenes studied 30 min earlier) and foils (each target was presented together with two thematically-related novel scenes). We replicated the preferential viewing effect: individuals looked longer at the selected item when it was correct than when it was incorrect. Importantly, the effect was stronger when individuals were more confident in their decisions and when their response times were shorter. Moreover, the size of the preferential viewing effect was strongly correlated with overall accuracy scores. Thus, the preferential viewing effect reflects conscious memory for which items are old and which items are new. In Experiment 2, participants made recognition memory judgments for targets (100 photographs of scenes studied 1 min earlier) and foils. Patients exhibited impaired declarative memory. Specifically, they were less accurate and exhibited smaller differences in confidence ratings and response times for correct versus incorrect trials. The controls exhibited the preferential viewing effect, but the patients did not. Taken together, these findings suggest that the preferential viewing effect reflects conscious, medial temporal lobe-dependent memory.

Title: Mnemonic discrimination tuning: A potential mechanism underlying the other-race effect

Authors: *J. YAROS, ESQ¹, D. A. SALAMA¹, M. A. YASSA² ¹UC Irvine, Irvine, CA; ²Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: The Other-Race Effect (ORE) is a social phenomenon in which people are better at recognizing individuals within their own, relative to other races. While behavioral research suggests the ORE is due to extensive experience with one's own race group, the neural mechanisms underlying the effect remain unclear. We believe that the enhancement in same-race (SR) recognition typical of the ORE, is due to enhanced mnemonic discrimination (MD), a process driven by pattern separation of similar inputs. In the present study, we sought to identify unique MD response profiles for subjects performing an encoding and memory task for faces of several different races. During encoding blocks, subjects viewed and were asked to remember a series of computer generated Caucasian, Asian, and Black faces. During the following test, subjects made 'Old'/'New' judgements, if they believed to have seen the faces before, or not, respectively. Some of the faces shown in test were parametrically altered so that the dissimilarity between encoded and test faces could be quantified. This allowed us to tax mnemonic discrimination selectively for numerous levels of interference between stimulus presentations. Given prior results in the lab, we anticipated performance for SR recognition accuracy to be sigmoidally tuned as a function of face similarity, and OR accuracy to increase linearly with face dissimilarity. This may reflect differences in mnemonic strategies employed for SR vs OR recognition. To further expound upon the role of experience in tuning these mnemonic strategies, subjects are being trained in OR faces, and will subsequently be re-evaluated for SR and OR recognition performance. We expect to see a tuning in the post-training MD function for OR faces, such that it approaches the sigmoidal function synonymous with SR recognition. This will serve as mechanistic evidence that experience alters the efficacy of discrimination in the face of overlapping face inputs.

Title: Acute mild exercise improves memory by enhancing hippocampal-neocortical connectivity

Authors: *K. SUWABE¹, K. BYUN², K. HYODO³, Z. REAGH⁵, K. SAOTOME⁴, G. OCHI⁷, M. A. YASSA⁶, H. SOYA⁸

Tsukuba, Tsukuba-city, Japan

Abstract: While a growing number of studies have demonstrated that physical exercise has beneficial effects on hippocampal functions especially on spatial memory, there are few studies on pattern separation associated with the dentate gyrus (DG). Additionally, the most effective exercise regimen (e.g., intensity) for improving hippocampal functions is undetermined. We recently showed that acute mild-intensity exercise without any stress responses has the potential to activate hippocampal neurons including those in the DG (Soya et al., BBRC, 2007) and that such mild training regimens cause neurogenesis (Okamoto et al., PNAS, 2012, Inoue et al., PLoS One, 2016). This led to the hypothesis that acute mild exercise may also enhance DG-mediated pattern separation, a hypothesis supported in part by our recent findings in humans that acute moderate-intensity exercise improves the performance of a mnemonic discrimination task designed to selectively tax pattern separation (Suwabe et al., Hippocampus, 2017). Using the same experimental protocol, here we aimed to investigate whether acute mild exercise improves hippocampal memory, and if so, to explore the exact neuronal substrate in terms of functional activation in the medial temporal lobe (MTL) using high-resolution functional MRI. Healthy young adults underwent a mnemonic discrimination task after 10 minutes of very light intensity exercise (30% VO_{2peak}; corresponds to "very light" in the ACSM's definition) on a recumbent cycle ergometer or rest (control) on separate days in randomized order. We compared neural activity between exercise and control conditions in the pattern separation contrast (lure correct rejections minus lure false alarms). Moreover, we explored cortical regions that were functionally correlated with the hippocampal subfield activity using psychophysiological interaction (PPI) analysis. Exercise improved mnemonic discrimination performance and enhanced fMRI activity in the DG/CA3 and surrounding neocortex. Exercise also enhanced the functional connectivity between the DG/CA3 and cortical regions including the parahippocampal, fusiform and angular gyri, regions that are involved in representing highprecision memories. Critically, the magnitude of the enhancement in functional connectivity predicted the extent of behavioral enhancement at the individual subject level. Thus, we

concluded that acute very light intensity exercise, which is comparable to traditional oriental bodywork such as Yoga and Tai Chi, is capable of enhancing hippocampal memory, and enhancement of the DG/CA3-neocortical functional connectivity is likely the neuronal substrate underlying the effects.

Title: Amygdala-hippocampal-orbitofrontal network dynamics support contextual modulation of facial expression

Authors: J. ZHENG¹, S. VADERA², R. T. KNIGHT⁴, *J. LIN³

¹Dept. of Biomed. Engin., ²Dept. of Neurolog. Surgery, ³Dept. of Neurol., Univ. of California, Irvine, CA; ⁴Psychology, Univ. of California at Berkeley, Berkeley, CA

Abstract: When interpreting an ambiguous facial expression, the context or "emotional" background provides situation specific cues to resolve ambiguity and guide interpersonal behavior. Thus contextual processing allows the meaning of a facial expression to be understood according to the emotional backdrop in which it is retrieved. We examined the spatiotemporal dynamics of contextual face processing by presenting a neutral face against a background scene from the International Affective Picture System (IAPS) that varied parametrically by emotional valence (positive, negative, neutral). During the task, the subject was asked to rate the emotional valence of the facial expression, which was displayed immediately after the IAPS background image. We recorded local field potentials (with high temporal and spatial resolution) from depth electrodes implanted in the orbitofrontal cortex (OFC), amygdala (AMYG) and hippocampus (HPC) of 5 patients undergoing evaluations for epilepsy surgery. We quantified how high gamma (HG, 70-250Hz) activity encoded different task-related factors at a single trial level (Fixation, Background IAPS Image, Face, Valence Rating). We found that: 1) the subjects' valence ratings of facial expression were positively correlated with the IAPS valence ratings; 2) electrodes from different brain regions were selective to distinct computational factor at different task stages and exhibited a systematic temporal propagation from AMYG to HPC to OFC; 3)

Single stacked trials (N=120) of high gamma activity in the OFC sorted by response time showed that the peak latency of the high gamma activity correlated with reaction time. These findings provide evidence of a circuit-level interaction within AMYG-HPC-OFC network that supports contextual processing of facial expressions.

Title: Gamma and theta activity in the human medial temporal and prefrontal cortices predicts performance on a spatial learning task

Authors: *R. F. STEVENSON¹, J. ZHENG¹, A. S. MOON¹, S. VADERA¹, R. T. KNIGHT², J. J. LIN¹, M. A. YASSA¹ ¹UC Irvine, Irvine, CA; ²UC Berkeley, Berkeley, CA

Abstract: The ability to learn novel associations is a critical feature of episodic memory. Accumulating evidence suggests that this ability involves local processing within the medial temporal lobe (MTL) and prefrontal cortex (PFC) as well as functional interactions between these two regions. However, the ways in which the MTL and PFC contribute to associative learning in humans as well as the dynamics of MTL-PFC interactions are still not well understood. To address this question, we tested pre-surgical epilepsy patients with depth electrodes implanted in both the MTL and PFC using a spatial learning task in which subjects attempted to learn object-location associations over the course of three training blocks. During encoding, thirty objects were presented at different locations on a computer screen and subjects were asked to try to remember the location of each object. For each training block, the same objects were presented at the top of the screen and subjects were asked to use the mouse wheel to move the object to where it appeared during encoding. After subjects finished placing each object, the object was shown in the correct location for one second as feedback. Following the three training blocks there was a final test during which no feedback was given. During retrieval, we found that there was a greater increase in gamma (40-100 Hz) power in the MTL and PFC for highly precise trials. In contrast, at feedback there was a greater increase in MTL gamma power for low precision trials. Together, these results suggest that while MTL activity during retrieval reflects the precision of an association, activity during feedback signals the amount of error. We also examined theta (3-8 Hz) activity in the MTL-PFC network during retrieval and feedback and found that both power and phase synchronization predicted spatial memory precision. Overall, these data suggest putative mechanisms for the learning of object-location associations.

Title: Performance on object pattern separation task predicts cognitive status and is linked to anterolateral entorhinal cortical thinning in cognitively normal older adults

Authors: *J. A. NOCHE¹, F. MARQUEZ³, N. TUSTISON⁴, D. DELISLE⁵, E. MURRAY⁵, V. KAPOOR⁵, M. WITBRACHT⁵, S. SIRIVONG⁵, J. R. STONE⁴, J. GRILL⁵, Z. REAGH², M. A. YASSA¹

¹Neurobio. and Behavior, ²Dept. of Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA; ³Neurobio. and Behavior, UC Irvine, Irvine, CA; ⁴Univ. of Virginia, Charlottesville, VA; ⁵Univ. of California, Irvine, Irvine, CA

Abstract: Developing cognitive tasks and biomarkers that are sensitive to the earliest stages of decline in Alzheimer's disease (AD) are one of the highest priorities for research. MRI studies in humans have shown that entorhinal cortical (EC) thinning is a highly sensitive measure of structural change in both mild cognitive impairment (MCI) and AD. Recent studies have suggested that human EC can be divided into functional subdivisions: the anterolateral EC (alEC) is thought to comprise an object/item information pathway, whereas posteromedial EC (pmMEC) is thought to comprise a spatial/contextual information pathway. In this study, we tested a sample of cognitively normal (MMSE 25 to 30) older adults using high resolution structural MRI and a novel cortical thickness segmentation pipeline as well as a suite of behavioral tasks that selectively tax mnemonic discrimination (pattern separation) of object identity or spatial location. The EC was subdivided into alEC and pmEC using expert anatomical

segmentations on a set of atlases that were propagated to the study cohort using a joint label fusion (JLF) and SyN diffeomorphic registration implemented within Advanced Normalization Tools. Behaviorally, we found poorer performance in object relative to spatial discrimination, replicating our prior work. We next calculated the magnitude of difference between performance on each task to establish a measure of asymmetry in response (i.e. an object vs. spatial performance bias), and found that this bias metric was a reliable predictor of scores on the Mini Mental State Exam (MMSE), a measure of global cognitive function. The higher the asymmetry, the more intact the participants' MMSE, suggesting that early changes in impairment are indexed by decreasing asymmetry. We also observed a relationship between performance on the object task and thickness of the alEC, which was not the case in the spatial task or the pmEC, linking alEC decline specifically to memory deficits for object/item information. These findings support the idea that deficits in object memory manifest prior to spatial memory, and that asymmetry in performance may be linked to earlier stages of cognitive decline. Thus, the contrast of object and spatial memory performance on a task designed to test these specific computations may serve as a useful behavioral assay in identifying subtle neurocognitive changes related to neurodegeneration. The results additionally suggest that alEC thickness may be an early biomarker that is associated with these cognitive changes. The combination of sensitive cognitive assay and biological marker offer promise for optimizing diagnosis and/or outcomes for clinical trials.

Title: Hippocampal integration and separation processes are driven by the strength of memory reactivation during learning
Authors: *R. J. MOLITOR, K. R. SHERRILL, N. W. MORTON, A. R. PRESTON Univ. of Texas At Austin, Austin, TX

Abstract: Efficient learning requires encoding of both detailed information from individual events and generalities across related experiences. In service of these goals, it is hypothesized that the hippocampus can create distinct, orthogonal memory representations through pattern separation or form integrated representations that code the common features among memories. To optimize learning, it is critical to identify how these seemingly opposing representational strategies coexist within the hippocampal network, as well as to determine the conditions that promote each type of representational strategy. One factor that may influence whether the hippocampus integrates or separates related memories is the strength of memory reactivation during new learning. Recent evidence indicates that when individuals learn about new events that overlap with past experience, they reactivate memories about related events. Such reactivation has been shown to promote integration of the new information into existing memory representations. Other data suggest, however, that memory reactivation during learning may lead to competition between co-active memories, thus requiring pattern separation to mitigate interference. Here, we test the hypothesis that the strength of memory reactivation may be an important determining factor in whether new events are integrated with or separated from reactivated memories within hippocampus. Participants initially studied a set of associations (AB pairs comprised of face-object or scene-object pairs), and then during fMRI scanning, they encoded overlapping associations (BC object-object pairs). Both prior to and immediately after learning, participants also viewed images (A and C) in isolation during scanning. We used representational similarity analysis to assess whether activation patterns for indirectly related images (A and C) become less similar (i.e., pattern separated) or more similar (i.e., integrated) in hippocampal subregions after learning. Additionally, we used a pattern classifier to measure the reactivation of related memories (A items) in ventral temporal cortex during overlapping event (BC) learning. Consistent with our hypothesis, we found that the degree of memory reactivation in neocortex predicted whether indirectly related memories were pattern separated or integrated in hippocampus after learning. Furthermore, this relationship between reactivation and representational change differed across hippocampal subregions. Together, these findings provide insight into the basis of the divergent yet complementary neural codes formed by the hippocampal memory system.

Title: The role of sleep in generalizing across disjointly presented information

Authors: *A. C. SCHAPIRO, M. BAYDA, E. CHO, R. COX, R. STICKGOLD Psychiatry, Beth Israel Deaconess Med. Ctr. / Harvard Med., Boston, MA

Abstract: Interleaving the presentation order of complex information is important for learning useful representations of its structure, but waking experience does not normally offer such an optimized exposure order. The Complementary Learning Systems theory (McClelland, McNaughton, O'Reilly, 1995, Psychol Rev) argues that sleep provides this function, helping the cortex uncover structure through interleaved replay of hippocampal traces. We tested this idea by exposing participants to information in a suboptimal order and assessing whether subsequent periods of sleep and wake result in differential understanding of the underlying structure. Participants learned visual and verbal features of three categories (A, B, and C) of "satellite" objects, where satellites in the same category shared most of their features. At the very end of this training, we exposed them to two additional satellites, each composed of a combination of features from categories A and B. These satellites provided a bridge between the two categories, supporting the potential generalization that other combinations of features from A and B could also produce plausible satellite objects. Because the satellites were presented after the categories were already learned, it should be difficult to update category representations to accommodate this new information without going back and revisiting already-learned objects. We reasoned that if sleep helps interleave information offline, participants who sleep should improve in their generalization to novel objects combining features from A and B, relative to participants who do not sleep, and relative to objects that combine features from categories B and C or categories A and C. Our tests of generalization involved asking if a novel satellite 1) had been previously viewed and 2) seemed like it would be "functional." Testing occurred immediately after training and again 12 hr later. Our predictions were supported for both test questions: Participants in the sleep, but not wake, condition showed increased generalization to novel combinations from the bridged categories in the second test session, falsely believing they had seen these satellites before, and judging them to be more functional. However, we additionally found differences in first session performance between the sleep and wake conditions, suggesting a potential influence of circadian factors. Contributions of sleep features and stages to learning based on high density EEG and PSG sleep recordings will also be discussed. The results provide evidence in support of the theory that sleep is important for interleaving information in order to better understand its structure.

Title: The medial temporal lobe and topographical memory

Authors: *Z. J. URGOLITES^{1,4}, R. O. HOPKINS^{5,6}, L. R. SQUIRE^{4,1,2,3} ¹Dept. of Psychiatry, ²Neurosciences, ³Psychology, UCSD, La Jolla, CA; ⁴Veterans Affairs San Diego Healthcare Syst., San Diego, CA; ⁵Dept. of Psychology and Neurosci. Ctr., Brigham Young Univ., Provo, UT; ⁶Dept. of Medicine, Pulmonary and Critical Care Div., Intermountain Med. Ctr., Murray, UT

Abstract: The medial temporal lobe (MTL) is essential for the formation of long-term (declarative) memory. There has been interest in the idea that the MTL might be especially important for spatial processing and spatial memory. We tested the proposal that the MTL has a specific role in topographical memory as assessed in tasks of scene memory where the viewpoint is shifted from study to test. Building on materials used previously for such studies and generously provided by Neil Burgess, we administered three different tasks in a total of nine conditions. Participants studied a scene depicting four hills of different shapes and sizes and made a choice among four test images. In the Rotation task, the correct choice depicted the study scene from a shifted perspective. MTL patients succeeded when the study and test images were presented together but failed the moment the study scene was removed (even at a 0-sec delay). In the No-Rotation task, the correct choice was a duplicate of the study scene. Patients were impaired to the same extent in the No-Rotation and Rotation tasks after matching for difficulty. Thus, an inability to accommodate changes in viewpoint does not account for patient impairment. In the Nonspatial-Perceptual task, the correct choice depicted the same overall coloring as the study scene. Patients were intact when test images were presented together with the study scene and also when the test image was presented 2 sec after the study scene was removed, but failed at longer, distraction-filled delays. We suggest that the impairment in these tasks reflects a broad deficit in the ability to remember both spatial and nonspatial material. We further suggest that the different results for the spatial and nonspatial tasks are related to differences in demand on working memory.

Title: Human hippocampal pre-activation predicts behavior

Authors: *A. JAFARPOUR¹, V. PIAI², J. LIN³, R. T. KNIGHT⁴

¹Helen Wills Neurosci. Instutite, Berkeley, CA; ²Dept. of Med. Psychology, Donders Ctr. for Cognition, Nijmegen, Netherlands; ³Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; ⁴Univ. of California Berkeley, Berkeley, CA

Abstract: The response to an upcoming salient event speeds up when the event is expected given the preceding events – i.e. a temporal context effect. For example, naming a picture (e.g. "boat") following a strongly constraining temporal context (e.g. "We sailed in a wooden") is faster than naming the picture after a weakly constraining context (e.g. "He looked at a wooden"). The human hippocampus represents mnemonically expected stimuli in their absence. Using intracranial electroencephalogram (iEEG) from the human hippocampus (n = 5), we tested if the hippocampal representation of expected stimuli emerges prior to the stimuli onset and if this pre-activation predicts behavior. Participants named pictures that were preceded by incomplete sentences presented auditorily. In each trial, naming the picture completed the sentence. The sentence manipulated the expectation on the upcoming picture. We observed more power in the hippocampal high-frequency band activity (50-250 Hz) prior to the picture onset (pre-picture interval) of strongly expected pictures than of weakly expected pictures (p = 0.014). We then applied pattern similarity analysis on the temporal pattern of hippocampal high frequency band activity in single contacts. We observed that the similarity between the prepicture interval and the expected picture interval predicted the picture-naming latencies (p = 0.008). Additional pattern similarity analyses indicated that the hippocampal representations reflect a semantic cognitive map. We conclude that hippocampal pre-activation of expected stimuli is a facilitating mechanism underlying the powerful contextual behavioral effect.

Title: Acute physical exercise improves memory consolidation in humans via BDNF and endocannabinoid signaling

Authors: *K. IGLOI, B. MARIN BOSCH, A. BRINGARD, G. FERRETTI, S. SCHWARTZ Neurosciences, Univ. of Geneva, Geneve, Switzerland

Abstract: Regular physical exercise enhances memory functions and neurogenesis in the hippocampus. In animals, a single session of physical exercise boosts BDNF (Brain Derived Neurotrophic Factor) levels, with parallel increases in neurogenesis and plasticity in the hippocampus. Furthermore, acute exercise promotes the release of endocannabinoids (especially anandamide, AEA), which are small lipophilic molecules that affect dopaminergic transmission and also enhance BDNF release. Whether these effects are also observed in humans and how they influence memory remain unknown. Here we combined blood biomarkers, behavioral measures and fMRI to assess the impact of medium and high intensity acute physical exercise on memory and underlying biomechanisms in humans. We hypothesized that medium intensity exercise improves memory consolidation and enhances hippocampal activity via BDNF and/or endocannabinoid signaling, while high exercise intensity causes physical stress detrimental to cognitive functioning. We tested associative memory performance in twenty healthy participants across three visits: each visit consisted of a learning and a test part performed in fMRI separated by a period of exercise (moderate or high intensity) or rest. All participants also came back for a single retest session three month after the last visit. Two blood samples were taken at each visit before and after the exercise or rest periods. Our results show a general increase in memory performance (measured by accuracy, reaction times, and confidence) after exercise at moderate intensity but not high intensity, compared to after rest. Levels of BDNF and AEA were higher after exercise compared to rest. Crucially, AEA increase after medium and after high exercise correlated with hippocampal activity during retrieval suggesting that AEA may have an acute effect on synaptic plasticity in human. Finally, long-term memory at retest was significantly better for elements learnt during the medium exercise visit than during rest or high exercise visits. Overall, these findings demonstrate that a single session of medium intensity exercise enhances long-term associative memory and shed light on the biomechanisms underlying the beneficial influence of acute physical exercise on human cognitive functions.

Title: Neural substrates of mnemonic discrimination: A whole-brain fMRI investigation

Authors: J. KLIPPENSTEIN¹, S. M. STARK², C. E. STARK², *I. J. BENNETT¹ ¹Dept. of Psychology, Univ. of California, Riverside, Riverside, CA; ²Univ. of California Irvine, Irvine, CA

Abstract: A fundamental component of episodic memory is the generation of discrete memory representations for unique events. Because we frequently encounter highly similar events (e.g., eating breakfast today versus yesterday), accurate memory depends on our ability to dissociate these memory representations, termed mnemonic discrimination. Numerous functional magnetic resonance imaging (fMRI) studies have revealed that the hippocampus, and specifically the dentate gyrus subfield, is involved in this type of mnemonic discrimination. However, few studies have assessed neural activity associated with mnemonic discrimination in regions beyond the medial temporal lobe. Therefore, the current study examined brain-wide fMRI activity in 11 younger adults (19-23 years, 3 female) during performance of a mnemonic discrimination task. In the incidental encoding phase, participants made "indoor"/"outdoor" judgments to a series of to-be-remembered objects. In the test phase, they made "old"/"new" judgments to a series of probe objects that were either repetitions from the memory set, similar to objects in the memory set, or novel. Behavioral results revealed that participants correctly endorsed repeated objects as "old" and novel objects as "new". Mnemonic discrimination was observed as a decrease in "old" responses as objects became less similar to those in the memory set. Mnemonic discrimination was also seen as a significant difference in sensitivity (d' > 0) when comparing distributions of "old" responses to repeated versus similar objects. Imaging data during the test phase were first examined during three task conditions ("old" repeated, "old" or "new" similar, "new" novel) relative to a baseline condition. Results revealed that both repeated and similar objects elicited significant activity in bilateral hippocampus, occipital cortex, and medial frontal cortex. Mnemonic discrimination-related activity was then assessed by comparing these task conditions, which revealed a trend for greater activity to similar versus repeated objects in these regions.

These preliminary findings add to a growing body of work suggesting that mnemonic discrimination is mediated by a broader memory network that extends beyond the hippocampus.

Title: Increased aerobic fitness is related to increased anterior dentate gyrus/CA3 volume in healthy young adults following exercise training

Authors: *R. K. NAUER^{1,2,3}, M. F. DUNNE³, T. W. STORER⁴, C. E. STERN^{1,2}, K. SCHON^{1,2,3}

Abstract: Converging evidence suggests a relationship between aerobic exercise and hippocampal neuroplasticity that is centered on adult neurogenesis in the dentate gyrus (DG) subregion of the hippocampus. In humans, this relationship has not been elucidated at the level of the hippocampal subregions, nor has it been examined functionally. Using structural MRI and a hippocampal-dependent behavioral task requiring disambiguation of similar stimuli, we tested the hypotheses that 1) aerobic fitness levels are positively associated with volume and function of DG/CA3 in humans, and 2) a 12-week exercise intervention will increase the volumes of the entorhinal cortex and DG/CA3 and increase disambiguation task accuracy. Healthy young adults (ages 18-35) participated in either an aerobic or resistance training intervention three times per week for twelve weeks. Changes in aerobic fitness were determined via a submaximal, incremental treadmill test using a modified Balke protocol prior to and following the intervention. We conducted volumetric analysis following manual segmentation of T₂-weighted MR images with high in-plane resolution (0.4 mm²; Philips 3 T Achieva). At baseline, greater aerobic fitness was associated with greater volume in the entorhinal cortex and anterior subregions of the hippocampus (DG/CA3 and subiculum). Aerobic fitness at baseline did not correlate with disambiguation task accuracy. Following the exercise intervention, results show

that an increase in fitness percentile selectively predicted greater volume change in the left anterior DG/CA3. Behaviorally, individuals who were lower fit at baseline showed a positive correlation between increased changes in fitness percentile and improved corrected accuracy for trials requiring the highest level of disambiguation. Extending our previous work (Whiteman et al. 2016), this suggests that improving fitness may lead to increased volume within the hippocampus in young adults, and lower-fit individuals may receive the most cognitive benefit.

Title: Simulated memory impairment: Neural correlates of memory decisions made in the face of conflict

Authors: *E. J. MAHONEY¹, D. E. HANNULA²

¹Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI; ²Psychology, Univ. of Wisconsin, Milwaukee, Milwaukee, WI

Abstract: Questions are addressed in the current investigation about the neural correlates of memory decisions that are made in the face of conflict, which requires increased cognitive control. Participants in this experiment studied several scene-face pairs and were tested with three-face displays preceded by studied scene cues. The associate of the scene cue was either present in the three-face display (target-present trials) or not (target-absent trials). On every trial, participants were to indicate whether the trial was target-present or -absent by making a button press. Half of the participants (controls; n=20) were instructed to perform optimally and the remainders were told to simulate memory impairment (simulators; n=20). fMRI and eye tracking data were acquired during encoding and test, and a final post-test, on which all of the participants were instructed to perform their best, was completed outside of the scanner. Consistent with instructions, simulators performed at chance levels when they were asked to make present/absent decisions during the test phase; controls outperformed simulators, as expected. In contrast to these between-groups differences in explicit recognition decisions, early eye movement behavior was comparable - participants from both groups spent a disproportionate amount of time looking at associates (target-present trials) within 500-750ms of 3-face display onset. Results from preliminary fMRI analyses show that activity differences in the hippocampus during presentation of the scene cue predicted early high viewing of the associate, even when explicit recognition decisions were incorrect, among simulators. Activity differences associated with explicit recognition performance during presentation of the 3-face display distinguished the two groups. While hippocampal activity was greater for correct than incorrect present/absent decisions among controls, the opposite pattern was evident in simulator data. This pattern - activity differences greater for incorrect than for correct responses - was also evident in anterior cingulate cortex for simulators, an outcome that likely reflects conflict between memory retrieval and decision making. Together, these results indicate that participants can successfully conceal memory in explicit recognition responses, but that eye movements and hippocampal recruitment are sensitive to retrieval of learned associations none-the-less. Furthermore, during the decision making process, the act of simulating memory impairment results in recruitment of brain regions implicated in cognitive control.

Title: The role of spatial context representations in medial temporal lobe regions in fear generalization: A virtual reality approach

Authors: *L. D. DE VOOGD¹, *L. D. DE VOOGD¹, Y. P. J. MURRAY¹, R. M. BARTE¹, A. VAN DER HEIDE¹, G. FERNÁNDEZ¹, C. F. DOELLER^{1,2}, E. J. HERMANS¹ ¹Donders Inst. For Brain, Cognition and Behaviour, Nijmegen, Netherlands; ²Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Correctly using contextual information to predict aversive events from environmental cues is a critical ability that protects from overgeneralization of fear responses. Animal models demonstrated the importance of spatial context representations within the medial temporal lobe (MTL) in contextualization of fear learning. In humans, this relationship has not been investigated. We hypothesized fear generalization is a result of a weak context representation. The present study was designed to test this hypothesis in humans using functional MRI and a virtual environment. Twenty-four healthy participants underwent a context training paradigm within the virtual environment. This environment involved a rich landscape including two buildings the participants were able to enter. The buildings had distinct features from the outside, but were identical on the inside. Within this environment, participants underwent a differential

delay contextual fear conditioning paradigm with spatial context as occasion setter. Two different cues (CS+ and CS-) were presented in both buildings in the same way, but the CS+ was consistently (reinforcement rate of 100%) paired with a mild electric shock in the threat context, but never in the safe context. The CS- was never paired with a shock. To confirm the effectiveness of our fear conditioning paradigm, we analyzed skin conductance responses (SCR) in response to the CS+ and CS- in both contexts. We found stronger SCR amplitudes for the CS+ compared to CS-. As expected this differential response was stronger within the threat compared to the safe context, but also present within the safe context. Similarly, we observed robust differential BOLD responses in regions commonly (de)activated in fear conditioning paradigms. These were stronger in the threat compared to the safe context, but also still present in the safe context. These results indicate that differential fear generalized across contexts. Further analyses should reveal whether interindividual differences in fear generalization can be explained from poor spatial context representations. These representations will be estimated using a linear SVM classifier that we will train on MTL patterns obtained during context training and test during fear conditioning. Higher classification accuracies can be interpreted as a stronger context representation. In conclusion, we successfully developed a paradigm that allows us to investigate spatial context-dependency of fear learning by combining neuroimaging with virtual reality. This is relevant because deficits in suppressing fear responses in safe contexts is a hallmark of fearrelated disorders.

Title: Reward modulates memory encoding for objects and scenes in the medial temporal lobe

Authors: *H. SCHULTZ^{1,2}, J. YOO², D. MESHI^{2,3}, H. R. HEEKEREN² ¹Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; ²Biol. Psychology and Cognitive Neurosci. Unit, Freie Univ. Berlin, Berlin, Germany; ³Dept. of Advertising and Publ. Relations, Michigan State Univ., East Lansing, MI

Abstract: The Medial Temporal Lobe (MTL), which is comprised of the hippocampus (HC) and MTL cortex, is critical for the processing of episodic memory. Human fMRI studies support a framework in which anterior and posterior MTL cortex act as parallel pathways processing object-related and spatial memory components, respectively, which are then integrated by the HC. A complementary line of research has established a functional loop between the HC and the

dopaminergic midbrain as crucial for the formation of new memories, and human fMRI studies show that these regions interact during reward-related memory encoding. However, it is unknown whether reward differentially modulates the encoding of distinct memory components (e.g., object-related vs. spatial) in anterior vs. posterior MTL cortex.

To address this, healthy adult participants (n=22, 8 male, mean age 25, range 18-32) solved a novel encoding task crossing category and reward while undergoing fMRI (Siemens 3T, 2x2x2 mm EPI sequence, TR 1.8s, multiband factor 2). In each trial, they deduced the value (high vs. low) of a stimulus from a combination of stimulus category (object vs. scene) and frame color (blue vs. yellow) (counterbalanced over blocks). Correct identification of the value resulted in immediate high vs. low reward feedback for that stimulus. The next day, participants returned for a surprise recognition test. FMRI encoding data were analyzed using a 2x2x2 model with the factors category (object vs. scene), reward (high vs. low), and subsequent memory (remembered vs. forgotten). We expected differential effects of high reward on encoding activity in anterior vs. posterior MTL cortex for objects vs. scenes, respectively.

Behaviorally, reward enhanced memory (F=17.4, p<.001), which was more pronounced for objects than scenes (F=13.6, p=.001). On the neural level, reward modulated memory encoding in a category-independent manner in the anterior MTL cortex (-26 -5 -33, t=3.86), posterior MTL cortex (29 -26 -26, t=3.27) and HC (-25 -30 -9, t=3.44). Importantly, category-specific subsequent memory effects complemented the behavioral asymmetry: successful scene encoding in the posterior MTL cortex (-31 -38 -11, t=5.00) and HC (-34 -25 -11, t=4.55) was not modulated by reward, while successful object encoding was enhanced by reward in the anterior MTL cortex (15 0 -42, t=3.15) (all p<.001 unc.).

To our knowledge, this is the first study investigating the differential effects of reward on category-specific MTL memory encoding. Our data suggest that, on both the behavioral and neural level, reward enhancement of memory is not independent of the stimulus category.

Title: Anterolateral entorhinal cortex volume affects both intra-item and inter-item configural processing

Authors: *L.-K. YEUNG¹, R. K. OLSEN², H. E. P. BILD-ENKIN¹, B. HONG¹, V. MIHAJLOVIC¹, M. C. D'ANGELO², A. KACOLLJA², D. A. MCQUIGGAN², A. KESHABYAN¹, J. D. RYAN², M. D. BARENSE¹ ¹Psychology, Univ. of Toronto, Toronto, ON, Canada; ²Rotman Res. Inst., North York, ON, Canada

Abstract: In humans, the anterolateral entorhinal cortex (alERC) is of particular importance, as it overlaps with regions where Alzheimer's disease pathology first appears (Braak & Braak, 1991; Khan et al, 2014). Further, its volume is reduced in participants who perform poorly on neuropsychological tests selective for AD (Olsen, Yeung, et al, in press). However, few human studies to date have investigated its cognitive role. Based on experimental findings in rodents and its anatomical connections, we hypothesized that it may play a role in configural processing for items. To test this hypothesis, we took high resolution (0.43x0.43mm in-plane) structural scans of the medial temporal lobes of a group of 40 older adults. We performed manual segmentation following the Olsen-Amaral-Palombo protocol (Olsen et al, 2013), supplemented by the protocol of Maass et al (2015) - which subdivides the entorhinal cortex based on functional connectivity with other MTL regions - to obtain structural volumes for the alERC and neighboring MTL regions. We then compared these structural measures to behavioral performance on two eyetracking-based incidental viewing paradigms designed to test intra-item, and inter-item configural processing. In the first study, participants viewed conjunctive objects with distinct top and bottom halves. We showed that among all the MTL regions we assessed, only alERC volume was associated with the proportion of fixations directed to the configurallyimportant central region, which served as a measure of intra-item configural processing. In the second study, participants studied scenes associated with one particular critical object, and were subsequently shown either repeated scenes, manipulated scenes (where the critical object has been moved), and novel scenes. We showed that alERC and parahippocampal cortex volumes were selectively related to the proportion of fixations directed to the critical object previously associated with a particular scene in the manipulated condition only, a behavioral measure of inter-item configural processing. Together, these two studies suggest that the alERC may play a cognitive role that includes configural processing for the spatial relations between the parts of a single object, as well as its spatial relations relative to other objects.

Title: Changes in item representations following category learning

Authors: *S. ASHBY, C. R. BOWMAN, D. ZEITHAMOVA Univ. of Oregon, Eugene, OR

Abstract: Learning about category membership can alter representations of individual items resulting in increased perceived similarity of items within a category and decreased perceived similarity of items from different categories. The current study aimed to investigate changes in subjective similarity ratings and neural pattern representations before and after category learning. Stimuli were faces constructed as 50/50 blends of never-seen "parent" faces. Across two experiments, two or three parent faces were selected to determine category membership, presented as a family surname. These family surname-relevant faces were blended with other parent faces, to generate face stimuli for presentation. Pairs of faces could share a parent face relevant for family membership, a parent face irrelevant for family membership, or not share a parent face. Participants first passively viewed the stimuli during functional MRI and then rated the similarity of pairs of faces prior to category learning. The same passive viewing and subjective similarity ratings were repeated after participants were trained to categorize the face stimuli into families (categories). Prior to category learning, subjective similarity ratings were the same for pairs of faces from the same category as for pairs of faces from different categories that had a common parent. After category learning, similarity ratings for items within a category increased, while rated similarity of faces that shared a common parent but belonged to different categories decreased. Similarity ratings for faces that had no shared features also decreased. Similar changes in perceived similarity within vs. across categories was observed even for a separate group of participants that were trained to remember item-specific information (faceunique full name) where category information (a common surname) was present but not emphasized. Preliminary fMRI data suggest the behavioral effects may be mediated by the formation of category representations in the ventromedial prefrontal cortex, where distributed neural patterns differentiated faces belonging to different families after learning but not before. These findings elucidate the neural mechanisms underlying the changes in item representations resulting from category learning.

Title: Disinhibiting inhibitory engrams elicits memory interference

Authors: *H. BARRON¹, R. KOOLSCHIJN¹, A. PANTELIDES², U. EMIR¹, T. BEHRENS¹ ¹Univ. of Oxford, Oxford, United Kingdom; ²Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Individual memories are thought to be stored by ensembles of neurons that are reactivated during recall. However, it remains unclear how a given ensemble of neurons can contribute to more than one memory without causing confusion at the time of recall. Here we show evidence to suggest that inhibition plays a critical role in protecting overlapping memories from interference. Using non-invasive methods in humans, we first train subjects to acquire two memories that are context specific but otherwise overlapping. We then assess interference between these two memories at both a behavioural and neural level. By combining ultra-high field MR spectroscopy, fMRI and transcranial direct current stimulation (tDCS), we then show that confusion between overlapping memories can be induced when neocortical GABA is reduced using brain stimulation. These results are consistent with evidence to suggest that neocortical excitation and inhibition are tightly calibrated except during sensory exposure or memory recall. Furthermore, the data suggest that deficits in inhibitory gating may underlie hallucinatory experiences observed in clinical conditions such as schizophrenia where the precise balance between excitation and inhibition is poorly maintained.

Title: Opportunity to link related memories during encoding reveals adolescent-specific neural strategy

Authors: *M. L. SCHLICHTING¹, K. F. GUARINO², H. E. ROOME³, A. R. PRESTON³ ¹Psychology, Univ. of Toronto, Toronto, ON, Canada; ²Loyola Univ. Chicago, Chicago, IL; ³The Univ. of Texas at Austin, Austin, TX

Abstract: Previous work shows that hippocampus (HPC) and prefrontal cortex (PFC) support the formation of relational memory networks. Such networks can be created during encoding itself, when related memories are linked to, or integrated with, current experience. It is known that adults bring related memories to mind during encoding to form integrated memories, and that doing so results in increased behavioral flexibility. Yet, how existing knowledge impacts encoding over development remains virtually unstudied. Both HPC and PFC undergo continued structural change well beyond childhood, with PFC maturation in particular continuing into adulthood. Children also show less memory flexibility than adults, suggesting that they may not retrieve and link related knowledge during learning. Whether adolescents show similarly rigid memory signatures remains to be seen. Here, human participants aged 7-30 years encoded AB and XY object-object associations across three study repetitions during high-resolution functional MRI scanning. Participants also studied related BC pairs, which included an object (B) that was part of an AB pair, as well as a new C item from one of two visual categories (face or scene). We used a pattern classifier to measure reactivation of related (C) memories across the three AB study repetitions. Adults showed sustained reactivation of related content through the third repetition, while children show no reactivation at all. Interestingly, both younger and older adolescents showed an intermediate pattern, with initial reactivation followed by decreases as learning continued. The relationship between reactivation and behavior—specifically, the ability to link indirectly related A and C items-also changed with age, with sustained reactivation slowing performance early and speeding performance later in development. These results suggest important developmental differences in the tendency to bring to mind related knowledge during new events. In particular, the intermediate signature observed in adolescents might suggest that when HPC-driven reactivation is mature but PFC control is not, suppressing an initially reactivated memory is beneficial. This adaptive suppression may protect adolescents from interference among related memories. In a broader sense, our results highlight the importance of considering that differences in neural mechanism may still be present during adolescence, even when adult-like memory behavior has been reached. These data also open the door to future investigations that use memory models to quantify developmental shifts in the neural strategy deployed during specific encoding events.

Title: Reinforcement learning over time: Spaced versus massed training leads to longer-lasting value associations

Authors: *G. WIMMER¹, R. A. POLDRACK²

¹Psychology, Univ. Col. London, London, United Kingdom; ²Psychology, 450 Serra Mall Bldg. 420, Stanford, CA

Abstract: Over the past few decades, neuroscience research has illuminated the neural mechanisms supporting learning from reward feedback, demonstrating a critical role for the striatum and midbrain dopamine system. Simple feedback learning paradigms are increasingly being extended to understand learning dysfunctions in mood and psychiatric disorders as well as addiction ("computational psychiatry"). However, one potentially critical characteristic that this research ignores is the effect of time on learning: human feedback learning paradigms are conducted in a single rapidly paced session, while learning experiences in the everyday environment and in animal research are almost always separated by longer periods of time. Recent work has shown that rapidly paced learning sessions rely predominantly on short-term working memory. Importantly, spacing is also known to have strong positive effects on item memory across species and in reward learning in animals, suggesting a quantitative or qualitative shift in the underlying learning mechanisms. Remarkably, the effect of spaced training on human reinforcement learning has not been investigated. In our experiments, we examined reward learning distributed across weeks vs. learning completed in a traditionally-paced single session. Participants learned to make the best response for landscape stimuli that were either associated with a positive or negative expected value. In our first study, as expected, we found that after equal amounts of extensive training, performance was near ceiling and equivalent between the spaced and massed conditions. Critically, in a final online test 3 weeks later, we found greater value association discrimination for spaced-trained stimuli. Our fMRI results suggest that in contrast to spaced value associations, massed associations elicited greater PFC engagement and differential putamen activity. In our second study, we found a significant positive relationship between early learning performance and working memory, supporting a role for short-term

memory in single-session tasks. Further, spaced training again showed a benefit: the rating difference for reward and non-reward stimuli in spaced-trained stimuli was maintained at a level of over 89%, versus only 31% for massed-trained stimuli. Our results indicate that single-session tasks may not lead to the kind of robust value associations that are characteristic of "habitual" value associations. Overall, these studies begin to address a large gap in our knowledge of fundamental processes of reinforcement learning, with potentially broad implications for our understanding of learning in mood disorders and addiction.

Title: Memory load modulates the dynamics of visual working memory

Authors: *M. F. PANICHELLO¹, B. D. DEPASQUALE¹, J. W. PILLOW^{1,2}, T. J. BUSCHMAN^{1,2} ¹Princeton Neurosci. Inst., Princeton, NJ; ²Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: Working memory is a dynamic process - it unfolds over periods of seconds to minutes and memories become less accurate with time. The nature of these dynamics places significant constraints on the nature of working memory representations and the neural mechanisms supporting working memory. Here, we combine psychophysical methods and computational modeling to precisely describe the dynamic forces governing working memory. We show that the accumulation of error in working memory over time is not random but reflects underlying

attractor dynamics. Furthermore, these dynamics are modulated by memory load. To identify these attractor dynamics, we trained both monkeys and humans to perform a continuous-report working memory task. In brief, subjects were asked to remember 1 to 3 colored squares. After a short memory delay, subjects had to report the color of a cued stimulus on a continuous color wheel. Dynamic models fit to the behavioral responses of both monkeys and humans showed random diffusion dominated the dynamics at low memory load but strong attractors dominated dynamics at high memory load. In other words, memory dynamics are load-dependent: attractor depth increased with the number of items in working memory. These results provide a mechanistic explanation of the severely limited capacity of working memory - the observation that as the number of items to be remembered (memory load) is increased, the accuracy of memory reports is reduced (Bays, Catalao, & Husain, 2009; Luck & Vogel, 1997; van den Berg et al., 2012; Zhang & Luck, 2008). Furthermore, the finding of increasing attractor depth with memory load may provide a normative way of reducing interference among memory items when memory load is high.

Title: Medial prefrontal cortex compresses concept representations through learning

Authors: *M. L. MACK¹, A. R. PRESTON², B. C. LOVE³ ¹Univ. of Toronto, Toronto, ON, Canada; ²The Univ. of Texas At Austin, Austin, TX; ³Univ. Col. London, London, United Kingdom

Abstract: Prefrontal cortex (PFC) is sensitive to the complexity of incoming information and theoretical perspectives suggest that a core function of PFC is to build efficient codes that highlight goal-relevant features by filtering out irrelevant content. At the heart of these accounts is the hypothesis that during learning, medial PFC (mPFC) performs data reduction on incoming information, compressing less critical features to emphasize encoding of goal-relevant information structures. Although emerging evidence suggests that goal-specific representations occur in the rodent PFC, such coding in human PFC remains poorly understood. Here, we directly assess the data reduction hypothesis by leveraging an information-theoretic approach to measure how learning is supported by neural compression processes. Participants learned to classify the same insect images composed of three features across three different problems. These problems were defined by rules for which 1, 2, or 3 stimulus dimensions had to be considered to successfully classify. By varying the number of relevant dimensions, we manipulated the complexity of the problems' conceptual spaces. For example, whereas a 1dimensional rule that depends on the insects' leg width means the dimensions of antennae length and pincer shape are irrelevant and should be compressed during learning, a 3-dimensional rule requires that all stimulus dimensions are represented with no compression. Critically, this design allowed us to test the prediction that learning shapes the dimensionality of neural concept representations: Brain regions that learn to compress will represent simpler problems with fewer dimensions. We recorded fMRI data while participants learned the three problems and measured the degree that multivoxel activation patterns were compressed through learning using principal component analysis. Throughout the entire brain, only mPFC showed the predicted relationship between compression and conceptual complexity: Greater neural compression was found for problems with lower dimensional concepts, and importantly, this effect emerged over learning. Furthermore, by leveraging a computational learning model, we found that individual differences in neural compression predicted attentional strategies to the stimulus dimensions. Specifically, learners with greater problem-specific neural compression showed more optimal attention such that relevant dimensions were attended to and irrelevant dimensions ignored. These findings support the view that mPFC is critical for transforming information into low-dimensional representations useful for the task at hand.

Title: Neural bases of automaticity

Authors: M. SERVANT, G. D. LOGAN, *G. F. WOODMAN Dept Psychol, Vanderbilt Univ., Nashville, TN

Abstract: Automaticity allows us to perform tasks in a fast, efficient, and effortless manner after sufficient practice. Theories of automaticity propose that across practice processing transitions from being controlled by working memory to being controlled by long-term memory retrieval. Recent event-related potential (ERP) studies have sought to test this prediction, however, these experiments did not use the canonical paradigms used to study automaticity. Specifically, automaticity is typically studied using practice regimes with consistent mapping between targets and distractors and spaced practice with individual targets, features that these previous studies lacked. The aim of the present work was to examine whether the practice-induced shift from working memory to long-term memory inferred from subjects' ERPs is observed under the conditions in which automaticity is traditionally studied. We found that to be the case in 3 experiments, firmly supporting the predictions of theories. In addition, we found that the temporal distribution of practice (massed versus spaced) modulates the shape of learning curves. The ERP data revealed that the switch to long-term memory is slower for spaced than massed practice, suggesting that memory systems are used in a strategic manner. This finding provides new constraints for theories of learning and automaticity.

Title: Dependence of facial attractiveness perception on categorization induced informational constraints: A Bayesian Statistical account

Authors: *C. K. RYALI¹, A. J. YU²

¹Computer Sci. and Engin., UC San Diego, LA Jolla, CA; ²Cognitive Sci., UC San Diego, La Jolla, CA

Abstract: Though interactions between high-level perception and memory are commonplace in real life, they are typically studied separately in neuroscience. However, recent experimental findings have indicated that processes dependent on both long-term memory and short-term memory significantly alter high-level perception in complex manners. Specifically, the classical perceptual phenomenon of Beauty in Averageness (BiA), in which a face morphed from two original faces is typically judged by humans to be more attractive than the originals, significantly diminishes when the original faces are recognizable (based on long-term memory), or when the attractiveness judgment is preceded by a judgment of the similarity of the morph to the two original faces (based on working memory). A previous qualitative account of these results hypothesized that a negative affect associated with the difficulty of "disfluency" of categorizing morphed faces (either explicitly by being asked to make similarity judgments, or implicitly by automatically matching morphed faces to well-known faces) is misattributed by subjects to be associated with the attractiveness perception, thus resulting in a diminution of the BiA. However, this disfluency account cannot explain why performing the similarity judgment leads to a subsequent increase in the perceived attractiveness of the original faces, nor the original BiA effect. Here, we propose a statistical theory of how humans use a latent low-dimensional representation of intrinsically high-dimensional data (e.g. faces) to efficiently perform high-level perceptual judgments (attractiveness rating), utilize working memory to compare such items (similarity judgment) and encode and retrieve such items in long-term memory (celebrity recognition). Essentially, the model assumes that the extent to which a face typifies or represents the faces stored in memory contributes positively to the perceived attractiveness of the face and that a concurrent perceptual categorization task selectively enhances the importance of certain featural dimensions in the typicality judgment, thus differentially modulating the perceived attractiveness of different faces. This model explains both the original BiA effect, as well as its modulation by short-term and long-term memory-dependent categorization processes. It also gives hints as to the nature of the neural representation of complex sensory data, as well as its transformation under top-down modulation of concurrent cognitive processes.

Title: Drift diffusion modeling of interactions between episodic and working memory

Authors: *A. NOVICK, A. M. BORNSTEIN, K. A. NORMAN, J. D. COHEN Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: A primary question in memory research is how different forms of memory interact. Previous work has shown episodic memory (EM) supports short-term memory tasks when working memory (WM) is overloaded or maintenance is interrupted (e.g., Brown, 1958; Peterson & Peterson, 1959). However, EM reactivation can occur automatically, regardless of its relationship to immediate behavioral goals (Gupta et al., 2010). We hypothesized that these ongoing EM reinstatements could affect WM maintenance, even in the absence of interference. We used a distraction-free delayed non-match to sample (DNMS) task. While accuracy in such tasks is typically at ceiling, we reasoned that response times might reveal the influence of EM. Four target words were followed by an 18 second delay, after which participants were asked whether a probe word matched the targets. Word stimuli used in the task were pre-trained in sets, each associated with a different context (face or scene picture). Temporal context models of memory predict that triggering one memory from a given context, or the context itself, will lead to other recalls from the same context (Howard & Kahana, 2002). We predicted that reinstating the context associated with the probe word during the delay period would introduce the probe word into WM, even if it was not one of the target words. We predicted that this errant presence of the probe in WM would slow response times when participants were asked whether the probe word was one of the targets (i.e., whether it matched the contents of WM) when it was not. To measure the influence of context reinstatement on performance in a specific trial, we used multivariate pattern analysis of fMRI BOLD signal in ventral temporal cortex to generate a trialby-trial measure of which specific contexts were reactivated during the delay period. We modeled WM search at response as a thresholded evidence accumulation process using drift diffusion models (Ratcliff, 1978). Using this approach, we fit a model in which drift rate (reflecting the consistency of information in WM) varied with neural evidence for context reinstatement, compared it to several alternative, behavior-only models, and found that the neural model provided a superior fit (p=0.01).

These results reveal a previously hidden effect of EM on WM, opening new questions about both WM representations and the adaptive benefits of EM replay.

Title: Efficient learning: Manipulating context to enhance (or diminish) memory

Authors: *J. R. MANNING¹, K. ZIMAN², A. C. HEUSSER³

¹Dept. of Brain and Psychological Sci., ²Psychological and Brain Sci., ³Psychology, Dartmouth Col., Hanover, NH

Abstract: Our memory systems leverage the statistical structure of our experience (context) to organize and store incoming information and retrieve previously stored information. Here we explore the extent to which (and the circumstances under which) these processes may be manipulated, and how they are similar and different across individuals. We developed a series of word list learning paradigms that enabled us to systematically manipulate the context in which each word is learned. Each word was imbued with a set of features (word category, size of the object the word referred to, location on the screen, word length, starting letter, font color, etc.). In Experiment 1, we had participants study a series of 16 lists. The words on the first 8 lists were presented in an order sorted along one feature dimension (e.g. words presented alphabetically), and the words on the second 8 lists were always studied in a random order. We could then ask: how does imposing this structure on early lists affect memory performance for those early lists, and to what extent do those effects linger on later lists where that structure is no longer maintained? In Experiment 2, we had our participants study a series of randomly ordered lists to estimate each person's tendency to organize their recalls along each feature dimension. For example, even though all of the words on those lists were presented in a randomized order, some participants were more likely to group their recalls by the word categories, others were more likely to recall the words in alphabetical order, etc. Given the participants' tendencies, we adapted the presentation orders of subsequent lists. We found that when participants studied words in an order that matched their recall tendencies on previous lists, they remembered more words overall. We also present preliminary data showing that people's memory tendencies may be decoded from electrophysiological data recorded as they study each word, suggesting that neuroimaging data might be incorporated into adaptive learning experiments to further enhance memory.

Title: Prototype model correlates in the VMPFC during concept generalization

Authors: *C. R. BOWMAN, D. ZEITHAMOVA

Univ. of Oregon, Eugene, OR

Abstract: Healthy memory function involves both the ability to remember specific details of prior events and the ability to integrate common event features to form generalized concepts. The ventromedial prefrontal cortex (VMPFC) has been shown to support the latter integrative memory function in episodic memory tasks. However, formation of integrated representations in these tasks is dependent on specific memory for individual components to be integrated. Whether this dependence is always the case has been of considerable debate. Some computational models of concept learning have proposed that abstract information is extracted from individual instances and need not be maintained as a distinct representation (exemplar models). Other models propose that representations of central tendency form separately or in the absence of exemplar representations (prototype models). We used a category-learning task to simultaneously measure abstract and event-specific representations that may dissociate. Participants were trained to sort exemplars into two categories, then underwent fMRI during a generalization test that probed for category knowledge applied to novel exemplars. Exemplar and prototype models were fit to behavioral data in individual subjects and then used as regressors in neuroimaging data to identify the neural correlates of each. Results showed predominant prototype use in behavior accompanied by robust prototype correlates in the VMPFC. Further, the strength of prototype representations in behavior correlated with the strength of category representations detected in VMPFC. Despite weaker exemplar model fits to behavior, exemplar correlates were found in visual and lateral prefrontal regions. Thus, results suggest that neural mechanisms supporting memory integration do so across memory domains and that multiple memory representations may be detected even when one dominates behavior.

Title: Adaptive cognitive flexibility improves both prospective and long-term remembering

Authors: *S. KOSLOV¹, J. A. LEWIS-PEACOCK^{1,2} ¹Psychology, Univ. of Texas, Austin, TX; ²Inst. for Neurosci., Austin, TX

Abstract: Prospective memory describes the ability to remember to perform goal-relevant actions at an appropriate time in the future. The multiprocess view of prospective memory posits that two separable control mechanisms underlie this ability: proactive control, which involves maintenance of goal information in working memory and monitoring of the environment for relevant cues; and reactive control, involving the formation of cue-response associations which are later automatically retrieved from episodic memory. Individuals will often engage proactive and reactive control strategies appropriately when the demands of the task environment are stable. For instance, individuals tend to rely on reactive control in situations with a high cognitive load, whereas proactive control is favored in situations with fewer cognitive demands (Lewis-Peacock, Cohen, & Norman, 2016). When task demands vary, sub-optimal strategy use can lead to performance costs and memory failures. Being able to adaptively implement control strategies in response to changing task demands is important, but little is known about if and how people accomplish strategy flexibility. Here, we sought to characterize the flexibility of control strategy use for prospective remembering in situations with rapidly varying task demands. Participants were asked to identify the reappearance of picture targets (a small set of faces and scenes, one per trial) while at the same time performing an orthogonal visual search task that fluctuated in difficulty. After the experiment, participants were given a surprise memory test for the target items. Behavioral results indicate that the degree to which subjects adapted their control strategy on a moment to moment basis (e.g., switching from a proactive strategy to a reactive strategy for the target when the search task became more difficult) predicted better delayed execution of goals and better long-term retention of those goals. Conversely, sticking with a non-adaptive strategy hurt both performance metrics. Preliminary neural results, using multivariate pattern analyses of fMRI data to track working memory use during each trial, corroborated the behavioral findings; subjects allocated cognitive resources in response to changing task demands in a fluid and flexible manner. Moreover, neural decoding of working memory content also demonstrated that the degree to which individuals adaptively adjusted

strategies was linked to improvements in memory performance. These results highlight an important link between cognitive control and memory, and motivate the use of adaptive cognitive flexibility as a target for cognitive training paradigms.

Title: Rational use of long-term and working memory in goal-directed behavior: A normative account of prospective memory

Authors: *I. MOMENNEJAD¹, K. NORMAN², J. D. COHEN², S. SINGH³, R. L. LEWIS⁴ ¹Princeton Neurosci. Inst., ²Princeton Univ., Princeton, NJ; ³Univ. of Michigan, Michigan, MI; ⁴Psychology and linguistics, Univ. of Michigan, An Arbor, MI

Abstract: The execution of planned action demands adaptive interaction between noisy streams of memory and perception. We propose a normative approach to modelling and understanding the strategic use of long-term memory (LTM) and working memory (WM) in planned dual tasks. We formulate such tasks as problems of computational rationality, asking how a rational agent would integrate information across noisy perceptual and memory streams to maximize goaldirected task performance. For instance, successful realization of non-immediate plans typically requires the organism to hold on to a future plan while accomplishing other intermediate activities, a capacity known as prospective memory. Thus we have selected a number of classic human experimental findings on prospective memory (PM), where the agent performs an ongoing task while monitoring the environment for rare goal states (target stimuli) upon which the agent performs a planned prospective task. We present a model of a dual-task setting involving a prospective memory task and an ongoing working memory task and assess model predictions against human performance reported in the prospective memory studies. To solve the WM-EM strategic allocation problem in these tasks, we adopt a Bayesian optimal control formulation in which both probabilistic task structure and bounds on the agent's memory and perception determine optimal behavior. We address the computational challenges of finding optimal behavioral policies using reinforcement learning algorithms, and explore the implications of varying the constraints on memory, perception, and policy space. The normative model offers a principled framework for understanding how LTM and WM should be used to

realize planned action. However, the nature of optimal behavior may vary across populations with different WM capacities, neural impairment, or memory disorders. Our approach can be extended to study model parameters that govern the bounded rationality of memory use in planned action in neuroimaging data, and across different populations.

Title: The precision of context-based prediction biases memory pruning

Authors: ***H. KIM**¹, M. L. SCHLICHTING², A. R. PRESTON^{3,4}, J. A. LEWIS-PEACOCK^{3,4} ¹Dept. of Psychology, Univ. of Texas At Austin, Austin, TX; ²Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; ³Dept. of Psychology, ⁴Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: When the statistics of our experiences change, our memory is updated by weakening ("pruning") unreliable memories that generate automatic, but incorrect, predictions (Kim et al., 2014). Here, our goal was to determine how the precision of context-based memory predictions (i.e., item vs. category) impacts memory pruning. We hypothesized that contexts that tend to generate specific predictions (e.g., "that striped tiger") would produce prediction errors that lead to pruning of those memories when an unexpected item appeared instead (e.g., a breakfast taco). However, contexts that tend to generate broader predictions (e.g., "some kind of animal") would not lead to pruning of the previous memory if the unexpected item satisfied the broader prediction. We tested this hypothesis by asking observers to make subcategory judgments (e.g., female vs. male) on a sequence of items for which we manipulated the transition probabilities. During this incidental learning task, certain items ("cues") appeared four times followed each time by a new item. Cues were either followed always by an item from a different category (e.g., Beyonce-tiger, Beyonce-taco, etc.), or followed by items from a single category (e.g., the cue is followed by "animals" such as Adele-deer, Adele-owl, etc.). We reasoned that when the reappearance of a cue reliably predicted the category of the following item, the precision of context-based predictions generated from this cue would broaden from item to category, and thus item-specific prediction errors would decrease. Consistent with our hypothesis, we found that cues which generated item-specific predictions led to pruning of the predicted items more often than when a cue reliably predicted the category of the upcoming item. fMRI results indicated that only for cues in the different-category condition that were followed by new items from new categories did stronger predictions of previous items lead to more forgetting of those items. This suggests that pruning occurs based on the prediction errors between specific items. These results also suggest that when memory predictions are broadened from item to category, as in the same-category condition, prediction error decreases and memory of the previous items are more likely to be preserved. However, once the predictions were broadened, this also reduced the encoding specificity and later recognition of the subsequent items, highlighting a tradeoff between preserving old memories and building new ones.

Title: Contributions of working memory and across-trial probability learning to context-based decisions

Authors: *O. LOSITSKY¹, M. SHVARTSMAN¹, J. D. COHEN¹, R. C. WILSON² ¹Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; ²Univ. of Arizona, Tucson, AZ

Abstract: Context (such as our location or current goal) can inform our decisions by predicting upcoming stimuli and relevant responses. However, we often face a trade-off between developing predictions that maximize reward for specific contexts vs. priors that generalize across contexts. We investigated this trade-off in a simple decision-making task (AX-CPT) in which a contextual cue (A or B) signals the correct response (left or right) to a probe (X or Y) that appears seconds later (AX or BY => right, BX or AY => left). To test when people form specific priors for each cue, subjects were given different probabilities of seeing X and Y depending on the cue. For A cues, all subjects saw X more frequently than Y (pressed the left button more). For B cues, some subjects saw more X's (pressed the right button more) while others saw more Y's (pressed the left button more). We hypothesized that subjects who pressed the left button more often for B would form a general expectation to press left, while subjects who pressed the right button more often for B would develop separate priors adapted to each cue.

Our hypothesis was partially correct. Using a drift diffusion model we had built, we measured people's priors (tendency to expect the left response) as a function of the cue. We found that response priors were averaged across A and B cues when they made sufficiently similar predictions, sacrificing reward rate in the service of simplicity. This averaging of response probabilities across cues was consistent with their explicit reports of the trial frequencies during debriefing. Explicit probability reports also revealed that, when A and B predicted the same probe but different responses, subjects did not form distinct priors for each cue as we had predicted: instead, they now averaged the probability of seeing X, instead of the probability of pressing left, across cues. In other words, subjects appeared to organize observations differently depending on which dimension was most predictive. To verify that this averaging reflected their internal representation of the task, we ran a follow-up study in which the probabilities of X / Y for B cues changed in the middle of the experiment. This study showed that subjects continued to group their observations according to the same dimension they learned earlier in the experiment, even when the environment no longer favored such groupings. Our work helps dissociate the contributions of across-trial learning from within-trial context memory to behavior on this task, which has been used to diagnose working memory deficits while leaving contributions from long-term memory unexplored.

Title: A Bayesian approach to inferring latent connectivity patterns from spike trains reveals that working memory maintenance induces rapid synaptic plasticity

Authors: *E. SPAAK¹, C. CONSTANTINIDIS², J. DUNCAN³, T. BUSCHMAN⁴, E. K. MILLER⁵, M. G. STOKES¹

¹Dept. of Exptl. Psychology, Oxford Univ., Oxford, United Kingdom; ²Wake Forest Univ. Sch. of Med., Winston Salem, NC; ³Med. Res. Council, Cambridge, United Kingdom; ⁴Princeton Neurosci. Inst. & Dept of Psychology, Princeton Univ., Princeton, NJ; ⁵Picower Inst. Learning Memory, Massachusetts Inst. Technol., Cambridge, MA

Abstract: Recent theoretical models suggest that rapid, temporary changes in effective synaptic connectivity (i.e., synaptic facilitation) might form a powerful potential substrate for working memory (WM) maintenance. According to these models, incoming information to be maintained in WM results in a rapid reorganization of the connectivity pattern of the neural network. The resulting WM-specific connectivity pattern will cause any future input to be processed according to the previous stimulation history, thus enabling present behaviour to be flexibly guided based on past input. Such a WM substrate is energy-efficient, robust to interference, and elegantly bridges short- and long-term memory systems.

Despite theoretical appeal, however, directly testing these models remains difficult, as it requires the simultaneous recording of large numbers of neurons and their connectivity strengths. A robust estimate of synaptic connectivity is particularly hard to obtain in populations of sparsely firing PFC neurons. We now overcome these challenges by (1) pooling data from a large archive of experiments involving simultaneous spiking recordings from multiple neurons of non-human primate PFC; and (2) developing a novel method for the detection of latent synaptic connectivity states in such recordings.

Our method to extract connectivity patterns from spike train recordings is based on Bayesian inference for generalized linear modelling (GLM) of stochastic point processes. We demonstrate that our method is highly sensitive in recovering latent connectivity states, even in the presence of considerable noise and potentially confounding fluctuations in firing rate. Furthermore, the GLM aspect of our approach enables the straightforward characterization of dynamics in the latent states, over and above 'static' connectivity.

Applying this novel method to our database of neural recordings, we discovered a significant subset of neurons that modulate their synaptic connectivity pattern as a function of WM contents. We thus identify, for the first time, an important role for short-term synaptic facilitation in the maintenance of WM. Our findings thereby extend classical models of WM maintenance based solely on persistent changes in firing rate.

Title: Memory reactivation modulates encoding and retrieval of relational memories

Authors: *N. W. MORTON, A. R. PRESTON

The Ctr. for Learning & Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Memories are not formed in isolation, but rather are learned in the context of a vast store of existing knowledge. In order to use this store of information flexibly, the memory system is thought to code information about relationships between different events. Formation of relational memories may be facilitated by complementary processes of memory integration, where existing memories are updated with information about related events, and active separation, where competing memories are stored with distinct codes to limit interference during retrieval. Recent evidence suggests that a network of regions within medial prefrontal cortex (MPFC), ventrolateral PFC (VLPFC), and hippocampus supports these complementary processes. To examine the role of memory integration and active separation in encoding of related events, we first had participants learn initial face-object and scene-object (denoted AB) pairs. Then fMRI data were collected while participants learned overlapping object-object (BC) associations, where one object (B) overlapped with the initial set of pairs. Finally, participants performed an associative inference task where they were tested on associations between A and C items, which were related indirectly through their association with the same B item. Prior evidence suggests that retrieval of indirect associations is faster when memories have been integrated into a relational network. Using multivariate pattern analysis, we found evidence of reactivation of initial pair memories during learning of overlapping object-object associations; the degree of reactivation predicted individual differences in reaction time on the inference test, consistent with our prediction that memory reactivation would support successful memory integration, facilitating flexible use of memory. We compared models of potential links between reactivation and accuracy on the inference test, and found that intermediate levels of reactivation were associated with decreased performance. Taken together, our findings suggest that intermediate levels of memory reactivation may lead to active separation of related memories, while higher levels of reactivation support memory integration. We also found that MPFC, VLPFC, and hippocampus were more active during indirect test trials where there was greater memory reactivation during encoding of the corresponding object-object (BC) association. This network of regions may serve an important role in organizing memories of related events.

Title: Sensitivity to written word structure is associated with diffusivity in ventral white matter pathways

Authors: M. YABLONSKI¹, K. RASTLE², J. S. H. TAYLOR³, *M. BEN-SHACHAR¹ ¹Bar Ilan Univ., Ramat Gan, Israel; ²Royal Holloway, Univ. of London, London, United Kingdom; ³Aston Univ., Birmingham, United Kingdom

Abstract: Morphological processing, the ability to extract information about the internal structure of words, is an essential component of skilled reading. For example, recognizing the morpheme govern inside the word government facilitates access to its meaning. Functional MRI studies have identified several cortical regions involved in morphological processing, yet the white matter underpinnings of this skill remain largely unknown. We analyzed the relationship between microstructural properties of white matter pathways, identified using diffusion MRI (dMRI), and behavioral sensitivity to written word structure, in adult English readers (N=49). To this end, we used the morpheme interference paradigm (Crepaldi et al., 2010) that quantifies sensitivity to real morphemes within invented stimuli (e.g., *addment = add+ment; compare with *addmant = add + *mant). We hypothesized that morphological processing relies primarily on ventral reading pathways, as morphemes provide cues for mapping between print and meaning. Accordingly, we targeted the inferior fronto-occipital fasciculus (IFOF), inferior longitudinal fasciculus (ILF) and uncinate fasciculus (UF). We further analyzed two dorsal pathways: the long and anterior segments of the arcuate fasciculus. Participants completed dMRI scans at Royal Holloway (3T Siemens scanner, b=1000 s/mm², 64 diffusion directions, voxel size: 2x2x2mm³) and a behavioral battery that included the morpheme interference task and measures of phonological and orthographic processing. Tracts of interest were identified bilaterally, using deterministic tractography and automatic tract segmentation (Yeatman et al., 2012). Fractional anisotropy (FA) and mean diffusivity (MD) profiles were calculated along each pathway, and Spearman's correlations were calculated between these profiles and morphemic sensitivity. Significant negative correlations were found between morphemic sensitivity and FA in the IFOF, bilaterally. Additionally, significant positive correlations were found between morphemic sensitivity and MD in the left UF and left ILF. Post-hoc analyses revealed that these effects all stemmed from positive associations with radial diffusivity. The correlations remained significant after partialling out nonword repetition scores, suggesting some level of cognitive specificity. Morphological processing thus appears to rely on ventral pathways, primarily in the left hemisphere. The results support the contribution of morphological processing to recognition and comprehension of complex words.

Title: Neural dynamics of verbal working memory in sentence comprehension

Authors: *T. KAMBARA^{1,2}, E. C. BROWN³, Y. NAKAI¹, E. ASANO^{1,4}

¹Dept. of Pediatrics, Children'S Hosp. of Michigan, Wayne State Unive, Detroit, MI; ²Postdoctoral Fellowship for Res. Abroad, Japan Society for the Promotion of Sci. (JSPS), Chiyoda-ku, Tokyo, Japan; ³Dept. of Neurolog. Surgery, Oregon Hlth. and Sci. Univ., Portland, OR; ⁴Dept. of Neurol., Children's Hosp. of Michigan, Wayne State Univ., Detroit, MI

Abstract: Sentence comprehension processes would be expected to require humans to exert verbal working memory operations in addition to semantic and syntactic processing. We attempted to dissect cortical activities attributable to verbal working memory from those involved in answering simple auditory questions. We studied 19 patients who underwent electrocorticography recording, and measured cortical high-gamma activity during both sentence comprehension and working memory tasks. The sentence comprehension task consisted of overt naming of an object (e.g.: 'Bird') relevant to a spoken question (e.g.: 'What flies in the sky?'). The working memory task, consisting of brief maintenance of a verbally provided set of two or four letters followed by deciding whether a subsequent target letter had been included, effectively allowed us to identify regions involved in verbal working memory maintenance and scanning processes. Superior-temporal high-gamma activity was augmented bilaterally during stimulus presentation commonly in both tasks. Left inferior precentral high-gamma activity began to be augmented in the middle of question stimuli and gradually built up afterwards in the sentence comprehension task, whereas activity was augmented throughout the maintenance period in the working memory task. Around the stimulus offset of the sentence comprehension task and during the scanning period of the working memory task, high-gamma activity was augmented commonly in widespread areas of the left temporal-parietal-frontal association neocortex. High-gamma augmentation specific to the sentence comprehension task was noted in the inferior-temporal gyrus, fusiform gyrus, occipital lobe as well as pars orbitalis of the inferiorfrontal gyrus of the left hemisphere. In summary, early left inferior-precentral high-gamma augmentation during the sentence comprehension task may be, in part, attributed to working memory maintenance function. Substantial proportions of subsequent high-gamma augmentation in the left temporal-parietal-frontal association neocortex may be attributed to working memory scanning function. High-gamma augmentation in the left ventral visual pathway following

question offset cannot be attributed to verbal working memory function and may reflect processing of mental images semantically relevant to the task. High-gamma augmentation in the pars orbitalis of the left inferior-frontal gyrus may reflect syntactic or semantic processing of sentence questions.

Title: Searching for the categorical structure of abstract concepts

Authors: *C. WALSH, S. J. GOTTS, A. MARTIN Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Object concepts fall naturally into easily identifiable and distinct categories such animals, tools, furniture, flowers and the like. In contrast, our large corpus of abstract concepts do not easily fall into distinct categories. In order to make progress on understanding the neural underpinnings of abstract concepts it seems that the first questions that must be addressed concern distinctions among abstract concepts. Do abstract concepts show a categorical structure? Do clear boundaries exist between these different categories? In this study we sought to address these questions using a novel behavioral sorting paradigm and a measure of automatic semantic priming.

We completed two experiments. In the first experiment, subjects (n=20) performed a computerized clustering task using 35 words that referred to abstract concepts. All words were rated very low on concreteness and imageability based on standard published norms (Coltheart, 1981; Brysbaert et al., 2014). Participants were presented with the words randomly distributed around a circular array on a computer screen and asked to group them in any way they saw fit. A k-means clustering analysis identified four consistent and robustly separated abstract word clusters, which we called: 1) cognition and thoughts, 2) negative qualities, 3) morality and personality, and 4) aesthetics and morals. When compared to chance (determined through random shuffling of rows/columns for each individual subject in permutation testing, 5000 iterations), within-cluster distances were all significantly smaller than chance (P<.0002, for all) and between-cluster distances were larger than chance (P<.002, for all but cluster 2 with cluster 3, P<.13). These results indicated that abstract concepts can be reliably categorized. We then used these clusters in an automatic semantic priming paradigm with 15 new subjects in

order to determine whether they were behaviorally relevant and automatically processed. Prime words were briefly presented (100 msec), pattern masked (50 msec followed by 100 msec blank screen), with the probe word presented for 250 msec and participants judging whether the probe was a concrete or abstract word. The prime-probe relationship did indeed influence response time, but not in the expected direction: within-cluster pairs yielded significantly slower, rather than faster responses relative to the across-cluster pairs (paired t-test: t=3.259 (df=14), P<.01). We are currently evaluating this inhibitory effect using different priming paradigms (e.g., lexical decision) and different subsets of abstract words.

Title: Decoding how the human brain parses continuous speech into linguistic representations

Authors: *L. GWILLIAMS, J.-R. KING, D. POEPPEL Psychology, New York Univ., New York, NY

Abstract: Language is generally described with multiple levels of description, building from speech sounds (e.g. /d/, /k/) to lexical items (e.g. dog, cat) to syntactic structures (e.g. dogs [SUBJECT] chase [VERB] cats [OBJECT]). How does the human brain encode and combine these hierarchical representations to ultimately derive meaning from continuous speech? Twenty-one native English participants listened to four fictional narratives that were fully annotated - from speech sounds to syntactic structures - such that each of these levels could be correlated with brain activity. This naturalistic but controlled setup allowed us to decode, localise and track phonemes, part of speech (POS) and syntactic operations from magnetoencephalography recordings (MEG) using machine learning algorithms. First, low-level phonetic features (e.g. voicing, manner, place of articulation) can be successfully discriminated from a sequence of

neural responses unfolding between ~100 ms to ~400 ms after phoneme onset. Second, POS (e.g. verb, noun, adjective), indicative of lexical processing, can be decoded between ~150 ms and ~800 ms after word onset. Third, we could decode and track both syntactic operations (e.g. number of closing nodes) and syntactic states (e.g. depth of tree) as predicted by theoretical linguistics. Interestingly, some of these syntactic representations are clearly present several hundreds of ms before word onset, whereas others maximally peak ~300 ms later. Overall, these sustained and evoked MEG responses show that the human brain explicitly represents each level of description, as proposed by linguistic theories. The corresponding neural assemblies overlap in space and time, which suggests that speech comprehension is implemented with a cascade architecture. Additionally, our study illustrates how the combination of machine learning and traditional statistics can bridge the gap between spatiotemporally-resolved neuroimaging data and rich but tractable naturalistic stimuli.

Title: Processing syntactic and prosodic information during sentence comprehension

Authors: *C. L. VAN DER BURGHT¹, T. GOUCHA¹, A. D. FRIEDERICI¹, J.

KREITEWOLF^{1,2}, G. HARTWIGSEN¹

¹Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; ²Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: In everyday conversation, various types of information need to be brought together. When processing a sentence, we understand 'who is doing what to whom' not only by the words used, but also by how the utterance is spoken. Both word forms and speech melody (prosody) establish which words belong together, creating syntactic boundaries between different parts of a sentence. For example, words can be grouped by syntactic cues (a particular word form) or by prosodic boundaries (a sentence pause). The neural correlate of how these different types of information contribute to sentence comprehension are yet to be specified. We used fMRI to address this issue, hypothesizing that if a prosodic boundary is processed as a syntactic boundary rather than only as a prosodic event this would lead to left hemispheric activation, possibly in the inferior frontal gyrus (IFG). In our experiment, we measured the processing of different types of utterances in which the message was established by either the word form, a sentence pause, or a combination of these. Subsequently, participants made a decision about which role a particular agent fulfilled in the action in the sentence, basing their response either on the syntax or the
prosody. Our results show that the contribution of the left IFG to speech processing depends on the information that is available and required for sentence comprehension. We found that taskrelated activity in the left IFG was increased when the syntactic boundary was marked by only one element (either syntactic or prosodic), as contrasted to sentences in which both syntactic and prosodic elements were marking the boundary. In accordance to the literature, a strong contribution of the left IFG was revealed when the syntactic cue was decisive for sentence meaning. As hypothesized, when a sentence boundary was indicated by a prosodic boundary only, the main activation was also found in the left IFG, as opposed to the right hemispheric activity commonly found for purely prosodic events. Our results suggest an involvement of the left IFG in function of the processing demands during sentence comprehension, regardless of whether a listener relies on what is being said, or how it is said.

Title: The neural bases of syntactic processing in American Sign Language: Evidence from fMRI and MEG

Authors: *A. K. VILLWOCK, W. MATCHIN, A. ROTH, D. ILKBASARAN, M. HATRAK, E. HALGREN, R. MAYBERRY UCSD, La Jolla, CA

Abstract: Language does not consist merely of sequences of words, but rather hierarchical linguistic structure. Previous research has illustrated that despite the fact that signed languages use a different modality than spoken languages, they involve the same syntactic properties. Neuroimaging studies on spoken languages using magnetoencephalography (MEG) and functional magnetic resonance imaging (fMRI) have routinely identified a core combinatorial language network consisting of left hemisphere brain regions, including the posterior and anterior temporal lobe and the inferior frontal gyrus by contrasting linguistically structured with unstructured stimuli. However, to date, the neural network for syntactic processing in signed languages is unknown. The present study investigated the neural bases of combinatorial linguistic processing in American Sign Language (ASL) in a group of congenitally deaf native

signers (N = 13). We conducted a parametric study of the processing of hierarchical linguistic structure using fMRI and MEG. The stimuli were sequences of six signs presented at three levels of syntactic complexity: unstructured word lists, simple two-word sentences, and six-word complex sentences. Stimuli were presented in blocks of three, six-word sequences. During both the fMRI and MEG experiments, participants determined whether a probe picture presented following a stimulus displayed the meaning of a sign in the sequence. We predicted increased activity for higher linguistic complexity in the same left hemisphere regions that have been identified in previous studies on spoken languages. The fMRI results showed that activity in both anterior and posterior portions of the left superior temporal sulcus increased parametrically with degree of structure. The MEG results showed the contrast of six-word sentences minus unstructured word lists to display increased activity for sentences in the temporal pole within the N400 time window (300–500 ms). These results are the first to demonstrate that the underlying neural basis of abstract syntactic processing is not altered by the sensory-motor channel of language reception and expression.

Title: Cerebellar Crus I and caudate nucleus volumes are associated with deficits in verbal working memory in FOXP2 point mutation

Authors: *G. P. ARGYROPOULOS¹, K. SCHULZE², M. MISHKIN³, F. VARGHA-KHADEM^{1,4}

¹Cognitive Neurosci. and Neuropsychiatry Section, UCL Great Ormond Street Inst. of Child Hlth., London, United Kingdom; ²Clin. Psychology and Psychotherapy Unit, Inst. of Psychology, Heidelberg Univ., Heidelberg, Germany; ³NIMH, Bethesda, MD; ⁴Great Ormond Street Hosp. for Children Natl. Hlth. Fndn. Trust, London, United Kingdom

Abstract: Introduction: We previously reported¹ an impairment in the phonological loop² component of working memory (WM) in affected members of the KE family (aKE), who have a verbal and orofacial dyspraxia resulting from a *FOXP2* point mutation³. We now report the

relationship between this deficit and volumes of the caudate nucleus and cerebellar Crus I. regions with pronounced structural/functional abnormalities in aKE members^{4,5}.

Methods: We assessed the WM of 5 aKE members with a test⁶ based on the Baddeley and Hitch WM model². We calculated their Crus I and caudate nucleus volumes (T₁-weighted MRIs), and correlated these volumes with their verbal (backward digit recall; counting recall; listening recall; word list recall; word list matching; digit recall) and non-verbal WM measures (block recall; mazes memory).

Results: Verbal WM scores were selectively lower for aKE members, and negatively correlated with their caudate nucleus and Crus I volumes. Non-verbal WM scores showed no decrement or correlation with those volumes (fig. 1).

Fig. 1: Crus I and caudate nucleus volumes correlate negatively with verbal (a-d) but not nonverbal WM (e-g); *: p < .05.

Discussion: Our results suggest an association between impaired articulatory rehearsal in WM¹ and the cerebellar/striatal abnormalities in aKE members^{4,5}, consistent with early FOXP2 expression in these structures³ and their reciprocal connectivity⁷. Our findings are in line with previously reported negative correlations of both volumes with measures of complex non-word repetition^{4,5}, and may reflect ontogenetic compensatory mechanisms resulting in abnormally increased GM density in basal ganglia structures of aKE members (e.g. putamen⁴).

Title: The effect of overt and covert speech on visual word recognition

Authors: *C. KOHEN, K. WINSLER, K. J. MIDGLEY, P. J. HOLCOMB Psychology, San Diego State Univ., San Diego, CA

Abstract: Efference copies are the internal representations of the perceptual consequences of a motor action. This copy is thought to be a crucial link between sensory and motor systems, however its top-down role in higher level perceptual processing remains overlooked. Recently Tian and Poeppel (2013) demonstrated an early role of efference copies in speech processing using overt and covert (imagined) production of single spoken syllables. Similarly, the current study investigated the role of efference copies in visual word recognition using event-related potentials (ERPs). Thirty participants viewed 40 trials in which they were cued to do nothing or produce speech (either overtly) of a repeated or unrelated monosyllabic three-letter word. This was split into two blocks, an overt block (say) or a covert (imagine saying) block. Results showed reduced negativities to repeated words as early as 150ms only if participants produced speech (either overtly or covertly; p = .02). Additionally, repeated words produced less negativity throughout the N400 (p < .01) and this effect was larger if either overt or covert speech was produced (p < .01). No statistical differences were found between overt and covert production. Overall, the results suggest an early, perhaps amodal, top-down influence of spoken word efference copies, comparably elicited via speech or imagined speech, on the perception of written words.

Title: Dynamics of start and stop signals during language production

Authors: *N. JANSSEN

Univ. De La Laguna, La Laguna, Spain

Abstract: The starting and stopping of movement plays a central role in many human behaviors. Previous research has revealed that starting and stopping motor behavior relies on a complex cortical-subcortical circuit involving, among others, the Sub-Thalamic Nucleus (STN), the Right Inferior Frontal Gyrus (RIF), and the pre-Supplementary Motor Area (pre-SMA). However, these conclusions are based almost exclusively on tasks that require manual responses (e.g., Aron et al., 2014). Here we examined the involvement of these areas in the starting and stopping of human speech using a verbal response task. We examined the temporal dynamics and functional connectivity between areas using a novel fMRI technique that permits the extraction of a more accurate and high temporal resolution BOLD signal (Slice-Based fMRI; Janssen et al., submitted).

We examined starting and stopping behavior in a blocked naming task in which 30 participants produced the names of objects presented at a high frequency (1.25 Hz). The high demands of this task required quick starting and abrupt stopping behavior. We first verified the involvement of various cortical and sub-cortical areas among which the STN, RIF, and pre-SMA in the task by extracting standard whole-brain activation maps during the start and stop periods. We then examined the temporal dynamics of processing in each area by obtaining time-relevant measures from Gaussian curve-fitting to the BOLD signals in start and stop periods. Finally, we used an AAL parcellation of the brain to examine the task-based functional connectivity and hierarchical clustering between the three areas and the rest of the brain at high temporal resolution (0.954 ms).

Our results revealed that whereas subcortical areas such as Caudate Nucleus, Putamen, and STN and cortical areas such as Primary Motor Cortex, RIF, and pre-SMA were active during both starting and stopping, only STN, RIF, and pre-SMA were more active during stopping than during starting. In addition, Gaussian curve fits revealed that the STN had an early time-to-peak that was similar to the RIF, while the pre-SMA had a slower time-course. Functional connectivity analyses revealed clusters in which STN and RIF were interconnected with areas

involved in motor control (putamen, thalamus, cerebellum, operculum), whereas pre-SMA was connected to areas involved in response evaluation (caudate, mid-cingulum, amygdala). Together these results provide evidence for a system of starting and stopping that generalizes across response modalities, and speak to on-going debates on the neural implementation of response inhibition (e.g., Duann et al., 2009; Forstmann et al., 2008; Wiecki & Frank, 2013).

Title: Neural entrainment to acoustic edges in native and foreign speech

Authors: *M. CUCU, N. KAZANINA, C. HOUGHTON Sch. of Exptl. Psychology, Univ. of Bristol, Bristol, United Kingdom

Abstract: Cortical neural oscillations in response to speech were found to show theta activity which is synchronous to the syllabic rhythm (Luo and Poeppel, 2007), yet the exact mechanism which triggers this synchronisation is yet to be discovered. One hypothesis is that the onset of the syllable provides an 'acoustic edge' to which neural populations may preferentially respond. These edges would act as landmarks in the speech stream, triggering phase locking between the sound and neural oscillations. In the current experiment, we manipulated the strength of the syllable edge by varying the nature of the consonant in the syllable onset: 'strong' stop consonants: 'b', 'd', 'g', 'k', 'p', 't' vs. 'weak' fricatives or approximant consonants: 'f', 'l', 'r', 's', 'v', 'z'. This manipulation yielded Strong-edge and Weak-edge conditions respectively, that contained length- and stress-matched sentences consisting of words in which every syllable started strong vs weak consonant.

Participants listened to four repetitions of 40 Strong-edge and 40 Weak-edge sentences while their EEG activity was recorded. Half of the sentences were in English, half in Russian, a language not understood by the participants. The sentences were recorded in the lab by a bilingual English-Russian speaker. In line with previous findings (Doelling et al, 2014), we predicted more entrainment in the Strong-edge then Weak-edge condition (see Figure 1), as well as more entrainment between the speech stream and the EEG signal when the language is understood by the participant (Peele and Davis, 2012). Entrainment will be assessed in terms of the phase coherence between the EEG signal and the envelope of the acoustic signal. The results will outline the importance of the acoustic quality of the syllable edge in resetting the theta rhythm, and potentially shed light onto the mechanisms of theta-gamma coupling during speech perception.

Title: Effects of language proficiency on cognitive control: Evidence from Resting-State functional connectivity

Authors: *X. SUN¹, L. LI², G. DING², P. LI³, R. WANG¹

¹Sch. of Psychology, South China Normal Univ., Guangdong, China; ²State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; ³Pennsylvania State Univ., University Park, PA

Abstract: Cognitive studies have suggested that bilingualism plays an important role in the development of cognitive control, specifically in that bilingualism has been found to promote cognitive domains in switching and inhibition. In recent years functional neuroimaging studies suggest that bilingual experience changes neural activity in the cognitive control network. The present study used resting-state functional connectivity (RSFC) to explore the impacts that bilingualism, especially language proficiency, had on the networks of executive function. Seed regions centering on different components were selected for the RSFC analysis. Our RSFC analyses of high versus low proficiency bilinguals show that bilingualism has effects on distinct components of executive control. Specifically, significant differences were observed in the left anterior cingulated cortex (left ACC) for cognitive switch, but in the right middle frontal gyrus (rMFG) for inhibition. No difference was found for components of working memory. Thus, language proficiency could be interpreted to cause changes on some but not others components of cognitive control in the neural network. Finally, our findings indicate decrease in the strength of functional connectivity in the cognitive control network in high proficiency bilinguals, suggesting that higher proficiency in the second language results in less effortful processing and lower cognitive effort.

Title: Spatial multiscale fMRI analysis of the human cortical language system

Authors: *P. KELLMEYER, R. BERKEMEIER, T. BALL

Dept. of Neurosurg., Univ. of Freiburg, Med. Ctr., Freiburg, Germany

Abstract: In the last two decades, neuroimaging research has provided important insights into structure-function relationships in the human brain. Recently, however, the methods and software used for analyzing fMRI data have come under increased scrutiny with studies questioning the cross-software comparability¹⁻³, the validity of statistical inference⁴⁻⁶ and interpretation⁷, as well as the influence of the spatial filter size on fMRI (and PET) analysis⁸⁻¹⁰. Here, we use a spatial multiscale analysis with a range of Gaussian filters from 1-20 mm at fullwidth half maximum (FWHM) in analyzing fMRI data from a speech repetition paradigm in 25 subjects with the widely used software "Statistical Parametric Mapping" (SPM). We show that analyzing the fMRI data over a range of Gaussian filter kernels ranging from 1 to 20 mm FWHM reveals substantial variability in neuroanatomical localization as well as the average signal strength (Fig. 1A) and size (Fig. 1B) of suprathreshold clusters depending on the filter size. We also demonstrate how small spatial filter kernels bias the results towards subcortical and cerebellar activation clusters and that the atlas-based anatomical assignment of suprathreshold clusters shifts in relation to the filter size. Furthermore, we found substantially different scale-dependent cluster size dynamics between cortical and cerebellar clusters (Fig. 1C and D).

Each of the different ensembles of regions at any given filter size could be discussed along the existing literature on speech processing. The vast majority of fMRI studies, however, only use a single filter for analysis within narrow range of filter sizes. Our findings suggest that this single-filter approach seems to severely constrain the interpretation of individual fMRI studies and the validity of meta-analyses based on this body of studies. The limited multiscale analysis used here may inform the interpretation of structure-function relationships in analyzing fMRI data. We propose to develop true spatial multiscale analyses to fully explore the deep structure of the BOLD signal in Gaussian scale space.

Authors: *S. GAO, Y. YIN, D. YAO UESTC, Chengdu, China

Abstract: While dynamic brain modularity has recently been proposed to explain the neural basis of consciousness it still remains unclear how modular networks specifically reconfigure to optimize their functional operation for conscious and non-conscious processing. Here we measure brain network flexibility by the allegiance of nodes to modules during a word masking procedure and show that the visibility of target words is characterized by shifts of certain nodes between three task-related modules recruited respectively for perception, action, and coordination. In our paradigm, participants were randomly presented with masked words, visible words, or corresponding control trials where word stimuli were replaced by blank screens, and asked to make a forced choice to categorize each stimulus as affectively positive or negative. Applying graph theory analysis to functional magnetic resonance imaging data, we defined individual voxels of activated clusters as nodes, functional connections between nodes as edges, and interconnected nodes as modules, and employed the modular allegiance of nodes as the index of dynamic reorganization of modular networks. Three modules were identified under each task condition and more importantly certain nodes updated their allegiance to modules as a function of task states. With words masked these flexible nodes, located mainly in the dorsal anterior cingulate cortex, were organized in the coordination module whereas they were reassigned to either the perception or action module when words were visible. These results suggest that the dorsal anterior cingulate cortex may act as a key region implicated in switching between conscious and non-conscious contexts. The masking-dependent reconfiguration of functional modules revealed in this study provides a novel insight into brain mechanisms supporting conscious access.

Title: The role of social cognition on pragmatic language comprehension: A meta-analysis of fMRI studies

Authors: *M. GIORDANO, *M. GIORDANO, E. VALLES-CAPETILLO, A. REYES-AGUILAR

Univ. Nacional Autónoma De México, Querétaro, Qro., Mexico

Abstract: The use of language as a means of social communication in humans requires more than the comprehension of the meaning of the individual words and their syntax, it involves understanding the intentions of the speaker, and the context in which the words are uttered. In addition, the listener may need to decode additional meaning present in the indirect or pragmatic language used by the speaker. Thus, we proposed the hypothesis that comprehension of diverse forms of pragmatic language would implicate activation of social cognition and theory of mind brain areas. To test this hypothesis, we did a meta-analysis of 39 studies published between 2006 and 2017 available through databases that reported the results of contrasts between the pragmatic forms (PF) of interest versus literal language, in healthy adults, and that used fMRI scanning throughout the whole brain. The PF included speech acts, metaphor, idiom, irony, and sarcasm. We used the software Signed Differential Mapping (SDM version 5.12; Radua & Mataix-Cols, 2012) for creating a SDM map for each study within a mask of gray matter. With the aim of finding the mean of the voxel values of the areas involved in the processes of interest, a "mean analysis" and "subgroup analysis" were performed; the comparisons between PF, and between natural languages were performed with the general linear model analysis; and the consistency of the results was tested with the jacknife analysis. We present the results according to the cluster center. For the contrast pragmatic>literal language, our results showed significant activation of the superior and inferior frontal gyrus (left; BA 32, 45); middle temporal gyrus (bilateral; BA21, 22), and inferior frontal gyrus (right; BA 45). The contrast speech-acts>all PF showed significant activation of the superior and inferior frontal gyrus (right; pre somatomotor area BA8, and orbital, BA47), and inferior frontal gyrus (left, triangular BA45); for idioms>all PF, significant activation of the inferior frontal gyrus triangular (BA46), and for the contrast irony + sarcasm>all PF, significant activation of the superior frontal gyrus, rostro medial prefrontal cortex (right; BA11). Metaphors did not show significant activation in comparison with all other PF. We also observed differences between the areas recruited by different natural languages, for instance the Japanese language only recruited paralimbic areas (left paracingulate gyrus, BA 24). These results suggest that pragmatic language comprehension recruits the extended language network more than literal language, as well as cortical areas involved in social cognition, emotion processing, and theory of mind.

Title: Phonological but not orthographic awareness is related to oral performance in post-stroke aphasia

Authors: *Z. CHEN¹, J. CAO², Y. CAI³, W. QIU¹

¹Rehabil. Med., ²Ultrasound Med., The Third Affiliated Hosp. of Sun Yat-Sen Unive, Guangdong, China; ³Otorhinolaryngology, Sun Yat-Sen Mem. Hosp., Guangdong, China

Abstract: The activation of right hemisphere was proposed to represent a compensatory visual/orthographic strategy when language networks were damaged in patients with post-stroke aphasia. Given that Chinese is a logographic language which emphasize orthography deeply, it is reasonable to hypothesize that aphasic patients speaking Chinese prefer to retrieve their ability of oral communication by switching toward visual/orthographic strategy following stroke. However, this hypothesis has not been confirmed and it remains unclear whether visual/orthographic strategy allows fully recovery of oral performance as what the original audio/phonological pathway dose. Here we addressed these questions by exploring a negativegoing event-related potential at ~400 ms (N400) indicating orthographic and phonological awareness in 18 post-stroke aphasic patients and 15 controls. Participants viewed line-drawing pictures of objects followed by a word in Chinese or a sound of speech for two respective session, being required to decide whether the word or the sound matched the picture. Results showed that the magnitude of N400 elicited by picture-word matching task (N400w) was larger than that of N400 acquired in picture-sound matching task (N400s), suggesting that both aphasic patients and control subjects speaking Chinese rely more on visual/orthographic pathway when they process semantic information. Although both tasks were finished with high accuracy, only N400s magnitude was positively correlated with patients' verbal production and speech fluency. Besides matching tasks, patients were required to name the same objects that were used in eventrelated-potential experiments. We found that N400s existed for the objects that could be named successfully and was absent for those could not be named, whereas N400w failed to demonstrate this pattern. The association between oral performance and phonological but not orthographic awareness even in a logographic language suggests that visual/orthographic strategy could be an inefficient alternation of the neural mechanisms following stroke. The preservation and reactivation of the audio/phonological pathway should be emphasized in order to recover a higher oral performance of aphasic patients.

Title: Structural connectivity subserving verbal fluency revealed by lesion-behavior mapping in stroke patients

Authors: *M. LI, J. DING, Y. FANG, Y. XU, Z. HAN State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: Abstract Tests of verbal fluency have been widely used to assess the cognitive functioning of persons, and are typically classified into two categories (semantic and phonological fluency). While widely-distributed divergent and convergent brain regions have been found to be involved in semantic and phonological fluency, the anatomical connectivity underlying the fluency is not well understood. The present study aims to construct a comprehensive white-matter network associated with semantic and phonological fluency by investigating the relationship between the integrity of 22 major tracts in the whole brain and semantic fluency (measured by 3 cues) and phonological fluency (measured by 2 cues) in a group of 51 stroke patients. We found five left-lateralized tracts including the anterior thalamic radiation (ATR), inferior fronto-occipital fasciculus (IFOF), uncinate fasciculus (UF), superior longitudinal fasciculus (SLF) and frontal aslant tract (FAT) were significantly correlated with the scores of both semantic and phonological fluencies. These effects persisted even when we ruled out the influence of potential confounding factors (e.g., total lesion volume). Moreover, the damage to the first three tracts caused additional impairments in the semantic compared to the phonological fluency. These findings reveal the white-matter neuroanatomical connectivity underlying semantic and phonological fluency, and deepen the understanding of the neural network of verbal fluency.

Title: A quantitative analysis of speech kinematics during word learning in children with autism

Authors: *J. V. JOSE^{1,2,3}, D. WU⁴, L. GOFFMAN⁵, L. BROWN⁶, A. GLADFELTER⁷ ¹Indiana Univ., Bloomington, IN; ²Stark Neurosci. Inst., Indiana Univ., Indianapolis, IN; ³Cell. and Integrative Physiol., Indiana Univ. Sch. of Med., Indianapolis, IN; ⁴Physics, Indiana Univ. Bloomington, Bloomington, IN; ⁵Univ. of Texas at Dallas, Dallas, TX; ⁶Purdue Univ., West Lafayette, IN; ⁷Northern Illinois Univ., DeKalb, IL

Abstract: Autism Spectrum Disorder (ASD) is characterized by communication deficits and repetitive motor behaviors and routines. One core component of ASD relates to learning-with impaired word learning a central feature. Often, the delayed onset of first words is a parent's earliest concern and is a key factor in securing a diagnosis. Words are a crucial building block for language because they connect concepts, word forms, and articulatory movement. While behavioral measures of concepts and word forms are well established, there is no current quantification of the distinction in the learning associated changes in the structure of underlying articulatory movement in children with ASD compared to their neurotypical peers. In our study, we apply kinematic analyses to continuously collected articulatory movements to quantify changes in underlying features of movement as children with ASD and their typically developing peers acquire new words. To keep information in the recording, we did our analyses without manipulating or averaging the articulatory kinematic data. Three phases were included in the paradigm: a pretest, a learning phase, and a posttest. Kinematics of lip/jaw movements were continuously recorded using a Northern Digital camera system. We extracted lower lip and jaw movement while children produced six new words multiple times each. We evaluated learning phase effects by calculating the correlations between pretest and posttest and further quantified pattern changes across the two phases. Findings were that children with ASD, although they produced the words accurately, did not acquire the differentiated movement patterns demonstrated by their neurotypical peers. This lack of motor change during tasks of word learning in children with ASD may be contributing to the delayed language development in these children; it is well-established in the motor learning literature that responsivity to change (i.e., variability) during initial learning leads to greater gains in later learning and retention. If children with ASD lack speech motor pattern change during their earliest experiences with new words, gains in language learning, retention, and generalization will be more difficult later. In summary, our findings reveal that application of complex signal processing approaches provides critical insights into the process of word learning at the sensorimotor level, as well as

the underlying link between the core diagnostic features of ASD, namely communication delays and repetitive motor behaviors. Additionally, our study establishes an approach to measurement of articulatory change that is applicable generally to future speech learning studies.

Title: Amplitude, latency and theta phase coherence of event-related source generators differ during visual processing for nonverbal/minimally-verbal children with autism and their controls

Authors: *S. ORTIZ-MANTILLA, T. REALPE-BONILLA, A. A. BENASICH Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: When children with Autism Spectrum Disorder (ASD) are nonverbal (NV) or minimally-verbal (MV), it is a challenge to assess how much language they perceive and comprehend. It is known that to acquire language, children must build phonemic maps of their native language, assemble a lexicon, and learn word-object associations by mapping auditory words to visual objects. This latter process consists of relating each object's features to its corresponding semantic information, including the object's name. Nine-month old infants understand word meanings and are also able to use visual cues of objects to facilitate phonetic and phonological learning. In a recent event-related (ERP) study using a picture-word matching paradigm, 4- to 7-year-old NV/MV children with ASD showed relatively intact early sensory processing but abnormal lexical-semantic processing compared to age/gender-matched controls. However, it is not clear whether the limited ability to express and perhaps comprehend language that is observed in NV/MV children with ASD is related to absent or deficient cortical representations of objects' features and/or deficits in linking an object with its semantic information. To investigate the oscillatory underpinnings of ERP responses to visual information source generators of the sensory/perceptual response were identified and peak amplitude and latency of the sources examined. In addition, inter-trial phase locking analyses were conducted within source space. During early (0-200 ms) and late (250- 500 ms) visual processing, 3 sources, located in left and right occipital cortices and frontally at the level of anterior cingulate

cortex (ACC), explained ~93% of variance. We found that as compared to typically developing controls, the ASD group exhibited smaller amplitudes and longer latencies particularly during late visual processing in the left occipital source, and smaller theta phase coherence during both early and late visual processing for all three sources. Reduced phase coherence in the ACC indicates the ASD group may allocate less attentional resources to process visual stimuli. These results also suggest that children with ASD may have difficulties encoding stimulus features and then mapping objects with their related information. We propose that poor memory representations of common objects accompanied by diminish attentional allocation could be a factor that might explain linguistic differences observed in ASD groups. Furthermore, these results may well advance our basic understanding of the neural mechanisms that support both typical and atypical visual processing in children.

Title: Investigating neural bias to speech using auditory event-related potentials in children

Authors: *A. WHITTEN, A. P. KEY, A. S. MEFFERD, J. W. BODFISH Hearing & Speech Sci., Vanderbilt Univ., Nashville, TN

Abstract: Several previous studies have found that infants and children exhibit a preference for speech over other types of sounds using behavioral paradigms. The present study sought to determine whether neural evidence could be found for this bias using EEG/ERP in a sample of 23 eight – twelve-year-old children. In the first experiment, we measured the N1 and P2 sensory auditory ERPs and the P3a orienting ERP response to a rarely presented synthetic speech vowel and complex tone in a passive oddball task. We hypothesized a neural bias to speech would be evidenced by faster latency of the N1, P2, and P3a ERPs to the speech sound as well as larger P3a mean amplitude to the speech sound. In contrast to our hypotheses, we found a significantly longer latency of both N1 and P2 to the synthetic speech compared to the non-speech tone (N1: t(22) = 5.23, p < .001; P2: t(22) = 3.3, p < .01), and no significant differences in the P3a latency or mean amplitude. We concluded that our results may not have replicated the behavioral findings because our study (like many EEG studies) used synthetic speech rather than natural speech, and thus the behavioral findings may reflect a bias to the human voice in general, rather than the linguistic content of the speech signal. In the second experiment, we tested this theory

by measuring N1, P2, and P3a auditory ERPs to a naturally spoken vowel /a/ compared to an acoustically and complexity-matched cow utterance. Here, we found support for a neural bias to the natural speech over the non-speech with a significantly shorter latency of the N1, P2, and P3a ERPs to the natural speech (p < .05 for all contrasts). Our results provide neural evidence for a bias to natural speech, but not synthetic speech, that occurs within the first ~300 ms of cortical auditory processing. These findings have implications for theories of language acquisition in which an early bias for listening to speech is driven by a preference for the human voice. In addition, our results suggest that future studies should compare neural differences in the cortical processing of synthetic vs. natural speech in order to determine whether synthetic speech is a valid proxy for natural speech in EEG/MEG studies.

Title: Resting state alpha oscillations correlate with language ability in young children

Authors: *E. KWOK, J. ORAM CARDY, B. ALLMAN, P. ALLEN, B. HERRMANN Univ. of Western Ontario, London, ON, Canada

Abstract: Resting state α -oscillations as recorded using electroencephalography (EEG) have been proposed to be related to the excitability/inhibition status of cognitive processes. However the role of α -oscillations in the development of language abilities is less well understood. The objective of this study was to explore the relation between resting state α -oscillations in typical language development in order to establish a standard for the understanding of language disorders.

Resting-state EEG was recorded in forty-one children with typical development (4 years, n = 12; 5 years, n = 14; 6 years, n = 15). Data were recorded while children had their eyes either open or closed (three minutes each). All participants scored within normal limits on standardized measures of language (*Clinical Evaluation of Language Fundamentals*-4) and Performance IQ (*Wechsler Abbreviated Intelligence Scale*). We explored three measures of posterior α -oscillations (7-10 Hz): α -spectral power, α -band long-range temporal correlations (using detrended fluctuation analysis; DFA), and fluctuation/flexibility of α -frequency over time. The difference between eyes-closed and eyes-open conditions (α -spectral, α -band long-range correlations and α -frequency) was entered into regression analyses using age, language ability,

and Performance IQ as predictors. Regression analyses showed that all three α -measures were predicted by participants' language ability. Higher language scores correlated with: lower α -power, longer α -band long-range correlations, and greater fluctuations in α -frequency. α -measures were not predicted by age or by IQ (with the exception of a significant IQ effect for the temporal correlation measure).

To our knowledge, this is the first study exploring the relation between α -oscillations and language ability in 4–6 year old children with typical language development. Our findings revealed a unique relationship between language ability and resting state α -oscillations that is independent of chronological age and global cognitive development. Our current findings suggest that α -oscillations, which have received limited attention thus far in language development studies, may be a useful biomarker for developmental language disorders.

Title: Evidence of maturational processes in linguistic brain (fNIRS) and physiological emotional (Thermal IR) responses in hearing infants to signing virtual humans

Authors: *B. MANINI^{1,2}, G. KARTHEISER^{1,2}, A. STONE^{2,1}, A. MERLA^{3,4}, L.-A. PETITTO^{2,1} ¹Brain and Language Lab. For Neuroimaging, Washington, DC; ²Gallaudet Univ., Washington, DC; ³Dept. of Neuroscience, Imaging and Clin. Sci., Universita' Gabriele D'Annunzio, Chieti, Italy; ⁴Next2U s.r.l., Pescara, Italy

Abstract: Sensitivity to linguistic patterns depends on brain development and undergoes rapid change between ages 6 to 12 months (Petitto et al., 2012). Younger infants engage linguistic processes when exposed to any linguistic input (e.g. phonetic discrimination, activation of classic

language systems) regardless of native language (e.g. Kuhl, 2010), and signed vs spoken modalities (Baker, Golinkoff, Petitto, 2006, Petitto et al., 2011). By ~12 months, universal processes attenuate to sensitivity to infants' native language(s). Infants with reduced linguistic exposure within this developmental period are at risk for phonological, linguistic, and reading deficits (Petitto et al., 2016). (1) Can a Virtual Human (VH) using American Sign Language (ASL) be effective as an augmentative linguistic partner for *all* infants, even those without signed language experience (Petitto et al., 2017)? (2) Can ASL input from VHs (vs other types of human and non-human biological movements) engage the same neural sites associated with linguistic processing in infants and emotional arousal responses, and developmental change? Methods. 9 hearing babies (5 boys); 2 age groups: 6-7 mo. (5) and 10-11 mo. Three conditions: 1) Language: VH signing an ASL nursery rhyme (+human form, +language), 2) Dancer: Producing gentle arm movements (+human form, -language) 3) Cat: A cat playing (-human, language). Novel integration of time-locked neural (fNIRS, block design) and psychophysiological (Thermal IR) responses were measured. Results. Only the Language condition showed age-related changes and yoked neural activity and physiological responses. Younger infants showed significantly left-lateralized IFC activity, indicative of linguistic processing that co-occurred with a peaked psychophysiological response (parasympathetic) typical of social engagement. Older babies showed bilateral IFC activity and no peaked emotional responses to the *Language* condition. Hearing babies' sensitivity to language patterns even in a silent sign language to which they were never exposed, and even with a VH, supports the hypothesis that babies are predisposed to core patterns in language (Petitto et al., 2016). VH learning tools may be effective as argumentative language partners for young infants at risk of minimal language exposure, particularly deaf infants. However, our first-time discovery of *linked* higher cognitive (language) neural activity and physiological (emotional) responses typical of linguistic processing in younger vs older infants suggests that the human language learning system involves a more powerful neural circuitry than was previously understood in child language history.

Title: Using inter-subject correlation to probe the neural response to article readability during natural reading

Authors: *Y.-F. LIU¹, W.-J. KUO³, F.-H. LIN²

²Inst. of Biomed. Engin., ¹Natl. Taiwan Univ., Taipei, Taiwan; ³Inst. of Neurosci., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The neural basis of high-level language function has been studied using natural story listening and telling, but reading comprehension has seldom been studied using natural stimuli. Particularly, besides our prior study, functional areas associated with subtle article properties such as genre and level of readability still remain unexplored. In this study, we presented articles of fiction/non-fiction contents translated from English to Chinese by human and machine to subjects and BOLD-contrast fMRI was measured. We identified spatial distributions of intersubject correlation (ISC) modulated by texts of fictional/non-fictional contents and machine/human translations. In the inter-genre contrast, reading news articles resulted in significant decrease in ISC at ventral PCC (BA 23), right somatosensory cortex (BA 1-3), bilateral secondary visual cortex (BA 18), bilateral fusiform gyrus (BA 37), bilateral precuneus (BA 7), bilateral anterior insulas, and right dorsal aTL (BA 38). No cortical area was found with significantly increased ISC value. In the inter-translation contrast, reading machine translation resulted in significant decrease in ISC at right precuneus only. Significant increase in ISC was observed at bilateral primary motor cortex (BA4), ventral anterior cingulate cortex (BA32), right inferior frontal gyrus (BA45). The result of the inter-translation contrast is in accordance with the coarse coding hypothesis and the gradient salient hypothesis. The right IFG may be related to the comprehension of less readable articles. Moreover, the result of the inter-genre contrast implies that the left aTL processes a natural article by directly associating language inputs to their semantic meaning; on the contrary, the right aTL associates language inputs to elements beyond their literal meanings. Distributed brain activation clusters in our data suggest that reading comprehension is a multi-modal task. Complex brain processes related to natural reading is hopefully to be further elucidated by our experimental design and analysis.

This study was approved by the IRB. 19 subjects were asked to read 8 Chinese translated by human or Google translate (semantic errors corrected manually) with fictional (Reader's Digest) or non-fictional (NY Times) contents. Articles were presented using vertical scrolling (3 lines per screen with fade-in and -out at top and bottom margins). Each subject read 2 articles of each translation-genre combination. Each article contained around 1,300 Chinese characters and took about 3.5 minutes to read. EPI data were collected on 3T scanner using a 32-channel head coil array.

The ISC of the first EPI 94 scans was calculated. A general linear model (GLM) was then applied to the z-transformed correlation coefficients to estimate the article translation/ content effects. We specifically examined two contrasts: "non-fiction vs. fiction" contents and "human vs. machine" translation. FDR correction was performed.

Title: A reexamination of click detection during statistical learning

Authors: *T. OVERATH¹, D. L. MURPHY²

²Psychology & Neurosci., ¹Duke Univ., Durham, NC

Abstract: Click-detection during segmentation of continuously presented nonwords has been proposed as an online measure of statistical learning during language acquisition. In such a task, subjects are instructed to respond to clicks superimposed over a stream of tri-syllabic nonwords. In a previous study, reaction times (RT) to clicks paired with syllables within words (syllable 2, S2) slowed more rapidly than clicks paired with syllables between words (syllable 1, S1; Gomez et al., 2011), over a 4 min exposure period. Later work (Franco et al., 2015) demonstrated that it is unclear if this effect is a reflection of statistical learning of word boundaries or of competing attentional demands during active or passive word segmentation. It is also unclear if postexposure measurements of statistical learning directly represent the efficiency of the segmentation process, subjects' short-term auditory memory, or a combination of both. Participants in this study listened to a stream of concatenated tri-syllabic non-words and were asked to detect clicks that were either placed between words (S1) or within words before the third syllable (S3), for which the composite within-word predictability is highest (previous studies placed within-word clicks before S2). The exposure time was also increased to 6 minutes to test the stability of statistical learning. The shift in click position to S3 was motivated by additional exploration of target detection during word segmentation: under explicit and implicit learning conditions, during which subjects were instructed to actively segment word boundaries, RTs were fastest during detection of target syllables occurring as the last in a trisyllabic word (Batterink et al., 2015). Here, we show that detection of S3 clicks is faster than S1 clicks during explicit learning, replicating the behavior observed in syllable detection tasks (Batterink, 2015), but contradicting previous studies comparing clicks at positions S1 and S2 (Gomez et al., 2011; Franco et al., 2015). This suggests that one syllable is insufficient to trigger learning-guided shifts in attentional demand, but two syllables, when part of a statistically generated model, have an immediate salience effect. We also find that in the 2AFC word recognition stage, accuracy is correlated with the relative changes in S1 and S3 RTs, and that differences in S1 vs. S3 RTs diminished during minutes 5-6. Title: Neural synchronization of syntactic priming during face-to-face communications

Authors: *W. LIU, X. BAI, 100875, H. ZHAO, 100875, Y. LONG, L. ZHENG, C. LU BEIJING NORMAL UNIVERSITY, Beijing, China

Abstract: Syntactic priming is a unique manifestation in psychological linguistics and has been proven in many experimental paradigms and in or across several languages, but the neural mechanism behind this phenomenon remains unclear. In this study, functional near infrared spectroscopy (fNIRS)-based hyperscanning was employed to measure brain activities of two communicators simultaneously during face-to-face communication with eye contact, face-to-face communication without eye contact, and back-to-back communication. The two communicators either produced the same syntactic structure [Double-Object(DO) or Prepositional-Object(PO) separately]] or different syntactic structures (DO and PO alternately, as a control task). Results showed that, in both face-to-face with eye contact condition and without eye contact condition, there was a significant increase of interpersonal neural synchronization (INS) in the DODO task relative to the control task in the left pSTC. The face-to-face with eye-contact condition additionally recruited the left SMC, whereas the task without eye contact additionally recruited the right TPJ. There was no significant increase of INS in the back-to-back condition. Also, no significant results were found for the POPO task in any conditions. In addition, the increase of INS correlated significantly with the accuracy of task performance in the DODO task, but not in the POPO task. These findings suggest that neural synchronization may underlies the alignment of syntax representation during communication, and different types of syntax representation corresponds to different level of neural synchronization. Thus, the neural synchronization can be considered as a neural marker of syntax representation in communications.

Title: Neural networks for understanding the intention of a speaker in discourse with explicit and implicit contexts

Authors: *S. TOKIMOTO¹, N. TOKIMOTO², Y. MIYAOKA³

¹Mejiro Univ., Tokyo, Japan; ²Shobi Univ., Saitama, Japan; ³Liberal Arts Educ., Hiroshima Univ. of Econ., Hiroshima-shi, Japan

Abstract: This study examines the neural basis for understanding the intention of a speaker in verbal communication. In a daily conversation, a speaker often expresses his/her intention indirectly, and the comprehender understands the implicit intention by pragmatic inference. For example, we often use an interrogative for asking something to others ('Will you open the window?'). To examine the neural activity elicited by pragmatic inference, we visually presented three types of Japanese discourse to participants to record the electroencephalogram. The discourses were manipulated in three ways: 1) control discourses in which the intentions of speakers were directly expressed, 2) experimental context-explicit discourses in which the contexts to derive the intentions from were given explicitly, and 3) experimental context-implicit discourses in which the relevant contexts were implicit. The recorded EEG was analyzed timelocked to the onset of the presentation of the utterance that required the participants to understand the intention of a speaker. As a result, negative event-related potentials were broadly observed around the latency of 500 ms for the two types of experimental discourse against the control discourses, but their amplitudes were greater and their topographies were broader in the context-implicit than the context-explicit discourses. We localized the generators of the negativity by dipole fitting to examine the relationship between the pragmatic inference and the ability for mind-reading (Theory of Mind (ToM)). The sources of the negativity of the two experimental discourses against the control discourses were localized in the medial frontal region, which is often pointed out to be a region of ToM. These localizations of the dipoles for the experimental discourses suggest a close relationship between the mechanisms of pragmatic inference and ToM. However, the sources corresponding to the difference in the negativity between the context-explicit and the context-implicit discourses were localized in the left frontal region. Moreover, the dipoles corresponding to the contrast between the context-explicit and the control discourses were localized in the right temporal region. Our results thus suggest that the

neural networks for pragmatic inference can vary according to the characteristics of the context, and that some part of pragmatic inference can be independent of ToM.

Title: Environmental stresses and psychiatric disorders based on genetic dysfunction of cannabinoid CB2 receptor

Authors: *H. ISHIGURO¹, K. TABATA¹, C. MOCHIZUKI¹, E. S. ONAIVI² ¹Univ. of Yamanashi, Chuo, Yamanashi, Japan; ²William Paterson Univ., Wayne, NJ

Abstract: Major depression and schizophrenia are mental health problems associated with stressful events in life based on certain genetic background. Cannabinoid system seems to have an important role in stress induced psychiatric disorders, and also each kind of stressor develops those disorders differently. In addition, there must be certain periods in life when brain neural network show fragility and dysfunction to the stressors. High incidence of polymorphisms in the Cannabinoid CB2 Receptor gene (CNR2) which related to low function of the receptors were found in both of schizophrenia, depression and alcoholism in Japanese population. We further examined a functional relationship between stressors and those molecules using those knockout mice as schizophrenia and depression models, as we had confirmed that neither Cnr2 knockout mice did not show any difference in PPI and in Zero maze test. Thus, the CB2 receptor has behavioral roles in response to pharmacological, immunological and psychological stresses possibly via HPA axis and neuroimmune system. We tested several stressors in mice models. Methamphetamine was injected to those mice to examine their locomotion as acute response and as acquired reverse tolerance. The Cnr2 knockout mice showed more locomotive activity after the acute treatment and also dramatic enhancement in locomotion after development of reverse tolerance. Poly-IC was injected i.p. to Cnr2 knockout mice, and their locomotor activity was measured 72 hours after the injection and compared with those of the wild type controls. The heterozygote mice relatively reduce their locomotion in the test cage. Also heterozygote Cnr2 knockout mice show more anxiety in Zero maze than wild type after Poly-IC injection. In those

model mice for psychiatric disorders, HPA or neuroimmune system related molecules could show similar changes in psychiatric patients. As results, *Fkbp5* and some cytokines' in *Cnr2* heterozygote knockout mice brain were expressed differently in comparison to wild type mice brain. It was interpreted that mice with those genetic dysfunctions develop psychiatric behaviors when they experienced certain stress and correspondent responses in HPA and immune system. Further studies are required to determine specific fragile age to the stressors based on each genetic background in the etiology of those psychiatric diseases.

Title: Neural CaMKIIa is lost in NMDAR hypofunction schizophrenia; putative opposing roles of IGF-1R and TLR4

Authors: *O. M. OGUNDELE¹, C. C. LEE²

¹Louisiana State Univ., Baton Rouge, LA; ²Comparative Biomed. Sci., Louisiana State Univ. Sch. of Vet. Med., Baton Rouge, LA

Abstract: Schizophrenia (SCZ) is a neuropsychiatric disorder associated with a deficiency in social behavior, among other deficits. Loss of Calcium-Calmodulin Dependent Kinase II alpha (CaMKII α) impairs hippocampal synaptic development, leading to behavioral symptoms of SCZ. However, since CaMKII α is involved in NMDAR-mediated synaptic plasticity, and inflammation, it is important to ascertain whether upstream receptors involved in specific aspects of synaptic function, and inflammation might be involved in altering CaMKII α during NMDAR hypofunction SCZ. This study was aimed at evaluating the expression of hippocampal CaMKII α in NMDAR hypofunction SCZ. Furthermore, we highlighted the role of neural IGF-1R and TLR4 in determining the fate of CaMKII α in this model. We found that WT-NMDAR hypofunction SCZ mice were deficient in sociability and social novelty tests. In addition to a loss of hippocampal CaMKII α (p<0.001), there was a significant decrease in IGF-1R versus the control (p<0.01). Subsequent analysis showed that the frequency of action potentials was reduced in SCZ neurons compared with controls (p<0.01). SCZ neurons showed a gap firing pattern, and a prolonged hyperpolarization leak current when compared with WT-control

(p<0.001). Since this current involves the movement of K^+ ions, we also found an increase in KCa2.2 expression in SCZ neurons versus the control (p<0.001). Owing to the role of TLR4 in synaptogenesis, we ask whether TLR4 contribute to the dysregulation of IGF-1R/CaMKIIα during NMDAR hypofunction. To elucidate this mechanism, NMDAR hypofunction was induced in TLR4^{loxp/loxp} and TLR4^{Cre/-} mice as described for WT. We found that IGF-1R/CaMKIIα loss was prevented in the hippocampus of TLR4^{Cre/-}, but not TLR4^{loxp/loxp} mice, after NMDAR hypofunction. Additionally, NMDAR hypofunction TLR4^{Cre/-} neurons showed no prominent change in the frequency of action potentials when compared with the control (WT). Likewise, KCa2.2-mediated AHP was attenuated. Ultimately, the TLR4^{Cre/-} mice recorded no substantive change in social interaction behavior when compared with a WT control. Taken together, the outcomes of this study indicate that loss of hippocampal CaMKIIα, and an increase in *KCa2.2*-mediated currents are characteristic of NMDAR hypofunction SCZ. Furthermore, the fate of hippocampal CaMKIIα- and TLR4 - which facilitates its depletion in NMDAR hypofunction.

Title: Clozapine activates autophagy through AMPK-ULK1-beclin1 signal pathway in the rat frontal cortex

Authors: *S. KIM, Y. KIM, S. PARK

Dongguk Univ. Intl. Hosp., Ilsandong-Gu, Goyang-Si, Gyeonggi-Do, Korea, Republic of

Abstract: Clozapine, one of the representative atypical antipsychotics, has superior efficacy and is used for the treatment of severe psychotic disorders. Therefore, studies on the action mechanisms of clozapine are important to unravel the therapeutic mechanisms of psychosis. Adenosine monophosphate-activated protein kinase (AMPK) is a serine-threonine kinase that plays a major role in maintaining metabolic homeostasis. Unc-51-like kinase (ULK1) is phsphorylated by AMPK and activates beclin1 which results in the activation of autophagy process. In this study, we have examined the effects of clozapine on AMPK-ULK1 and autophagy signaling in the rat frontal cortex. Clozapine (10 mg/kg) administration increased AMPK phosphorylation at Thr172 in rat frontal cortex at 1, 2, and 4 hr after injection, as we have previously reported. Phosphorylation of ULK1 at Ser317 and that of beclin1 at Ser93 was also increased at 2 and 4 hr after clozapine administration. At the same time, protein level of

LC3-II and ATG5-ATG12 conjugation were increased, which represent the activation of autophagy process. To investigate the involvement of AMPK in the clozapine-induced autophagy, the effect of intracerebroventriular injection of compound C, an AMPK inhibitor, was examined. Intrabrain administration of coumpond C efficiently inhibited the phoshporylation of AMPK substrates indicating the effective inhibition of AMPK pathway in the brain. In this condition, compound C attenuated the clozapine-induced increase in the phosphorylation of ULK1 and beclin1, LC3II, and ATG5-ATG12 in the rat frontal cortex. Taken together, clozapine induces autophagy signaling through AMPK-ULK1 signal pathway in the rat frontal cortex.

Title: Identification of long-term gene expression changes in adult rat frontal cortex after neonatal treatment of NMDA receptor antagonist

Authors: *Y. KIM¹, H. PARK², S. KIM¹

¹Dongguk Univ. Med. Sch., Goyang-Si, Gyeonggi-Do, Korea, Republic of; ²Burke Med. Res. Inst., White Plains, NY

Abstract: Early postnatal administration of NMDA receptor antagonist induces long-term psychotomimetic behavioral changes in adult period, which have been used as one of the neurodevelopmental animal model of psychotic disorders. The model could provide the tool to understand the time-dependent alterations in the brain through the evolving process of psychosis development. In this study, we have examined the effects of MK-801 treatments on postnatal 7 day (PN7) of rats on the long-term changes in the gene expression and in the rat frontal cortex at PN60, and, subsequently, the effects of repeated treatments of electroconvulsive seizure (ECS) on these changes were investigated. MK-801 1.0 mg/kg was injected twice 8 hr apart at PN7. The rats showed reductions in the weight gain through developmental process, and showed dysfunctions in sensorimotor gating at PN60 as evidenced by prepulse inhibition (PPI). DNA microarray analysis using frontal cortical tissues at PN60 revealed that transcript of transthyretin gene was most highly up-regulated in MK-801 group compared to control group. Quantitative realtime PCR confirmed the increased expression of mRNA level of transthyretin in the rat frontal cortex of early-MK-801-treated group. Repeated ECS treatments for 10 days (E10X) were applied during PN50-PN59 period after MK-801 treatments at PN7, and the effects of ECS on MK-801-induced changes at PN60 were investigated. Reduced PPI in MK-801 group was

ameliorated by E10X and PPI in MK-801/E10X showed no significant difference compared to control group. In this condition, increased expression of transthyretin by MK-801 was reduced by E10X that mRNA level of transthyretin reached to the level in control group. AP-1 protein is involved in the transcriptional regulation of transthyretin. mRNA level of Egr1 and c-Fos, but not c-Jun, showed similar pattern of changes. In addition, expression of neprilysin gene which expression is regulated by histone acetylation concurrently with transthyretin is increased in MK-801 group and reduced to control level when E10X was applied. The findings suggest that transthyretin might play the important role in psychotomimetic behavioral changes induced by early postnatal treatment of NMDA receptor antagonist, and the investigations on underlying regulatory mechanisms could enhance the evolving process of psychotic disorders.

Title: Mismatch negativity (MMN) in rats - A translational model in schizophrenia research

Authors: *N. UPTON¹, G. WADSWORTH¹, D. R. ANDERSON², T. PISER², S. C. LESIER² ¹TRANSPHARMATION LTD, LONDON, United Kingdom; ²CADENT THERAPEUTICS, CAMBRIGE, MA

Abstract: The mismatch negativity (MMN) component of the auditory event-related potential (AEP) is a key biomarker for the study of auditory sensory dysfunction in schizophrenia and other neuropsychiatric disorders. MMN reflects pre-attentive processing and is elicited clinically by an auditory oddball paradigm in which a physically different, deviant ('oddball'; DEV) stimulus occurs infrequently and unexpectedly within a sequence of repetitive identical stimuli ('standards', STD). Here we developed a system whereby we utilized the Data Sciences International telemetry system to provide the flexibility of wireless recording up to 8 male SD rats simultaneously in sound-attenuated chambers with the robust data handling and timestamping capabilities of the Cambridge Electronic Design micro1401 processor. A custom sequencer file enabled Spike2 software to generate tonal stimuli delivered to all rats simultaneously and timestamp the EEG data with digital precision. Rats were subjected to a standard oddball paradigm using 6kHz and 8kHz tones. This protocol elicited significantly larger components of the AEP during DEV than STD, specifically in the regions defined as equivalent to the clinical N1 and P2. Component values were calculated on the Difference Waves (DIFF) which were generated by subtracting STD from DEV. After validating rats elicited a robust MMN, we also set forth to demonstrate that the MMN could be pharmacologically impaired

using the NMDA antagonist MK-801. Given that NMDA receptors have a central role in the generation of the MMN, we hypothesized that MK-801 would impair MMN. Here we present this data. Under pre-drug conditions rats exhibited similar peak amplitudes for N1 (30-60ms after stimulus) and P2 (50-150ms) components of the difference wave. Between 40-60 minutes after administration vehicle-treated animals retained robust MMN, with DIFF wave component values for the N1 and P2 of $-10.6\pm1\mu$ V and $10.0\pm1\mu$ V, respectively. The MK-801 0.1mg/kg, s.c. dose elicited a slight, non-significant decrease in the DIFF wave (N1: $-8.1\pm1\mu$ V; P2: $7.5\pm1\mu$ V). Most importantly, however, MK-801 at 0.3mg/kg, s.c. significantly reduced the DIFF wave in comparison to vehicle, thereby demonstrating impaired MMN. Following 0.3mg/kg the DIFF N1 was $-4.6\pm1\mu$ V and P2 was $5.1\pm1\mu$ V. The 0.5mg/kg, s.c. dose elicited similar results as the 0.3mg/kg dose. In conclusion, we have demonstrated that rats have a clear electrophysiological correlate to clinical MMN and further that this potential can be impaired with NMDA antagonism. This establishes a key translational tool in the effort to detect novel therapeutics targeting the NMDA receptor to treat neuropsychiatric disorders.

Title: Simultaneous array recording in monkey MD thalamus, DLPFC, and the ACC related to cognitive control in a task measuring deficits in schizophrenia

Authors: *A. L. DENICOLA¹, M.-Y. PARK², J. L. ZICK¹, K. SCHULTZ³, D. A. CROWE⁴, M. V. CHAFEE⁵

¹Univ. of Minnesota, Minneapolis, MN; ²Univ. of Minnesota, Minneapolis, MN, MN; ³Neurosci., Univ. of Minnesota, Minneapolis, MN; ⁴Biol., Augsburg Col., Minneapolis, MN; ⁵Dept Neurosci / Brain Sci., Univ. Minnesota, Minneapolis, MN

Abstract: Patients with schizophrenia experience a range of cognitive deficits that are strongly correlated with functional outcome but are not well treated by available therapeutics. The Dot-Pattern Expectancy Task (DPX) isolates a specific cognitive deficit in patients. First, a cue

stimulus is presented, followed by a delay, and then a probe stimulus that triggers a response. The cue provides contextual information that is required to properly respond to the probe. The four categories of 'Cue-Probe' pairs are 'AX', 'AY', 'BX', and 'BY'. 'AX' trials, 67% of the total trials, require a target response. The three other trials require a non-target response. Patients with schizophrenia perform selectively worse on 'BX' trials. Target brain areas associated with cognitive control and hypoactive in schizophrenia include the dorsolateral prefrontal cortex (dlPFC), the mediodorsal nucleus of the thalamus (MD), and the anterior cingulate cortex (ACC). These three brain regions are also intricately connected, creating a cognitive control network that may be directly affected in patients. Previous work in our lab has demonstrated that monkeys exhibit the 'BX' impairment when given an injection of Ketamine or Phencyclidine (PCP), N-methyl-D-aspartate receptor antagonists during DPX performance. The current study attempts to define the neural correlates of cognitive control in relation to DPX at baseline in the MD, dlPFC, and ACC, to further delineate the specific roles each of these brain structures play in cognition. Using 32 channel multi-electrode arrays, we recorded in two brain regions simultaneously, either MD-PFC or ACC-PFC, during DPX performance. Generally, task-related modulations in neural firing rate were found in parallel between the MD, dlPFC, and ACC, with some subtle differences. MD thalamus was strongly activated during the task, and MD neurons exhibit a 'switch' pattern of activity preferring B-cues during the cue period and A-cues during the probe period that we previously found was a hallmark of PFC activation in this task. MD neurons showed a prominent tendency to ramp to the response, and more neurons preferred the target (habitual) response in MD relative to PFC. This was found in ACC as well, where neural responses preferred target response over nontarget. Cue-selective and delay responses were notably weaker in ACC relative to the other two areas. Our results indicate an overarching distribution of DPX task-defined signals across MD, PFC and ACC with differences evident at the population level indicative of differential contributions to cognitive control, which may be affected in schizophrenia.

Title: Whole-brain mapping analysis of the NMDAR antagonist-induced neuronal activation

Authors: *K. SEIRIKI^{1,2}, A. KASAI², T. KUWAKI², M. NIU², Y. NAKA², H. IGARASHI², T. NAKAZAWA³, S. YAMAGUCHI⁴, Y. AGO², H. HASHIMOTO² ¹Osaka Univ., Suita, Japan; ²Grad. Sch. of Pharmaceut. Sciences, Osaka Univ., Suita, Japan; ³Grad. Sch. of Dentistry, Osaka Univ., Suita, Japan; ⁴Grad. Sch. of Medicine, Gifu Univ., Gifu, Japan

Abstract: Non-competitive N-methyl-D-aspartate receptor (NMDAR) antagonists impair neurobiological functions and induce psychotomimetic effects. Although pharmacological models of schizophrenia using NMDAR antagonists (e.g. MK-801) have been widely studied, brain regions responsible for the behavioral alterations are not well understood due to the ubiquitous expression of NMDARs. To explore the candidate brain regions responsive to NMDAR antagonists, we performed mapping of neuronal activation induced by MK-801 using Arc-dVenus reporter mice, in which a fluorescent protein, dVenus is driven by an Arc promoter. MK-801 increased dVenus expression in various cortical regions, and the most activated regions included the orbitofrontal cortex. Chemical lesions of this region attenuated the MK-801-induced hyperlocomotion without affecting the basal locomotor activity in the novel environment. We also performed whole-brain imaging of Arc-dVenus mice treated with MK-801 or methamphetamine, and compared the brain-wide activation patterns between these mice. The activation pattern induced by MK-801 was significantly different from that by methamphetamine, especially in the orbitofrontal cortex. We then examined the effects of antipsychotics on the MK-801-induced neuronal activation and found that the dVenus expression in the orbitofrontal cortex was effectively suppressed by an atypical antipsychotic, clozapine, but not by a typical antipsychotic, haloperidol. These results indicate that the orbitofrontal cortex is involved in the NMDAR-induced hyperlocomotion, and that the suppression of this region could be related to the therapeutic effects of clozapine. These findings will contribute to a better understanding of neural mechanisms for psychotic symptoms associated with NMDAR hypofunction.

Title: COMT inhibitors improve cognitive flexibility in a modified version of the rat attentional set-shifting task

Authors: S. T. BYERS¹, I. BUCHLER¹, M. DEPASQUALE¹, J. C. BARROW^{2,3}, *G. V. CARR^{4,3}

¹Drug Discovery, Lieber Inst. for Brain Develop., Baltimore, MD; ²Lieber Inst. for Brain Develop., Lieber Inst., Baltimore, MD; ³Pharmacol. and Mol. Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; ⁴Drug Discovery, Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Impaired executive function is a core feature of many neurological and psychiatric disorders, including schizophrenia. Cognitive flexibility is a component of executive function that is highly predictive of outcome for patients with these disorders, making it an important target for drug development. The rat digging version of the attentional set-shifting task (ASST) is a validated measure of cognitive flexibility, but it is labor and time-intensive. Here we present a modified ASST protocol for testing cognitive flexibility. We validated our new protocol as a reliable assay for drug development using multiple catechol-O-methyltransferase (COMT) inhibitors. Our version of the ASST is a three-day protocol using adult, male Sprague Dawley rats. The first day consists of habituating rats to the testing room, task apparatus, and ensuring reliable digging for rewards. During day two, rats are trained to perform simple discriminations based on two perceptual dimensions (odor/digging medium). ASST testing occurred on day three, in which rats perform all seven stages of the task. Previously published habituation and training schedules were adapted in our task. These changes included a more structured habituation period and less restrictive time limits during training trials. Using neurochemical correlates of dopamine metabolism, we selected a couple of compounds to assess the utility of a COMT inhibition strategy as a means of increasing cognitive flexibility. Tolcapone, a potent COMT inhibitor, shows efficacy in a different version of the ASST and we used it as a positive control. Rats consistently dug for food rewards and learned positive environmental cues, allowing for a pre-testing dropout rate of <10%. The decrease in dropout rate did not affect group performance in the ASST as scoring in test stages was similar to those from previously published versions of the odor/medium ASST. Importantly, COMT inhibition increased cognitive flexibility measured as improved performance in the extradimensional shift stage, but did not affect performance in other stages, as had been previously reported. These results

confirm that COMT inhibition is a viable strategy for increasing cognitive flexibility in rats and the ASST is a useful screen for the procognitive effects of therapeutic candidates.

Title: Novel brain-penetrant COMT inhibitors alter peripheral and central dopamine metabolism

Authors: G. CARR, *G. ZHANG, S. T. BYERS, M. DEPASQUALE, I. BUCHLER, J. C. BARROW

Drug Discovery Div., Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Catechol-O-methyltransferase (COMT) is a critical enzyme that metabolizes dopamine and other catecholamines in the periphery and central nervous system (CNS). COMT inhibitors have served as an adjunct treatment in Parkinson's disease (PD). COMT inhibitors boost central L-DOPA levels by inhibiting its peripheral metabolism in PD patients. COMT is also present in the brain and regulates dopaminergic function there, but the current FDAapproved COMT inhibitors have limited brain penetration. One COMT inhibitor, tolcapone, is able to cross the blood-brain barrier and exploratory, proof of concept studies have indicated that high doses may improve cognition in multiple neurological and psychiatric disorders. However, tolcapone has multiple disadvantages as a long-term treatment option. The brain to plasma ratio for tolcapone is 1:100. Due to a poor pharmacokinetic profile, tolcapone requires three doses a day and long-term use is associated with high risk for fatal liver toxicity. The limitations of tolcapone highlight the need for brain-penetrant COMT inhibitors with improved safety and efficacy profiles to determine if COMT inhibition is a viable strategy for cognitive enhancement. Here we describe novel brain-penetrant COMT inhibitors that are structurally distinct from the nitrocatechol inhibitors (tolcapone, entacapone, opicapone), but produce similar effects on peripheral and central dopamine metabolism. We utilized direct sampling of cerebrospinal fluid (CSF) and microdialysis within the medial prefrontal cortex (mPFC) of rats and our novel COMT inhibitors increased the concentration of 3,4-dihydroxyphenylacetic acid (DOPAC) and decreased the concentration of homovanillic acid (HVA). These changes in DOPAC and HVA indicate that our compounds significantly inhibit central COMT activity. Our compounds also inhibit the degradation of L-DOPA in the periphery, suggesting that these new COMT inhibitors

would also be effective as adjunctive therapies in PD patients. Taken together, these results indicate that the novel brain-penetrant COMT inhibitors may provide the same benefits as peripherally-restricted inhibitors with additional potential in the treatment of cognitive dysfunction and other indications modulated by central dopaminergic neurotransmission.

Title: Tegmental GABA receptor expression in a model for tardive dyskinesia

Authors: *S. E. BACHUS

Psychology, Univ. of Maryland Baltimore County, Baltimore, MD

Abstract: We have previously found nigral and tegmental glutamate decarboxylase (GAD) mRNA to be correlated with chronic haloperidol (HAL)-induced vacuous chewing movements (VCM), a rat model for tardive dyskinesia (Bachus et al., Behav. Brain Res. 231:323, 2012). Here we have measured GABA-A alpha-1 mRNA in tegmentum in this cohort, to explore the possibility that altered tegmental GABA receptor expression might mediate the effect of HAL on tegmental GAD activity.

Group housed male Long-Evans rats, with starting body weights of 90-165g, were treated for 24 weeks with HAL (28.5mg/kg/ml, i.m.: n=43) or vehicle (sesame oil: n=21) injections every 3 weeks. VCM were counted for each rat for 2 minutes weekly, for 7 weeks prior to HAL treatment and then throughout HAL treatment, by observers blinded to treatment group. Over the final 2 weeks, 4 samples were rated under both quiet (only ambient air-conditioning) and noisy (constant loud music and key-rattling) conditions. Cryostat-cut sections from fresh-frozen brains, containing the nigrotegmental projection field, were assayed by in situ hybridization histochemistry with oligonucleotide probes complementary to the GABA-A alpha-1 subunit mRNA, or a mis-sense control probe.

There was a non-significant trend toward an increase in tegmental GABA-A alpha-1 expression in HAL treated rats (t=-1.26, p=.21). Tegmental GAD mRNA was highly negatively correlated with tegmental GABA-A alpha-1 mRNA (r=-.59, p<.005) among controls, suggesting that there is normally an inverse relationship between these variables, but not among HAL-treated rats (r=-.23). Nor was tegmental GABA-A alpha-1 expression significantly correlated with VCM among HAL-treated rats. Interestingly, among HAL-treated rats, previously measured nigral tyrosine hydroxylase mRNA was highly correlated with tegmental GABA-A alpha-1 expression (r=.41, p<.006), suggesting that chronic HAL can upregulate tegmental GABA-A alpha-1 expression in HAL-treated rats in which nigral tyrosine hydroxylase is upregulated. However, altered tegmental GABA receptor expression does not appear to mediate the neural changes responsible for chronic HAL-induced VCM.

Title: Translational utility of the mismatch negativity: Implementing MMN in rats for drug discovery

Authors: *D. BREGNA¹, D. R. ANDERSON², T. M. PISER², S. C. LEISER¹ ¹Translational EEG, Psychogenics, Tarrytown, NY; ²Cadent Therapeut., Cambridge, MA

Abstract: Mismatch negativity (MMN) is a validated, objective measure of central auditory processing and has become a key clinical biomarker in schizophrenia and holds utility in other neuropsychiatric disorders. MMN is an auditory evoked potential (AEP) elicited clinically by an auditory oddball paradigm in which a different, deviant ('oddball'; DEV) auditory (tonal) stimulus occurs infrequently and unexpectedly within a sequence of repetitive identical tonal stimuli ('standards', STD) and reflects pre-attentive processing dependent upon NMDA receptor function. Here we demonstrate back-translatability of this AEP in Sprague-Dawley (SD) rats and show that NMDA receptor antagonism can impair rat MMN. First, we developed a system whereby we utilized the Data Sciences International (DSI) telemetry system to provide the flexibility and high-throughput nature of wireless recording up to 16 SD rats simultaneously in sound-attenuated chambers with the robust data handling and timestamping capabilities of the Cambridge Electronic Design (CED) micro1401 processor. A custom sequencer file enabled Spike2 software to generate tonal stimuli delivered to all rats simultaneously and timestamp the EEG data with digital precision. Rats were subjected to a standard oddball paradigm using 6kHz and 8kHz tones and assessed 40-60min following MK-801 treatment. Vehicle-treated rats had a significantly larger response to DEV than STD as measured by the N1 peak (between 20-60ms) and the area under the curve (AUC) for N1 (30-60ms) while the N1 and N1-AUC for STD and DEV did not differ after MK-801 (0.3 mg/kg), revealing clearly inhibited AEPs after NMDA antagonism. Further, the Difference Waves (DIFF), generated by subtracting STD from DEV, revealed MK-801 significantly suppressed both N1 and P2 (between 50-150ms) peak amplitudes and AUCs. Showing clear dose-dependency, MK-801 (0.1 mg/kg) had intermediate effects but did not demonstrate as robust an impairment of MMN as 0.3mg/kg. This work further validates

that rats have a MMN correlate to that of the human and that this biomarker is dependent upon NMDA receptor function. Further, we demonstrate the ability to perform this in a higher-throughput manner necessary for drug discovery, which will lead to the further work needed to validate the translatability and predictive validity of the rat MMN.

Title: Rapastinel, a novel NMDA receptor modulator, produces prolonged rescue of subchronic phencyclidine - induced deficits in episodic memory as well as other beneficial effects on cognitive function in a rapamycin sensitive manner

Authors: *L. RAJAGOPAL¹, M. HUANG¹, J. LI¹, W. HE¹, D. SONI¹, P. BANERJEE², H. Y. MELTZER¹

¹Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; ²Allergan Inc., Jersey City, NJ

Abstract: Rapastinel (GLYX-13), a novel NMDAR modulator with rapidly-acting antidepressant (RAD) properties, lacks the psychotomimetic and cognitive impairing effects that sometimes occur with ketamine, another RAD under development. We have previously reported that rapastinel (i.v.) significantly prevented ketamine-induced deficits in novel object recognition (NOR), a test of episodic memory, in mice (Rajagopal et al., Behav Brain Res. 299:105-110). The antidepressant effects of rapastinel and ketamine are mediated by synaptic effects, suggesting neuroplasticity, which have been reported to be blocked by the mTOR signaling pathway inhibitor, rapamycin. The subchronic phencyclidine treatment produces an enduring deficit in NOR and other cognitive functions in rodents, mediated in part by the effects on GABAergic neurotransmission, which can be reversed both transiently and for several weeks by atypical antipsychotic drugs (AAPDs) and selective ligands which restore synaptic function (e.g., the 5-HT_{1A}R partial agonist, tandospirone and the 5-HT₇R antagonist SB269970). We now report that rapastinel (1 mg/kg sub cut), administered to subchronic PCP-treated C57BL/6J mice 30 min before acquisition trial, can restore NOR transiently, while rapastinel, (1 mg/kg b.i.d sub cut for 3 or 5 days), can restore NOR for 7 and >9 weeks, respectively, the most prolonged rescue by any drug we have observed. A single dose of rapastinel (1 mg/kg), was also able to restore NOR to normal levels following the wearing off of beneficial effects of 3 days of rapastinel b.i.d.
treatment. Rapastinel, tested 30 min, but not 24 h, post-injection restored cognitive flexibility, as measured by reversal learning (RL) in subchronic PCP-treated mice. These effects are comparable to those of AAPDs such as lurasidone. The ability of rapastinel (1 mg/kg sub cut) to restore NOR and RL in subchronic PCP-treated mice was blocked by rapamycin (0.2 nM, given ICV). The effects of rapastinel, PCP, and ketamine on neurotransmitter efflux in mPFC and hippocampus were compared. Rapastinel selectively enhanced DA efflux in the mPFC, while ketamine and PCP produced marked increases in efflux of glutamate and other neurotransmitters in both regions. DA and glutamate efflux were increased in the cortex and hippocampus during NOR in mice treated for 5 days with rapastinel b.i.d. and studied 8-10 weeks post-treatment. These results suggest rapastinel may improve cognitive impairment in mood disorders and that intermittent treatment schedules may be effective for both depression and cognitive impairment.

Title: The effect of inactivation of amygdalar GABAergic neurons on behaviors associated with schizophrenia in rats

Authors: *N. PREM¹, L. T. RAO¹, J. P. JOHN², B. M. KUTTY¹ ¹Dept. Of Neurophysiol., ²Dept. of Psychiatry, Natl. Inst. of Mental Hlth. & Neurosci., Bangalore, India

Abstract: Schizophrenia (SZ) is a complex neuropsychiatric disorder with heterogenous symptoms, characterized by abnormalities in sensory processing and cognition. Several postmortem studies in SZ patients postulates GABAergic transmission dysfunction in the limbic-lobe circuitry, that consists of interconnected brain regions such as dorsolateral prefrontal cortex, hippocampus, basolateral amygdala, anterior cingulate cortex (ACCx) etc. In previous studies, when a noncompetitive GABA_A receptor antagonist, picrotoxin was stereotaxically infused in the basolateral amygdala (BLA) in rats, it resulted in decrease in inhibition in BLA and increase in excitatory output from BLA to hippocampal formation and ACCx. Consequently, a decrease in density of glutamate decarboxylase 65 and 67 immunoreactive terminals was observed in sub-regions of hippocampus, specifically CA3 and CA2 regions in these rats. These changes mimics

postmortem findings and GABA defects implicated in SZ pathophysiology.

In the present study, we used this "partial" rodent model for neural circuitry abnormalities based on postmortem findings in schizophrenia to assess various schizophrenia-like behavior including cognitive dysfunction. Seven days after infusion of picrotoxin into the BLA and postsurgical recovery, the rats were subject to test battery consisting of open field test, social interaction test and pre-pulse inhibition to assess locomotor activity, social withdrawal and sensorimotor gating, respectively. Following assessment in test battery, two separate cohorts were used to assess long term effects of picrotoxin infusion in BLA on cognitive functions in these rats. One cohort was used to assess working memory deficits using radial arm maze task and another cohort was used to assess episodic memory deficits using Morris water maze task.

The rats infused with picrotoxin in BLA did not show locomotor hyperactivity; however, we could demonstrate deficits in social interaction and pre-pulse inhibition. When tested in working memory and episodic memory based tasks such as 8-arm baited radial maze task and Morris water maze task, respectively, these rats did not show cognitive deficits and results were comparable to that of control rats. The neural circuitry abnormalities found in this rodent model may be more specifically responsible for social cognition as we could demonstrate deficits in social interaction. However, episodic memory (spatial learning and memory) and working memory were spared, as this is predominantly hippocampal and prefrontal cortex dependent task, respectively and may not be affected by the changes found in the neural circuitry in this rat model.

Title: The metabolites clozapine-N-oxide (CNO) and N-desmethylclozapine (NDMC, norclozapine) both share discriminative stimulus properties with the parent compound clozapine in mice and rats

Authors: *J. H. PORTER¹, D. F. MANVICH², K. A. WEBSTER¹, S. L. FOSTER², C. J. HERTING³, S. N. BRAMLETT³, M. S. FARRELL⁴, D. WEINSHENKER² ¹Psychology, Virginia Commonwealth Univ., Richmond, VA; ²Dept. of Human Genet., ³Grad. Program in Mol. & Systems Pharmacol., Emory Univ. Sch. of Med., Atlanta, GA; ⁴Dept. of Genet., Univ. of North Carolina at Chapel Hill Sch. of Med., Chapel Hill, NC

Abstract: The atypical antipsychotic drug clozapine has two major metabolites: clozapine-Noxide (CNO) and N-desmethylclozapine (NDMC, norclozapine). NDMC is considered to be the "active" metabolite and we have previously demonstrated that it shares discriminative stimulus properties with its parent compound clozapine in both mice (Philibin et al 2009; Wiebelhaus et al 2011, 2012) and rats (Prus et al 2009). In contrast, CNO is considered to be an "inactive" or "inert" metabolite of clozapine and has been utilized in many studies as an inert molecule to activate DREADDs (Designer Receptors Exclusively Activated by Designer Drugs). This has been called into question as MacLaren et al (2016) recently demonstrated that CNO reduced acoustic startle reflex and significantly attenuated d-amphetamine-induced hyperlocomotion in rats that lacked DREADD receptor expression. The present study examined the discriminative stimulus properties of CNO in both mice and rats trained to discriminate 1.25 mg/kg clozapine from vehicle in a two-lever drug discrimination paradigm. After clozapine discrimination was established, substitution tests with CNO (1.0 - 40.0 mg/kg) revealed that CNO partially substituted for the clozapine stimulus in both species. When CNO was tested in combination with low NON-generalizing doses of clozapine, partial to full substitution for clozapine's discriminative cue was obtained. These data replicate previous findings with NDMC and demonstrate that BOTH major metabolites of clozapine share discriminative stimulus properties with the parent drug. Thus, these data demonstrate that CNO is a behaviorally active compound in both mice and rats lacking DREADD receptors trained to discriminate clozapine. These results, along with recent findings by others, emphasize the need for appropriate control groups in studies employing DREADDs.

Title: A critical role for NF- κ B in the HDAC2-dependent control of synaptic remodelling and antipsychotic-related behaviours

Authors: *D. IBI^{1,2,3}, M. DE LA FUENTE REVENGA², J. GONZÁLEZ-MAESO^{2,3} ¹Chem. Pharmacol., Meijo Univ., Nagoya, Japan; ²Physiol. and Biophysics, Virginia Commonwealth Univ. Sch. of Med., Richmond, VA; ³Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Antipsychotic drugs, including both typical such as haloperidol and atypical such as clozapine and risperidone, were first described in the mid-twentieth century, yet they still remain the current standard of care for schizophrenia. Despite showing relatively tolerable effectiveness in treating hallucinations and delusions, chronic antipsychotic drug exposure leads at present to either persistent or exacerbated cognitive deficits in both clinical studies and preclinical animal models. However, the underlying molecular mechanism of antipsychotics' negative effects on cognition remains enigmatic. Here we identify functional dysregulation of the NF-κB pathway as a principal mediator responsible for deleterious effects of chronic antipsychotic drug treatment along numerous behavioural and physiological traits. Chronic treatment with atypical antipsychotics selectively enhanced NF- κ B (p65) translocation into the nucleus of pyramidal neurons in mouse frontal cortex-trafficking event that was triggered via serotonin 5-HT2A receptor and MAPK/ERK-dependent down-regulation of expression of the NF-kB repressor IκBα. Such up-regulation of NF-κB activity occurred in association with its increased binding at the promoter region of the Histone deacetylase 2 (Hdac2) gene, thereby augmenting Hdac2 transcription. This paradoxical increase in Hdac2 expression was impeded by either pharmacological or genetic inactivation of NF-kB. Notably, selective deletion of HDAC2 function in forebrain pyramidal neurons prevented the unfavourable effects of chronic antipsychotic treatment on cortical synaptic remodelling and cognitive processes. Conversely, virally mediated activation of cortical pyramidal NF-kB-dependent transcriptional activity minimized the formation of mature spine structures, decreased synaptic plasticity, and exacerbated psychosis-related behaviours and cognitive deficits through a signaling mechanism that required up-regulation of HDAC2. Together, our results suggest that activation of the NF-κB pathway by chronic atypical antipsychotic treatment increases HDAC2-dependent negative effects on synaptic plasticity and behaviour. These observations may aid in efforts to develop therapeutic strategies that improve the currently poor outcome in schizophrenia patients.

Title: Gamma frequency oscillations are altered by a novel Kv3 channel modulator in rodent and human neocortical slices

Authors: *T. MODEBADZE¹, C. GILLOUGLEY¹, C. H. LARGE², G. S. ALVARO², F. LEBEAU¹, M. CUNNINGHAM¹

¹Inst. of Neurosci., Newcastle Univ., Newcastle, United Kingdom; ²Autifony Therapeut. Limited, Stevenage Bioscience Catalyst, United Kingdom

Abstract: Schizophrenia is a severe psychiatric disorder associated with a range of cognitive deficits. Studies in patients with schizophrenia and preclinical animal models have demonstrated abnormal synchronized high-frequency network activity and a dysfunction of parvalbumincontaining (PV+) GABAergic interneurons, both of which are critical for cognitive processing. Inhibitory fast-spiking PV+ interneurons coordinate synchronized activity (30-80 Hz) by firing at gamma frequencies and entraining large populations of cortical pyramidal cells. The fast spiking properties and temporal fidelity of PV+ interneurons are endowed by the selective expression of Kv3 channels on these cells. Thus, targeting Kv3 channels, and enhancing the activity of PV+ interneurons, has potential as a pharmacological treatment for cognitive symptoms of schizophrenia. Using the sub-chronic phencyclidine (PCP) rodent model of schizophrenia, we examined a range of concentrations of a novel Kv3 modulator (AUT00206) in vitro. Prior to brain slice in vitro studies, animals were behaviourally tested in the novel object recognition task to confirm cognitive deficits in PCP treated animals versus vehicle treated rats. Kainate/carbachol induced gamma oscillations were recorded from the prelimbic (PrL) region of prefrontal slices obtained from both groups of animals. We also examined the effect of AUT00206 in slices of human neocortical tissue. Non-epileptic tissue was obtained during tumour debulking procedures. Gamma frequency oscillations were elicited by the bath application of kainate (400-600 nM). The results show that higher concentrations of AUT00206 (10 and 20 µM) significantly increased the area power of gamma oscillations in PrL region in slices from PCP treated animals (10 μ M: 250 ± 59 μ V² v. 301.7 ± 88 μ V², 21.4 ± 8.9 %, p = 0.02, n = 15; 20 μ M: 148.6 ± 71 μ V²v. 157.6 ± 59 μ V², 27.2 ± 10.2%, p = 0.037, n = 10). Slices from vehicle treated animals showed a significant reduction in gamma area power at 20 µM AUT00206 (209.1 ± 99 μ V² v. 131.7 ± 57 μ V², -29.5 ± 7.3%, p = 0.016, n = 8). In human slices the power of kainate evoked gamma oscillations was unaltered by 10 μ M AUT00206 (-8.5 \pm 4.9

%, n = 9). In slices exposed to kainate and 10 μ M PCP, the power of gamma oscillations was increased by the drug (35.15 ± 10.5 %, p = 0.016, n = 7). Our results suggest that modulation of Kv3 channels by AUT00206 may have the potential to correct aberrant neuronal oscillations in patients suffering from schizophrenia by augmenting gamma frequency oscillations.

Abstract: The anterior cingulate cortex (ACC) plays a role in remote spatial memory, attention and executive functions. These cognitive functions are associated with network oscillations in the beta (20-30 Hz) and gamma (30-80 Hz) range. We have recently demonstrated that *in vitro* bath application of kainate can generate both beta and/or gamma oscillations either alone, or in combination, in the deep and superficial layers of ACC (Adams et al 2017). Changes in cortical beta and gamma frequency activity occur in patients with schizophrenia which may be linked to changes in NMDA function. We therefore wished to investigate the effects of NMDA modulation on both beta and gamma frequency activity in the ACC.

Following transcardial sucrose perfusion in anaesthetised rats ACC slices 450 uM thick were prepared from normal adult animals. Slices were transferred to an interface chamber for recording. Network oscillations were evoked using bath application of kainate (800 nM) for 1-3 hours until oscillation magnitude stabilised.

Following application of kainate beta and/or gamma frequency oscillations were observed in ACC. In slices in which beta frequency only activity was present acute application of the non-competitive NMDA receptor antagonist phencyclidine (PCP 10 microM) caused a dramatic increase in the power of the beta oscillations with an increase in the power of $110 \pm 42\%$ (n = 5). There was also a significant slowing of the frequency of the oscillation in the beta band from 25

 \pm 1.2 Hz to 20.6 \pm 0.5 Hz (P<0.05, n = 5). In contrast, in slices in which only a gamma frequency oscillation was present, PCP reduced the power of the gamma activity (n = 6). Interestingly the effects of PCP on network oscillations were considerably greater than those seen with either ketamine, MK-801 or DAP-5.

These results suggest that in the ACC NMDA blockade with PCP has different effects on beta and gamma frequency oscillations.

Title: Effects of Intranasal Orexin-A on MK-801-induced attentional deficits

Authors: *E. B.-L. MANESS¹, J. R. FADEL², J. A. BURK¹

¹Psychology, Col. of William and Mary, Williamsburg, VA; ²Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Schizophrenia (SZ) is a debilitating condition wherein those afflicted experience positive symptoms, including hallucinations and delusions, as well as negative cognitive and social symptoms. Antipsychotic pharmacotherapies targeting dopaminergic dysregulation are effective in alleviating positive symptomology of the disorder, but these drugs are unsuccessful in addressing the cognitive deficits. The glutamate hypofunction hypothesis of SZ asserts that the pathology of SZ primarily results from suppression of hippocampal NMDA receptor input, inciting imbalances in neurotransmitter release to striatal and cortical regions pertinent to cognitive processing. Orexin-A (OxA), an excitatory neuromodulator principally involved in wakefulness, has been suggested to potentiate NMDA receptor activity and enhance cognition. In the present study, the effects of OxA on attentional performance were examined in a NMDA receptor antagonist model of SZ. Male Fischer 344 Brown Norway F1 Hybrid rats received both intraperitoneal injections of MK-801 (0, 0.075, 0.125mg/kg) and intranasal administration of OxA (0, 5, 10nM) prior to placement in a sustained attention task requiring differentiation between signal trials (500, 100, and 25ms illumination of a central panel light) and non-signal trials (no light illumination). Following a dose-dependent impairment in both signal and nonsignal trial performance as well as an increase in trial omissions induced by MK-801 administration. OxA modestly improved detection of the 500 and 100 ms signals at the highest

and lowest doses of MK-801, respectively. OxA also reduced trial omissions following the smallest MK-801 concentration. However, at the highest dose of MK-801, OxA administration diminished relative correct rejection rates. Systemic NMDA receptor blockade and OxA are known to elevate cortical acetylcholine, a neurotransmitter that is necessary for performance in this attentional task. Thus, the decrease in correct rejections may be due to overstimulation of cortical cholinergic inputs. Taken together, despite potential overexcitation of prefrontal cortical neurons, OxA may have some beneficial impacts on cognition for individuals with conditions stemming from a hypofunctioning NMDA receptor system.

Title: Finasteride rescues some schizophrenia-like behaviours of the dopamine transporter knockout and MK-801-treated mice

Authors: *P. WONG¹, D. GROENEWOUD², L. MAK¹

¹Dept. of Pharmacol., ²Dept. of Biol. Sci., Natl. Univ. of Singapore, SINGAPORE, Singapore

Abstract: Neuroactive steroids are endogenously synthesized cholesterol-derivatives with multifaceted effects on brain function. Converging evidence implicates neuroactive steroids in the behavioural manifestations of mood disorders and their treatment. Recent research has shown that inhibitors targeting the 5α -reductase enzyme, such as Finasteride, have potential therapeutic efficacy in schizophrenia. $5-\alpha$ reductase is the rate-limiting enzyme of one of the three major metabolic pathways in brain steroidogenesis, and converts progesterone into $5-\alpha$ -dihydroprogesterone. Inhibition of 5α -reductase depletes brain levels of allopregnanolone, whilst increasing brain levels of progesterone and its downstream metabolites. These changes can alter behaviour. Here, we investigate the effects of Finasteride on the abnormal behaviours of two mouse models of schizophrenia; the dopamine transporter knockout (DAT-KO) mouse and the MK-801-treated mouse. The DAT-KO mice exhibit hyperdopaminergic tone due to their inability to reuptake dopamine from the synaptic cleft. These mice exhibit hyperactive and stereotypic behaviours, and recapitulate some schizophrenia-like behaviours, such as psychomotor agitations and sensorimotor gating deficits. MK-801 is a non-competitive

antagonist of the *N*-Methyl-*D*-aspartate receptor. When administered, MK-801 causes schizophrenia-like behaviours in mice, including hyperactivity and disrupted sensorimotor gating.

An single dose of 50mg/kg Finasteride was intraperitoneally administered to DAT-KO mice, 0.1mg/kg MK-801-treated mice, and their respective controls. The animals were then subjected to the open field and prepulse inhibition tests, to examine the effect of Finasteride on locomotor activity and sensorimotor gating, respectively. In the open field test, Finasteride normalized the hyperlocomotion of DAT-KO and MK-801-treated mice. The locomotor activity of control mice were not affected by Finasteride treatment. In the prepulse inhibition test, Finasteride rescued the sensorimotor gating deficits of DAT-KO mice, but only partially rescued the sensorimotor gating deficits of MK-801-treated mice. Finasteride did not affect sensorimotor gating in controls. Our findings join a growing body of literature suggesting that Finasteride has antipsychotic properties. Abstract: Epidemiological evidence implicates maternal immune activation (MIA) as a risk factor for developing neuropsychiatric disorder in later life, including bipolar disorder, autism, and schizophrenia. We investigated whether tianeptine treatment might function therapeutically on behavioral activity impairment and protein expression in offspring induced by MIA. Polyriboinosinic-polyribocytidilic acid (PolyI:C, 5 mg/kg) was administered intravenously to pregnant dams at gestational day 9. Adolescent offspring received daily injection of tianeptine (10 mg/kg i.p.) and clozapine (5 mg/kg i.p.) for 30 days starting on postnatal day 35. Changes in sensorimotor gating, forced swim test, open field test, and social interaction test and

neurodevelopmental protein expression were measured. Exposure to Poly I:C in early, gestation resulted in transient impairments in social interaction and sensorimotor gating deficits. Several neurodevelopmental proteins were downregulated in medial prefrontal cortex of MIA model. Chronic administration of tianeptine recovered sensorimotor gating deficits in MIA offspring. Additionally, the administration also reversed the downregulations of protein induced by MIA. Our results provide initial evidence that in MIA-induced model of schizophrenia, the disturbances in behavioral patterns and neurodevelopmental protein expressions were affected by the tianeptine administration.

Title: Region specific effects of astrocyte DISC1 on cognitive behaviors in mice

Authors: *C. TERRILLION¹, J. A. CRAWFORD², A. V. SHEVELKIN², S.-H. KIM³, D. FUKUDOME², A. SAWA⁴, A. KAMIYA⁵, M. V. PLETNIKOV² ¹Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; ³Psychiatry and Behavioral Sci., ⁴Dept. of Psychiatry, ²Johns Hopkins Univ., Baltimore, MD; ⁵Dept Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Background: DISC1, which is expressed in both neurons and astrocytes, has been identified as a genetic risk factor associated with major psychiatric disorders, including schizophrenia. Neuronal Disc1 in the hippocampus and the prefrontal cortex has been implicated in cognitive function. However, the role of Disc1 in astrocytes, which have increasingly been shown to play a role in normal cognition, has not been evaluated. We hypothesized that decreased expression of DISC1 in astrocytes in the hippocampus or prefrontal cortex would impair cognitive behavior in mice.

Methods: Mice were injected with the vector AAV1-GFAP::GFP-miR30-DISC1 (Disc1 KD) in the hippocampus or prefrontal cortex (PFC) to knock down DISC1 in astrocytes, or the scrambled control vector AAV1-GFAP::GFP-mir30-Ctrl (Ctrl). 2 weeks following injections, mice were tested in anxiety related measures including elevated plus maze and the open field, as

well as several complex cognitive behaviors, including social interaction, Barnes maze and trace fear conditioning.

Results: Injection of AAV1-GFAP::GFP-miR30-DISC1 led to significant reduction of DISC1 expression compared to mice injected with the control vector. DISC1 KD in hippocampal or prefrontal cortex astrocytes did not alter locomotor activity or anxiety related behavior. DISC1 KD in astrocytes in the hippocampus, however, significantly decreased social preference and reduced preference for a novel mouse in the social interaction test. Additionally, DISC1 KD in hippocampal astrocytes impaired performance in the Barnes maze and reduced cue-dependent freezing in in trace fear conditioning. While DISC1 KD in PFC astrocytes also impaired performance in the Barnes maze, no significant effects of this KD were observed on cue-dependent freezing in trace fear conditioning. We found that DISC1 KD altered astrocyte morphology through increased branch diameter.

Conclusion: Reduction of DISC1 expression in brain astrocytes leads to brain region-dependent deficiencies in complex cognitive tasks. Changes in astrocyte morphology following DISC1 KD suggests that astrocytic dysfunction likely contributes to the cognitive deficits. Further understanding of the role DISC1 has in astrocyte function in relation to cognitive behaviors will allow us to improve treatment of cognitive symptoms in patients with major psychiatric disorders.

Title: Oxytocin effects on social behavior are genetically modulated by cortical functioning

Authors: *M. NIGRO¹, S. BRUNI², V. FERRETTI³, F. PAPALEO⁴ ¹Neurosci., Inst. Italiano Di Tecnologia, Genova, Italy; ²Neurosci., Baylor Col. of Med., Houston, TX; ³Inst. Italiano di Tecnologia, Genova, Italy; ⁴Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Social behavior is a complex function mediated by multiple brain regions and neural circuits, which is crucial for animals' survival and development. Neuropsychiatric diseases such as schizophrenia and autism are characterized by social dysfunctions, and there is growing enthusiasm concerning the potential use of intranasal oxytocin (OXT) for the treatment of social deficits. However, clinical and preclinical findings are warning that OXT might not be indiscriminately beneficial, but could even produce detrimental effects in healthy subjects. There

is then a need to understand the brain mechanisms at the base of such variability. Here, we explored the hypothesis that clinically-relevant dysbindin-1 genetics might indicate a subpopulation of subjects positively responding to intranasal OXT. Genetic variations reducing dysbindin-1 in mice results in social deficits and alterations in the OXT system. Following intranasal OXT, we observed improved social responses in dysbindin-1 mice, while in control mice we confirmed the socially detrimental effects previously described. Recent studies from both humans and mice reported that intranasal OXT strongly activates the prefrontal cortex (PFC), a brain region involved in social functioning. Thus, we performed in vivo single-unit electrophysiological recordings in the medial PFC (mPFC) of wild-type and dysbindin-1 heterozygous mice treated with either vehicle or intranasal OXT during free social interactions. We found an increased activity of the mPFC before the onset of social behaviors in wild-type mice treated with vehicle. This effect was abolished after intranasal OXT treatment. Remarkably, dysbindin-1 mice treated with vehicle showed an increased basal activity of the mPFC compared to control mice with no modulation by social contacts. In contrast, intranasal OXT recapitulated a similar pattern of mPFC activation as that observed in wild-type mice treated with vehicle. In summary, we found a divergent effect: in wild-type mice OXT induced alterations in PFC neuronal patterns and social deficits; in dysbindin-1 mice OXT restored PFC neuronal patterns and rescued social deficits. These findings provide initial evidence on how intranasal OXT might tightly regulate social behaviors and associated mPFC activity depending on different genetic backgrounds.

Title: Light sheet theta microscopy for high-resolution quantitative imaging of large biological systems

Authors: *B. MIGLIORI¹, M. S. DATTA², M. C. APAK³, O. HERMANSON⁴, R. TOMER³ ¹Biol. Sci., Columbia UNIVERSITY, New York, NY; ²Neurobio. and Behavior, Columbia Univ., New York, NY; ³Columbia Univ., new york, NY; ⁴Dept. of Neuroscience, Karolinska Institutet, Stockholm, Sweden

Abstract: Advances in tissue clearing and molecular labelling methods are enabling unprecedented optical access to large intact biological systems. These advances fuel the need for

high-speed microscopy approaches to image large samples quantitatively and at high resolution. The Light Sheet Microscopy (LSM) approach of illuminating a sample with a thin sheet of light, and detecting the emitted signal with an orthogonally arranged detection arm provides two main advantages: minimal energy load and high imaging speed. However, LSM as a general approach has been restricted in the lateral dimension of image volumes because the illumination light sheet enters from the side of the sample, and needs to penetrate the entire sample and the working distance of the illumination objective places a hard physical limit of the imaging volume. In addition, physical tissue expansion approaches for achieving high imaging resolution are producing even larger samples. To address these challenges, we developed a conceptually distinct imaging framework, called Light Sheet Theta Microscopy (LSTM). As for LSM, LSTM is based on planar illumination, but achieves this goal by using non-orthogonally arranged illumination objectives to produce light sheets that intersect the detection plane in a line profile, which is then synchronously (along with line-by-line detection of sCMOS camera) scanned along the detection plane. An immediate advantage of such a configuration is that it alleviates the restrictions on lateral sample dimensions, while providing uniform image quality for achieving true quantitative imaging. We found that a strategy of simultaneous 2-axes illumination (i.e. along and perpendicular to light sheet propagation) provided the best imaging performance. In comparison to LSM, LSTM allows imaging of larger samples such as a ~2 cm wide and ~5mm thick rat brain slice - with high uniform resolution across the entire sample. Moreover, LSTM is uniquely compatible with live imaging of highly motile samples, which undergo non-isomorphic change

Title: Rapid high-resolution mapping of mammalian brain architecture

Authors: *M. S. DATTA¹, B. MIGLIORI³, M. C. APAK², R. TOMER² ¹Neurobio. and Behavior, ²Columbia Univ., New York, NY; ³Karolinska Institutet, Stockholm, Sweden

Abstract: Advances in tissue clearing and molecular labelling techniques are enabling unprecedented optical access to large intact biological systems. The current imaging approaches,

however, are limited in capabilities to quantitatively image large specimens, such as a rat or large human brain slice, with uniform high-resolution and high-speed. To address these limitations, we recently developed a high-speed and high-resolution quantitative microscopy framework, called Light Sheet Theta Microscopy (LSTM). By building upon the principles of Light Sheet Microscopy (LSM), LSTM allows for rapid quantitative high-resolution imaging of large biological systems while maintaining the imaging depth and speed. Building upon this work, we have also developed a highly optimized integrated pipeline, including optimal clearing, imaging and data analytics, for high-resolution and high-content mapping of large biological systems. We validate the pipeline with several large-scale example datasets, including from rodent and human brains. These methods can enable a detailed three-dimensional view of normal and abnormal tissue architecture to facilitate deeper understanding of the structure-function relationships of highly complex organs such as the brain.

Title: Automated neuron tracing with deep learning and random sample consensus

Authors: *S.-L. WANG, S. MOUSAVI KAHAKI, A. STEPANYANTS Physics, Northeastern Univ., Boston, MA

Abstract: Recent advances in genetic engineering and optical microscopy have allowed neuroscientists to label sparse populations of neurons and image their arbors in 3D on the scale of the entire brain. At present, semi-manual tracing is the only reliable way of extracting information about the layout of axonal arbors of individual neurons from such imaging data. However, semi-manual tracing is extremely time consuming, can be prone to user bias, and, therefore, it is unsuitable for high-throughput experiments. In this study we describe an automated algorithm which has the potential to overcome the challenges of semi-manual tracing. This algorithm consists of four major steps. In the first step, a feed forward artificial neural network is trained on optimized, semi-manual traces of expert users to segment neurites. Our result show that one or two hidden layers in the network trained with the stochastic gradient descent method are sufficient to produce satisfactory segmentation results. In the next step, seed points are detected in the segmented image by using the multi-scale Laplacian of Gaussian filter. These points are subsequently connected all-to-all with the minimum cost paths generated with the A* algorithm. In the third step, multiple trees are produced by sampling the seed points and applying the Minimum Spanning Tree algorithm to the matrix of costs associated with connecting the sampled seeds. These trees are then combined with the modified RANdom SAmple Consensus method. Finally, topological errors in the branching pattern of the combined trace are corrected by using a specifically designed Support Vector Machine. The described automated tracing approach produces results comparable to semi-manual traces in terms of accuracy, while providing tremendous improvement in tracing time.

Title: Automated registration of light microscopy image stacks designed for whole-brain imaging experiments

Authors: *S. MOUSAVI KAHAKI, S.-L. WANG, A. B. STEPANYANTS Physics, Northeastern Univ., Boston, MA

Abstract: The ability to map neural circuits on the scale of an entire brain is critical for advancing our understanding of brain functions. Circuit mapping can be based on whole-brain imaging of sparsely labeled populations of neurons with 3D confocal or two-photon microscopy. Such an imaging experiment, if applied to the mouse brain, will result in tens of thousands of image stacks, totaling several terabytes of data. Registration of these image stacks is the first step on the way to accurate, automated circuit mapping. Because, imaging is generally done with small overlaps between neighboring stacks, the information contained in the stack overlap region can be used for registration. Here, we describe an automated registration method which consists of the following steps. First, multi-scale Laplacian of Gaussian filter is used to detect small features in all stacks associated with background fluoresce. Second, for all overlapping stack pairs we compute a matrix describing similarity for features detected in the stacks. This similarity matrix is then used as an input to the Hungarian algorithm to establish initial correspondence between the features. Third, Random Sampling Consensus algorithm is employed to eliminate outliers from the initial set of corresponding features. Fourth, global optimization is performed to find the best rigid or non-rigid transformation for simultaneously registering the entire set of stacks. Finally, the registered stacks are resampled into nonoverlapping tiles that can be used for visualization and neuron tracing. Accuracy of the proposed

algorithm was tested by tracing multiple axons in individual stacks and calculating the distances between traces of same axons in the stack overlap regions before and after the registration.

Title: Computational anatomy methods for registration of high resolution mouse brain histology images using multichannel LDDMM

Authors: ***B. LEE**¹, D. J. TWARD², D. D. FERRANTE³, K. RAM⁵, P. P. MITRA⁴, M. I. MILLER¹

²Biomed. Engin., ¹Johns Hopkins Univ., Baltimore, MD; ³Cold Spring Harbor Lab., Cold Spring Harbor, NY; ⁴Cold Spring Harbor Lab., Cold Spg Hbr, NY; ⁵IIT Madras, Chennai, India

Abstract: New developments in histological brain sectioning techniques have enabled histology imaging at sub-micron resolution, creating a need for computational methods for large scale imaging data. This work describes the development of a pipeline for registering histology volumes of different imaging modalities to an atlas and presents an application in mouse brain connectivity analysis.

Brain sections are downsampled and reconstructed into volumes using a variational method which simultaneously optimizes the position of all slices along with a regularizing prior to weight the relationship between slices against global distortions. Bayesian template estimation is used to compute a population average atlas. Mapping of the estimated atlas' coordinate systems onto each reconstructed brain is computed by the multichannel LDDMM algorithm, wherein

multiple high-dimensional matching markers arising from image intensity and the convex hull of brain structures are defined and their sum of squared error minimized, producing the optimal diffeomorphic mapping. Cross modality registration is driven by non-MSE metrics for cases where a corresponding atlas modality may not exist. Due to the smooth, 1-to-1 properties of diffeomorphisms, the resulting transforms can be upsampled back to native resolution where they retain these desirable traits.

The pipeline has been applied in collaboration with the Mouse Brain Architecture Project to register 600+ high resolution mouse brains for connectivity analysis. Brains in this dataset had been injected with fluorescent tracer prior to being sectioned at 20 um. Sections were alternately Nissl stained and fluoro imaged at 0.46 um coronal resolution.

Each of the full resolution reconstructed MBA volumes were mapped onto a common atlas space, with the resulting segmentation viewable online through the MBA Portal's online viewer. The viewer overlays the Nissl and fluorescence image data with the registered atlas segmentation, and provides interactive cell-counting tools for connectivity studies. Workflow and sample results are shown in the figure.

Title: Tape-transfer enabled 3D digital histology for whole human brains with MRI coregistration

Authors: *A. S. TOLPYGO¹, Z. LODATO¹, A. GRIFFIN², B. C. LEE³, M. M. MILLER³, L. LATOUR², P. P. MITRA¹

¹Cold Spring Harbor Lab., Cold Spring Harbor, NY; ²Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD; ³Johns Hopkins Univ., Baltimore, MD

Abstract: High-fidelity 3D neuro-histological reconstructions of whole brains with light microscopic resolution have not yet been achieved for human. Our laboratory previously standardized a tape-transfer based, high-throughput method for 3D digital histology in Mouse, Rat, Zebrafinch, and Marmoset. We present an extension of this method for processing hemisphere slabs of human brain that will permit histological processing and imaging of entire coronal sections without tissue blocking. This is the first step in a larger effort for creating a pipeline for whole human brain digital histology.

Processing of neuroanatomical tissue is subject to many forms of distortion. Some are due to the sectioning method, others to the handling of the tissue through embedding, and blocking tissue to fit on traditional histology slides. In most cases, these result in damage to select regions of a given histological section with distortion of the tissue morphology that causes problems in applications that require the co-registration of 2D sections and subsequent 3D reconstruction. A fixed hemisphere slab of brain tissue of a TBI subject imaged at 7T postmortem was processed to capture every section onto large format slides (100x130mm or larger). Brain tissue was sectioned at 20µm using a custom tape-transfer system; mounted sections were stained with H&E and Iron/Prussian blue. A third series was kept for additional stains. All sections are scanned using a whole-slide imager at 0.46µm/pixel. This large-format approach studies the morphology of traumatic vascular injury seen in human post-mortem tissue and adds microscopic details to findings on the in-vivo MRI. Mechanical forces acting on the parenchyma are suspected to cause direct injury to the vasculature; microbleeds can be seen on T2* weighted or SWI MR images of patients. It is suggested that iron accumulates along the track of the vessel and surrounds the neighboring area. Pathology demonstrates iron-laden macrophages in perivascular space, along small and large vessels associated with the damage site along with disruptions in cellular structure and myelination. We create a brain stack by aligning images within a reference frame via 2D rigid transformations. The stack is registered to the MRI by optimizing correspondences between the volumes through a nonlinear transformation. The transformation is computed using the large deformation diffeomorphic metric mapping algorithm with a mutual information cost metric suitable for cross-modality matching, producing smooth and 1-to-1 deformations inherent

to diffeomorphisms. The aligned 3D-stack is further processed to yield reconstructed intensity projections in each plane.

Abstract: We developed a new, scalable strategy of volumetric imaging with single beam scanned illumination and perpendicular planar detection that achieves $0.5*0.5*5\mu$ m voxel resolution imaging of an entire mouse brain structure within 3 hours. We also developed an optimized pipeline of thick brain slice sample preparation as well as automated 3-D reconstruction and image analysis. The whole procedure from sample preparation to cell counting for activity mapping of multiple mouse brains with antibody-based cell type identification could be completed within 5 days.

Title: Hybridization chain reaction based fluorescence *In situ* hybridization in iDISCO cleared brain tissues

Authors: *V. KUMAR¹, D. M. KROLEWSKI¹, B. MARTIN², H. AKIL³, S. J. WATSON, Jr.³ ¹Mol. and Behavioral Neurosci. Inst., ²MBNI, ³Univ. of Michigan, Ann Arbor, MI

Abstract: Fluorescence in situ hybridization (FISH) in intact tissues has potential to provide vital spatiotemporal information for molecular characterization of heterogeneous neuronal populations. At present, mainly two fluorescent methods are available for detecting mRNAprobe hybridized complex: 1) Peroxidase catalyzed tyramide amplification method- using Digoxigenin/biotin/FITC labelled oligo/cRNA probes. This method however fails to give uniform signal across the depth in tissues thicker than 300-500 µm which is mainly due to the rapid deposition of reactive tyramide on the superficial layers. Additionally, this method is not fully compatible with CLARITY or iDISCO clearing methods. 2) The Hybridization chain reaction (HCR) method - where binding of single stranded cDNA probes to the target mRNAs initiate chain reactions in which metastable fluorophore-labeled DNA hairpins self-assemble into tethered fluorescent amplification polymers (Choi et al., 2014). Although HCR method has been shown to work with CLARITY, it remains unexplored with clearing methods like iDISCO or CUBIC which depending upon molecular targets and tissue type can yield better volumetric staining and visualization. Hence, we investigated the compatibility of HCR-FISH with different clearing methods- iDISCO and CUBIC along with CLARITY. Following the tissue processing and FISH, slices were imaged on confocal/COLM systems and quantified for the uniformity of cellular labelling and S/N ratio across the tissue depth and region. Based on our preliminary results, iDISCO showed the most uniform labelling of cells and high S/N ratio for FISH in fresh frozen slices thicker than 2 mm, whereas with CLARITY (<400 µm) or CUBIC (<100 µm) failed to show comparable staining. The combination of two simpler methods-HCR and iDISCO provides the best opportunity for high resolution intact tissue FISH. However, generation of functional 50-mer DNA probes flanked by initiator sequence appears to be the most challenging part of this method.

Title: Novel variants of adeno-associated virus type 2 provide enhanced anterograde transsynaptic gene delivery

Authors: *A. PLANUL¹, M. DEROSIERS¹, C. NGUYEN², F. MARTI², D. DALKARA¹ ¹Thérapie génique et modèles animaux des maladies neurodégénératives, Inst. De La Vision, Paris, France; ²Neurophysiologie et Comportements, Inst. de Biologie Paris-Seine, Paris, France

Abstract: Viral tracers are widely used tools to study the neural circuitry of the brain. Adenoassociated viruses (AAVs) are particularly versatile vectors as they are non-pathogenic and display low immunogenicity. Despite the success of new AAV variants for retrograde transsynaptic labeling; no such variant exists for anterograde trans-synaptic transport. The only available vectors capable of anterograde axonal spreading are the toxic rabies and HSV1 viruses and to some extent AAV serotypes 1 and 9. However, AAV1 and 9 are not efficient enough and need amplification of the transported transgene to be useful. Thus, we lack an efficient, non toxic vector capable of trans-synaptic anterograde transport. Here we used a high-throughput screening approach, called directed evolution on AAV serotype 2 (AAV2) to find new AAV variants with enhanced trans-synaptic anterograde transport abilities. Because the anterograde trans-synaptic transport capacity depends on the viral capsid, three random DNA libraries of the cap2 gene coding the viral capsid of AAV2 have been created. Then, 3 random viral libraries were made on which we applied 6 consecutive cycles of selection. For each selection cycle, viral libraries transporting their own *cap* gene were injected into the eye and the *cap* genes found into visual regions of the brain were amplified. After 4 cycles, a convergence toward two modified capsids was observed. These variants were able to do efficient trans-synaptic anterograde transport and provide strong reporter gene expression in post-synaptic neurons after delivery in the brain. Our data suggests that we were able to improve the anterograde trans-synaptic transport properties of AAV2. These new variants open many new opportunities to study brain circuits. Currently, we are in the process of evaluating them for functional studies. Indeed, if these variants are capable of sufficient trans-synaptic expression of reporter genes like GCamP, we would be able to measure simultaneously the activity and the connectivity of neuronal networks without toxicity impairing the signal. We anticipate these variants will also be useful in gene therapy approaches where efficient spreading of regenerative factors in connected brain regions is necessary. Transsynaptic gene delivery might limit the number of injection sites in gene therapy approaches for diseases like Parkinson's disease.

Title: Dendritic anatomy analysis using oblique light sheet tomography

Authors: *A. NARASIMHAN¹, U. SÜMBÜL², K. UMADEVI VENKATARAJU¹, D. F.

ALBEANU¹, P. OSTEN¹ ¹Cold Spring Harbor Lab., Cold Spring Harbor, NY; ²Grossman Ctr. for the Statistics of Mind, Columbia Univ., New York City, NY

Abstract: Oblique Light Sheet Tomography (OLST), which operates on the principle of light sheet fluorescence microscopy, is a whole brain volumetric imaging platform. The oblique orientation, in which the illumination/detection paths are oriented obliquely (45°) with respect to the tissue surface, allows for imaging the surface of the brain upto ~400 µm depth in an x-y raster pattern. Once the raster scan is completed, the brain is translated to an integrated vibratome to section the imaged portion of the tissue. The raster scan and automated sectioning is repeated iteratively to obtain whole brain coverage. Since tissue scattering limits the light penetration depth, we modified and optimized a clearing protocol based on the CUBIC protocol for clearing the brains. Clearing removes the lipids in the tissue, making the brain structurally soft. We developed a novel gelatin based embedding to improve the rigidity of the brain so that it can be sectioned in our integrated vibratome. Based on the current instrument configuration, a cleared adult mouse brain is imaged within ~14 hrs at 0.4 x 0.4 x 2.5 µm voxel resolution with overlapping regions for image registration and reconstruction. We use this custom built OLST to understand the somatodendritic morphology and axonal projections of pyramidal cells in the mouse neo-cortex. This is achieved by sparse labeling of the pyramidal cells (Emx-Cre) using

intra-venous injections of Cre dependent reporter viruses. Manual annotation of neuronal morphology is time consuming and labor intensive. To overcome these problems and to process the large volumes of data that our OLST platform generates, we developed a supervised machine learning-based approach: deep neural networks are trained to enhance binarize the raw microscopy images to and subsequently obtain the skeletons of neuronal arbors automatically. This framework allows us to study branching and positioning patterns of cortical neurons at an unprecedented scale, which is a prerequisite for robust identification of cell types.

Title: A spherical aberration free microscopy system for live brain imaging

Authors: *Y. UE^{1,2}, H. MONAI^{3,2}, K. HIGUCHI^{1,2}, D. NISHIWAKI^{1,2}, T. TAJIMA^{1,2}, K. OKAZAKI^{1,2}, H. HAMA³, H. HIRASE³, A. MIYAWAKI^{3,2} ¹R&D Group, OLYMPUS Corp., Hachioji-shi / Tokyo, Japan; ²RIKEN BSI-Olympus Collaboration Ctr., Wako, Japan; ³RIKEN BSI, Wako, Japan

Abstract: The high-resolution in vivo imaging of mouse brain for quantitative analysis of fine structures, such as dendritic spines, requires objectives with high numerical apertures (NAs) and long working distances (WDs). However, this imaging approach is often hampered by spherical aberration (SA) that results from the mismatch of refractive indices in the optical path and becomes more severe with increasing depth of target from the brain surface. Whereas a revolving objective correction collar has been designed to compensate SA, its adjustment requires manual operation and is inevitably accompanied by considerable focal shift, making it difficult to acquire the best image of a given fluorescent object. To solve the problem, we have created an objective-attached device and formulated a fast iterative algorithm for the realization of an automatic SA compensation system. The device coordinates the rotation and the z-position of an objective, enabling correction collar adjustment while stably focusing on a target. The algorithm provides the best adjustment on the basis of the calculated contrast of acquired images. Together, they enable the system to compensate SA at a given depth. As proof of concept, we applied the SA compensation system to in vivo two-photon imaging with a 25×water-immersion objective (NA, 1.05; WD, 2 mm). It effectively reduced SA regardless of location, allowing quantitative and

reproducible analysis of fine structures of YFP-labeled neurons throughout the mouse cerebral cortical layers.

Title: Contributions of lipid extraction, RI-matching and size expansion in tissue clearing

Authors: ***J. KIM**¹, J. CHOI¹, E. LEE^{1,2}, W. SUN^{1,2} ¹Anat., Col. of Medicine, Korea Univ., Seoul, Korea, Republic of; ²Brain Korea 21, Korea Univ., Seoul, Korea, Republic of

Abstract: Tissue clearing techniques, such as CLARITY and ACT (active CLARITY technique), have received great attention for deep (brain) tissue imaging and for the potential application to the diagnosis in recent years. In principle, tissue clearing is achieved by a simple combination of extracting lipids, tissue swelling, and matching refractive indices (RI) between imaging solution and a cleared tissue whose main component is cellular and extracellular matrix (ECM) proteins. However, the contributions of major factors in tissue clearing, lipids extraction, tissue swelling and RI matching, have not been evaluated systematically yet. Interestingly, we found that four organs (brain, liver, kidney, and lung) shows different contribution of three factors during the ACT process in this study. While matching RI which depends on the volume of collagen in the tissue contributes to reducing light scattering, lipid extraction is expected to greatly improve antibody staining in a thick tissue, affecting the diffusion rate of the molecules into the tissues. We estimated the optimal time for the completion of lipid removal by measuring diffusion rate of RI matching solution into the tissue, which could be utilized for the Q/C process during the tissue clearing. Finally, we propose that the changes in the tissue clearing properties can be used as diagnostic measures. Our preliminary proof-of-concept results with traumatic brain injury (TBI) model will be presented.

Title: Novel modernisation of Golgi-Cox stain and its optimisation of tissue clearing

Authors: *M. KULIGOWSKI¹, M. KASSEM², S. FOK³, K. SMITH⁴, B. BALLEINE² ¹Univ. of Sydney, Camperdown, Australia; ²Sch. of Psychology, ³Biomed. Imaging Facility, Univ. of New South Wales, Sydney, Australia; ⁴Brain and Mind Ctr., The Univ. of Sydney, Sydney, Australia

Abstract: High resolution neuronal information is extraordinarily useful in understanding the brain's functionality. Development of the Golgi-Cox stain allowed observation of the neuron in its entirety with unrivalled detail and remains still one of the best ways to visualise a neuron. However, the Golgi-Cox method is restricted by tissue transparency, so imaging is typically 200µm in depth using confocal microscopes

Within recent years, modern tissue clearing techniques such as CLARITY and CUBIC have been used to great effect, completely clearing tissue. Currently, there is no literature on the combination of Golgi-Cox and modern tissue clearing. The application of a Golgi-Cox stain to cleared brain tissue would allow complete neurons to be 3D rendered within intact biology, offering the most accurate data on neuron morphology.

We will show modernisation the Golgi-Cox stain, by combining with modern clearing techniques, and visualization with multiphoton microscopy, which has the advantage of deeper laser penetration, penetrating up to 2 mm. This will rectify the restrictions currently imposed by the Golgi-Cox stain and lead to even greater neuron resolution, allowing for improved 3D rendering and morphology visualisation.

Title: Improved uDISCO clearing for 3D imaging of the nervous system

Authors: *A. J. PARRA-DAMAS, R. CAI, C. PAN, M. TODOROV, B. FÖRSTERA, A. ERTÜRK

Inst. for Stroke and Dementia Res., Muenchen, Germany

Abstract: Tissue clearing technologies provide substantial advantages over conventional histology and tissue sectioning approaches in terms of preserving structural three-dimensional information as well as increased time and cost efficiency. Imaging transparent specimens with single plane illumination (light-sheet) ultramicroscopy has become a golden standard for system biology level analysis of tissues in entire organs and organisms, including mammalian brains. We recently developed the 'ultimate DISCO' (uDISCO) clearing method, which preserves signal from fluorescent proteins over months while reducing the size of the specimens up to 65%, allowing to image not only whole organs but also entire rodent bodies. Here we present an uDISCO-based approach to simultaneous image neurons, glia and vasculature through the intact skull, thus preserving not only the deep brain vasculature but also meningeal vessels. Importantly, our protocol is also compatible with standard immunolabeling once the brain tissue has been rehydrated after clearing and imaging, expanding the possibilities for further phenotypic characterization of the specimens. Thus, this new clearing method can provide novel insights about the neurovascular environment, which would not be possible using standard histology protocols based on tissue sectioning.

Title: Lipid-preserving index matching for prolonged imaging depth

Authors: *Y. LIU¹, A. M. ROLLINS¹, M. WATANABE², M. W. JENKINS² ¹Biomed. Engin., ²Pediatrics, Case Western Reserve Univ., Cleveland, OH

Abstract: Light scattering limits the imaging depth in microscopy. Recently, several optical clearing techniques have been developed to reduce scattering and increase imaging depth enabling imaging of large regions of interest. These techniques are especially attractive for 3-D imaging of complex morphology in the nervous system. Here, we introduce a new optical clearing method called lipid-preserving index matching for prolonged imaging depth (LIMPID). Because LIMPID contains no detergent or organic solvent, it maximally preserves the cell's lipid bilayers. In addition, it has a higher clearing capability than most water soluble optical clearing agents due to a high refractive index (1.47). Low viscosity and optimal osmolarity properties reduce tissue processing time and minimize tissue distortion. We have also verified its compatibility with some common fluorescent proteins and antibodies. A significant benefit of LIMPID over other clearing methods is its simplicity. The clearing solution is easy to make and the clearing process only requires one step (immersion of the labeled sample in the clearing agent before imaging). Using LIMPID, we are able to investigate the organization of the peripheral nervous system and the state of innervation in different embryo tissues in 3D with fluorescent confocal microscopy.

Title: Parafilm assisted microdissection: An alternative and effective technique for the microdissection of the mice nucleus accumbens

Authors: *M. F. PAGLIUSI, JR, *M. F. PAGLIUSI, JR, A. D. BRANDÃO, I. J. M. BONET, C. R. SARTORI, A. S. VIEIRA UNICAMP, Campinas, Brazil

Abstract: The Nucleus Accumbens (NAc) is a fundamental structure for the reward system and, therefore, influences several types of behavior. The literature shows several studies that highlight the importance of NAc in conditions like drug addiction, depression, nociceptive behavior and in conditioned behaviors in general. However, many of these studies fail to deepen into the real importance of NAc in these conditions because they have difficulty in accessing molecular changes that may occur in this structure. A major limitation in accessing such changes is the lack of knowledge and studies that describe how to identify and perform the microdissection of the NAc in a simple and inexpensive way. Therefore, the objective of this work is to describe the parafilm assisted microdissection procedure, a simple and inexpensive technique to microdissection the mouse NAc. We first described the best way to perform the mouse euthanasia and how to remove the brain from the skull without damaging the tissue. Next we describe how to prepare the slides with parafilm that will be used to receive the slices of the brain. In the next step we describe in detail how to position the brain in the object holder of the cryostat, how to align the cerebral hemispheres and how to identify the beginning and the end of the NAc. We also describe how to perform the staining and the dehydration of the slices, a critical step to facilitate the identification of the structure for the microdissection and also to preserve protein, DNA and RNA molecules from the sample. In the final step of this procedure we describe how to identify the anatomical limits of the NAc in each slices made in the cryostat and, finally, we also describe how to perform the microdissection of the structure. The microdissection is performed in a simple way, using a scalpel that the researcher will use to cut the tissue belonging to the NAc. This technique allows the researcher specifically collect the NAc tissue, from which intact RNA and proteins can be extracted to perform real-time PCR and Western Blot as well as others molecular analysis.

Abstract: Subcellular resolution imaging of the whole brain and subsequent image analysis is prerequisites for understanding anatomical and functional brain networks. We have developed a high-speed imaging apparatus based on automated mechanical sectioning and confocal imaging,

named FAST (block-FAce Serial microscopy Tomography), and image data processing pipeline for 3D image construction without tissue-clearing techniques. FAST acquires submicrometerresolution images of whole mouse brain in a speed range comparable to those of light-sheet fluorescence microscopy. FAST allows unbiased quantitative comparisons between normal and disease model brain based on the cell numbers obtained from 3D image analysis. Moreover, FAST is scalable to the brains of nonhuman primates, which visualizes neuronal projections in the whole brain of an adult marmoset. Thus, FAST provides new opportunities for global approaches to gain a better understanding of brain systems.

Program, ⁵Dept. of Chem., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: The brain consists of billions of cells that are organized in a large number of distinctive regions which have specific functional properties. In case of mammalian brain, the "cytoarchitecture" assembly is diverse and still remains to be significantly explored. In each brain region many different cells types are present, such as oligodendrocytes, astrocytes, microglia, and neurons along with an extensive blood vessel network. The cells are organized into localized multicellular units, in the vast cortical cell layers, and the "niches" of neural stem cells. Overall, a comprehensive mapping of the whole brain using combined optical microscopy and spectroscopy tools has not yet been achieved, and much remains unknown about the brain's structure illuminated by this technology. Here we report on rat brain chemical maps using vibrational hyperspectral spectroscopic imaging and high-performance computing. We report

two different methods: 1. Fourier Transform Infrared (FTIR), and 2. Stimulated Raman Scattering microspectroscopies. Both methods measure the fundamental vibrational modes of molecules to provide multiplexed chemical information on major classes of molecules (lipids, proteins, etc) and microscopic (micron and submicron) morphological details. The spectroscopic data obtained from these methods are the foundation of developing a chemical brain map based on computational methods and signal processing techniques. Another goal of our research is to develop a digital staining method from the hyperspectral IR data by combining high-performance computing to quantify the cytoarchitecture in the brain and pathophysiological conditions studies in the near future. The chemical map will provide the chemical and molecular details to capture the molecular specificity and structural complexity of brain tissue that are not possible to obtain from other histological imaging methods.

Title: Determining and documenting the anatomical location of experimental neuroscience data: Best practice recommendations

Authors: *I. E. BJERKE, K. A. ANDERSSON, M. ØVSTHUS, M. A. PUCHADES, J. G. BJAALIE, T. B. LEERGAARD Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway

Abstract: Anatomical location is a key parameter for interpretation and comparison of neuroscientific data. Location is typically determined by looking up diagrams in anatomical reference atlases, communicated using anatomical terms, and shown in representative images. But the documentation provided varies considerably among scientific publications. Essential information about nomenclature and reference atlases, or criteria used to define boundaries of structures is often missing. This lack of accuracy limits the opportunities for comparing and integrating data from different publications, and could lead to failure in replicating scientific

experiments. To clarify and address this challenge, we have investigated current practice for assigning and documenting anatomical location for different categories of experimental neuroscience data reported in > 120 articles investigating the rodent brain. Our findings show that the specificity and accuracy of anatomical documentation in most cases can be considerably improved with relatively simple procedures. We here suggest some general and method-specific recommendations for such improvements, and discuss how these steps may contribute to increase the accuracy of anatomical descriptions and data interpretation. We demonstrate how new three-dimensional rodent brain reference atlases, and associated software tools for spatial registration of brain image data to a common anatomical space, offer new opportunities for efficient integration and comparison of neuroscience data.

Abstract: [Introduction]PET plays a crucial role in evaluating brain glioma, and a number of PET tracers are investigated to validate clinical application. Among these, the mitochondrial translocator protein (TSPO)-ligand is a novel and promising biomarker for brain glioma, but little is known about glioma occurring in spinal cord. The purpose of this study is to evaluate spinal cord glioma in mouse xenograft model using PET imaging with TSPO-ligand, (¹⁸F-FEDAC). [Method]Adult female NOD-SCID mouse received a transplantation of human glioblastoma multiforme cell line U-251 MG (GBM group) or phosphate-buttered saline (PBS group) into the tenth level thoracic spinal cord. U-251 MG cells were cultured and labeled with firefly luciferase (ffLuc) genes via lentiviral transduction. Three weeks after transplantation, gadolinium-enhanced MRI was performed. PET imaging was performed with ¹⁸F-FEDAC in the transplanted

site was measured. Then the animals were immediately sacrificed and the spinal cord was dissected for autoradiography. The correlation between in vivo imaging data and immunohistochemistry was evaluated for the expression of TSPO.[Result]Gadolinium-enhanced MRI showed enhancing lesions in the transplanted site of the GBM group compared with the PBS group. In vivo dynamic TSPO-ligand PET imaging revealed an increase in tracer uptake in the transplanted site compared with the PBS group. These results were consistent with enhancing area of MRI. Autoradiography confirmed the high affinity and specific ¹⁸F-FEDAC bindings in the transplanted site of the GBM group compared with the bindings of the PBS group. Immunohistochemistry showed a high level of TSPO expression in the transplanted site of the GBM group. These cells were human nuclear antigen antibody-positive .[Conclusion]¹⁸F-FEFDAC PET imaging can elucidate the area of increased TSPO expression that can be visualized and quantified in vivo after transplantation. These results suggest that TSPO-ligand PET could be a promising in vivo imaging modality to visualize spinal cord glioma as well as brain glioma. In the future, we will evaluate the FEDAC-PET against spinal cord glioma in clinical settings.

Title: The Janelia MouseLight Database: Complete axonal reconstructions from hundreds of individual long-range projecting neurons

Authors: *J. WINNUBST, E. BAS, J. DUDMAN, C. GERFEN, A. HANTMAN, W. KORFF, S. MURPHY, N. SPRUSTON, S. STERNSON, K. SVOBODA, J. CHANDRASHEKAR MouseLight, HHMI Janelia Res. Campus, Ashburn, VA

Abstract: One of the main goals of modern neuroscience is to understand how communication between different brain regions facilitates complex sensory processing and behavior. While much is now known about the gross anatomical connectivity between different brain areas, there is still a lack of information regarding how individual neurons within a brain region differ in their projection targets. Here, we combined a custom tissue clearing technique with serial two-photon tomography to image labeled neurons throughout the entire mouse brain with sub-micron precision. This allowed us to fully reconstruct the neuronal morphology of hundreds of

individual neurons in several key output areas of the brain: motor cortex, thalamus, hypothalamus and subiculum. We found that neurons within a brain area, which would classically be described as belonging to the same projection class, showed significant variation in their projection targets and axonal branch patterning. Reconstructed neurons will be made available in an online database that includes extensive search features and 3d visualization capabilities. By sharing these resources and techniques with the wider neuroscience community we hope to facilitate new insights into the fundamental properties of neuronal connectivity in the mammalian brain.

Title: Reversible clearing of rat brains for interrogation of histopathology using visikol histo approach

Authors: X. E. FLOWERS¹, T. VILLANI², G. GARDNER², M. JOHNSON², N. CRIDER², *J. H. GOODMAN^{3,4}

¹Biol., Col. of Staten Island - CUNY, Staten Island, NY; ²Visikol Inc., New Brunswick, NJ; ³NYS Inst. For Basic Res., Staten Island, NY; ⁴Physiol. and Pharmacol. and Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Since the introduction of the CLARITY tissue clearing technique in 2013, interest in tissue clearing techniques and three-dimensional tissue imaging has increased dramatically. While current tissue clearing techniques (CLARITY, iDISCO, Scale, CUBIC) result in highly transparent samples for 3D imaging, these processes irreversibly alter underlying tissue chemistry (e.g. hyperhydration and denaturation of proteins, extraction of lipids and/or cross-linking to polyacrylamide) and result in tissues that cannot be subsequently analyzed by traditional section-based histological processes. As such, these techniques, while showing great promise in an academic setting, cannot be directly validated against the gold-standard histological approaches, and as such have limited scope beyond basic research. Furthermore, while these techniques have been successfully applied to mouse tissues of all types, difficulty has been reported with rat tissues due to their size and extent of myelination. Many experimental

models of epilepsy, stroke and traumatic brain injury are performed in rats, and as such there exists a need for a histology-preserving tissue-clearing technique suitable for use in rat brains. To this end, the Visikol HISTO clearing technique was employed in conjunction with immunolabeling to obtain three-dimensional image stacks for large sections (>1 mm) and hemispheres of rat tissue highlighting vasculature, neurons, and astrocytes. The distribution of distance to nearest vessel was calculated for neurons and astrocytes. After clearing and imaging, tissues were subsequently un-cleared and sectioned for H&E and Nissl stain, to afford traditional histopathological correlation to 3D datasets.

Title: Towards unified mouse brain atlas anatomical segmentation: Paxinos label on Allen common coordinate framework

Authors: *U. CHON¹, Y. KIM²

¹Dept. of NBS, Pennsylvania State Univ. Col. of Med., Hershey, PA; ²Dept. of NBS, Penn State Univ. Col. of Med., Hershey, PA

Abstract: Anatomical brain atlas is essential to study anatomical and functional organization of the brain. For mice, most widely used atlases include Paxinos and Franklin's The Mouse Brain in Sterotaxic Coordinates (Paxinos), and Allen Institute for Brain Science's the Allen Mouse Brain Atlas (Allen). By utilizing Nissl staining for a single mouse brain, Paxinos and Franklin created 120 micrometer spaced 2D atlas with unique abbreviations and boundaries. In addition, the Allen

Institute recently created 10 micrometer spaced 3D digital atlas with another set of labels and boundaries. With two different atlases used, labeled regions and their boundaries are inconsistent with one another. Moreover, nomenclatures of brain regions differ significantly between the two atlases. This caused confusion and misinterpretation of brain regions in many studies. As an initial step to reconcile the two different atlases, Paxinos labels were manually imported into latest Allen common coordinate framework within matching coronal *z* planes. Thus, we created a digital adult mouse brain atlas with 2 independent labels merged into a single atlas framework. We compared the anatomical borders and names of brain regions, and identified significant discrepancy between the two atlases on the same 2D plane. We envision that the converged atlas will provide an important bioinformatical platform for future neuroanatomical studies.

Title: Identification of specific brain regions by triple fluorescent images and Voronoi tessellation

Authors: *S. INOUE, K. HOTTA, K. OKA Keio Univ., Yokohama, Japan

Abstract: Brain has many anatomically identified regions with specific functions. For the comparative studies of brains from different animals, brain draft map plays an important role. However, in previous studies, specific brain regions are generally identified by the cytoarchitectures visualized by several staining methods, and their borders have been arbitrarily determined. In this study, we propose a new method for identifying specific brain regions and generating the draft of brain map rationally and automatically by using the triple florescent imaging and Voronoi tessellation. This new method enables us to divide a brain preparation into sub-regions (Voronoi polygons) by vertical bisectors among cell nuclei. The advantage of Voronoi tessellation is that it divides the brain preparation into Voronoi polygons uniquely. Furthermore, their area and distribution of Voronoi polygons should reflect anatomical information for the density of cells.

We applied this method to the brain of zebra finch (Taeniopygia guttata). The whole brain was coronally sliced as more than 200 sections. Cell nuclei, myelin and cell bodies of neurons were fluorescent stained by DAPI, fluoro-myelin and fluoro-nissl (NeuroTrace), respectively, by the method used for visualization of brain regions in previous studies (Karten et al., 2014). The coordinates of cell nuclei were determined from DAPI images, and Voronoi tessellation was
applied to them in each brain section. Each section was divided into about tens of thousands of Voronoi polygons. The fluorescent intensities of myelin and nissl were assigned to each Voronoi polygon to integrate multiple information of brain cytoarchitecture. Furthermore, we visualized relationship between the mean fluorescent intensities of myelin and nissl in each Voronoi polygon by the scatter plot. Each Voronoi polygon was grouped into three clusters: nissl-rich, myelin-rich and the others. This method could identify both nissl-rich and myelin-rich brain regions rationally and automatically. We succeeded in identifying brain regions of the zebra finch by multiple brain tissues and Voronoi tessellation.

Title: Multi-scale volumetric imaging of whole mouse brains using correlated x-ray microtromography, magnetic ressonance imaging and electron microscopy

Authors: *R. VESCOVI¹, V. DE ANDRADE⁵, S. FOXLEY², M. DU⁶, K. FEZZAA⁵, H. LI³, P. LA RIVIERE², D. GURSOY⁵, S. MIKULA⁷, C. JACOBSEN⁶, N. B. KASTHURI⁴ ¹Biol. Sci. Dept., ³Neurosci., ⁴Neurobio., ²Univ. of Chicago, Chicago, IL; ⁵Argonne Natl. Lab., Chicago, IL; ⁶Northwestern Univ., Chicago, IL; ⁷Electrons - Photons - Neurons, Max-Planck Inst. For Neurobio., Martinsried, Germany

Abstract: The mammalian brain has the most complex cellular architecture of any known biological tissue. Neurons can span great distances (several centimeters in the human brain) but connect with each other at the nanoscale. Fully characterizing this architecture and the web of directional connections would allow for an hierarchial understanding of the nervous system and its potential pathologies. However, no existing imaging approach can span the six orders of length-scale magnitude required to bridge those levels of understanding. At low resolution scales (e.g. mm voxels), magnetic resonance imaging (MRI) techniques allow for in vivo or ex vivo mapping of neuronal tracts through a combination of diffusion-weighted imaging techniques and post-imaging computational tractography. While powerful, they cannot achieve the nanometer-scale resolution required to identify neuronal connections. Moreover, they have never been thoroughly validated against ground truth high-resolution data. At the highest resolution scale

(e.g. nm voxels), recent efforts at automated electron microcopy (EM) provide synapse-level resolution (3 nm) but are currently limited to brain volumes of the size of a grain of sand and face serious computational challenges scaling to even 2 pixels of MRI data at 1 mm resolution (i.e. almost 2 petabytes of EM data). This unresolved mismatch between these imaging modalities (and others) partitions our understanding of the brain into 'silos' divided by resolution scales with little to no cross validation. The strengths of each modality are not leveraged for a more comprehensive understanding of the brain. This problem is only exacerbated since brains potentially operate at multiple scales in parallel (from communication via individual connections between neurons to communication between brain regions). Multi-resolution multi-modal brain maps are critically necessary for a more complete understanding of the brain. We propose to use synchrotron-based micro-CT (uCT) to fill this gap, bridging the resolution divide between MRI and EM by providing intermediate resolution (e.g. micron voxels) over entire brains and with sample preparation conditions compatible with MRI and automated EM on the same brains. We propose to use uCT as a 'Rosetta Stone' enabling mapping of complete neuronal paths, allowing, for the first time, validation of dtMRI, and identifying areas of interest in both coarser resolution modalities for subsequent nanometer reconstructions with automated serial EM.

Title: An internet based histological atlas of the Göttingen minipig brain

Authors: *D. ORLOWSKI¹, A. N. GLUD², N. PALOMERO-GALAGHER³, J. SORENSEN⁴, C. R. BJARKAM⁵

¹The Dept. of Neurosurg., Dept. of Clin. Medicine, Aarhus Univ., Aarhus C, Denmark; ²Ctr. for Exptl. Neurosci. (CENSE), Inst. of Clin. Medicine, Aarhus Univ., Aarhus C, Denmark; ³Inst. of Neurosci. and Med., Res. Ctr. Julich, Julich, Germany; ⁴Aarhus Univ. Hospital, Head-Neuro Ctr., Aarhus C, Denmark; ⁵Dept. of Neurosurg., Aalborg Univ. Hosp., Aalborg, Denmark

Abstract: In recent years, pigs have become popular as large animal models in translational neuroscience as the feasible substitute for non-human primates. However, the anatomy of the pig brain is not well described. Minipigs are often used in such research and to our knowledge, there are no published cytoarchitectonic atlases describing the Göttingen minipig brain. We present accordingly an Internet based atlas describing cytoarchitecture of the Göttingen minipig telencephalon. The Atlas was built using 24 consecutive Nissl stained sections with depictions of the cortical and deep brain structures. Sections used in the atlas were derived from female Göttingen minipigs aged 10-14 months as approved by the Danish Animal Experiments Inspectorate and following the "Principles of laboratory animal care" (NIH). The animals were 4% PFA perfused and the brains were removed. To obtain sections presented in the atlas, one brain was paraffin embedded in toto, sectioned into serial 15 µm thick coronal sections and stained with Nissl or myelin (autometallographic) staining. Additional brains (n=17) were frozen and sectioned on cryostat into 40 µm (coronal) or 100 µm (horizontal or sagittal) thick sections followed by Nissl, myelin or DARPP32 staining. Sections from both frozen and paraffin embedded brains were used for preparation of the atlas descriptions. The atlas web page is accessible on http://www.cense.dk/minipig atlas/. It was constructed using HTML and CSS, ensuring easy transferring to the server as well as off-line work. To enable a magnified view of the sections, the JQuery library and a freeware Image Zoom plugin was used. The atlas was built using two pictures of every section, full sized one (6836 x 8223 pixels) for magnified view, and a small one (650 x 782 pixels) for presenting on web page. We tried to keep navigation through atlas simple. The section can be selected either using the thumbnails, or on the drawing presenting sagittal cross-section of the brain with embedded sectioning planes. For every atlas section, its own list of abbreviations can be shown. Additional full lists of all abbreviations, sorted in alphabetical order or grouped according to the brain anatomy, include the links to the first atlas page where the structure appears. The unique feature of our atlas is the presentation of the approximate borders between various cortical areas, which may serve as a great help in planning animal experiments. The structure of the atlas web page is open and allows subsequent addition of detailed information about various brains structures. Likewise, the analysis of the brain connections using DTI and addition of the MRI pictures to the atlas are in progress.

Title: Methods and applications for magnetic resonance imaging in hamsters: Characterization of sex differences through DTI and T2-weighted imaging

Authors: *T. R. MORRISON¹, S. C. IRIAH¹, X. CAI², P. P. KULKARNI³, C. F. FERRIS⁴ ¹Psychology, ²Northeastern Univ., Boston, MA; ³Psychology, Northeastern Univ. Dept. of Psychology, Boston, MA; ⁴Psychology, Northeastern University, Ctr. for Translational NeuroImaging, Boston, MA

Abstract: The Syrian hamster is a research model most widely used in studies focusing on sleep, aggression, and hormone regulation. Most recently, the Syrian hamster has been developed as a model of Ebola and Marburg hemorrhagic fever due to its superiority over other rodent models regarding its many similarities to human clinical signs and pathology. Despite its usefulness, the Syrian hamster remains an underutilized model that possesses a highly translatable neuroanatomy and behavioral repertoire that parallels (and in some cases supersedes) that of mice and rats. Magnetic resonance imaging (MRI) techniques are a virtual toolbox of analytic modalities that allow for the imaging of changes in the brain and identification of novel biomarkers associated with genetic variation, disease states, and the dynamic effects of pharmacotherapeutics. With these methods, it is possible to repeatedly and reliably scan an individual animal throughout its lifetime to follow changes in neurobiology and physiology brought on by any number of genetic and/or environmental insults. Using images from highresolution T2-weighted scans we developed 3D segmented and annotated MRI atlases for both male and female hamsters with over 140 brain regions in each. When data from different imaging protocols e.g. BOLD, functional connectivity, manganese enhanced MRI, from multiple animals are registered to the atlas it is possible to reconstruct distributed and integrated neural circuits that constitute virtual "fingerprints" of brain activity. In this example, we applied diffusion weighted imaging (DWI) and quantitative morphometry to identify differences in grey matter microarchitecture and region specific differences in brain volumes between sexes. The tools and data we have generated are of great value to pre-clinical researchers that currently use, or are interested in working with the Syrian hamster model. Moreover, to our knowledge, this is the first imaging study using the Syrian hamster thus highlighting an important addition to the wider pre-clinical animal imaging field.

Title: Development and characterization of primary neuronal-glia networks

Authors: *H. A. ENRIGHT, D. LAM, S. K. G. PETERS, J. OSBURN, C. HUANG, D. SOSCIA, A. SALES, K. KULP, E. K. WHEELER, N. O. FISCHER Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: Organ-on-a-chip systems are designed to recapitulate the microenvironment of human tissue and organ systems, and hold promise in evaluating new drugs, characterizing toxicants, and to aid in elucidation of disease mechanisms. Multi-electrode arrays (MEAs) provide a means of non-invasively interrogating neuronal health and function, and are traditionally used to assess cultured networks of purified primary neurons. While these primary cultures can provide key insights into neuronal response and function, they fail to recapitulate the cellular complexity in vivo as they lack supporting glia including astrocytes, microglia, and oligodendrocytes. In this study, we have developed a complex in vitro system which incorporates these other cell types using primary rat cortical neurons and glial cells on a MEA device. Flow cytometry was used to identify cell-type specific populations. Immunocytochemistry was used to identify each cell type, evaluate cell morphology, and assess the phenotypic state of supporting microglia, oligodendrocytes, and astrocytes. Electrophysiology measurements were compared between complex and simple neuronal cultures over several weeks in vitro. Significant differences in electrophysiology responses were observed as neuronal complexity increased, including an earlier firing response and increased burst rate. These results suggest that complex neuronal/glial cultures may provide additional insight and relevance when evaluating the effects of new drugs and toxicants on primary neurons. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 through LDRD award 17-SI-002.

Title: *Ex vivo* electrical imaging of retinal and hippocampal layers using CMOS-based highdensity microelectrode arrays

Authors: ***G. ZECK**¹, F. JETTER¹, M.-J. LEE¹, L. CHANNAPPA¹, T. HERRMANN¹, F. HELMHOLD²

¹NMI at the Univ. Tübingen, Reutlingen, Germany; ²Inst. of Med. Psychology and Behavioural Neurobiology, Eberhard Karls Univ. Tübingen, Tübingen, Germany

Abstract: Electrical imaging refers to the mapping of electrical activity in neural networks at high spatial (~ 10 μ m) and temporal (~ 20 kHz) resolution. The technique has been used to evaluate (i) signal propagation in dissociated cultured networks, (ii) the functional diversity in the ganglion cell layer of mammalian retinas and (iii) the interplay of field potentials and single unit activity in brain slices. Two conceptually different microelectrode techniques are currently in use, one employing metal-based electrodes, the second technique using capacitive electrodes insulated by a thin dielectric.

Here, we first compare the recording performance of the two techniques by analyzing the signalto-noise (SNR) ratio from identified ganglion cells in the mouse retina under equivalent experimental conditions. For the two techniques signal amplitude and recording noise differ by about an order of magnitude; however the SNR ratio are undistinguishable. Secondly, we apply CMOS-based MEAs with capacitive electrodes to electrically image signal propagation in brain slices (hippocampus and retina) over a wide temporal range. Spectral analysis of the hippocampal recordings reveals spatially segregated signal power in frequency bands ranging from the alpha regime up to sharp-wave ripples (200 - 500 Hz). Electrical imaging in retinal slices reveals signal propagation across layers from outer nuclear layer to ganglion cells but also horizontal signal spreading within layers.

The presented experiments demonstrate the power of electrical imaging using high-density microelectrode arrays for the investigation of signal propagation across different neural layers and reconcile the two approaches of electrical imaging using metal-based or capacitive electrodes.

Title: Human Cerebrospinal fluid promotes long-term neuronal viability and network function in human neocortical organotypic brain slice cultures

Authors: *H. KOCH¹, N. SCHWARZ¹, U. HEDRICH¹, F. BEDOGNI², H. SCHWARZ¹, N. DAMMEIER¹, E. AUFENBERG¹, H. LERCHE¹, H. PA¹, J. B. HONEGGER¹, T. V. WUTTKE¹ ¹Univ. Tübingen, Tübingen, Germany; ²San Raffaele Res. Inst., Milan, Italy

Abstract: Pathophysiological investigation of CNS-related disease, such as epilepsy or neurodegenerative disorders, largely relies on histological studies on human post mortem tissue, tissue obtained by biopsy or resective surgery and on studies using disease models including animal models, heterologous expression systems or cell culture based approaches. However, in general it remains elusive to what extent results obtained in model systems can be directly translated to the human brain, calling for strategies allowing validation or even primary investigation in live human CNS tissue. In the work reported here, we prepared human organotypic slice cultures from access tissue of resective epilepsy surgery. Employing different culture conditions, we systematically compared artificial culturing media versus human cerbrospinal fluid (hCSF), obtained from patients with normal pressure hydrocephalus (NPH). Presented data demonstrates sustained cortical neuronal survival including not only maintenance of typical cellular electrophysiological properties and activity, such as robust action potential generation and synaptic connectivity, but also preservation of tonic and phasic network activity up to several weeks in vitro. As clearly delineated by immunocytochemistry, single cell patch clamp- and extracellular recordings, we find that in contrast to artificial culturing media, hCSF significantly enhances neuron viability and maintenance of network activity.

Title: Feasibility of brain slice electrophysiology in the swine

Authors: *J. G. ROHAN¹, S. M. MCINTURF¹, M. K. MIKLASEVICH^{1,2}, N. M. GARGAS^{1,2}, P. M. SHERMAN³, K. L. ARMSTRONG⁴, K. L. MUMY⁵ ¹Naval Med. Res. Unit Dayton, Wpafb, OH; ²Henry Jackson Fndn. for Military Res., Bethesda, MD; ³59 MDW - USAFSAM/FH, San Antonio, TX; ⁴AFMC 711 HPW/RHDV, Wpafb, OH; ⁵Naval Med. Researh Unit Dayton, Wpafb, OH **Abstract:** The swine model is becoming a popular alternative to nonhuman primates in translational neuroscience research mainly because of the reduced cost and ethical liability, especially when performing large cohort studies. Unlike brains from small animals such as rodents, swine brains are gyrencephalic and are believed to better represent the human brain. There has been a recent surge in neuroscience-related studies in swine that utilized non-invasive imaging technologies such as positron emission tomography (PET) and magnetic resonance imaging (MRI), as well as behavioral testing to characterize neurological impairments. However, to our knowledge, there has been no documentation reporting electrophysiology recordings on viable brain slices from swine. Electrophysiological (EP) recordings provide critical information pertaining to the integrity of synapses throughout the brain. Its use in neuroscience research is vital not only in understanding the mechanisms of various neurological disorders but also in developing therapeutics that target various ion channels, receptors, enzymes and other synaptic proteins. A major difficulty in performing electrophysiology work in swine is obtaining rapid access to the brain while maintaining neuronal viability. Unlike rodents, swine possess a very thick skull that is extremely difficult to penetrate. Here, we describe how to quickly harvest the brain from the swine while maintaining neuronal viability and how to prepare functional hippocampal slices. Two different strains of female minipigs at different ages were used. The first is the Yucatan strain, ages 9-11 months weighing 41-57 kg. The second is the Sinclair strain, ages 3-4 months, weighing approximately 15 kg. We were able to obtain signals from a majority of intact slices, and recordings can be made for hours following brain harvest. From these slices, we were able to collect spontaneous spiking data, input/output relationship plots, and short term plasticity assessments using paired pulse stimulation protocol.

Title: Simultaneous multiwell optogenetic stimulation and microelectrode array recording for neural electrophysiology assays

Authors: *M. BEAUMONT^{1,2}, H. B. HAYES², A. M. NICOLINI², C. A. ARROWOOD², I. P. CLEMENTS², D. C. MILLARD² ¹Inst. for Genomic Med., Columbia Univ. Med. Ctr., New York, NY; ²Axion BioSystems, Atlanta, GA

Abstract: Microelectrode arrays (MEAs) monitor and manipulate cultured cell activity *in vitro*, providing insight into neuronal network interactions to inform "disease-in-a-dish" models, stem cell characterization, toxicology screening, and drug safety and development. Recentlydeveloped multiwell MEA systems, such as the Maestro, enable high-throughput assessment of functional endpoints at greatly reduced time and cost. While network activity may be monitored under spontaneous conditions, stimulation of neural activity allows evaluation of evoked activity measures, reduces variability across wells, reduces assay duration by increasing activity levels, and enables creation of application specific protocols to assess features of network connectivity. Optogenetics integrates fast, light-activated channels (opsins) that allow targeted, precise manipulation of cellular activity, and provides advantages such as targeting of specific cell types, the ability to suppress activity, minimal stimulus artifact, and uniform stimulus delivery across a culture. Here, we demonstrate the application of Lumos, a commercial multiwell optical stimulation system, to characterize the use of opsins for in vitro neurophysiology assays. ChR2, Chronos, Chrimson, and Jaws were evaluated at multiple light intensities across four wavelengths (470nm, 530nm, 612nm, 655nm) to assess spectral separation in the neural response. As expected, ChR2 exhibited a greater evoked response for 470nm light than other wavelengths, whereas Chronos was slightly green-shifted, with consistent evoked response for 470nm and 530nm wavelengths. Chrimson had the broadest activity across wavelengths, but the peak response occurred for the 612nm wavelength. Additionally, stimulation frequency was varied to quantify the effect of opsin kinetics on neural response, with Chronos exhibiting the highest precision. Finally, measures of evoked neural response were used to quantify changes in activity induced by pharmacological manipulation with carbamazepine and picrotoxin, which produced significant decrease and increase, respectively, in the evoked response. These findings demonstrate the potential of optically-integrated multiwell MEA systems to improve assessment of neuropharmacological effects.

Title: Investigation of primary rat neuronal-glial networks on hydrogel scaffolds using a 2D cell culture system

Authors: *D. LAM¹, H. A. ENRIGHT¹, J. OSBURN¹, S. K. G. PETERS¹, D. A. SOSCIA², K. KULP¹, E. K. WHEELER², N. O. FISCHER¹ ¹Physical and Life Sci. Directorate, ²Engin. Directorate, Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: Multi-Electrode Array (MEA) devices present a noninvasive experimental approach for long-term interrogation of neuronal networks. Often, a monolayer of purified primary neurons is used to form these spontaneously active networks in vitro, in the absence of neuroglia. In this regard, it is not fully understood how supporting glial cells influence the neuronal network and bioelectrical activity in a more complex culture system. We have recently developed a complex culture system using primary rat neurons and glial cells (i.e. astrocytes, oligodendrocyte precursor cells, and microglia) on a poly-d-lysine (PDL)-coated MEA device. Preliminary work has shown an earlier firing response (e.g. firing rate, burst events) with complex cultures versus neuronal cultures alone. However, this system lacks tissue-like features. Hydrogels have been used to mimic, to some extent, the extracellular matrix found in the brain. In this study, we used electrophysiology and imaging techniques to investigate the effects of natural and synthetic hydrogels on primary rat mixed neuron and glial cells for long term cultures in vitro. We compared electrical activity of the neuronal-glial networks grown on the 2D scaffold interfaced to a PDL-coated MEA device to the PDL-MEA device alone. Immunocytochemistry was used to identify the cell-type specific populations, examine cell morphology, and characterize the phenotypic state of astrocytes and microglia. Preliminary results show that the 2D construct represents a reproducible and reliable method to study the complex neuronal-glial network, and can be further enhanced to recreate a 3D tissue model relevant to the brain.

Title: Multi-region recordings from the hippocampus of free-moving rats with a Parylene-based multi-electrode array

Authors: *H. XU^{1,2}, A. HIRSCHBERG², K. SCHOLTEN², E. MENG², T. W. BERGER², D. SONG² ²Biomed. Engin., ¹USC, Los Angeles, CA

Abstract: The hippocampus is crucial for the formation of long-term declarative memories. Unitary activities recorded from the hippocampus of free-moving animals can provide valuable insights into understanding how short-term memories are transformed into output signals for long-term storage by hippocampal sub-regions. In order to target different regions of the

hippocampus simultaneously a multi-electrode array with a complex layout and high spatial resolution is necessary. In this work, we developed a 64-channel, flexible, penetrating electrode array which uses Parylene-C, a polymer with the highest USP biocompatibility rating, as its structural material. The layout of the electrode array was designed to conform to the cell body layer of the rat hippocampus. Temporarily reducing the effective length of the Parylene probe with a dissolvable polyethylene glycol (PEG) brace increases the probe buckling threshold and enables the successful implantation of the probe into the desired hippocampal region. Immunohistochemistry (IHC) staining performed one month post-implantation verified the depth of insertion (>4 mm). No severe immune response was observed around the Parylene probe. Neural activities were monitored both during the implantation and after the animal recovered. Unitary activities with amplitudes greater than 200 µV were recorded from both the CA1 and CA3 region of the rat hippocampus during the implantation. After the animal fully recovered, spike activities from the CA1 and CA3 region were recorded while the animal ran freely in an open field. Complex spikes with maximum signal to noise ratios (SNR) of up to 12 were recorded with the Parylene probe. Units with an average SNR of 3 to 4 were successfully recorded with the Parylene probe over the period of one month after implantation.

Italiano di Tecnologia, Genova, Italy; ⁷Neurobio., Harvard Med. Sch. Dept. of Neurobio., Boston, MA

Abstract: Over the last decade, significant advancements in CMOS electrode array devices permitted neuroscientists to start monitoring with cellular and sub-millisecond resolutions the electrical activity of large neuronal networks and brain circuits in-vitro. These devices counterpart recent developments in optogenetics and biotechnology (such as iPS cells, cellular reprogramming, organoids), thus enabling to face fundamental questions in neuroscience and brain diseases with innovative experimental designs exploiting large-scale neuronal activity recordings. An ongoing challenge consists in advancing this CMOS-MEA technology to realize implantable devices capable of large-scale neuronal activity recordings in-vivo. With this aim, we are developing a novel generation of micro-structured microelectronic neural probes integrating hundreds of densely integrated microelectrodes on single-shafts. Here we will present the design of the current platform and acute recordings obtained from anesthetized and behaving mice. Current probes were designed in a standard CMOS technology based on the active pixel sensor concept. They provide low-power circuits for 512 active sensing electrodes, including inpixel circuits for amplification underneath each electrode site and on-chip circuits for reading out the whole-array at 20 kHz/electrode using time division multiplexing. The whole sensing area occupies an area of 96 μ m \times 6 mm (W x L) and it provides an electrode density >1000 electrodes/mm² (electrode size of 15 μ m × 15 μ m, centre-to-centre pitch of 29 μ m). For implantation, silicon micromachining techniques were used to shape the CMOS devices and to reduce their thickness from 500 µm down to 40-50 µm. To manage potential issues that might arise from power dissipation and heating we also implemented a dynamic power scheduling solution and we achieved a power consumption of < 3 mW, well below the limit of 40 mW reported in the literature. Electrodes were post-processed by electrodepositing platinum, gold or PEDOT and the resulting impedances (< 1 M Ω at 1.1 kHz) and noise performances were assessed with electrical testing. To operate these devices we realized a complete hardware and software platform. Preliminary in-vivo results confirmed that these devices are able to resolve biological signals in a frequency band including both LFPs and spikes (amplitudes ranging from 100uV up to 400uV) and that these CMOS-probes provide adequate mechanical properties for multiple implantations and recordings.

Title: In situ recordings of brain activity using organic electrochemical transistor-depth probes

Authors: *L. KERGOAT¹, M. DONAHUE², P. QUILICHINI¹, A. GHESTEM¹, A. WILLIAMSON¹, I. UGUZ², G. MALLIARAS², C. BERNARD¹ ¹Inst. de Neurosciences des Systèmes, Aix-Marseille Univ., Marseille, France; ²Lab. de bioélectronique, Ecole des Mines de Saint-Etienne, Gardanne, France

Abstract: A better understanding of the nervous system requires accurate electrophysiological recordings necessary for diagnostic purposes and for brain-machine interfaces. State-of-the-art recordings are currently performed with microfabricated arrays of metal electrodes (silicon probes, Utah arrays and tetrodes), which capture the local field potentials (LFPs). Such probes are also being used in the clinic to improve diagnosis and treatments. A key parameter for such electrodes is the impedance, which should be as low as possible in order to achieve high signal to noise ratio. Organic electronic devices constitute a promising class of devices because of their mixed ionic/electronic conductivity, mechanical flexibility and biocompatibility, making them ideal to interface with brain tissues. The use of conducting polymer-coated metallic electrodes have shown to decrease the impedance of metallic electrodes by one order of magnitude, leading to a higher resolution signal. To further improve the resolution of the signal, one can use organic electrochemical transistors (OECTs). In the same way than a transistor, OECTs are devices with an inherent amplification property, leading to higher intensity signal. It has been shown than using an ECOG made of OECTs lead to higher signal to noise ratio compared to an ECOG made of conducting polymer coated metallic electrodes. The quality of the signal achieved was of the same magnitude than the one obtained using state-of-the-art depth silicon probes. However, to further improve the accuracy of the recordings, one needs to go deeper into the brain. We developed a depth probe made of OECTs to achieve high signal to noise ratio recordings of the brain activity. We fabricated OECTs on a flexible parylene substrate, which was later on attached on a laser-cut glass capillary (25 um x 115 um). Passive conductive polymer electrodes were also fabricated and located near the OECTs to compare the performance of both kinds of electrodes. The sharp tip obtained thanks to the laser cutting insured smooth implantation in the brain. The electrophysiological signals were first recorded from the hippocampus of anesthetized rats. We also investigated the stability of the signal over time in chronic experiments. The quality of the signals obtained, both for LFPs and single-unit recordings, with the OECTs, makes them promising candidates for accurate electrophysiological recordings.

Title: Laser-printed porous graphene microelectrodes with high charge injection capacity for cortical stimulation

Authors: *D. KUZUM¹, Y. LU¹, A. G. RICHARDSON², T. H. LUCAS, JR² ¹Univ. of California San Diego, La Jolla, CA; ²Neurosurg., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neuroscience research and clinical brain-machine interfaces require safe and efficient neural sensing and stimulation. To-date, most of the neural stimulation systems have relied on sharp metal microelectrodes with poor electrochemical properties that induce extensive damage to the tissue and significantly degrade the long-term stability of implantable systems. Therefore, efficient and durable electrophysiological sensing and stimulation without penetrating brain tissue is of great research interest. Here, we demonstrate a flexible cortical microelectrode array based on porous graphene. Microelectrodes based on porous graphene show low impedance and high charge injection capacity, which is critical for high efficiency cortical sensing and stimulation. We demonstrate that porous graphene microelectrodes exhibit no physical delamination or degradation after 1 million biphasic stimulation cycles, confirming long-term endurance. Moreover, porous graphene is easy to fabricate with direct laser pyrolysis, providing great potential for large area fabrication and commercialization. In *in vivo* experiments with rodents, same porous graphene array is used to sense brain activity patterns with high spatiotemporal resolution and to control leg muscles with high precision electrical stimulation from the cortical surface. Flexible porous graphene array offers a minimally invasive but high efficiency neuromodulation scheme with potential applications in cortical mapping, brain-computer interfaces, treatment of neurological disorders, where high resolution and simultaneous recording and stimulation of neural activity are crucial.

Title: Fabrication and validation of a low pitch and high channel count carbon fiber electrode array using a minimal and stackable silicon support structure

Authors: *P. R. PATEL¹, D. EGERT², E. J. WELLE¹, J. D. BERKE², C. A. CHESTEK¹ ¹Biomed. Engin., Univ. of Michigan, Ann Arbor, MI; ²Neurol., UCSF, San Francisco, CA

Abstract: Our group has shown that arrays of ~8µm carbon fiber electrodes can record chronically from rodent motor cortex for at least 5 months and cause minimal damage (Patel 2016), essential properties for future implanted microelectrodes in humans. Those arrays were built by manually securing bare fibers to exposed gold traces on a printed circuit board (PCB) using silver epoxy, then encasing the fibers in poly(ethylene-glycol) to facilitate insertion. However this approach has limited capacity for further enhancements in electrode density, length, and channel count above 16. To improve on the existing arrays, we have developed a silicon support structure that allows for more accurate assembly, range of target depths, and ease of insertion.

Fabrication of silicon supports starts with a bare 4" silicon wafer. The wafer undergoes a deep reactive-ion etching (DRIE), creating two trenches. The first is a narrow trench (10 x 11um (h x w)), designed to hold the carbon fiber, with length depending on the target brain region. Connected to the backend of this trench is a larger trench (11 x 100 x 290µm (h x w x l)) for the silver epoxy. Next, the wafer undergoes a deep boron diffusion step followed by insulating layers of silicon oxide (1585Å) - nitride (487Å) - oxide (1506Å). Then, a stack of chrome/gold (300/3000Å) is deposited and patterned, creating a connection from the larger trench, with the silver epoxy - carbon fiber bond, to a bond pad at the device periphery. A final DRIE defines the shape of the device including shank length (1.5-9mm) and width, which starts at 25µm at the base of the device and tapers to 15µm for the last 300µm of the shank. The devices are released from the wafer using a wet etch.

We have successfully fabricated a 4-layer cortical version of this device with 16 1.5mm long shanks (pitch= 80μ m) per layer. Each shank was populated with a carbon fiber that extended past the device by 500um and stayed well aligned. Two preliminary non-functional 64-channel devices were inserted 1.5mm into rodent motor cortex. To our knowledge this is the highest density array able to self-insert without a shuttle. To perform a preliminary functionality test, a single fiber was insulated with parylene-c, the tip re-exposed with a laser, and then wire bonded

to the PCB. This device was implanted in motor cortex and able to detect activity from two units with amplitudes of $162\mu V \& 77\mu V$. While placement of the silver epoxy and carbon fibers is still done manually and will require further refinement, the support structure vastly improves the scalability, accurate placement, and ease of insertion of our carbon fiber electrodes.

Title: A bilayer insulation scheme for carbon nanotube fiber neural microelectrodes

Authors: *S. PAMULAPATI¹, F. VITALE³, R. G. BRYANT⁴, C. KEMERE², M. PASQUALI¹ ¹Dept. of Chem. & Biomolecular Engin., ²Dept. of Electrical & Computer Engin., Rice Univ., Houston, TX; ³Ctr. for Neuroengineering and Therapeut., Univ. of Pennsylvania, Philadelphia, PA; ⁴Advanced Materials and Processing Br., NASA Langley Res. Ctr., Hampton, VA

Abstract: Neural electrode implants hold great potential for the diagnosis and treatment of neurological disorders such as Parkinson's disease and epilepsy. Recently, high performance carbon nanotube fibers (CNTfs) were employed as multifunctional neural electrodes ^[1,2]. However, the longevity and consistent performance of these CNTf electrodes heavily relies on the properties of insulation material used in the design. An ideal insulation is one that is conformal, stable, and biocompatible with good dielectric and impermeable barrier properties. Commonly used insulation materials like parylene, silicon nitride, and silicon carbide either tend to show a dramatic degradation and water penetration under in vivo and in vitro aging conditions or require high deposition temperatures [3, 4]. Here, we present a hermetic insulation scheme for CNTf microelectrodes using a bilayer encapsulation of polyimide (PI) over aluminum oxide (Al₂O₃), which is highly conformal and biocompatible with superior dielectric, chemical and moisture resistance properties. The inner Al₂O₃ layer serves a powerful moisture barrier, while the flexible outer layer of new solution-based PI acts as an excellent external water and ion barrier in addition to providing overall structural stability ^[5,6]. Individual single filament CNTfs were insulated with Al₂O₃ using atomic layer deposition (ALD) and then PI by dip coating technique at low deposition temperatures. The electrochemical properties and integrity of the bilayer insulation and individual layers were assessed using electron microscopy, leakage current and impedance measurements. Further, we evaluated the long-term stability of bilayer coated

CNTf electrodes using longitudinal impedance analysis under *in vitro* electrode aging tests against commercial platinum-iridum (PtIr) metal electrodes. The impedance of PtIr electrodes at 1 kHz decreased by 45% and 77% after second and ninth weeks respectively. However, impedance of bilayer-CNTf electrodes at 1 kHz increased by 10% after first week and remained consistent suggesting a reliable and stable electrode performance. High coating conformality, low leakage current and stable long-term insulation impedance prove the bilayer encapsulation as a promising insulation scheme for chronic implantable neural electrodes. Title: Nanofabricated fMRI probes for the detection of neuronal electrical signaling

Authors: *A. HAI¹, E. A. LIMA², B. P. WEISS², Y. LIN³, A. JASANOFF¹ ¹Biol. Engin., ²Earth, Atmospheric and Planetary Sci., ³Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Different functional neuroimaging modalities are currently used for in-vivo studies of brain function and dysfunction. While blood-oxygen- level-dependent functional magnetic resonance imaging (BOLD-fMRI) currently provides neuroscientists with the highest quality, noninvasive whole-brain readout in animal models as well as humans, it can only give information about areas of changing blood flow in the brain, and leaves substantial guesswork as to the underlying electrical neural activity patterns that constitute the communication mechanism of the nervous system. Novel methods to perform direct whole-brain readouts of neural activity would address this limitation, and allow for the elucidation of the neural basis of neuropathological disorders, as well as have an enormous effect in basic neuroscience. Here, we

present a novel strategy by which nanofabricated electrical components can be used as fMRI contrast agents that are specifically coupled to neural activity. We describe the synthesis of voltage sensitive probes that convert electrical neural activity to detectable magnetic field perturbations that can be measured using MRI. This strategy will ultimately allow for the non-invasive detection of neural signals and provide an unprecedented tool for the study of brain function and dysfunction in neurodevelopmental disorders, as well as normal cognition and behavior.

Title: Conductive polymer based silk electrode for bio-activity measurement

Authors: *K. TORIMITSU, Y. TAKIZAWA, K. MIURA, H. TAKAHASHI Tohoku Univ., Sendai, Japan

Abstract: Development of a bio-flexible electrode for neural measurement is one of our interest. We reported previously usage of a conductive polymer, poly(3,4-ethylenedioxythiophene) based compound improved the biocompatibility and the electrical characteristic of the electrode. We used this type of electrode for biological activity measurement, such as neural development. Here we report the flexible silk electrodes using as for a wearable/ implantable electrode. The conductive polymer modified silk allowed us for a higher biocompatibility and longer measurement capability. Neural activities and/or muscle activities of mouse and chick were measured. Stable signal detection has been achieved. Detected activities were used for controlling machinery movement. As the conductive silk electrode is a flexible and stable measurement, activity-based interaction could be achieved for a primary evaluation of activity - dependent interface.

Title: A distributed real time multiple processor system to capture neural data from 40,000 channels or 300 imager devices over long times from behaving animals

Authors: *D. J. WOODWARD¹, J. CHANG²

¹Neurosci. Res. Inst. of North Carolina, Winston Salem, NC; ²Neurophysiol., Neurosci Res. Inst. North Carolina, Winston Salem, NC

Abstract: A goal of modern neural instrumentation is to capture streams of time stamped data from enough sites within interconnected circuits so that ongoing logic operations can be determined. A key desired feature is the need to expand the traditional computer workstation to control capture of analog and digital signals from a very large number of multiple sensor types. Our aim has been to establish the framework for a parallel acquisition system on a local network that can grow and accommodate use of new high site density recording probes and other devices. The new system has three major components. A first is a configuration service based on Microsoft .net framework that allows members of a cluster to be recognized by a master control CPU and assign functions to each. Separate machines on a network can operate for control, data acquisition, or storage and real time analysis. A second feature is an advanced use of precision time protocol that allows all acquisition processors to share a common high precision clock. A third feature is use of a real time state machine software module installed on all cpus in the cluster to pace data collection, time output to stimulation devices, and control behavioral protocols. This system is linked to a cascade of parallel field programmable gate arrays (FPGAs) with internal ARM processors. These units process bit streams or frames from groups of 24 ADs, 16 bit ADs, SPI interfaces (from IntanTechnologies VLSI recording interface), or other DIGIO devices. Interfaces include ability to capture data flow with signals processing from most available imager devices. We are interfacing this system with one or more experimental chambers to collect data over many days in behaving rats from multiple imagers for light field, mini-microscopes, multiple compressed video streams, light-field, tissue voltages from microwire arrays, arrays of carbon fibers, or other probes with modified surfaces as chemical sensors for tissue oxygen, dopamine, etc. Real time control and timing is provided for output of timing pulses, waveform generation, or HD video displays. This enhanced workstation provides a platform for very high throughput behavioral neurophysiology. NIAAA 2 R44 AA02067

Title: Microfluidic actuation of flexible microelectrodes for neural recording and stimulation

Authors: *A. V. RODRIGUEZ¹, D. G. VERCOSA², F. VITALE⁷, E. M. LEWIS³, S. PAMULAPATI⁴, J. S. YAN⁵, M. PASQUALI⁶, C. KEMERE¹, J. T. ROBINSON³ ²Applied Physics Program, ³Electrical and Computer Engin., ⁴Dept. of Chem. & Biomolecular Engin., ⁵Bioengineering, ⁶Dept. of Chem. and Biomed. Engin., ¹Rice Univ., Houston, TX; ⁷Ctr. for Neuroengineering and Therapeut., Univ. of Pennsylvania, Philadelphia, PA

Abstract: The development of implantable devices to record and stimulate neural circuits has led to breakthrough discoveries on the connectivity and functionality of the brain. Despite tremendous advances, technologies for high-resolution electrical recording and modulation of neural activity at the cellular level still rely on rigid metal or silicon components which poorly match soft brain tissue and cause extensive acute and chronic injury.

Flexible electrodes and ultra-small microwires have been shown to significantly reduce neural damage during chronic implantation and increase the quality and longevity of neural recordings. However, flexible electrodes require stiffening agents to overcome the buckling force upon implantation. These agents increase the device footprint and potentially cause additional damage to the brain during implantation.

To overcome this challenge, we have developed a novel technology to precisely actuate and

implant high-performance soft carbon nanotube fiber (CNTf) microelectrodes without using stiffening agents. Instead, our technology uses fluid flow in a microfluidic device to drive electrodes into tissue. The device's hydraulic design with embedded valves enables precise control of the CNTf position with minimum fluid output. In vitro experiments in brain phantoms show that microfluidic-actuated CNTf electrodes can be implanted up to a 4 mm depth with 30 μ m precision, while keeping the total volume of fluid injected below 0.5 μ L. To demonstrate the feasibility of this technology as a tool for recording neural signals in vivo, we performed acute anesthetized recordings in rats. We used the microfluidic drive to insert CNTf electrodes into the left parietal cortex to a depth ranging from 0.5 to 4 mm. After insertion, the microdrive can be retracted, leaving the CNTf inserted in the brain. Following device retraction and electrical connection, we were able to record spike waveforms from neurons in the cortex and deeper brain regions such as hippocampus. These waveforms were stable across minutes of recording, with firing patterns that varied with the depth of the probe. Future work will focus on chronic stability of electrical recordings in comparison to standard insertion strategies of flexible electrodes.

Title: Electrode designs for reducing the edge effect in transcranial electical stimulation (TES)

Authors: *M. P. WEISEND¹, L. F. BURCH², C. L. DUCKETT², D. P. MARSHALL², M. J. VILARDO²

¹Rio Grande Neuroscience, Inc., Dayton, OH; ²Dept. of Biomedical, Industrial, and Human Factors Engin., Wright State Univ., Dayton, OH

Abstract: Transcranial Electrical Stimulation (tES) targets brain networks and shows promise in the treatment of multiple neurological disorders and in cognitive enhancement. Application of a current during tES produces an edge effect at the electrode-skin interface (ESI). This edge effect is a high current density at the edge of the ESI with a low concentration in the center of the contact surface. The edge effect arises from a difference between the conductivity of the electrode and the skin. Common complications in tES include unpleasant skin sensations and

redness. Partially or fully mitigating this edge effect may reduce these complications. We investigated the edge effect with Finite Element Analysis (FEA) using Solidworks, Simpleware ScanIP, and COMSOL. Our model included a Ag-AgCl electrode, electrode gel to serve as an electrically conductive medium between the electrode and skin, and an acrylonitrile butadiene styrene (ABS) plastic housing to hold the electrode and gel. The conductivity of the electrode was set to 654.50 S/m, skin 0.45 S/m, Signagel 4.00 S/m, and ABS Plastic 1.00*10⁻¹⁶ S/m. Our baseline housing was circular with a diameter of 20.32 mm, height of 8.64 mm, a right angle at the ESI, and a sparse internal structure of three ridges to hold the Ag-AgCl electrode in place. The team made modifications to the internal geometry of the ABS electrode housing to alter the path of current through the electrode assembly to reduce edge effect during tES. Seventy variations of the baseline housing were created. FEA of the baseline housing showed the peak current density (PCD) was 7.41 A/m^2 at the edge of the ESI. Our designs ranged from greater than 30 A/m^2 to 5.04 A/m^2 as the PCD at the edge of the ESI. We observed that small holes and sharp angles at the ESI increased PCD. The creation of an obtuse angle at the base of the electrode housing lowered the PCD at the edge of the ESI. Varying the diameter of the gel column immediately under the Ag-AgCl electrode also decreased the PCD. The most effective design, 5.04 A/m^2 , at reducing edge effect consisted of a 6.00 mm central hole ending 1.00 mm above the ESI. The cavity between the ESI and the bottom of the central hole had a lofted cut 0.88 mm high and 4.42 mm in length with a 6.00 mm radius fillet at the edge of the ESI. Variations in the internal geometry can alter the PCD at the ESI. Our best design improved the overall PCD by 32% at the edge of the ESI. However, some designs increased the PCD by over 400%. Our results indicate exotic electrode shapes should be used with caution. Future human testing of the housings will determine if decreased PCD at the ESI reduces tES complications.

Title: Novel algorithm to discriminate bursts and tonic activity in spike trains: Extended Hill-Valley method

Authors: ***B.** CHUNG¹, D. H. EDWARDS²

¹Emory Univ., Atlanta, GA; ²Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: As the size of neural networks in simulations and experiments increases, analysis algorithms need to consistently and efficiently identify a range of activity patterns including tonic spiking and bursting across large datasets. Visual classification can be time consuming and subjective as baseline firing rates change. Algorithmic approaches focus mainly on detecting bursts and classify activity using inter-spike interval (ISI) thresholds based on the ISI distribution. Depending on the mixture of neural activity, however, ISI distributions of a spike train vary. Consequently, visual inspection and burst detection algorithms yield variable results across datasets that contain different activity patterns. The Extended Hill-Valley (EHV) method builds off of concepts used in the Hill-Valley analysis technique. EHV detects both bursting and bouts of tonic spiking using a smoothed, history-dependent analysis signal derived from a spike train. Because events are classified based on the height-to-width ratio of peaks and troughs, EHV can accurately classify activity across a large dataset consisting of a range of activity patterns without recalibration. The performance of EHV was compared to two other methods, including the Poisson Surprise method, based on events identified by visual inspection. EHV outperformed both algorithms across a range of activity patterns after an initial calibration. EHV can also be used to identify hierarchical features, such as phasotonic bursts that occur when a neuron fires a burst and then spikes at a lower, constant frequency. EHV objectively identified bursts and bouts of tonic spiking across a range of neural activity and can be used to qualitatively classify the activity of individual neurons or networks of neurons in large datasets.

Title: Characterization of carbon fiber electrode coatings using a complex impedance model

Authors: *E. J. WELLE¹, P. R. PATEL¹, F. POURDANESH¹, F. DEKU³, D. EGERT², A. GHAZAVI³, A. JOSHI-IMRE⁴, J. D. WEILAND¹, J. D. BERKE⁵, C. A. CHESTEK¹ ¹Biomed. Engin., ²Dept. of Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI; ³Bioengineering, ⁴Ctr. for Scientific Innovation, Univ. of Texas at Dallas, Richardson, TX; ⁵Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Brain-computer interfaces rely on recordings from a large number of neurons consistently for long durations. Carbon fiber electrodes have a diameter of ~8µm and have been shown to cause minimal scarring in the brain and record high fidelity signals when coated with PEDOT (Patel *et al.*, 2015). However, PEDOT-coated carbon fiber electrodes often only record single units for several months after implant (Patel *et al.*, 2016). One possible explanation for this decrease in recording ability is PEDOT degradation over time. In a previous study from our lab, PEDOT-coated carbon fibers were soak tested in 1x PBS at 60°C for 35 days, and it was found that the 1kHz impedance values significantly increased over time by 151% (p < 0.001, n=16) indicating PEDOT degradation.

To better analyze coating integrity, a model of the complex impedance behavior of these electrodes was developed using nonlinear least squares fitting. This model was used to determine the resistivity of the Warburg-like element of the electrode, where parameter α denotes a how resistive or capacitive the element is in the range of 0-1, with the aim of a more resistive recording electrode (Otto *et al.*, 2006). This model was applied to PEDOT-coated carbon fibers and α values were found to significantly increase over time by 11.1% (p < 0.001, n=16) indicating PEDOT degradation and an increase in capacitive behavior.

Therefore we have begun exploring other more robust surface treatments and coatings, beginning with verifying single unit recording ability acutely *in vivo*. We first attempted to roughen the surface of the carbon recording site using oxygen plasma treatment after laser removal of 50-100µm of parylene. This process reduced impedance, but increased recording surface area. High α values of 0.87 (n=26) for oxygen plasma treated probes indicated that the electrodes were acting in a capacitive manner, although single units were still detectable. We also tried two additional coatings: platinum iridium (Pt-Ir) and electrodeposited iridium oxide (EIROF) (Petrossians *et al.*, 2011, Meyer *et al.*, 2001). The impedance of these two coatings at recording sites of ~40µm² were 182 kOhm (n=16) and 2.11MOhm (n=15) respectively. For comparison, the impedance of PEDOT was 140kOhm (n=83). The α values of both coatings, 0.640 and 0.635 respectively, were similar to that of PEDOT at 0.609.

All electrodes achieved functional recording of single units at depths of 1.2mm, 1.3mm, and 1.5mm in rat M1 with average amplitudes of $173\mu V_{p-p}$ for oxygen plasma (n=15 units, 7 fibers), $308\mu V_{p-p}$ for Pt-Ir (n=5 units, 1 fiber), $193\mu V_{p-p}$ for EIROF (n=8 units, 2 fibers), and $243\mu V_{p-p}$ for PEDOT (n=53 units, 14 fibers). Soak tests are currently on going.

Title: Nearly equidistant spacing of EEG electrodes on a scalp surface coverage area

Authors: *M. E. PFLIEGER^{1,3}, A. M. THIRAKUL², L. T. SMITH²

¹Cortech Translational Solutions Ctr., Cortech Solutions, Inc., La Mesa, CA; ²Cortech Solutions, Inc., Wilmington, NC; ³Computat. Sci. Res. Ctr., San Diego State Univ., San Diego, CA

Abstract: Optimal sampling of EEG scalp potential fields typically calls for bilateral symmetry and uniform spatial density, i.e., fixed spacing within a coverage area. The adequacy of particular spatial densities for a given purpose (such as source estimation) needs more study, which needs, in turn, a method to generate uniform arrays with arbitrary inter-electrode spacing. The International 10-20 electrode system (Jasper, 1958; Klem et al., 1999)--a proportional landmark-based nomenclature that accommodates 74 locations--was extended to a 5% system that accommodates 345 locations (Oostenveld and Praamstra, 2001). Using combinatorial optimization, we sought nearly uniform subsets of the 5% locations for specific numbers of locations, but found this approach to be infeasible. An alternative approach based on icosahedral geometry was designed expressly for uniform sampling of a sphere (Tucker, 1993); but arbitrary spacing is not supported because each refinement of triangles cuts the spacing by one half. We devised an algorithm that generates nearly uniform arrays with any specified target spacing (see rows of the figure) on a given scalp wireframe (here, MNI average head) for a defined coverage area (here, we digitized the boundary of a cap designed to extend coverage on the back and sides of the head). From a central seed point (here, 12 mm anterior to FCz), sagittal midline points at the target spacing are generated to the boundaries. Parasagittal rows have either hexagonal or orthogonal spacing relative to the midline. A parallelogram rule generates a new point from three existing points; a triangle rule may generate one more point near the boundary from two existing points; and a skip rule keeps spacing within a percentage (here, 80%) of the target. The parallelogram rule supports intermediate arrangements between hexagonal and orthogonal.

Electrode arrays of various densities may used for both modeling and experimental studies of optimal spatial sampling. Of note, the algorithm can generate custom layouts for developmental (e.g., infant) research and for highly-studied individuals.

Title: Evaluation of amorphous silicon carbide multielectrode arrays in rodent motor cortex

Authors: *F. DEKU, E. SHIH, A. KANNEGANTI, A. JOSHI-IMRE, J. J. PANCRAZIO, S. F. COGAN Dept. of Bioengineering, Univ. of Texas At Dallas, Richardson, TX

Abstract: Microscale electrode arrays with small cross-sectional dimensions provide potential alternatives to avoid adverse tissue reactions over time, thereby improving their ability to reliably record single-unit and multi-unit extracellular potentials. These arrays also permit recording of neural spikes with high spatial resolution and present the potential of using novel current steering patterns for stimulating neural activity using subthreshold current densities. Along these lines, previously reported sub-cellular scale carbon fiber multielectrode arrays (MEAs) with cross-sectional area less than 50 μ m² have provided chronically stable and high fidelity neural recordings with reduced immune response overtime. However, carbon fiber assembly are not

amenable to large scale manufacturing processes thereby impeding design flexibility, scaling and control of the geometric surface area (GSA). To this end, we investigated the development of MEAs based on photopatternable thin-film amorphous silicon carbide (a-SiC) with shank crosssectional area similar to carbon fiber. We demonstrated functionality of a 16 channel, 150 μ m² Pt electrodes by recording decoupled neural signals in zebra finches basal ganglia. Translation and feasibility in mammalian animal models is yet to be evaluated. Here, we investigated similar electrode arrays with GSA of 50 μ m² in the motor cortex of rat brain for their chronic reliability. The MEAs were fabricated using plasma enhanced chemical vapor deposited a-SiC as the sole substrate and insulator to conformably encapsulate a thin layer of Au on both sides. Electrode sites and bond pads were defined in the top a-SiC layer using SF₆ reactive ion etching techniques. Additionally, we sputter-deposited iridium oxide films on the electrode sites to reduce the electrode impedance and improve the charge storage and charge injection capacities of the electrode. The arrays were then evaluated in motor cortex for recording and stimulation properties. Our preliminary acute testing showed successful implantation into rat motor cortex using PEG 2000 stabilized tips. We also observed a 56% yield for recording single/multi-unit activity under anesthetized preparations. We are currently investigating the reproducibility in a larger number of animals. Moreover, we also plan to evaluate the chronic performance of such electrode arrays for rodent cortical interfacing over a period of 4 months by periodically assessing the in-vivo recording stability, electrochemical properties and charge injection limits. In summary, this study aims to address the implementation of ultra-microscale a-SiC MEAs for chronic rodent cortical interfacing.

Title: Chronic tracking of neuronal clusters using ultraflexible electrode arrays

Authors: ***H. ZHU**¹, X. LI¹, Z. ZHAO¹, X. WEI¹, L. LUAN^{2,3}, C. XIE¹ ¹Biomed. Engin., ²Dept. of Physics, The Univ. of Texas At Austin, Austin, TX; ³Biomed. Engin., The Univ. of Texas at Austin, Austin, TX **Abstract:** The ability to reliably record and track an ensemble of neighboring neurons over months and longer are of great importance to basic and clinical neuroscience, as a large number of brain functions are realized by coordinated activation of a local neuronal population. Assorted Multi-site dense electrode arrays have been designed based on conventional structures, but their chronic recording capacity is often compromised by the instability of the tissue-probe interface. Ultraflexible, cellular-dimensioned neural electrodes have recently demonstrated seamless integration with brain tissue and reliable recording of individual neurons for several months. Here we design dense electrode arrays with oversampling capacity on the ultra-thin (1 µm) and flexible architect to achieve chronic tracking of neuronal clusters. Recordings were performed on head-constrained awake behaving mice who received intracortical implantation in somatosensory or motor cortices for over three months. The oversampling electrodes maintained stable impedance, single-unit yield, and single-unit amplitude during the experiment period. Klusta, a multi-channel spike sorting software was used to detect and isolate unit activities. After extracting the mean waveform of every unit, a semiautomatic program that evaluated the mean square error in the pair-wise comparison between longitudinal recording sessions was used to track the same unit. Multiple units were repeatedly identified and tracked over three months as shown in Figure 1. Repeated in vivo two photon imaging was performed to verify the minimal relative displacements between electrodes and neurons. These results show that the novel electrode design improves from previous studies for the simultaneous recording of closely spaced neuronal populations with minimal tissue damage and stable long-term recording performance.

Figure 1. Left: Representative Tracking results from one animal showing that 10 units were repeatedly detected and tracked using the ultraflexible oversampling electrodes. Right: Representative waveforms from detected units in one week's recording overlaid on the schematic diagram of the 4x8 electrode arrary(electrode dimension: 25 x 25 µm; inter eletrode spacing: 5 µm. A Cross marks the 2D projected location of the neuron from triangulation. Scale bar is 50µV.

Title: Probing brain function with a novel combination of optogenetics and neuroimaging

Authors: *E. ROGERS^{1,2}, G. ALBERTO¹, D. KLORIG¹, J. R. STAPLETON-KOTLOSKI², V. POPLI², C. CONSTANTINIDIS¹, J. B. DAUNAIS³, D. W. GODWIN^{1,2,3} ¹Dept. of Neurobio. & Anat., ²Dept. of Neurol., ³Dept. Physiol. & Pharmacol., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Magnetoencephalography (MEG) is a unique, non-invasive technology that allows for studying biomagnetic signals. A major criticism of MEG is centered on the assumption that biomagnetic signals recorded from the brain are distorted due to the complexity of the brain's cytoarchitecture. Convolutions in the cortex are thought to distort dipoles, nuclei are assumed to be very difficult to localize due to irregular distribution of axons, and signals from deep sources with distance from the MEG sensors. Prior work has suggested that we are able to accurately induce oscillatory current into a non-human primate brain using optogenetics ("OptoMEG"). We stereotaxically injected 5µL AAV10-CaMKIIa-ChR2-eYFP into CA3 of hippocampus and separately into the arcuate sulcus in the prefrontal area of a vervet monkey. After 3 weeks of recovery, we stimulated optically through a 400µm diameter implanted fiber optic while simultaneously performing MEG scans. Analyses revealed that we were able to localize both superficial and deep sources of activity in a spatially- and temporally- precise manner using the beamforming technique synthetic aperture magnetometry (SAM). Optical pulse stimuli, pulse trains, and sinusoidal modulation produce distinct and reproducible oscillatory MEG activity consistent with the stimulus type. Our ability to localize both superficial and deep brain regions provides evidence that SAM can aid in detecting relevant sources of magnetic flux. To further understand the contribution of complex oscillatory activity, we performed dual-site stimulation of CA3 and arcuate sulcus simultaneously in an anesthetized preparation while recording MEG. Stimulation consisted of fast and slow modulation of sinusoidal optical input as well as ongoing sinusoidal stimulation in hippocampus with pulsatile stimulation in cortex. We were able to detect temporal and oscillatory components at both stimulation sites using magnetic source imaging. OptoMEG permits a novel kind of functional brain mapping that relies on whole brain recording of experimenter-determined signals introduced into discrete areas of the brain - these may include oscillatory activity within physiological ranges (e.g. beta, gamma, etc) or pathological patterns of activity (e.g. interictal spike-like discharges). This method allows the stimulation and recording of coordinated brain activity to study the complexity of brain networks, with possible extension to pathological oscillations that underlie seizures and epilepsy. Title: Large-scale microelectrode array for closed-loop cellular-resolution electrophysiology of the retina

Authors: *D. TSAI¹, D. SAWYER², A. BRADD¹, R. YUSTE², K. L. SHEPARD¹ ¹Electrical Engin., ²Columbia Univ., New York, NY

Abstract: The ability to observe and manipulate, with single-cell precision, the activities of large neuronal populations is an essential step toward better understanding of the nervous system. However, conventional approaches in electrophysiology is fundamentally unable to achieve simultaneous, cellular-resolution recordings at scale, while providing sufficient signal-to-noise-ratio (SNR). This is due, in particular, to the need for low-pass anti-aliasing filters at each recording channel front-end, where at-scale electrophysiological systems experience the highest density constraints. In the simplest form, these filters are RC-networks, consisting of a capacitor and resistor. We show that, with high-quality, foundry-grade capacitors in today's advanced microelectronic processes, these RC-filters cannot be made smaller than approximately 20-times the size of the average mammalian neuronal soma, thus limiting the scalability of electrophysiology.

We present an acquisition paradigm, based on compressed sensing, that obviates the need for these spatially inefficient, per-channel filters. To prevent aliasing, the spectral content contributed by the under-sampled thermal noise is digitally constructed, and removed, from the sparsely-sampled channel data. We built an extracellular electrophysiology platform with 65,536 simultaneously recording and stimulation electrodes, with cellular-resolution electrode pitch of $25.5 \,\mu$ m. The platform is able to record with 10 uV rms input referred noise over the spike waveform bandwidth, providing greater than 2- to 5-fold SNR improvements over existing high-channel count systems. When recording from the whole-mount mouse retina, the system senses

single-unit activities from more than 34,000 electrodes - 10-fold more than the best existing attempts.

In conjunction with a high-performance processing pipeline, built from GPU-based streaming multiprocessors, the platform automatically sorts and classifies in excess of 1700 retinal ganglion cells (RGC) following visual stimulation over a 1-mm spot in the mouse retina, including automated identification of rare RGC types.

Using the voltage-based, capacitive stimulation capability built into each recording front-end, we show that the system is able to evoke activities from single neurons, while providing the ability to simultaneously track activities across the entire retina. This capability opens the possibility to examine the relationship between stimulus strength and focal activation, at a higher spatiotemporal resolution than previously achievable.

Title: Design and validation of a 0.75 cc networked implantable neuromodulation device with 32 channels of sensing and stimulation

Authors: *J. J. WHEELER¹, J. R. LACHAPELLE², C. K. BJUNE¹, C. A. SEGURA¹ ¹Draper Lab., Cambridge, MA; ²Draper laboratory, Cambridge, MA

Abstract: An implantable neuromodulation device is described which provides on-the-fly reconfiguration of sensing and stimulation across 32 electrodes in a highly miniaturized sub- 1cc hermetic package. While useful for a wide variety of neuromodulation applications, this poster describes the use of the system to control and deliver sensory feedback from a sensorized neuroprosthetic limb in amputees. Each implantable module is 14mm in diameter and less than 5mm in height, allowing surgical placement of multiple systems within the arm adjacent to electrodes. Close proximity to electrodes enables high-resolution recordings with noise <1uV RMS, sampling rates up to 100ksps, and selectable referencing. The system can deliver stimulation ranging from 200nA to 100mA with 1us waveform resolution. Complete ISO-14708 human-implant safety is maintained through custom ASIC safety circuits. A percutaneous version of the system is wired to an EIC60601-clinic-capable controller through flexible helical

cables for durability. Results from benchtop, non-human primate, and human studies will be presented.

Title: jULIEs: ultra-low impedance neural probes for minimally invasive in-vivo recordings in the mouse olfactory bulb

Authors: *R. R. RÁCZ, M. KOLLO, W. WRAY, G. RACZ, A. T. SCHAEFER Neurophysiol., The Francis Crick Inst., London, United Kingdom

Abstract: Simultaneous, stable, scalable and minimally invasive interrogation and interaction with electrogenic cell populations of behaving animals is of fundamental importance for the advancement of our understanding of how different neural systems interact. Extracellular recordings using electrical charge sensing probes are considered the most powerful techniques capable of addressing this issue. Technical challenges in neural probe size, recording capability, channel count have limited our understanding of brain function. To overcome these challenges, we introduce a modular, flexible, insulator-ensheathed metal microwire platform with ultra-low interfacial impedance recording sites compatible with industry standard read-out electronics. At the center of this approach are glass-ensheathed cast microwires with outer diameter of $25\mu m \pm 2\mu m$ and inner diameters of $1\mu m \pm 0.2\mu m$, resulting in minimal stray capacitance (<0.1pF/mm length). These wires have been semi-automatically polished at an angle of <30° to facilitate brain

insertion and penetration. Interfacial impedance was reduced by modification of the recording sites with nanostructured iridium oxide (IrOx) to achieve coupling capacitances above $1pF/\mu m^2$ with the extracellular space. Bundles containing 16 individual microwires have been assembled into DIL connectors through a low-ohmic connection $(100\Omega \pm 2\Omega)$. Site impedances have been determined using electrochemical impedance spectroscopy between 1Hz and 200kHz by applying a 10mV since-wave around the open circuit potential in 150mM PBS. Advantages of jULIEs are their recording sites which are up to 50x smaller than in conventional electrodes $(1.3\mu m^2 \pm 0.05\mu m^2)$ designed to result in reduced tissue displacement and damage as well as in highly localized, high signal-to-noise recordings. To test jULIE properties in-vivo we performed recordings in the olfactory bulb (OB) of anaesthetized mice (4-6 weeks old) using conventional amplifiers. Action potentials were reliably recorded with amplitudes of up to 1.6mV. When jULIEs were lowered several mm into the brain and returned to a superficial recording position, extracellular units were reliably obtained throughout the OB. Confirming the predicted minimal damage to the tissue, jULIEs were found to be exceptionally suited for recording both large amplitudes (300-1500µV), well isolated units (20-30µm) and multicellular activity throughout the travelled vertical distance. We conclude, that the combination of glass-ensheathed metal wires with nanostructured surface modifications provides a versatile platform for minimally invasive, highly localized neural recordings.

Title: Isotropic recording of whole mouse brains by light sheet microscopy breaking the diffraction limit

Authors: *H.-U. DODT^{1,2}, S. SAGHAFI¹, K. BECKER^{1,2}, M. PENDE^{1,2}, C. HAHN^{1,2}, I. SABDYUHSEVA-LITSCHAUER^{1,2}, M. WANIS¹ ¹Tech. Univ. Vienna, Vienna, Austria; ²Med. Univ. Vienna, Vienna, Austria **Abstract:** Visualization of complete neuronal networks in the brain is an important goal of neuroscience. To this end chemical clearing and recording of mouse brains with light sheet microscopy has become increasingly popular in recent years. Several microscopic setups have been developed for light sheet microscopy but normally there is a trade-off between speed and resolution of the recording.

This is due to the fact that Gaussian light sheets have either a thin beam waist then with a short Rayleigh range or a long Rayleigh range but with a thick beam waist. If one wants to record the brain at high resolution this necessitates the recording of many small tiles with the thin part of the light sheet and subsequent cumbersome aligning and stitching of the single recorded tiles. We therefore developed new optics creating a light sheet with submicron thickness and a vastly extended Rayleigh range. The diffraction limit according to Abbe's formula is normally cited for illumination with high numerical aperture (NA). It applies however also to low NA beams. As our new long light sheet is already rather thin when it leaves the last lens of the light sheet generator our results indicate that we broke the diffraction limit by a large factor. With the new light sheet we were able to image whole mouse brains quickly with one single stack of images giving isotropic resolution.

For recording we used commercial low magnification air objectives with a dipping cone which we optically corrected for imaging in clearing solutions. Apart from brains we also imaged adult GFP labelled drosophilae and cm large pieces of human cancers in autofluorescence. We expect that this breakthrough in optics will become pivotal for the recording of large samples with highest resolution.

Title: SEURAT: A semi-automated pipeline to localize and visualize intracranial electrodes

Authors: *Y. PATHAK¹, T. G. DYSTER¹, J. OH², E. H. SMITH¹, S. SRINIVASAN¹, N. FELDSTEIN¹, C. A. SCHEVON¹, G. MCKHANN, II¹, S. A. SHETH¹ ¹Columbia Univ., New York City, NY; ²Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract: Intracranial electrode implantations for deep brain stimulation and seizure localization are common functional neurosurgical procedures. In order to refine therapeutic targets and meaningfully interpret electrophysiological data, intracranial electrodes need to be accurately localized. There is a demand for efficient methods to localize implanted electrodes as the volume

of these procedures continues to increase. In this study, we aimed to build a semi-automated, user-friendly pipeline (SEURAT) to determine electrode locations.

The pipeline integrates MATLAB and FSL to determine the centroids of potential electrode contacts. If all contacts are not localized through the automated algorithm, users have the ability to interpolate contacts on depth electrodes and to manually choose to add or remove contacts. These contacts are localized in patient-CT space, but can be mapped on to the patient-MRI space and standard-MNI space in order to draw relevant insights.

We tested SEURAT on imaging data from epilepsy patients (n=16) who underwent electrode implantation. Without using the manual option in the pipeline, we localized 1427 contacts out of 1520 implanted. We attribute this discrepancy to low image-quality or to some contacts being outside the brain; the toolbox defines a search area based on patient-specific brain extraction. Within-patient accuracy for the number of contacts localized was 94.5% (Figure 1). Visual inspection, validated with clinical implant maps, demonstrated that contacts were localized and mapped on to correct brain regions.

SEURAT is an accurate and user-friendly pipeline that will be useful to clinicians who need to identify the anatomical location of intracranial electrodes, and for basic science investigations that require an understanding of the relationship between contact location and physiology. Compared to similar open access methods, this pipeline requires minimal user input, which reduces time and error. This pipeline allows for seamless analysis of surgical targets with the potential to inform image-guided surgical protocols.

Figure 1: A) Snapshot from MATLAB with localized contacts superimposed on an axial CT slice. B) All contacts for the example patient mapped and visualized on a standard-MNI brain

Title: Miniscope.org: An open-source imaging platform and online resource focused on developing the next generation of miniature fluorescence microscopes

Authors: *D. AHARONI¹, T. SHUMAN⁴, D. J. CAI², C. LEE³, B. S. KHAKH⁵, A. SILVA⁶, P. GOLSHANI⁷

¹Dept. of Neurol., ²Neurobio., ³UCLA, Los Angeles, CA; ⁴Univ. of California Los Angeles, Los Angeles, CA; ⁵Dept Physiol, Univ. of California Los Angeles Dept. of Physiol., Los Angeles, CA; ⁶Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA; ⁷UCLA Dept. of Neurol., Los Angeles, CA

Abstract: One of the biggest challenges in neuroscience is to understand how neural circuits in the brain process, encode, store, and retrieve information. Meeting this challenge requires tools capable of recording and manipulating the activity of intact neural networks in freely behaving animals. Head-mounted miniature fluorescence microscopes are among the most promising of these tools. Taking advantage of the past decade of advancements in fluorescent neural activity reports and miniaturization of high quality imaging sensors, these microscopes use wide-field single photon excitation to image activity across large populations of neurons in freely behaving animals. They are capable of imaging the same neural population across months and in a wide range of different brain regions.

Here we present the current status of our open-source miniature fluorescence microscope project, Miniscope.org. This project aims at accelerating innovation of miniature microscope technology while also extending access to this technology to the entire neuroscience community. Through online guides and in-person workshops, over 250 labs across 18 countries have begun building and using the Miniscope system. Functioning as a robust imaging system as well as a miniature microscope development platform, labs are able to building on the open-source design, extending its use to new areas of interest. We have built and tested a wire-free Miniscope powered by a LiPo battery that is capable of recording for over 20 minutes in large behavioral assays. Our current work ranges from adding optogenetic stimulation and wire-free operation to simultaneous optical and electrophysiology recording. With a fundamental redesign of the Miniscope system, we are adding additional imaging modalities to the platform while making the entire system smaller, lighter, and more flexible. Through continued optimization and
innovation, miniature microscopes will likely play a critical role in extending the reach of neuroscience research and creating new avenues of scientific inquiry.

Title: Overlapping retrosplenial cortical ensembles encode memories close in time

Authors: *M. SEHGAL¹, S. HUANG², S. MARTIN¹, A. LAVI¹, D. J. CAI³, A. SILVA⁴ ¹Neurobio., Univ. of California Los Angeles, Los Angeles, CA; ³Neurobio., ²UCLA, Los Angeles, CA; ⁴Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA

Abstract: Memories are dynamic in nature. A cohesive representation of the world requires memories to be altered over time, linked with other memories and eventually integrated into a larger framework of sematic knowledge. In an attempt to unravel these questions, our laboratory has recently demonstrated that two contextual memories encoded close in time are stored by overlapping hippocampal CA1 neuronal ensembles and the recall of one can lead to the recall of another, i.e. the two memories are linked (Cai et al. 2016). Although, learning- and CREBdependent changes in intrinsic neuronal excitability most likely facilitate the co-allocation of memories in overlapping ensembles, very little is known regarding how this plasticity biases neurons to be preferentially recruited for memory formation. Similarly, we do not know whether memories are linked due to overlap in neuronal ensembles in certain key brain regions, such as hippocampus for contextual memories, or the entire neural circuit involved in contextual memory formation displays this neuronal overlap. We addressed this question by investigating the overlap in neuronal ensembles encoding contextual memories at varying time intervals within the retrosplenial cortex, a brain structure necessary for spatial and contextual information processing. Using head-mounted miniature microscopes (UCLA Miniscopes), we imaged GCaMP6f-meadiated calcium dynamics in retrosplenial cortical neurons of mice that explored distinct contexts. We found greater overlap in the neuronal ensemble activated in response to two distinct contexts when the contexts were explored 5h vs. 7d apart. These data indicate that retrosplenial cortex can mediate temporal memory linking by recruiting a shared neuronal ensemble for memories encoded within the day. In addition to time, we also wanted to investigate the role of context similarity in neuronal ensemble overlap. In order to do this, we

measured calcium dynamics while mice explored the same context 5h or 7d apart. As before, we found greater overlap between the neuronal ensembles activated when the contexts were explored 5h vs. 7d apart. We are currently investigating whether neuronal overlap is greater when the same, or a distinct context is explored 7d apart. Our data indicate that co-allocation of neuronal ensembles encoding temporally proximate contextual memories may be a generalized mechanism, and memory linking may be mediated by many brain structures.

Abstract: Epilepsy causes significant cognitive deficits in both humans and rodent models yet the circuit mechanisms leading to cognitive dysfunction remain unknown. We first developed a wireless miniature microscope (Miniscope) for *in vivo* calcium imaging to examine the spatial representation of freely behaving epileptic and control mice running on a linear track. Following pilocarpine-induced status epilepticus, chronically epileptic mice had reduced precision of CA1 place fields which completely remapped across days. Next, using silicon probes to record hippocampal interneurons during head-fixed virtual navigation, we found that epileptic mice had profound deficits in theta and gamma power and coherence, and altered phase preferences to ongoing theta oscillations. In particular, dentate hilar interneurons had a similar magnitude of theta phase modulation of their firing rate, but the preferred phase of these cells as a group was highly dispersed and shifted to a later phase of theta. Finally, we transplanted embryonic interneuron precursors from the medial ganglionic eminence into the hippocampus of epileptic mice and found a partial rescue of theta power. Together, these results support the role of circuit dysfunction in poor spatial processing in epileptic mice.

Title: The Crystal Skull: A chronic mouse preparation providing long-term optical access to neurons across the dorsal neocortex

Authors: *T. KIM¹, Y. ZHANG¹, J. LECOQ², J. JUNG¹, J. LI¹, H. ZENG², C. M. NIELL³, M. SCHNITZER¹ ¹Stanford Univ., Stanford, CA; ²Allen Inst., Seattle, WA; ³Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: A major technological goal in neuroscience is to enable the interrogation of individual cells across the live brain. By creating a curved glass replacement to the dorsal cranium and surgical methods for its installation, we developed a chronic mouse preparation, termed the 'Crystal Skull', that provides optical access to an estimated 800,000-1,100,000 individual neurons across the dorsal surface of neocortex. Post-surgical histological studies revealed comparable glial activation as in control mice. In behaving mice expressing a Ca²⁺ indicator in cortical pyramidal neurons, we performed Ca²⁺imaging across neocortex using an epi-fluorescence macroscope and estimated that 25,000-50,000 individual neurons were accessible per mouse across multiple focal planes. Two-photon microscopy revealed dendritic morphologies throughout neocortex, allowed time-lapse imaging of individual cells, and yielded estimates of >1 million accessible neurons per mouse by serial tiling. The Crystal Skull preparation supports a broad range of imaging and optogenetic methods, is compatible with many different behavioral assays for head-fixed mice, and enables studies of cells across >30 neocortical areas. Thus, we expect that this preparation will facilitate a wide variety of experiments probing the interactions between multiple brain areas in awake behaving mice.

Abstract: The brain mediates our interaction with the external world by performing complex computations undertaken by highly interconnected brain regions spread across several centimeters. There is a need for tools to measure and manipulate the activities of these widespread brain regions at the single cell resolution, and at multiple timescales. We are engineering a suite of technologies that enable wide-field, cellular resolution neural interfacing with the rodent cortex. We have implemented a precise computer numerically controlled (CNC) surgery robot to excise very accurately and precisely, arbitrarily shaped skull sections for replacement with a morphological conformant cranial implant or 'brain window'. The brain windows allow optical access to the surface of the whole dorsal cortex and can be implanted for long durations (>100 days). Preliminary histology experiments indicate little or no immune response to chronic implantation. We have established an easy to configure design methodology that allows the brain windows to be adapted for both high resolution imaging using two photon (2P) microscope in head fixed animals, as well as mesoscale cortical activity mapping in head fixed and freely moving mice. We have performed cellular resolution 2P imaging through the windows implanted on transgenic mice expressing the calcium indicator GCaMP6f, in the somatosensory, visual and granulate cortices. Building upon the brain windows we are developing a suite of technologies that enable wide field activity mapping in awake, freely behaving animals. These devices are easy to fabricate using readily available laboratory tools. Finally, the flexibility of the device architecture allows numerous modalities to be incorporated within the windows for multi-modal, bidirectional, brain wide neural interfacing.

Title: Open source computer numerical control neurosurgery platform for automated craniotomies in small animals

Authors: *G. JOHNSON¹, L. GHANBARI¹, J. HU², M. LAROQUE¹, G. SHULL², J. DOMINGUEZ¹, M. RYNES², S. KODANDARAMAIAH^{1,2} ¹Mechanical Engin., ²Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Many in vivo neuroscience techniques require access to the mouse brain through the skull, which is often obtained by performing craniotomies by a skilled experimenter. With the advent of optogenetics and wide field calcium imaging using 2-photon microscopy, scientists are moving towards excising increasingly large sections of the skull for such experiments. Such operations are challenging to perform and great care must be taken to ensure the underlying dura and brain tissue are not perturbed unnecessarily. Accordingly, progress has been made in automating the process of opening craniotomies. Pak and colleagues (Pak et al J Neurophysiology 2014) recently reported on a closed-loop robotic system for craniotomies using impedance sensing demonstrating the utility of using robotics for performing precise surgical operations in mice. A potential limitation of the impedance sensing approach is the detection of false positives due to the presence of vasculature in some parts of skull. Here, we demonstrate an alternative, generalizable and robust approach using surface profiling and iterative depth milling that enables craniotomies to be opened throughout the mouse dorsal cortex. We first automatically profile the outer surface of the skull in three dimensions using a simple mechanical surface probe mounted on a robotic three-axis stereotaxic robot, a technique common in industrial coordinate inspection tools. Our initial characterization demonstrates that our profiling technique achieves accuracy on the order of single micrometers, which is well within the requirements for ultra-precise, large area craniotomies in mice. Using this 3D profile of the skull, we next map the desired craniotomy contour to the individually measured 3D geometry of the mouse. Finally, we use the three-axis stereotaxic robot to mill the craniotomy contour at precisely controlled iterative depths until the skull fragment can be excised by the experimenter. All of this can be accomplished with a sub-\$1000 lab-built stereotaxic robot. The robot is fully open source, utilizing inexpensive stepper motor electronics and control software with active online development communities. The setup is easy to build, requiring minor technical skills. We are currently working on including robotic manipulators for soft tissue manipulation, perfusion apparatus and computer vision guidance to fully automate the rodent surgery procedure.

Title: Miniature fluorescence imaging microscope for the study of spinal cord sensory processing

Authors: *I. LECKER¹, Y. SOUDAGAR², R. P. BONIN¹ ¹Univ. of Toronto, Toronto, ON, Canada; ²Neurescence Inc., Toronto, ON, Canada

Abstract: An estimated 20% of the general population suffers from chronic pain. The mechanisms underlying this highly debilitating condition are not fully understood and the most effective therapeutic options, such as opioids and analgesic, simply numb the pain without addressing its root causes. There is therefore a strong need to understand the molecular mechanisms that give rise to pathological pain in order to identify novel approaches for treating or reversing it. The study of pain pathways in the spinal cord has been limited, in part due to a lack of in vivo strategies for studying sensory processing at the cellular level in freely-moving animals. We have recently developed a new miniature microscope which improves upon existing in vivo imagining technology by enabling multi-site imaging to facilitate the study of neuronal activity across receptive fields of the spinal cord dorsal horn. The miniature imagining microscope uses flexible, customized endoscopic fibers and implantable micro-objectives to enable chronic measurement of fluorescence activity in freely-behaving mice. This design of the microscope does not impair animal mobility, enables the animal to participate in normal behaviors, and does not impede experimental conditions. The goal of this project was to implement the novel miniature fluorescence microscope to study the circuitry of sensory plasticity as it relates to pathological pain in the spinal cord of freely behaving mice.

Title: Three-dimensional imaging of neural activity in freely-behaving mice by a head-mounted two-photon fiber-coupled microscope with electrically tunable focus

Authors: *B. OZBAY¹, G. L. FUTIA¹, M. MA², E. G. HUGHES², D. RESTREPO², E. A. GIBSON¹

¹Bioengineering, ²Cell & Developmental Biol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Two-photon microscopy is increasingly used for imaging brain activity in head-fixed animals due to the benefits of higher imaging depth compared with single-photon widefield imaging. At the same time, there is a desire to image neuronal activity in freely-behaving animals to expand the types of behavior studies that can be done. Head-mounted single-photon microscopes are commercially available for freely-moving studies, however they are unable to resolve true three-dimensional information. Two-photon head-mounted microscopes have also been described but typically do not incorporate active focusing. We present a miniature twophoton fiber-coupled microscope (TP-FCM) for neuronal imaging in freely-behaving mice with active axial focusing enabled with a miniature tunable electrowetting lens. A high-density imaging fiber-bundle is used to achieve lateral scanning when coupled to a laser-scanning twophoton microscope system. Axial scanning is performed by changing the voltage applied to the electrowetting lens incorporated in the miniature microscope distal to the fiber-bundle. The headmounted miniature microscope is made using a precision 3D-printed housing with a total weight less than 4 g. The working distance of the microscope is 450 µm with an additional 200 µm of active axial focusing. The resolution is $\sim 1.5 \,\mu m$ laterally and $\sim 10 \,\mu m$ axially with a field-of-view of 220 µm. For imaging, the microscope is attached to a baseplate that is permanently affixed to the mouse above a cranial window. After the imaging session, the microscope is detached. The reproducibility for repeated imaging was measured to be stable over four weeks, enabling repeated imaging of the same brain region over time. We acquired multiphoton images of GCaMP6s fluorescence showing calcium transients in layer 2/3 neurons in the motor cortex while the mouse was freely-behaving. We recorded distinct neuronal activity from multiple focal planes in the same imaging session. Our TP-FCM demonstrates true three-dimensional twophoton neuronal imaging enabled for freely-behaving animals.

Title: Ultrafast two-photon microscopy for high-speed brain imaging in awake mice

Authors: *O. HERNANDEZ¹, R. CHRAPKIEWICZ¹, T. ZHANG¹, A. S. SHAI¹, M. J. WAGNER¹, Y. ZHANG¹, C.-H. WU¹, J. ZHONG LI¹, Y. GONG¹, M. INOUE², H. BITO², M. J. SCHNITZER¹ ¹Stanford Univ., Palo Alto, CA; ²The Univ. of Tokyo, Tokyo, Japan

Abstract: Laser-scanning two-photon microscopy is a mainstay technique for optical brain imaging and normally provides frame-acquisition rates of ~10-30 Hz. However, it has often been challenging to track fast biological events by two-photon microscopy with millisecond-scale temporal resolution, due to the limitations of the existing mechanisms for laser-scanning. Considerable past research has sought faster two-photon microscopes, and much of this has focused on developing faster scanning mechanisms; however, attaining kilohertz-scale image frame acquisition rates requires not just fast optical scanners but also sufficient fluorescence photons to support high-speed imaging. Here we present a two-photon microscope based on 400 illumination beams that can sample 45,000-135,000 μ m² specimen areas at rates up to 1 kHz. Using this microscope, we visualized microcirculatory flow, fast bridging vein constrictions, and Ca²⁺ spiking by neocortical pyramidal and cerebellar Purkinje neurons with millisecond-scale timing resolution in the brains of awake mice. When combined with state-of-the-art neural activity indicators, the superior temporal resolution of our two-photon microscope offers new means of probing the fine temporal features of neural coding by identified cell types.

Title: Multifocal two-photon microscopy for high speed functional circuit imaging

Authors: *P. QUICKE, A. J. FOUST, T. KNOPFEL, M. NEIL, S. R. SCHULTZ Imperial Col., London, United Kingdom

Abstract: We present our implementation of a multifocal two-photon microscope for high temporal resolution functional imaging of neural activity. Understanding neural microcircuit function depends on monitoring large numbers of neurons with high temporal and spatial resolution. Two-photon point scanning (TPPS) systems spatially resolve signals deep in scattering tissue but are limited in temporal resolution due to the serial nature of each frame's acquisition. Monitoring large numbers of neurons with TPPS is achieved through the use of slower calcium sensors that allow lower sampling rates. In order to capture neural circuits' full dynamics, faster calcium or voltage indicators need to be used and better imaging methodologies developed to fully exploit their potential. Single point scanning strategies, such as traveling salesman scanning or fast acousto-optic targeting require *a priori* knowledge of signal location and sacrifice full coverage of the field of view to increase acquisition rates. Signals of interest from calcium and especially voltage indicators are distributed throughout neurons' dendritic trees and are often not fully sampled. Parallelising two-photon microscopy by using multiple excitation foci allows increased frame rates and dense spatial sampling without sacrifice of emission photons necessary to resolve small and fast functional signals. This comes at the loss of depth penetration due to the need to image the resulting fluorescence onto a spatially resolved detector, which is vulnerable to image degradation due to scattering. We have implemented a spatially sparse multifocal two-photon microscope using a micro lens array and a commonly used TPPS laser, the Mai Tai HP. Our implementation resolves cellular-resolution calcium transients at 200Hz with a field of view of $110 \times 200 \,\mu$ m in Cal-520 AM loaded mouse cortical slices. We present our implementation and assess its performance, relative merits and disadvantages compared to single point scanning systems for use with a mouse brain slice preparation. We compare achievable signal to noise ratio and scattering resistance for different excitation foci and scanning patterns. We also discuss the factors limiting the achievable imaging depth, which will determine the accessibility and adaptability of this technique to other users and systems. This technique could prove particularly useful for cell-resolved two photon voltage imaging and we will assess the outlook for this application.

Title: A head-mounted two-photon fiberscope for high-resolution imaging in freely-moving mice

Authors: *Y.-T. A. GAU, W. LIANG, X. LI, D. E. BERGLES Johns Hopkins Univ., Baltimore, MD

Abstract: Our perception of the world is shaped by our behavioral states. Such context-specific sensory processing is achieved through integration of external inputs and internal states. Determining how this process occurs at the level of cells and synapses in defined circuits remains a central goal in neuroscience. Recent in vivo two photon imaging studies in mice that were engineered to express genetically encoded Ca^{2+} indicators specifically within astrocytes have revealed that cortical astrocytes are significantly activated by neuromodulators such as norepinephrine (NE) and acetylcholine (ACh). As a single astrocyte contacts tens of thousands of synapses and neighboring astrocytes are extensively coupled through gap junctions, astrocytes could serve as an amplifier through which sparse neuromodulatory inputs convey internal behavioral states to shape local neural output. However, restraining mice beneath a microscope restricts behavior and increases stress, which may profoundly alter internal states. Head mounted microscopes have been developed to enable visualization of neuronal and glial cell activity in freely moving animals; however, the low resolution of epifluorescence-based systems limits presents significant challenges for analyzing subcellular activity. To address these challenges, we developed a high-resolution fiber optic endoscope that allows two-photon imaging in freely moving mice. This system consists of: (i) a Ti:Sapphire laser pre-chirped by a single mode fiber plus a grating pair, (ii) a piezoelectric actuating tube that enables spiral laser scanning, (iii) a noise-reduced double-clad fiber to enhance light collection, (iv) a compound lens probe with a working distance of 280 µm, and (v) a head-mounted three- axis manipulator for micropositioning. This fiberscope achieved a lateral resolution of $<1 \mu m$ and an axial resolution of \sim 7 µm. Moreover, the working distance is sufficient to resolve individual axons, dendrites and glial cell processes in Layer I and II/III through a 50 µm-thick cranial window. The spatial and temporal resolution of the fiberscope was sufficient to detect dynamic activity of individual noradrenergic and cholinergic axons (induced to express membrane anchored GCaMP6s) in mice during locomotion. Neuronal dendritic and astrocytic microdomain Ca²⁺ signals were also clearly resolved in the upper layers of the visual cortex. This novel high- resolution imaging platform,

when combined with cell specific manipulations, will help assess the intricate interplay between long-range neuromodulatory projections and local neuron-astrocyte communication in state-dependent cortical processing.

Title: High yield cranial window technique for imaging cortical neuron activity with headmounted miniaturized microscopes

Authors: *X. LI¹, V. CAO², W. ZHANG¹, S. MASTWAL¹, Q. LIU¹, S. OTTE², K. WANG¹ ¹NIH, Bethesda, MD; ²Inscopix Inc.,, Palo Alto, CA

Abstract: Cranial windows and viral reporters are commonly used to image cortical neuronal activity through two-photon microscopes in head-fixed animals. Recently, head-mounted miniaturized one-photon microscopes have been developed to image neuronal activity in freely behaving animals. However, dura membrane overgrowth and inflammation beneath the cranial window often decrease the optical clarity of chronic windows, and variation in viral spread and damage by intracortical injection add further challenges for imaging cortical neurons with headmounted microscopes. Here, we describe an improved cranial window technique to enhance the yield of successful imaging experiments. We used a glass pipette with large tip diameter to attach to the brain surface and injected virally encoded calcium indicator AAV-GCaMP6 into the cortex without pipette penetration. Immediate after virus injection and window implantation, we sutured the scalp skin over the implanted window to facilitate postoperative recovery. After a couple of weeks, we removed the suture and attached a miniature microscope to image cortical neuronal activity in freely behaving mice. We found that cortical surface virus injection efficiently and selectively labeled neurons in superficial cortical layers. Compared to traditional open-scalp surgical recovery method, skin suturing decreased the tissue growth underneath the optical window and improved its clarity. Together, these improvements in labeling and surgery procedures significantly increased the success rate of cortical neuron imaging by head-mounted microscopes in freely moving animals. Our high-yield cranial window technique may be also applicable to other in vivo optical techniques such as two-photon imaging and optogenetic perturbation.

Title: Rapid whole brain imaging of neural activities in freely behaving larval zebrafish

Authors: K. WANG¹, L. CONG¹, Z. WANG², Y. CHAI², W. HANG¹, C. SHANG¹, W. YANG², L. BAI¹, J. DU¹, *Q. WEN² ¹Inst. of Neurosci., Shanghai, China; ²Univ. of Sci. and Technol. of China, Anhui, China

Abstract: Understanding how collective neural activities give rise to complex behaviors has

Abstract: Onderstanding how conective neural activities give rise to complex behaviors has long been a central question in systems neuroscience. Larval zebrafish has emerged as a powerful vertebrate model system for investigating the neural basis of sensorimotor behaviors due to its small size, optical transparency and genetic tractability. In particular, whole brain calcium imaging of head fixed larval zebrafish in virtual reality [1], where visual sensory feedback can be accurately controlled, has provided significant insight into motor learning and optomotor behaviors.

On the other hand, freeing the fish from the *Matrix* while monitoring neuronal activity would be an ideal strategy for investigating more sophisticated behaviors, when the animal is interacting in a more meaningful way with its natural environment and when *all* sensory feedback loops are intact and active. However, imaging whole brain activity with sufficient spatiotemporal resolution in a speeding brain is very difficult.

Here we have made a step towards this goal, by developing a novel volume imaging and 3D tracking technique that performs whole brain imaging of neural activities in a freely swimming larval zebrafish. Whole brain neuronal activities over a volume of 800 μ m × 800 μ m × 200 μ m can be simultaneously monitored at ~ 3.4 μ m × 3.4 μ m × 5 μ m spatial resolution and at 77 Hz volume rate, a technique we call eXtended field of view Light Field Microscope (XLFM). Armed with XLFM tracking microscope, we were able to capture, for the first time, whole brain neural activities during the entire prey capture process in larval zebrafish. Our technique provides a new window into the brain dynamics during animal's natural behaviors at unprecedented resolution.

Title: *In vivo* scattering compensation with increased FOV using conjugate F-SHARP microscopy

Authors: I. N. PAPADOPOULOS¹, D. I. KAPLAN², M. E. LARKUM³, *B. JUDKEWITZ¹ ¹Einstein Ctr. for Neurosci., Charite Berlin / Humboldt Univ., Berlin, Germany; ²NeuroCure Cluster of Excellence, Charité Univ. Hosp. Berlin, Berlin, Germany; ³Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Optical techniques have become indispensable tools for neuroscience, but their depth reach is limited by scattering. Aberration correction and scattering compensation techniques can deliver improved image quality, but only within a certain field of view (FOV). This limitation arises from the spatial variation of the inhomogeneities that light encounters while scanned around the focus location. The corrected FOV area can be increased considerably by conjugating the wavefront-shaping device to the dominant scattering layer rather than the back pupil of the microscope objective. Although the conjugation of the wavefront-shaping element to the dominant scattering layer can be implemented by a physical movement of the wavefront-shaping device within the optical path of the microscope, such an implementation is limited only to one particular layer. Here, we overcome this limitation by developing and demonstrating a method for dynamically conjugating the wavefront-shaping element to different depths inside the inhomegeneous medium without the need for the physical movement of the wavefront shaper inside the optical path. Our method, conjugate F-SHARP microscopy, allows us to change the conjugation distance between the wavefront shaper and the imaging depth in real time. We demonstrate the power of conjugate F-SHARP microscopy by performing volumetric imaging with an increased FOV through the thinned mouse skull in vivo.

Title: Characterization and application of a quadruple labelled mouse line

Authors: *J. GAIRE¹, H. LEE², R. WARD¹, S. CURRLIN¹, E. W. ATKINSON¹, A. WOOLLEY³, J. E. COLEMAN¹, K. J. OTTO¹ ¹Univ. of Florida, Gainesville, FL; ²Univ. of Texas Southwestern Med. Ctr., Dallas, TX; ³Symic Bio, Inc, Emeryville, CA

Abstract: The advancements in the field of microscopy has been instrumental in three dimensional imaging of thick tissues and whole organs circumventing the need to mechanically section, stain, image and re-construct the 3-D image. This has been facilitated by the ever growing list of clearing techniques that renders the sample's refractive index to match with the mounting medium and optics. Regardless of the clearing techniques used, the sample has to be immunostained with the antibodies of interest for fluorescent imaging. Immunostaining, especially in thick tissues, has many issues including prolonged incubation, limited penetration depth of antibodies and the need for exposure to high temperature and/or strong detergent concentrations. To address this, mainly focusing on the brain, we created a transgenic mouse model that express distinct fluorophores in different cell types. Here we present the application of this mouse model in thick tissue imaging utilizing previously developed clearing methods and studying cellular response to an injury model of cortical implant. For clearing studies, tissues were processed with slight modifications from previously developed clearing methods. Brains were cut into thick sections of varying thickness and imaged using various imaging modalities. We were able to detect endogenous fluorophores in thick samples cleared using the CLARITY protocol. Currently, we are investigating if the fluorophores will be retained using other clearing techniques. For implant studies, silicon microelectrodes were implanted in the somatosensory cortex and sacrificed at 3 different time points. We observed an increase in microglial cells around the implant at earlier time points and a subsided response a later time point whereas the astrocytic response was progressive. Both of these observations are in line with previous studies

that were carried out in wild type mouse and rat models. Together, these data highlight the compatibility of our mouse model with recently developed volumetric imaging modalities. This mouse model, in addition with emerging microscopy, helps to increase efficiency of experiments both in normal and injury models (cortical impact, stroke, etc.) where neuroinflammation cascade is perturbed.

Title: Two-photon calcium imaging of medial prefrontal cortex and hippocampus without cortical invasion

Authors: *M. KONDO^{1,2}, K. KOBAYASHI³, J. NAKAI⁴, M. OHKURA⁴, M. MATSUZAKI^{1,2} ¹Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; ²Div. of Brain Circuits, Natl. Inst. for Basic Biol., Okazaki, Japan; ³Natl. Inst. For Physiological Sci., Okazaki, Japan; ⁴Saitama Univ., Brain Sci. Inst., Saitama, Japan

Abstract: In vivo two-photon calcium imaging currently allows us to observe the activity of multiple neurons up to ~900 μ m below the cortical surface without cortical invasion. However, many other important brain areas are located deeper than this. Here, we used a 1100 nm laser, which underfilled the back aperture of the objective, and red genetically encoded calcium indicators to establish two-photon calcium imaging of the intact mouse brain and detect neural activity up to 1200 μ m from the cortical surface. This imaging was obtained from the medial prefrontal cortex (the prelimbic area) and the hippocampal CA1 region. We found that the neural activity related to reward timing is higher in the prelimbic area than in layer 2/3 of the secondary motor area, while it is negligible in the hippocampal CA1 region. Reducing the invasiveness of imaging is an important strategy to reveal the brain processes active in cognition and memory.

Title: Optical coherence tomography reveals depth-resolved responses during functional cerebral activation by infrared neural stimulation

Authors: *P. LI¹, P. LI³, W. XI⁵, E. AKSHAY⁴, A. W. ROE²

¹Dept. of Optical Engin., ²ONPRC-NEUROSCIENCE, Zhejiang Univ., Zhejiang, China; ⁴ZIINT, ³zhejiang university, Hangzhou, China; ⁵Zhejiang Univ., ZIINT, Hangzhou, China

Abstract: Infrared neural stimulation (INS) has been reported as a promising modality for evoking neural response during cerebral activation. Optical imaging is an effective tool for measuring the activated dynamics and responses. In contrast to conventional optical intrinsic signal imaging (OISI) modality that provides two-dimensional, depth-integrated maps of stimulus-evoked dynamic activation, we used optical coherence tomography (OCT) to provide depth-resolved, cross-sectional images of functional cerebral activation by INS. In this study, 0.5s-lasting pulsed infrared light (central wavelength 1.875 μ m, pulse width 250 μ s and fiber diameter 200 μ m) was utilized to stimulate the cortex of anesthetized rats with different radiant exposure (0~1 J/cm²) and different repetition rates (50~200 Hz), respectively. Temporal fractional OCT signal change was calculated to evaluate INS efficacy. It revealed statistically significant depth-resolved signals, comprised of both positive and negative responses. These responses were detectable at cortical depths of >1 mm during functional activation. This suggests that OCT is a promising in vivo imaging method for mapping functional neural coupling in neuroscience research.

Title: Multimodal two-photon random access pointing and scanning to any 3D position or direction at high speed in awake animals using a compact Acousto-Optic Lens (AOL)

Authors: V. GRIFFITHS, *T. FERNANDEZ-ALFONSO, G. KONSTANTINOU, N. NADELLA, P. KIRKBY, A. M. VALERA, H. ROSS, F. LANORE, A. SILVER Univ. Col. London, London, United Kingdom

Abstract: To understand brain function it is essential to identify how information is represented by the firing patterns of large neuronal populations and establish how synaptic inputs are integrated and transformed by individual neurons within microcircuits. This requires monitoring activity in large numbers of neuronal compartments distributed in 3D space at high spatiotemporal resolution in awake animals. In order to meet these requirements, we (and others) have previously developed 3D random access acousto-optic lens (AOL) two-photon microscope technology that can focus to any arbitrary position and scan a laser beam within the imaging volume within 12-40 microseconds. Our AOL design consists of 4 acousto-optic crystals, wave plates and polarizers arranged in a compact unit (12cm x 12cm x 22cm). To simplify its integration into existing and new microscopes, we have developed a new opto-mechanical design for easier alignment and new controller box with state-of-the-art FPGA and custom DAC boards. The FPGA-based AOL control system, which generates the radio frequency (RF) signals for the AOD transducers, supports 5 different imaging modes. High-speed raster scan volume imaging (Z stacks), multiple subvolume imaging, multiplane x-y imaging, multiple x-y patch, and serial pointing mode. All these imaging modalities are achieved with linearly ramped RF waves fed into the acousto-optic crystals. In experiments on awake animals, tissue brain movement can be problematic. The high speed random access functionality enables our system to image reference objects allowing brain movement to be tracked. By feeding back this information to the AOL controller we have previously developed a real time 2D movement correction system. However, the use of linear ramps limits the raster scanning to a single x-y plane, precluding fast tracking of axial movement and thus correction for movement in 3D. Here, we describe and demonstrate the use of non-linear ultrasound ramps to achieve both axial scanning and real-time movement

correction in 3D, and new imaging modalities based on raster scanning in arbitrary 3D angles (e.g., 'skeleton scanning'). This technology enables movement-stabilized, high-speed random access pointing and line scanning along fine neuronal structures *in vivo*. In conclusion, our prototype compact AOL module not only adds real-time movement correction in 3D and axial scanning, but it is also smaller, more adaptable and can be fabricated at a relatively low cost.

Title: Large volume functional imaging in the mouse brain

Authors: *S. WEISENBURGER¹, R. PREVEDEL², A. VAZIRI¹ ¹Lab. of Neurotechnology and Biophysics, The Rockefeller Univ., New York, NY; ²European Mol. Biol. Lab. (EMBL), Heidelberg, Germany

Abstract: Unlocking the mystery of how the complex dynamics of neurons in the brain give rise to cognition, perception and behavior is not only of paramount importance to science but may also affect the treatment of neurological diseases impacting hundreds of millions of people around the world. Seminal breakthroughs like multiphoton microscopy, fluorescent indicators and optogenetics have positioned optical microscopy as a key technology in modern brain research. The next frontier in neuroscience is to interrogate neuronal dynamics of large populations in awake, behaving animals in real time in order to unravel the complex interactions

of neurons that underlie cognitive function and behavior. Here, we will introduce a technique termed light sculpting microscopy which was pioneered in our laboratory. It is based on temporal focusing which allows an effective decoupling of the axial and lateral confinement of the excitation volume combined with the advantage of high penetration depth and low scattering of two-photon excitation. The ability to tailor the three-dimensional spatial distribution of light within biological samples allows to maintain optical sectioning while introducing parallelization of excitation and thereby obtain high-speed acquisition rates. We will present different in vivo applications of this method including large-scale calcium imaging of neuronal networks in mouse brain using our latest approach termed scanned temporal focusing (s-TeFo). By optimizing the signal-to-noise ratio using a one-pulse-per-voxel excitation and synchronized detection scheme, we demonstrate unbiased high-speed single plane recordings of mouse posterior parietal cortex (PPC) expressing GCaMP6m of $> 0.5 \times 0.5$ mm field of view at > 200Hz frame rate. We also demonstrate dual-plane calcium imaging from two $> 0.5 \times 0.5$ mm field of views at different depths and at > 10 Hz frame rate. Furthermore, we show volumetric calcium imaging of large volumes (> 0.5 x 0.5 x 0.5 mm) at single-cell resolution and fast volume rates (>4 - 6 Hz) from mouse hippocampus CA1 and across cortical layers 1-5 in PPC with GCaMP6m/s and jRGECKO1a labeling. These advances allow for near-simultaneous in-vivo recording of the calcium dynamics from several thousand active neurons across cortical layers and in the hippocampus of awake behaving mice. We will discuss the challenges, future developments and applications of our technique in fundamental neuroscience questions.

Title: High-content functional imaging reveals differential effects of inflammation on two distinct populations of human nociceptive neurons

Authors: ***A. GHETTI**¹, Y. MIRON¹, J. ZHANG¹, G. PAGE¹, C. GHETTI¹, B. A. COPITS², S. DAVIDSON³, R. W. GEREAU, IV², P. E. MILLER¹ ¹Anabios Corp., San Diego, CA; ²Pain Ctr. and Dept. of Anesthesiol., Washington University, Sch. of Med., St. Louis, MO; ³Pain Res. Center, Dept. of Anesthesiology,, Univ. of Cincinnati, Cincinnati, OH

Abstract: The etiology of chronic neuropathic and inflammatory pain remains incompletely understood, creating serious challenges to the development of new, non-addictive medications. Pain drug discovery has had very limited success in translation from animal models to humans. Some have proposed that animal models have limited ability to predict analgesia in humans, and there has been a call for new approaches that better predict clinical analgesic efficacy. We have developed a novel preclinical discovery strategy, which relies on human sensory neurons isolated from organ donors. In the current study, we describe the high content imaging-based profiling of human sensory neurons under normal as well as inflammatory conditions. Human DRG neurons isolated from organ donors were loaded with Fluo-8-AM and the intracellular calcium dynamics elicited by electrical and chemical stimuli were investigated. By sequentially stimulating the cells with electrical fields, capsaicin, allyl isothiocyanate (AITC), and cold, we were able to define, for each individual sensory neuron tested, the array of functional expression of voltage gated sodium channel subtypes, as well as different TRP channels. When cells were activated with carefully calibrated electric field stimulations (EFS) delivered at two different voltage intensities and frequencies, all responses were blocked by lidocaine, indicating that EFS-induced activities were purely dependent on voltage gated sodium channels (VGSC) but not voltage gated calcium channels (VGCC). The observed intracellular calcium dynamics were therefore the result of EFS-induced activation of VGSC, which led to cell depolarization and consequent activation of VGCC and calcium release from internal stores. Using these EFS protocols we were able to identify two major classes of cells based on: 1) the EFS activation threshold and, 2) the maximal firing frequency. Interestingly the two classes of cells also exhibited differential sensitivity to TTX. We also observed that the inflammatory agents bradykinin and prostaglandin E2 (PGE2) exerted different effects on the two cell classes, whereby the firing frequency was increased in one class of cells, while the other showed increased expression of TTX-R VGSC. The strategy described in the present work has the potential to significantly advance preclinical drug profiling by allowing the human-specific profiling of new drug candidates' selectivity for functionally defined sub-populations of cells therefore improving the ability to select humanactive drugs for clinical trials.

Title: Three-dimensional (3D) volumetric Ca^{2+} imaging of astrocytes reveals novel properties of brain networks

Authors: A. VOLTERRA, *I. A. SAVTCHOUK, E. BINDOCCI, N. LIAUDET, D. BECKER, G. CARRIERO

Univ. De Lausanne, Lausanne, Switzerland

Abstract: Astrocytes sense neuronal inputs and in turn modulate synapses and blood vessels via intracellular Ca^{2+} signaling. Despite their importance, the properties of astrocytic Ca^{2+} signals are not well understood.

Most of the astrocytic structure presents functional barriers to intracellular Ca^{2+} propagation, with the result that Ca^{2+} events are highly compartmentalized throughout the cell, and exhibit large variability in amplitude and duration, as well as spatial spread. It is difficult to reliably study Ca^{2+} events because only an absolute minority, at best ~5%, of the total astrocyte lies within a given 2-photon focal plane.

We report here our recent success in performing fast 3D volumetric imaging, monitoring entire individual astrocytes in adult hippocampal and cortical slices, and *in vivo*. Morphology of individual astrocytes was visualized using SR101 dye uptake, while genetically-encoded indicator GCaMP6f was used to monitor Ca^{2+} elevations. Both optically resolved (core) structure

of the astrocyte, and optically sub-resolved fine processes (gliapil) were analyzed using two independent strategies.

By visualizing the whole astrocyte, we were able to correctly capture and describe the full gamut of Ca^{2+} events and their properties, including duration, kinetics, and spread volume. Majority of the observed events were three-dimensional, and would not be otherwise properly captured in 2D. Moreover, we were able to simultaneously compare activity across all individual processes on the same cell: something previously impossible due to the limitations of 2D microscopy. We found that most of the activity lies outside the soma, and is concentrated in the processes and endfeet. A large portion of this activity is highly compartmentalized and asynchronous. As a further practical application of the 3D method, we were able to study functional interactions between astrocytes and axons, and between endfeet and blood vessels, as well as astrocytic population activity *in vivo*.

Our volumetric imaging and analysis method has important implications outside the glial Ca^{2+} field. While independently surveilling tens of thousands of um3 per cell, we identified the presence of multiple "hot" and "cold spots," and observed a large diversity of highly compartmentalized Ca^{2+} signals happening within a single astrocyte, as well as functional "coupling" between some but not other "voxels". This is methodologically comparable to monitoring and analyzing the connections between thousands of neuronal cell bodies within a brain circuit/network. We believe our methods and strategies will therefore be useful also for neuronal network Ca^{2+} analysis.

Abstract: Traditionally, the cerebellum has long been known to coordinate movement on short time scales. In addition, recent evidence suggests that it may also modulate flexible and social behavior. To monitor cerebellar activity during complex behavior, we monitored calcium and delivered optogenetic perturbations in Purkinje cell (PC) dendrites in freely-moving mice using a Doric head-mounted miniature microscope to perform wide-field fluorescence microscopy and deliver light to optogenetic probes. In Pcp2-Cre mice, which express Cre in PCs, we injected cerebellar vermal lobule VI with Cre-inducible adeno-associated virus (AAV2/1-CAG-DIO) coding genetically encoded calcium indicator (GCaMP6f) or optogenetics probes (ChR2 or ArchT). Identified regions of interest showed rapid transients with rise times of 91 ± 4 ms and half-decay times of 189 ± 7 ms, and occurring at a rate of 0.7 ± 0.1 Hz, consistent with prior studies of PCs using two-photon microscopy in awake head-fixed mice (Ozden et al. 2012, PLoS ONE 7(8):e42650). Simultaneous with optical measurements and perturbation, animal behavior was recorded with two cameras, a low-speed, low-resolution, depth-sensitive 3D camera and a high-speed, high-resolution 2D camera, which together can be used to capture poses of the head, body, limbs, and tail. We identified behavioral correlates of PC activity using unsupervised computational methods to classify animal poses and movements. Together, pose classification and imaging with miniature microscope allow us to explore the fine details of behavior in a more natural setting on subsecond time scales.

Top, GCaMP6f signals from Purkinje cell dendrites. *Bottom*, sample ethogram of six identified features of behavioral activity.

Title: Non-degenerate 2-photon excitation for increased fluorophore brightness and deep tissue imaging

Authors: M.-H. YANG¹, C. G. L. FERRI², M. THUNEMANN³, P. SAISAN⁴, E. A. RODRIGUEZ⁵, S. R. ADAMS⁵, S. VINOGRADOV⁷, Y. FAINMAN¹, *A. Imaging, MGH, Harvard Med. Sch., Charlestown, MA

Abstract: In conventional 2-photon microscopy, a fluorophore is excited by the simultaneous absorption of two photons of the same energy within the near infrared (NIR) spectrum, derived from the same pulsed laser beam. This is called "degenerate" 2-photon excitation, D-2PE. Alternatively, the same energy needed for the transition to the excited state can be delivered via absorption of two photons of different energy (i.e., different color) [1]. In this "non-degenerate" 2-photon excitation (ND-2PE) regime, the first laser beam can be tuned within the standard NIR range of excitation wavelengths used in conventional 2-photon microscopy, placing the second laser beam within the infrared (IR) wavelengths range for excitation of visible emission fluorophores. Recently, we experimentally demonstrated that, under ND-2PE, an increase in the IR power can be used to compensate for the scattering losses of NIR power, achieving deeper excitation in scattering media [2]. Here, we provide additional data from phantoms and biological samples to support this conclusion and demonstrate another advantage of ND-2PE: an

increase in the excitation cross section leading to more efficient fluorophore excitation. We used both D-2PE and ND-2PE to characterize the 2-photon absorption cross sections of several fluorophores widely used for brain imaging, including eGFP, eYFP, mCerulean, mCitrine and fluorescein. When compared to the optimal D-2PE case, up to 3x enhancement in brightness was observed for this selection of fluorophores over an excitation wavelength range of 740-870nm, for the NIR beam, and 1000-1400nm, for the IR beam (see figure). The enhanced fluorescence brightness combined with a reduction in laser attenuation positions ND-2PE microscopy as a competitive alternative to conventional 2-photon microscopy and, possibly, 3photon microscopy, for deep imaging applications.

Title: A novel multisite confocal system for rapid Ca^{2+} imaging from submicron structures in brain slices

Authors: *M. CANEPARI¹, L. FILIPIS¹, K. AIT OUARES¹, P. MOREAU¹, D. TANESE², V. ZAMPINI², V. EMILIANI²

¹Equipe MOTIV, LIPhy, CNRS UMR 5588, St Martin d'Hères cedex, France; ²Wavefront-Engineering Microscopy Group, Neurophotonics Laboratory, Ctr. Natl. de la Recherche Scientifique UMR8250, Paris Descartes Univ., Paris, France

Abstract: In brain slices, resolving Ca²⁺ fluorescence signals from submicron structures, such as spines, terminals or small dendritic and axonal branches, is typically achieved using two-photon or confocal microscopy by scanning the recording region of interest. Yet, the condition for a signal to be above the photon noise sets a limit to the number of recording sites at a given acquisition rate, since the required number of collected photons is inversely proportional to the number of scanned points. Here, we present a novel multiplexing confocal system based on a fast spinning disk and a rapid high-resolution CMOS camera that overcomes the limitations of scanning confocal microscopy. The spinning disk, running at 20,000 rpm, has a custom-designed spiral pattern that maximizes light collection while rejecting out-of-focus fluorescence to discriminate the smallest neuronal compartment. The spinning disk is fed with a 1W multimode laser providing a laser line at 470 nm. Using a 60X objective and no magnification, the novel CMOS camera permits acquisitions of tens of thousands of pixels at the virtual resolution of 240 nm per pixels in the kHz range with a digital depth of 14 bits. By focussing the laser onto a 60 µm diameter spot, we demonstrated the ability of our system to resolve fluorescence signals of the order of 1% from submicron structures positioned 20-40 µm from the slice surface, using the low affinity Ca²⁺ indicator Oregon Green BAPTA-5N. In particular, we monitored Ca²⁺ transients at 0.25-1.25 kHz in single trials or through averages of less than ten recordings from dendritic spines and small parent dendrites in cerebellar Purkinje neurons, following either the stimulation of the climbing fibre or of parallel fibre inputs. Altogether, the unprecedented high spatiotemporal resolution of these Ca^{2+} recordings is obtained with a relatively simple and economical implementation. Thus, we expect that the present approach will be adopted in several laboratories for projects where multisite monitoring of physiological signals from submicron structures is required.

Title: Correcting micro-positioning artifacts for 3D microscopy

Authors: *J. L. LIN¹, M. A. NAVARRO¹, J. V. K. HIBBARD², L. S. MILESCU¹ ¹Div. of Biol. Sci., Univ. of Missouri, Columbia, MO; ²Mol. Biosci., Univ. of Texas, Austin, TX

Abstract: Precise 3D neuronal targeting and data mapping in electrophysiology and imaging experiments requires the use of motorized micro-positioners. Most commercially available positioning devices have sub-micron resolution, but they are subject to a variety of positioning artifacts and errors. One particularly important aspect is the ability to consistently reach the same 3D position. We found that, with some equipment, the errors in this regard can be up to 10 microns, which may be unacceptable for certain studies. While normal backlash is corrected by the hardware controller, this re-positioning error is not. We have mathematically modeled this error and added correcting code to our QuB software for 3D data mapping and real-time experimental control. With this correction, the same 3D target can be repeatedly reached with improved resolution.

Title: Skeleton scanning: A method for imaging 3D dendritic trees at high speed

Authors: *A. M. VALERA, G. EVANS, P. KIRKBY, G. KONSTANTINOU, V. GRIFFITHS, B. MARIN, S. K. M. N. NADELLA, A. R. SILVER Dept. of Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Understanding how synaptic inputs are integrated within complex 3D dendritic trees requires fast recordings of patterns of activity across many dendritic branches. While recordings from individual dendritic branches projecting in the x-y plane is straightforward with conventional galvanometer-based 2-photon technologies, accessing the complete 3D dendritic tree is much more challenging. Acousto-Optic Lens (AOL) 3D two-photon microscopes can

randomly access up to 40000 points or lines per second in a 3D space, with an inertia-free focusing system. However, the linear acoustic drives typically used to date only permits linescans in the x-y plane. Here we show how non-linear drive of the AOL can be used to create line-scans in any arbitrary direction, enabling us to rapidly image the complex 3D branching structures of dendritic trees unprecedented speed. We have developed a software tool chain to image, trace and segment the morphology of a neuron during the experiment. This enabled us to generate a 3D 'skeleton' representation of the neuronal morphology and to calculate the nonlinear AOL drives required to image it with a series of line-scans. This 'skeleton scanning' approach allows the 3D dendritic tree of a neuron to be imaged at high rates. We have tested the performance of skeleton scanning by imaging L2/3 cortical pyramidal cells in acute slices patch loaded with Alexa594 and Fluo4. Our preliminary experiments show that skeleton scanning can be used to monitor $[Ca^{2+}]$ across the dendritic tree at frequencies between 100 and 150 Hz. Local, spontaneously occurring $[Ca^{2+}]$ transients could be detected, as well as more widespread increases induced by backpropagating action potentials triggered by somatic current injection. The 'Skeleton Scan' can be extended to multiple contiguous lines allowing both dendrites and spines to be monitored, confirming that the technology has the capacity to measure both the activity of dendritic branches and spines at high temporal resolution. We are currently working on integrating this technology with real-time movement correction in order to image GCaMP6f expressing-L2/3 pyramidal neurons in visual cortex of behaving animals.

Title: Quantifying wide-field maps of the human corneal subbasal nerve plexus

Authors: *Y. VAISHNAV¹, S. RUCKER², K. SAHARIA³, N. MCNAMARA¹ ¹UCSF Proctor Eye Fndn., San Francisco, CA; ²Phillips Exeter Acad., Exeter, NH; ³TechLab Educ., Saratoga, CA

Abstract: A significant proportion of corneal sensory nerves lie beneath the anterior corneal epithelium within the subbasal nerve plexus (SBP). The morphology of these nerves is altered by keratopathy and refractive surgery. Corneal Confocal Microscopy (CCM) is an imaging modality used to image and quantify corneal nerves. There are two barriers that currently limit the use of CCM as a diagnostic modality: the small-scale field of view given by individual CCM images and the time required to quantify nerves in collected images. We present here a modified OpenCV image stitcher and a vector quantification method to map and obtain measurements of SBP nerve morphology. The stitcher uses feature detection to stitch CCM frames into wide-field maps of the SBP. Our method takes 3-5 minutes to stitch and quantify 40-100 CCM frames on an Amazon EC2 Micro instance. The vector quantification method is a novel, proof-of-concept algorithm that can quantify montages of SBP nerves. The method is more rapid and user-friendly than previous iterations of similar corneal nerve mosaicking software and proposes a new method to quantify CCM morphological parameters.

Abstract: For decades, patch-clamp recording has been the gold-standard technique for highquality electrophysiological measurements and morphology reconstruction of single cells. However, it is a highly manual, laborious technique that requires extensive training to master. Here we present the patcherBot, a robotic system that permits walk-away automation of in-vitro patch-clamp recording. This is enabled by two key innovations: (1) pipette cleaning which enables immediate reuse of the pipette and (2) machine vision for accurate pipette positioning. The patcherBot is the first system that can patch-clamp multiple cells sequentially without human intervention, enabling multi-hour user-free operation. The system was tested in cultured cells and in brain tissue slices. In cultured Human Embryonic Kidney (HEK293) cells, the patcherBot achieved a medium-high success rate of whole-cell recording (median: 80%; range: 60 to 100%; n=70 patch-clamp attempts) over a combined user-free operation of over 5 hours. In mouse VI cortical tissue slices, the patcherBot achieved lower success rate (median: 55%, range: 22 to 67%; n = 44 patch-clamp attempts), commensurate with the increased difficulty of patch-clamp in brain slices. Combining the patcherBot with existing single-cell activity imaging techniques could open the door to "circuit mappers", generalizable tools for profiling electrophysiology, morphology, and synaptic connectivity patterns in the brain on a single-cell level.

Title: Capping patch clamp pipettes for improved gigaseal yield

Authors: *W. STOY¹, I. KOLB¹, G. L. HOLST², G. B. STANLEY¹, C. FOREST² ¹Wallace H. Coulter Dept. of Biomed. Engin., ²George W. Woodruff Sch. of Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Whole-cell patch clamping *in vivo* often requires a recording electrode, a pipette, to travel through several millimeters of heterogeneous brain tissue. During this process, called regional pipette localization, the tip of the pipette can encounter obstructions including the dura, pia, blood vessels, and ventricular membranes. When these obstructions are encountered, they often contaminate the pipette tip, preventing the formation of a gigaseal. Application of high positive pressure to the pipette to prevent contamination introduces intracellular solution to the extracellular space, causing high osmotic pressure on nearby cells as well as off-target staining if a contrast agent is present in the solution. To overcome these limitations we have developed several methods to maintain the cleanliness of pipette tips, including a method to avoid obstacles

encountered during regional pipette localization *in vivo*. Here, we present a reversible cap to protect the pipette tip during regional pipette localization. We demonstrate in vitro that this cap, a polymer microsphere, can be reversibly attached to the tip of a pipette with the application of suction, that under atmospheric pressure the microsphere remains attached to the pipette, and that the microsphere remains attached when moved through slices of brain tissue. We demonstrate that when a cell is penetrated with a freshly pulled pipette *in vitro*, it contaminates the pipette tip (visible as an increase in pipette tip resistance), which prevents this same pipette from gigasealing onto a second cell (0 gigaseals, 5 attempts). However, when a cell is penetrated with a capped pipette, there is no contamination following removal of the microsphere (no increase in pipette tip resistance) and gigaseals are reliably formed on subsequent cells at a rate similar to traditional *in vitro* slice patching (4 gigaseals, 5 attempts). These results indicate that a reversible cap may protect sensitive pipette tips from contamination during regional pipette localization.

Title: Cell membrane tracking in live brain tissue with differential interference contrast (DIC) microscopy

Authors: *J. LEE, I. KOLB, C. R. FOREST, C. J. ROZELL Georgia Inst. of Technol., Atlanta, GA

Abstract: Differential interference contrast (DIC) microscopy is a practical imaging modality for live-cell experiments. However, DIC microscopy of thick tissue samples (>100 μ m) is notoriously challenging for automatic cell segmentation due to the low signal-to-noise ratio (caused by increased probability of light scatter due to tissue thickness) and unclear cell

boundaries due to the presence of surrounding organic tissue. Real-time detection of cell boundaries is desirable for automating electrophysiology experiments, and current algorithms are unable to reliably detect DIC cell boundaries under such demanding conditions. We present the first DIC deconvolution and cell-segmentation algorithm to track membrane locations in DIC imagery of living brain tissue with high fidelity. The proposed algorithm is formulated as a regularized least-square optimization that incorporates (1) a filtering mechanism that effectively and efficiently suppresses boundary-corrupting cellular interference, and (2) a robust edgesparsity regularizer that exploits dynamical information with edge-tracking capabilities. Our algorithm was applied on the experimental setting of patch-clamp recording in brain tissue and it demonstrated state-of-the-art performance boundary-tracking errors of 1-2 μ m. In addition, the algorithm is designed to remove glass-pipette artifacts via image inpainting and this was tested on patch clamp video data from mouse brain tissue. Shown in the figure is (a) DIC Microscopy image with identified target cell and glass-pipette (b) Deconvolution and pipette-removal with inpainting using proposed algorithm (c) Segmentation output using global thresholding, with pipette mask.

Abstract: The implantable multimodal peripheral recording and stimulation system (IMPRESS) is a novel, bi-directional neural interface technology, consisting of a high-density (16 stimulation and 64 recording channel) interneural probe to be used in an advanced peripheral neuroprosthetic that decodes motor intent and encodes sensory feedback. The probe, which is a high-density (hd) version of a transverse intrafascicular multichannel electrode (TIME), consists of a CMOS chip that is embedded in a highly flexible and hermetic polyimide ribbon cable. The chip is designed to contain circuitry for multiplexing and on-site stimulation as well as the electrode sites. However, this work presents a first generation of the IMPRESS hd-TIME that does not include active CMOS circuitry on the silicon chip. Rather, a passive CMOS-compatible chip with matched form factor of the final design is fabricated with stimulation and recording electrodes, only. Also, a high precision, stimulating analog front-end (SAFE) controller integrated-circuit chip was designed to test efficacy of this 1st generation IMPRESS TIME for in vivo neural stimulation in a rat model. Establishing ideal stimulation protocol to elicit meaningful sensory feedback first requires understanding the effects of and optimizing a wide range of stimulation parameters. Thus, computational modeling was employed to fundamentally understand the optimum range of parameters (i.e. pulse amplitude, pulse width, and interpulse width) of a charge balanced, biphasic stimulus for an intrafascicular probe. Moreover, the model was used to assess whether pulse amplitude or pulse width modulation had an inherent advantage over the other for a sensory encoding scheme. We present the model results that allow us to narrow down the range of stimulus parameters as well as *in vivo* stimulation results of our 1st generation IMPRESS TIME. Pulse amplitude modulation to be used with frequency modulation was selected as an effective encoding scheme for IMPRESS and in vivo stimulation results show good selectivity between different fascicles in the sciatic nerve of the rat. This work is sponsored under the auspices of Dr. Doug Weber by the US Defense Advanced Research Projects Agency (DARPA) (contract No. N66001-15-C-4018 to the University of Florida).

Title: Novel approaches to optimize neuronal computational models

Authors: *R. BEN-SHALOM¹, K. KIM¹, K. J. BENDER²

¹UCSF, San Francisco, CA; ²Sandler Neurosciences Building, San Francisco, CA

Abstract: Compartmental neuronal models are a powerful tool to both validate experimental observations and make quantifiable predictions. The quality of such predictions depends critically on model detail and accuracy. Model parameters, including the distribution and properties of ion channels and receptors, are often based on a combination of experimental observation and experimenter intuition. Unfortunately, while such "hand-tuned" models can capture some aspects of neuronal function, they are often not robust to perturbation, indicating that they have failed to identify optimal parameter conditions that accurately capture neuronal physiology. Optimization algorithms have been developed to address this issue. These algorithms search throughout the parameter space using a score function that compares model output to experimental data to identify simulations that reach a certain accuracy criterion. This process often generates multiple models, each with different underlying parameter sets that nevertheless all match the experimental data to similar extents. Identifying which of these models best reflects neuronal physiology remains a challenge.

Here, we demonstrate a new technique that identifies the optimal combination of score functions, which in turn shed light on how such scores can be improved with revised experimental stimuli. Using well-established models, we extensively sampled the parameter space at different distances from the original parameter set. By applying a battery of score functions and evaluating their performance, we could identify the most effective score function for parameter estimation. A similar analysis can identify the stimulation protocols that most effectively estimate correct parameter sets. Ultimately, we plan to apply these tools to guide which is the best experimental data set for neuronal parameter estimation, allowing for efficient optimization of physiologically realistic compartmental models.

Abstract: Pyramidal cells are the major excitatory neuron type in the cerebral cortex and represent 70-85% of all neurons in the mammalian cortex (Markram, Muller et al, 2015). The generic anatomy of PCs in the neocortex is characterized by a triangular soma, two distinct dendritic domains emanating from the base and apex of the soma (basal and apical dendrites, respectively), and a single axon. While it has been well established that PCs generally differ in their overall size of the apical dendrite in order to reach layer 1, the classification based on global morphological features obscures much of the diversification within each layer. On the other hand, a more detailed classification derived from the human expert assignment of classes is inconsistent and unsupported by feature classification techniques (DeFelipe et al, 2013). We use a topological method based on persistent homology methods to quantitatively capture the branching shapes of neurons, the Topological Morphology Descriptor (TMD, Kanari et al, 2016) to establish an objective classification scheme for cortical pyramidal cells. The TMD of neuronal trees allows different neuronal populations to be clearly distinguished, including those whose visual appearance is only subtly different, and therefore provides an objective classification of cells into discrete morphological classes.

The classification based on the TMD is sufficient to objectively classify cortical PCs and yields a quantitative measure of the uncertainty in the classification. Using this scheme, we found two major types of PC in layer 2, one in layer 3, three in layer 4, three in layer 5, and five types in layer 6. We conclude that a TMD classification scheme provides a reliable approach to standardizing the classification of neuronal morphologies, unlike previous methods.

Title: ACQ4: An open-source software platform for developing patch-clamp experiments

Authors: *L. CAMPAGNOLA¹, M. B. KRATZ², S. SEEMAN¹, P. A. DAVOUDIAN¹, A. HOGGARTH¹, J. F. PERKINS¹, D. D. REID¹, T. JARSKY¹, P. B. MANIS² ¹Allen Inst. for Brain Sci., Seattle, WA; ²Dept Otolaryngol/Head & Neck Surgery, Univ. N Carolina-Chapel Hill, Chapel Hill, NC

Abstract: ACQ4 is a software development platform that provides a set of fully open-source tools for acquiring data in neurophysiology experiments, with emphasis on automation in patchclamp electrophysiology. Building from the modular components provided by ACQ4, we have prototyped and streamlined software for experiments ranging from simple patch-clamp recordings to photostimulation mapping, 2-photon calcium imaging, in vivo intrinsic imaging, and multipatch recordings. The core of ACQ4 consists of a set of device classes supporting patch-clamp amplifiers, cameras, laser scanning hardware, microscopes, and micromanipulators. These device classes are complemented by a set of user interface modules that each streamline different aspects of typical patch-clamp experiments, while a centralized management system facilitates communication and synchronization between devices and modules. All data acquisition is accompanied by comprehensive metadata collection, with particular care given to tracking physical and temporal relationships; synchronization between devices is handled and recorded automatically, and all spatial data such as images, pipette positions, and laser scanning patterns are recorded relative to the same coordinate system. ACQ4 is built on the free and open scientific Python stack, which helps us promote open, reproducible science while reducing the barriers to access.

Title: A method for cardiac pacing together with local field potential recordings from the brain in a freely moving rat

Authors: *Y. SHIKANO, T. SASAKI, Y. IKEGAYA

Pharmaceut. Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: The brain and the heart are interconnected to each other. However, it remains largely unknown whether cardiac oscillatory activity could impact brain activity. To address this issue, we developed a novel technique that reversibly controls cardiac rhythm by electrically stimulating peripheral tissues in a freely moving rat. The method can be combined with electrophysiological recordings of systemic bioelectrical signals, including cortical local field potential signals, electrocardiogram, electromyogram, and respiratory rhythm. For heartbeat acceleration, electric stimulation was directly applied to the heart through two wire electrodes attached in the vicinity of the sinus node and the apex, allowing us to set a heart rate with a range between 400 bpm and 750 bpm. For heartbeat deceleration, electric stimulation was applied to the efferent vagus nerve, leading to a decrease in a heart rate as low as 240 bpm. Electrical artifacts included in brain recording channels could be removed by subtraction of averaged artifacts from the original electrical signals. We expect that this technique serves as a tool to examine cardiac activity-triggered modulation of brain functions and behaviors.

Title: Meso-scale structure and quotidian variation of neuronal networks estimated from twophoton imaging of mouse auditory cortex

Authors: *R. BETZEL¹, K. C. WOOD², C. F. ANGELONI², M. N. GEFFEN², D. S. BASSETT¹ ¹Dept. of Bioengineering, ²Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neural systems can be modeled as complex networks in which neural elements (cells, populations, or brain areas) are represented as nodes linked to one another through structural or functional connections (synapses, projections, and fiber bundles or statistically interdependent activity). The resulting "network" (or "graph") can be analyzed using mathematical tools from network science and graph theory to quantify the system's topological organization and better understand its function [1].

While the network-based approach has become common in the analysis of large-scale neural systems (i.e. MRI, EEG, MEG), few studies have used network science to study the organization of biological neural networks reconstructed at the cellular level. Even the most fundamental questions, such as how best to estimate the presence/absence and weights of connections between cells, remain largely unanswered [2].

Here, we record spontaneous and stimulus-evoked activity from the same set of cells in mouse auditory cortex over four days using two-photon calcium imaging. We reconstruct functional networks in which cells are linked to one another by edges weighted according to the maximum lagged correlation of their filtered fluorescence traces [3]. We show that the global structure of the network is largely preserved across days, as measured by the correlation of edge weights. We further show that network meso-scale architecture, i.e. partitions of cells into topologically-related sub-networks called "communities", are also largely stable, revealing consistently anticorrelated clusters of cells [4]. Finally, we show that despite quotidian stability, over shorter timescales (~minutes), network meso-scale structure is variable, revealing a stable core and fluctuating periphery [5].

The methods presented here are flexible and easily extended to additional datasets, opening the possibility of studying cellular level network organization of neural systems and how that organization is modulated by stimuli and disease.

Title: Microcoil-driven responses induced by magnetic stimulation spatially restricted to the local surface of the mouse auditory cortex *In vivo*

Authors: *H. OSANAI, S. MINUSA, T. TATENO Hokkaido Univ., Sapporo, Hokkaido, Japan

Abstract: Transcranial magnetic stimulation has been utilized as a non-invasive method to treat neurological disorders (e.g. tinnitus) and to investigate nervous system functions. However, the large coil size of the stimulation and the less focal stimulation prevent the chronic application. Recently, micro-magnetic stimulation (μ MS), which utilizes a micro coil with implantable size (< 0.5 mm diameter), was proven to be capable of activating the neural circuitry in vitro and in vivo. Although most μ MS studies examined its effects on single neurons, little has been known about the effect on brain tissues. Here, we demonstrate μ MS can non-invasively induce the local neural activity in the mice auditory cortex in vivo using the multi-channel and ECoG electrode recordings. By stimulating from the cortical surface, we found that the local field potentials and the firing activities were evoked locally in cortical layer 2/3, and they were propagated into the deeper layers. We also examined characteristics of the horizontal locality in the μ MS-driven neuronal activity. The result indicates that field potential responses at the sites close to the micro

coil were profoundly (three times) larger than those at the sites horizontally apart (> 1200 μ m) from the coil. Additionally, we found that μ MS-driven neuronal responses depended on the coil orientation to the surface, implying that the direction of the electric field was critical for the extent of neuronal activation. Our results can provide the basis for a future improvement of non-invasive μ MS devices for the chronic neurotherapeutic applications at the local-circuitry level.

Title: Implication of synchronous spiking to the auditory steady-state response interpretation: An EEG study

Authors: *I. GRISKOVA-BULANOVA¹, A. VOICIKAS², C. PACORET³ ²Inst. of Biosci., ¹Vilnius Univ., Vilnius, Lithuania; ³Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: Introduction: Auditory steady-state response (ASSR) is widely used in neuroscience and is regarded as a periodic response to a periodic stimulation, for example click trains. However, the nature of ASSRs is still an open question, giving some evidence to both the superposition of evoked potentials (Capilla et al. 2011; Bohórquez and Özdamar 2008) and to the entrainment of the network (Ross et al. 2000; Picton et al. 2003) theories. At the neural level, the phenomena of synchronous spiking in response to clicks is acknowledged (Eggermont 1994), appearing on the time-frequency representation as a sharp broad-band gamma response (Pavlov et al. 2012). As this phenomenon is detectable on EEG recordings, this study proposes to revisit ASSR nature in the light of spiking-network interactions.

Methods: 64 channel EEG was recorded in a sample of healthy volunteers (n=40, 19-46 years). Click (1.5ms white noise bursts) trains of 500 ms were presented binaurally at 60 dB with ISI at 700-1000 ms through earphones in the following frequency ranges with 1 Hz steps: 12-30Hz and 35-55Hz with 80 trials per frequency. EEG data were conventionally cleaned. The inter-trial phase coherence (ITPC) of the cycle for each stimulation frequency was extracted at the subject level for analysis of spiking profiles. Waveform grand averages of the responses to click stimulation were created and re-averaged by cycle. The waveforms and the ITPCs were evaluated 1) aligned to the click stimulus and 2) to the synchronous spiking event, i.e. sharp – broadband gamma burst, allowing observation of time-locked and phase-locked components of the response.

Results: A grand average of waveform aligned on the click stimulus revealed the time-locked

peaks (No, Na, Pb, Nb, P1) for all stimulation frequencies, suggesting an event-based response. Inter-trial phase coherence revealed one broad band gamma (30-100Hz) bursts at ~21ms delay from the stimulus for all stimulation frequencies. The alignment of cycles on this event resulted in observation of phase-locking for frequencies above 30Hz.

Conclusion: The study shows the superposition of evoked potentials below 30Hz (Miyazaki et al. 2013) and the entrainment from the constructive interference of the electric field created by overlapping responses to local synchronous spiking at higher rates. The entrainment is phase-locked to the cortical synchronous spiking and not to the auditory stimuli. Entrainment in this case, is a local consequence of the local synchronous spiking and its involvement in the process of information transmission of clicks should be addressed further.

(CBBS), Magdeburg, Germany

Abstract: We use tetrodes coated with carbon nanotubes to study single-unit activity in the rodent auditory cortex during learning. Carbon nanotubes allow us to lower the impedance of our tetrodes from approx. 600 k Ohm down to approx. 10 k Ohm. This low impedance is stable over months, both *ex vivo* and *in vivo*. The low impedance and resulting high signal-to-noise ratio of our recordings allow us to record stable single units in behaving rodents over weeks. In this poster, we present evidence for the stability of our recordings, and characterize physiological changes in this unit-activity as animals learn a cortically-dependent GO/NOGO auditory discrimination task.

Title: A real-time processing technique for 40 Hz auditory steady-state response: The parameters and effect of surgical interventions

Authors: *S.-I. HIRANO, Y. NISHIKAWA

Osaka Dent. Univ., Osaka, Japan

Abstract: Brain surgery sometimes involves a risk of causing nervous system dysfunction due to surgical manipulation. Many neurophysiological monitoring methods have been introduced to solve this problem. Each method has advantages and disadvantages, but none meet the definite need for an intraoperative monitor. To realize an intraoperative acoustic monitor that will provide a rapid functional alert, a real-time technique for processing the 40 Hz auditory steady-state response (40Hz-ASR) was investigated in cerebellopontine angle surgery.

Twelve rabbits underwent surgical interventions. The 40Hz-ASR during the interventions was recorded. The response was recorded between a silver ball electrode that was implanted at the bregma and needle electrodes that were inserted at the roots of the bilateral pinnae. Auditory clicks were successively presented at 40 Hz. In order to fulfil the demand, the signals of the 40Hz-ASR were immediately digitized and analyzed by the Fast Fourier Transformation (FFT) method. The spectral power (SP) and the phase coherence measure (PC) were calculated simultaneously. A real-time technique for processing the 40Hz-ASR was studied under a variety of experimental conditions.

This analytical method proved the 40 Hz-specificity of this response. The PC increased as the number of sweeps that were averaged increased. In contrast, the SP declined. In the verification experiment that was conducted to seek the optimum parameters of this series, both the PC and SP reached a plateau at an average of approximately 30 times. At a sample size of 15 or 20, the dispersion of PC values was minimal. The calculation of PC at an average of 30 times and a sample size of 15 to 20 permits evaluation of the 40Hz-ASR with sufficient reliability and sensitivity. Under general anesthesia, the PC showed no change, where the SP showed considerable attenuation. Surgical lesioning on the acoustic nerve or the brainstem caused a worsening of both the PC and the SP. The magnitude of deterioration was in proportion to the extent of lesioning.

Properties of the 40Hz-ASR that have been identified previously were reconfirmed in this realtime analysis, and the optimum values for each parameter, which were determined in early experiments in this sequence, permitted real-time monitoring with sufficient accuracy and rapidity. Our results indicate that the on-line measurement of the PC and SP enables rapid evaluation of acoustic and brainstem functions, which may be applicable in intraoperative monitoring. The author has obtained approval from the Institutional Animal Research Committee prior to launching this study, and has no COI to declare.

Title: Wireless flexible neural clip achieves deep visceral nerve targeting for micturition in rats

Authors: *N. V. THAKOR^{1,2,3}, S. LEE^{2,3}, W. PEH^{2,3}, S.-C. YEN^{2,3}, C. LEE^{2,3} ¹Biomed. Engin. Dept., Johns Hopkins Univ., Baltimore, MD; ²Singapore Inst. for Neurotechnology (SiNAPSE), Singapore, Singapore; ³Electrical and Computer Engin., Natl. Univ. of Singapore, Singapore

Abstract: Background: Bladder dysfunction is a widely studied area in the field of neuromodulation that remains a major healthcare challenge in the daily lives of patients. The pelvic nerve is a promising stimulation target for the control of bladder function as it provides autonomic efferent outputs to contract the bladder detrusor muscle. However, the pelvic nerves are small visceral nerves located deep inside the body, which leads to difficulties using current electrodes in implantation, as well as maintaining contact for reliable stimulation. Here, we demonstrate a flexible neural clip interface (NCI) that is suitable for implantation on small pelvic nerves for bladder neuromodulation.

Methods: Bladder pressure and urine output were measured and detected during pelvic nerve stimulation to assess functionality. Stimulation parameters were biphasic rectangular waveforms with a frequency of 10 Hz, 150 μ s phase width, duration of 5 seconds, and amplitudes that ranged from 100 to 1000 μ A. All acquired data were then analyzed using custom MATLAB code. Pressure data were low-pass filtered at 30 Hz, and a 5 second window prior to each electrical stimulation was taken as the baseline to calculate changes in pressure.

Results: The clip design enabled easy and reliable implantation on the pelvic nerve in a manner analogous to clipping a paper clip. We performed repetitive stimulation using supra-threshold amplitudes to show the reproducibility of bladder voiding through pelvic nerve stimulation using the NCI (n = 8 trials). Repeatable voiding responses were obtained in all 8 trials during a single recording session, with pressure changes. To examine how reliable our NCI worked across different animals, we reused the same NCI for experiments carried out in another rat on a

different day. We found that in both rats, applying higher stimulation amplitude caused greater peak changes in intra-bladder pressure, and decreased the time taken to reach the peak pressure, indicating that the NCI can be reliably implanted without much loss in electrode performance, and is mechanically robust for handling across different experiments.

Conclusions: The present findings indicate that the pelvic nerve can be stimulated in a graded manner to control bladder contractions leading to reproducible voiding events comparable with other published techniques. Notably, we showed that our novel flexible clip electrode can provide effective electrical contact with the pelvic nerve for reliable and repeatable stimulation in acute *in vivo* anesthetized animals.

Title: Recapitulation of the neurovascular unit (NVU) in a microfluidic platform using primary human cells

Authors: *A. M. ANDREWS¹, S. H. RAMIREZ²

¹Pathology, Temple Univ., Philadelphia, PA; ²Dept. of Pathology and Lab. Med., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Endothelial cells (ECs) form the basis of the blood-brain barrier (BBB), a physical barrier that selectively restricts transport into the brain. *In vitro* models can provide significant insight into BBB physiology, mechanisms of human disease pathology, toxicology and drug delivery. In terms of BBB models, co-culture microfluidic chips are an advanced model allowing for the recreation of 3D architecture and mechanical forces (fluid flow). Here, we detail the use of human fetal tissue as a source to build syngenic tri-cultures from the same host in a microfluidic chip that recapitulates the *in vivo* neurovascular unit. Aside from the syngenic aspect to this model, the microfluidic chips allow for inclusion of cell-cell interactions through the ability of CNS cells to extend into the "column-matrix" to make connections with the ECs.

We show that our brain ECs formed a fully functional barrier as assessed by the restriction of fluorescently labeled tracers (sodium fluorescein, NaFluo, 3 kDa Cascade Blue-Dextran, 40 kDa Tetramethyrhodamine-Dextran) in the EC flow compartment. Morphological findings include, an EC appearance that is consistent with cells exposed to fluidic flow and an astrocytic configuration that resembles the physiologic cytoarchitecture. Additionally, assessment of known triggers of BBB dysfunction, produced increases in the apparent permeability in the reconstituted NVU. Overall, we show the potential to develop human syngenic BBB models in microfluidic chips, which provide important functional aspects of the *in vivo* NVU environment.

Title: Thin-film softening multi-contact cuff electrodes: current steering and sub-chronic neuromodulation

Authors: *M. A. GONZÁLEZ GONZÁLEZ, A. G. HERNANDEZ REYNOSO, G. S. BENDALE, L. PATIL, A. KANNEGANTI, R. MODI, A. JOSHI IMRE, W. VOIT, M. I. ROMERO-ORTEGA

Bioengineering Dept., Univ. of Texas At Dallas, Dallas, TX

Abstract: Silicone cuff electrodes are used clinically for the stimulation of the tibial nerve in patients with drop foot, the vagus nerve (VN) for multiple conditions including epilepsy, depression and tinnitus, and the pudendal nerve for lower urinary tract disorders. While these electrodes are effective, the material, cuff size and stiffness of these devices, often cause fibrosis, increasing electrode impedance, and eventually leading to failure. In addition, most cuff electrodes stimulate the entire nerve sometimes recruiting undesired fascicles causing deleterious side-effects. In VN stimulation (VNs), unwanted fiber activation cause arrhythmias and laryngopharyngeal dysfunction. In this study, we photo-lithographically fabricated thin-film cuff electrodes using a shape memory polymer (thiol-ene/acrylate; SMP) which softness at 37°C from GPa to 500 MPa elastic modulus. A 16-electrode array with both titanium nitride (TiN) and gold sites raging from 3300-18500 um² in size, and from 0.8 K Ω to 1 M Ω in impedance, were fabricated and bonded to Omnetics connectors. The electrodes were tested in acute and sub-

chronic implantations onto the sciatic nerve (ScN) and the stimulation tested by the evoked EMG activity. Successful recording were confirmed during bladder filling in cuffs placed onto the pelvic nerve (PN). We confirmed the selective stimulation of the tibial and peroneal fascicles from cuff wrapped around the ScN by the evoked selective plantar- and dorsi-flexion movements, and respective EMG activity from the gastrocnemius and tibialis anterior muscles. Thirty days after implantation, the animals showed a reduced fibrotic tissue, (50%) compared to commercial silicon cuffs. In summary, we present a flexible, thin and sensitive multi-contact cuff electrode that can selectively stimulate specific nerve fascicles while inducing minimal fibrotic response. Together, the data supports the use of softening multi-contact cuff electrodes as a viable alternative for peripheral nerve neuromoduation.

Title: Characterization of cerebral organoid activity using two-photon calcium imaging and acute electrophysiology techniques

Authors: ***A. NEMES**¹, D. JGAMADZE², J. T. LIM², M. SCHAFF³, C. ADAM², J. A. WOLF², H.-C. I. CHEN⁴

¹The Univ. of Pennsylvania, Philadelphia, PA; ²Neurosurg., ³Univ. of Pennsylvania, Philadelphia, PA; ⁴Dept. of Neurosurg., Univ. of Pennsylvania Dept. of Neurosurg., Philadelphia, PA

Abstract: <u>Introduction:</u> The emergence of cerebral organoids provides a new approach for modeling human neurological disease and potentially repairing brain circuitry. These neural tissues, derived from the self-organization of pluripotent stem cells, recapitulate many brain-specific structures, including the layered architecture of cerebral cortex. While technical refinements in organoid generation protocols continue to improve the degree to which organoids mimic the brain, less is known about the neuronal and network activity of these entities. We

sought to study the early development of organoid activity.

<u>Methods</u>: We grew cerebral organoids from a federally improved embryonic stem cell line (H9) and a healthy volunteer induced pluripotent stem cell line using two different differentiation protocols (Pasca et al., 2015 and Qian et al., 2016). At different time points, we measured the calcium activity of Fluo-4 loaded organoids using two-photon microscopy. Videos of this calcium activity were analyzed using a semi-automated process. We also performed acute electrophysiology using laminar multi-electrode probes.

<u>Results:</u> In the two-photon experiments, we observed spontaneous calcium activity starting on differentiation day (dd) 50. There were a higher frequency of calcium events per cell at dd80 compared to dd50. Additionally, dd80 organoids had groups of cells with synchronous calcium activity. Although single units could not be resolved at this time point, electrophysiological recordings demonstrated a significant increase in multi-unit voltage amplitude at later time points compared to earlier time points. This activity was effectively eliminated with a depolarization block induced by the addition of potassium chloride.

<u>Conclusion</u>: The recently published paper by Quadrato et al. showed that cerebral organoids do not generate spontaneous action potentials until 8 months of growth. Our results demonstrate that cerebral organoids develop spontaneous calcium and electrical activity as early as dd50. The clustering of calcium activity at dd80 is suggestive of the development of some level of network structure. Further studies are required to better characterize this early activity and correlate it with the development of spontaneous single-unit activity.

Title: Pyloric rhythm extraction using signal processing tools

Authors: ***F. DOS SANTOS**, K. LAM, P. ANDRAS Keele Univ., Newcastle, United Kingdom

Abstract: Voltage sensitive dyes (VSDs) are used to record membrane voltage changes by measuring the corresponding changes in absorbance or fluorescence.

Voltage-sensitive dye imaging (VSDi) has been used in the stomatogastric ganglion (STG) of the *Cancer pagurus* the past decade, however identification of individual neurons is difficult due to the noise in the data.

The Pyloric Rhythm (PR) in the STG is characterised by a tri-phasic rhythm with phases

corresponding to the activity of the lateral pyloric (LP), pyloric (PY) and pyloric dilator (PD) neurons. The PR activity can be recorded in the lateral ventricular nerve (lvn).

We present our work on a signal decomposition method, using signal-processing tools to identify the neurons of the pyloric rhythm (PR).

In a first stage we identify the slow wave activity of neurons showing the PR, matching them with the signal recorded from the *lvn* with a blind sample. The match between the VSD recorded activity of pyloric neurons and the *lvn* recording of the PR is almost perfect.

To test our method we used three PY neurons with injected dye (these were previously identified by intracellular recording) as ground truth. Our results show that the proposed method works accurately. We were able to identify the PY bursts in each cycle allowing the reconstruction of the PY phase of the pyloric cycle recorded in the lvn. We were able to calculate accurately the duty cycle for the PY cells.

Future work will involve finding accurately the duty cycle of all PR cells and possibly some gastric mill rhythm cells without requiring the intracellular recording of the neurons. This will make possible the study of the complete STG network with a simple bath imaging settings. Figure 1a) shows the pyloric rhythm extracted from the image recording data, figure 1b) shows the extracted rhythm of the three pyloric cells overlaid with the lvn recoding.

Abstract: The human brain is >3,000 larger than the mouse brain. Yet, key elements of their basic neural architecture are conserved. Understanding how variations in brain morphology relate to measures of structural connectivity is essential to allow an understanding of how the brain processes information, and gives rise to cognitive functions, in different species.Recent tract tracing studies in macaque and mouse [1-3] have revealed conserved cortical network properties. Here we provide an intermediate point of comparison between these two mammals by analyzing the first collective database of the weighted and directed cortico-cortical connectivity obtained from >75 retrograde tracer injections in the cerebral cortex of the common marmoset (Callithrix jacchus), a small (~350g) monkey. In addition, a consensus of cortical areas between macaque and marmoset is proposed, which allows direct comparisons of the connectivity profiles between homologous cortical areas (or groups of areas) in these two primate species. We found that the obtained inter-areal connectivity matrix is dense, similar to results in macaque and mouse. The connection weights are heterogeneous, as they span over five orders of magnitude and are log-normally distributed. Additionally, similar to macaque and mouse, the inter-areal distances are normally distributed and the inter-areal connection probability decays with wiring distance as well as with the functional similarity distance between two cortical areas. Moreover, all three species show similar three-motif distribution, clique distribution, and have a dense core structure. A key network property found in macaque and mouse is that the probability of axons of a given length decays exponentially, the so-called exponential distance rule, which can predict many structural connectivity properties [4,5]. We found that this rule stands also for the marmoset and that the decay rate scales with brain size with a power law, from which the decay factor for the human brain can be predicted.

Our consistently collected tract-tracing data provide the cornerstone for future studies of the network characteristics of the brain in marmosets, as well as for comparative studies involving other mammalian species. Our results suggest conserved properties of the connectivity matrix across mammals, while allowing estimates of quantitative parameters that may result in different information processing and cognitive characteristics.

Title: Distinct structure-function dependencies across different connectivity scales in the rat brain

Authors: *M. STRAATHOF¹, M. R. T. SINKE¹, T. J. M. ROELOFS^{1,2}, E. L. A. BLEZER¹, O. SCHMITT⁴, W. M. OTTE^{1,3}, R. M. DIJKHUIZEN¹

Abstract: Resting-state fMRI and diffusion MRI have contributed to the elucidation of neural network connectivity in healthy and diseased brains. Partial correspondence between functional connectivity and diffusion-weighted tract reconstructions suggests a structure-function dependency in the brain, but the exact relationship remains unclear. Diffusion-weighted tract reconstructions only map the macroscale connections and may contain spurious tracts. In contrast, neuronal tracers allow detailed histological visualization of monosynaptic directed axonal connections at the cellular level. We aimed to further characterize the structure-function relationship by performing specific dependency mapping at the macro- and mesolevel, for which we combined high-resolution datasets of functional and structural MRI and neuronal tracing in rat brains from independent datasets.

Resting-state fMRI time-series were acquired under 1.5% isoflurane anesthesia at 9.4T in 19 young adult male Sprague Dawley rats and 14 adult male Wistar rats. Time-series were motion-corrected and band pass filtered between 0.1-0.01 Hz. Sixty diffusion-weighted images were acquired in ten post-mortem brains from adult male Wistar rats at 150-µm isotropic resolution (b=3842 s/mm²). Tracts were reconstructed with state-of-the-art constrained spherical deconvolution tractography. Images were matched with a Paxinos and Watson brain atlas. Macroscale functional connectivity and tract-based connectivity were determined between 84 bilateral cortical and 8 subcortical regions. Mesoscale neurotracer-based connectivity was obtained from the NeuroVIISAS database (~7800 tract-tracing publications). Structure-function

relationships were mapped for homotopic and non-homotopic regions, cortical-cortical and cortical-subcortical pairs, within and between hemispheres.

We found a positive relation between functional and macroscale structural connectivity in both datasets for homotopic and non-homotopic connections (r=0.17-0.52). This differed from the relationship between functional connectivity and mesoscale structural connectivity. There we found a – dataset consistent –negative correlation between homotopic cortical regions (r=-0.25 & r=-0.34) and no clear relationship for non-homotopic connections.

Our study suggests a distinct dependency between functional connectivity and underlying axonal wiring. While functional and structural connectivity corresponded positively at macroscopic level, indefinite correspondence at mesoscale level implies the importance of hierarchical characterization for thorough assessment of whole-brain connectivity.

Title: Mild blast injury acutely changes intracellular calcium in hippocampal neurons and reduces the coding ability of the neuronal network

Authors: *K. R. HANSEN, G. DEWALT, A. I. MOHAMMED, H.-A. TSENG, V. SALIGRAMA, B. NAZER, W. D. ELDRED, X. HAN Boston Univ., Boston, MA

Abstract: Traumatic brain injury (TBI) represents an important public health concern for both veterans and the general public. Mild brain injury can result from head trauma and is often associated with changes in mental state or consciousness. Much of what is understood about brain injury comes from long term studies in cell signaling and anatomical pathology, but very little is understood about the transient functional changes that occur in neurons in response to brain injury. Using a wide field Ca^{2+} imaging technique our lab recently developed, we characterized the intracellular Ca²⁺ dynamics of thousands of individual hippocampal neurons in awake mice upon mild blast directed towards a freely moving cranium. We found that immediately following blast, the intracellular Ca^{2+} levels decreased over a time scale of minutes. In addition to slow changes in the baseline intracellular Ca²⁺ levels, we also found a wide spread reduction in neuronal spiking activity measured as Ca^{2+} transients at the time scale of seconds. At a population level, the reductions in individual neuronal activity resulted in reduced network information coding ability as estimated with Shannon entropy. Blast induced changes in both intracellular Ca²⁺ levels and neuronal activity patterns gradually recovered in approximately one hour. Together, these results demonstrate that mild blast leads to profound changes in both the function of individual neurons and the computational ability of the population of cells in the neuronal network, and highlight the potential of applying such imaging techniques to study blast induced pathologies.

Title: Selective modulation of neural population In vivo by ultrasound stimulation

Authors: *H.-A. TSENG, A. MOHAMMED, S. BENSUSSEN, K. R. HANSEN, X. HAN Boston Univ., Boston, MA

Abstract: Non-invasive neural stimulation techniques are critically needed for medical application. Ultrasound, due to its non-invasive nature, has been of interest over the years as a potential non-invasive neural stimulation technique that can be focused into intact brains. For

example, stimulations over mouse motor cortex induced muscle contraction, and stimulation over human sensory cortex hindered sensory discrimination ability. However, it is unclear how neurons or neural networks respond to ultrasound stimulation in intact brain.

To examine the effect of ultrasound stimulation on individual neurons and neural networks in vivo, we applied ultrasound stimulations at various intensities to the brains of awake and head-fixed mice, and recorded neural activity in two brain areas: the hippocampus and the motor cortex. Calcium indicator (GCaMP6f) was expressed in neurons and observed with wide-field microscope. We found that, ultrasound selectively modulate different neuron populations at different intensity levels. The modulation effects were either activation or suppression, and often sustained several seconds after stimulation. These results highlight the potential of ultrasound stimulation as a non-invasive neural stimulation technique, and the stimulation effects can be tuned by altering ultrasound strength.

Title: Cholinergic and parvalbumin interneurons coordinate distinct aspects of dorsal striatal network dynamics during voluntary movement

Authors: *M. ROMANO¹, W. HOWE³, H. GRITTON², D. ZEMEL², M. BUCKLIN², X. HAN²

¹Grad. Program in Neurosci., ²Dept. of Biomed. Engin., Boston Univ., Boston, MA; ³Dept. of Neurosci., Icahn Sch. of Med. at Mt Sinai, New York City, NY

Abstract: Medium spiny projection neurons (MSNs) are the principal outputs of the striatum. Local interneuron populations are thought to organize the activity of MSNs to support the multiple behaviors mediated through striatal function. However, the sparse distribution of these interneurons has made it difficult to assess their capacity to modulate MSN network activity *in vivo*. Here, we build upon recent improvements in wide-field optical imaging to monitor the activity of two major interneuron classes, parvalbumin (PV) and cholinergic (ChI) cell types, in tandem with large networks of MSNs, in mice engaged in voluntary motor output. We reveal evidence that the activity of PV interneurons strongly gates the activity of nearby, but not far away, MSNs to modulate the gain of on-going motor output. Surprisingly, the activity of these neurons was largely unsynchronized across the dorsal striatum, arguing against broad and nonselective inhibition facilitating movement selection. Cholinergic interneurons (ChIs) in contrast, poorly tracked overall movement, but engaged and synchronized MSN activity over hundreds of microns during discrete changes in ongoing motor plans. Our combined evidence demonstrates the unique capacity of striatal interneurons to organize networks of MSNs in support of distinct aspects of motor control.

Title: Discrete networks of neurons differentially track conditioned and unconditioned stimuli in the hippocampus through the process of learning and extinction

Authors: *M. ABDULKERIM, K. R. HANSEN, A. I. MOHAMMED, H.-A. TSENG, H. GRITTON, X. HAN Biomed. Engin., Boston Univ., Boston, MA

Abstract: The hippocampus is a region of the brain important for new memory formation and recall and is essential for trace-learning. We previously applied wide-field microscopy and calcium imaging to monitor CA1 neural activity in a well characterized trace eyeblink task. We found that through the process of learning approximately ~25% of neurons in the hippocampus exhibit task relevant activity. As a follow-up, we recently examined how extinction training, within this task, alters the response properties of these neurons. In addition, we asked if extinction training recruits new neurons within the hippocampus as a function of new learning. We applied trial-by trial neural network analysis to determine how stability of the network changes across each state of training and whether the state of the network is a reliable indicator of trial performance. We discovered that individual neurons were poor predictors of trial outcome on a trial-by trial basis but that networks of neurons were strong predictors of behavior. We also found that the responsivity of discrete and separable populations of neurons became largely dissociable as new learning occurred and that each particular population of neurons was more or less influential in network computations depending on the training stage of the animal.

Title: Automatic fluorescence intensity based adaptive thresholding (FIBAT) for rapid image segmentation of large scale calcium imaging datasets

Authors: H.-A. TSENG¹, S. SHEN³, K. R. HANSEN², R. WU³, J. SI³, *X. HAN² ²Biomed. Engin., ¹Boston Univ., Boston, MA; ³Sch. of Electrical, Computer and Energy Engin., Arizona State Univ., Tempe, AZ

Abstract: Recent development in high performance calcium indicators enabled researchers to observe neural activity from a large number of neurons over days or weeks, generating increasingly large datasets. Such large datasets pose great challenges to neuroscientists. One critical step in processing imaging datasets is to identify regions of interest (ROIs), where each ROI corresponds to an individual neuron, so that the fluorescence of each ROI can be used to understand neural activity patterns. Although manual selection of ROIs has been a common approach for small imaging datasets, it is not suitable for large datasets due to its labor-intensive and time-consuming nature. Thus, an algorithm that automatically identifies ROIs is critically needed to analyze large imaging datasets. We developed an algorithm for rapid automatic image segmentation using adaptive thresholding of fluorescence intensity, an algorithm we named automatic fluorescence intensity based adaptive thresholding (FIBAT). We first generated a static image representing the mean intensity of each pixel over time. We then applied an intensity threshold globally to the static image to isolate potential ROIs. The threshold was adaptively adjusted so that the largest number of ROIs was obtained. We then applied adaptive threshold locally around the immediately surrounding area of each ROI identified, segmenting each ROI into smaller ROIs if possible. This process was iterated multiple times to capture as many ROIs possibly. We tested the algorithm on two calcium imaging datasets, one from the hippocampus area and anther from the striatum area, where neurons are different in sizes. Compared to manual selection of ROIs, FIBAT successfully identified about 80% of the manually generated ROIs. Upon further visual examination of false positive ROIs identified by FIBAT, we found that many are neurons missed by manual selection. Overall, the performance of our algorithm is

comparable with manual selection, and can outperform manual selection by identifying ROIs with low intensity that were often missed by manual selection.

Title: Low-dimensional representations of learning in multi-trial datasets

Authors: ***A. H. WILLIAMS**¹, B. POOLE¹, N. MAHESWARANATHAN¹, T. H. KIM¹, F. WANG¹, S. VYAS¹, K. V. SHENOY¹, M. J. SCHNITZER², T. G. KOLDA³, S. GANGULI¹ ¹Stanford Univ., Stanford, CA; ²Stanford Univ. Dept. of Biol., Stanford, CA; ³Sandia Natl. Labs., Livermore, CA

Abstract: Dimensionality reduction methods, such as Principal Components Analysis (PCA), provide compact statistical summaries of large population recordings and thus have become a cornerstone tool for modern neural data analysis [1]. Existing methods reduce the dimensionality of fast, within-trial neural dynamics, but ignore how dynamics change over repeated behavioral trials. These across-trial trends are of broad interest as neural correlates of attention, memory consolidation, learning, and other internal cognitive states.

We present two approaches - canonical polyadic (CP) tensor decomposition and time-warped principal components analysis (twPCA) - that reduce the dimensionality of within-trial firing rates and find low-dimensional representations for across-trial dynamics. CP tensor decomposition, an existing and well-studied statistical technique [2], formally generalizes

existing network models of low-dimensional gain modulation (e.g. [3]), while twPCA models temporal shifts and scalings of neural dynamics, similar to dynamic time warping (DTW). These complementary methods can be jointly applied to neural data to accommodate low-dimensional changes in both amplitude and timing.

In experimental datasets collected from different species, brain regions, and behavioral tasks, these unsupervised methods recover sub-populations of neurons with interpretable within-trial as well as across-trial dynamics, reflecting experimental conditions, rewards, behavioral strategies, and motivational states. CP decomposition identified functional types of excitatory neurons in prelimbic cortex while mice switched navigational strategies in a four-armed maze. In separate experiments, CP decomposition and twPCA characterized neural dynamics while a Rhesus macaque learned to compensate for a visuomotor rotation in a brain-machine interface task. We have developed open-source computational tools for fitting these models to neural data [4,5]. [1] Cunningham JP, Yu BM (2014). Nat Neurosci. 17:11, 1500-1509.

Title: Detection of rodent social behavior using machine learning based method with convolutional neural network

Authors: *H. MUKAI, I. YABE, Y. OKADA, T. INOUE Meiji Univ., Kawasaki, Japan

Abstract: Determination of rodent behavior from video images obtained in experimental record is important in numerous branches of neuroscience. Freezing is most frequently studied phenomenon related to wide range of intrinsic behaviors such as contextual fear conditioning which is thought to mainly depend on the hippocampus as well as auditory fear conditioning, where amygdala plays a major role. Not restricted to the behaviors in individual animals,

freezing behavior has been studied in researches of social interaction, namely observational fear, which is associated with neuronal activities in the cingulate cortex. Existing methods of automated analysis, partly rerouting time-consuming and labor-intensive manual image identification in large data sets, are mostly depending on simple image feature analysis, not incorporating recent huge progress of machine learning, including deep learning. Introducing the results of machine learning methods has potential power allowing more efficient analysis for more complex phenomena in rodent behavior. To achieve the goal, we employed convolutional neural network (CNN) for the current study. CNNs are widely used neural network which are making tremendous success in recent computer visual object recognition contests. Among number of CNN implementation for various objectives, we employed C/C++ based, relatively light weight CNN for our purpose because the network could work with small computer resources. Training neural network has been carried out on PC with GPGPU (General purpose graphic processing unit) with labelled data. We are currently applying our machine learning based method to data obtained in recording social interactions of mice during/after observational fear. We are obtaining parallel results with conventional image processing method for simple freezing behavior, and further pursuing to identify a novel classification index of rodent behavior by the network. Our method is expected to be a better alternative to analyze vast amounts of recorded behavior data in many fields of neuroscience. Title: A novel probabilistic framework for estimating of neural connections from partially observed neural spikes

Authors: *T. IWASAKI¹, H. HINO², M. TATSUNO³, S. AKAHO⁴, N. MURATA¹ ¹Dept. of Electrical Engin. and Biosci., Waseda Univ., Tokyo, Japan; ²Dept. of Computer Sci., Univ. of Tsukuba, Tsukuba, Japan; ³Dept. of Neurosci., Univ. Lethbridge, Lethbridge, AB, Canada; ⁴Mathematical Neuroinformatics Group,, Natl. Inst. of Advanced Industrial Sci. and Technol., Tsukuba, Japan

Abstract: Plasticity is one of the most important features of the nervous systems that enables animals to adjust their behavior to an ever-changing external world. A major mechanism of plasticity is the changes in synaptic efficacy between neurons, and therefore estimation of neural connections is crucial for investigating information processing in the brain. Although many analysis methods have been proposed to this end, most of them suffer from a mathematical difficulty that stems from the fact that activity of only a limited number of neurons are available. That is, many existing methods ignore the effects from unobserved neurons. To overcome this difficulty, a novel probabilistic framework is proposed for estimating neural connections from partially observed spikes. We extract connections between observed neurons by explicitly quantifying influence from unobserved neurons to observed neurons. By modeling all possible propagations of influence over multiple neurons, the proposed method is able to eliminate pseudo-correlations; the pseudo-correlation is the problem that an indirect connection is detected as a direct connection. The method provides a macroscopic measure of connection within a temporal window of interest and it can be used for selecting the specific connections for further analyses. The proposed method is validated by artificial data and its applicability to real electrophysiological data is demonstrated as well.

Title: An efficient modeling approach for brain connectivity analysis of saltatory pneumotactile velocity stimulus

Authors: *K. JUNG¹, H. OH², J. LEE¹, S. M. BARLOW^{3,4}

¹Educational Psychology and Leadership/IMMAP, Texas Tech. Univ., Lubbock, TX; ²Neurosci., Baylor Col. of Med., Houston, TX; ³Special Educ. and Communication Disorders, ⁴Ctr. for Brain-Biology-Behavior, Univ. of Nebraska, Lincoln, NE

Abstract: Previous fMRI studies of the sensorimotor system have demonstrated the location, velocity, and direction of tactile stimuli on the skin's surface are discriminable features of sensorimotor processing. To better understand the representation and processing of dynamic saltatory tactile stimuli in the sensorimotor cortex, brain connectivity is utilized to delineate how sensorimotor areas are connected and how they influence each other. Here, we employed a pathanalytic structural equation modeling (SEM) approach for such a brain connectivity analysis of moving tactile stimuli on the glabrous skin of the digits, called path-analytic generalized structured component analysis (GSCA; Hwang & Takane, 2014). Path-analytic GSCA enables specification and estimation of the relationships among ROIs. For parameter estimation, pathanalytic GSCA applies a least squares estimation method, and the standard errors of parameter estimates are estimated by the bootstrap method. As such, path-analytic GSCA is computationally efficient in dealing with more elaborate and complicated brain connectivity models without recourse to distributional assumptions. We applied path-analytic GSCA to a bidirectionally connected structural model of the BOLD response time courses data extracted from four ROIs chosen a priori to investigate primary sensorimotor regions contralaterally to the two different velocity stimuli (5cm/s and 25cm/s) on the right hand (BA3b_Left(L), BA1_L, BA3a_L, and BA44_L) in neurotypical adults (n=11). The result of our analysis revealed that there were statistically significant differences between the 5cm/s and 25cm/s stimuli on the structural paths in the hypothesized model. Future work will apply Dynamic GSCA to timeseries data to further delineate connections not only within the sensorimotor control network but also within somatosensory related areas such as cerebellum and posterior parietal cortex (PPC) and the influence of reorganization of these connections on fine motor control in individuals with stroke.

Title: Unsupervised latent variable extraction from neural data to characterize processing across states

Authors: *R. CHAUDHURI¹, B. GERCEK¹, B. PANDEY¹, I. R. FIETE² ¹Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX; ²Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: In circuits at the sensory and motor periphery and in rare instances in cognitive areas, the identity of the primary independent variable represented by the neural responses is known. This is the exception: In many brain regions or in different states (e.g. sleep), the independent encoded variable is unknown. To what extent is it possible to discover the identity of the independent variable and decode its value from neural data, without direct knowledge of what it is? We present efforts to discover structure in multiple single-unit data, extract the unknown independent variable, and perform fully unsupervised decoding of it. Our method involves parameterizing low-dimensional manifold structure in high-dimensional data. We apply it to recordings from the mouse thalamus and postsubiculum (Peyrache et al., 2015) to examine neural circuit dynamics during awake exploration, REM, and slow-wave sleep (SWS). The method discovers a ring structure, which it parameterizes to extract a circular variable, consistent with head direction coding in these circuits. The accuracy of unsupervised decoding of the latent variable on many sessions is on par with decoders constructed using head direction. Per-neuron tuning curves for the latent variable match (up to rotation) the actual head direction tuning curves. REM states and a subset of SWS states fall on the waking manifold, showingwithout the assumptions involved in applying awake-state encoding models to sleep decodingthat sleep and awake states share the same structure. Unlike waking, REM states perform a random walk on the circular variable, while SWS states sample a subset of angle values and make large jumps between them.

Thus, we show it is possible to discover the structure of a variable that drives neural responses and decode it without knowing its identity, simply from time-series neural data. Such approaches can help understand encoding and dynamics in neural circuits, across behavioral states.

Title: Determination of awake and sleep stages using objective detection criteria and analyses of long-term continuous intrahippocampal LFP recordings and video activity measures in mice

Authors: L. MOLNÁR¹, I. FERANDO², *I. MODY³

¹Electrical Engin., Sapientia Hungarian Univ. of Transylvania, Targu Mures, Romania; ²Neurol., UCLA, David Geffen Sch. of Med., Los Angeles, CA; ³Dept Neurol., UCLA Sch. Med., Los Angeles, CA

Abstract: Numerous algorithms exist to determine separate sleep stages and awake periods in mice. However, most of the methods for identifying such stages rely on subjective thresholds for their detection. We wanted to devise a method that does not rely on such thresholds, but separates the behavioral stages based on the intrinsic properties of the various oscillatory events in the LFP. We recorded CA1 or dentate gyrus δ , θ and γ oscillations (2048 Hz sampling) in adult mice freely moving in their home cages. The mice were kept with ad libitum access to water and food, on a 12:12 hours dark(D):light(L) cycle. The animals were also continuously monitored using an infrared sensitive video camera that recorded digital video files at 10-11 frames/s through the iSpy software. This software also calculated the movement and activity (A) of the animals by a digital frame-to-frame subtraction procedure. Each 12 hrs, for the L and D periods, recordings were down-sampled for the detection of δ , θ and γ oscillations. Using Igor Pro, the traces were band-pass filtered with an FIR filter between 1-4 Hz for δ , 5-12 Hz for θ , and 30-120 Hz for γ oscillations. The RMS values of 8 s epochs (0.5 or 1 s shifts) were obtained from the filtered recordings in each bandwidth and all-point histograms of δRMS , θRMS and γ RMS values were plotted for 12 hr L and D periods. In addition, the "peakiness" (P) of the θ oscillations was calculated and given values corresponding to the separation of its power from neighboring frequencies. We then calculated the ratio of $\gamma RMS/\delta RMS$ (G/D) for the duration of the recordings. The histograms of G/D showed a bimodal distribution well fitted by two Gaussians. The Gaussian with a lower mean and a very low variance could be easily separated. This distribution was then used to define the non-REM sleep periods (NREM) using a Gaussian probability-weighted function. Once the NREM episodes were defined, we separated the epochs outside the NREM into A and REM periods using an Euclidean vector space normalization and weighting of four vectors: A, θ RMS, P and γ RMS. Judging by the similarities between the durations of the various behavioral stages obtained by our method and those previously published, our approach accurately determined the behavioral stages of the animals without the requirement of recording EMG activity and subjective thresholding.

Title: Toward a common, extensible cloud architecture for images to graphs

Authors: *N. DRENKOW¹, P. ADAIR², D. HILL², J. LI², R. NORMAN-TENAZAS², R. RAIS², K. TORGAS², B. A. WESTER³, W. R. GRAY RONCAL⁴ ¹JHU/APL, Laurel, MD; ²Johns Hopkins Univ., Baltimore, MD; ³Johns Hopkins Univ. Applied Physics Lab., Laurel, MD; ⁴Johns Hopkins Univ. Applied Physics Lab., Baltimore, MD

Abstract: Electron microscopy (EM) datasets used for building and analyzing connectomes will soon approach petabyte-scale. It is well understood that trained human annotation of EM datasets is accurate, yet time-consuming, costly, and not scalable. While automated computer vision and machine learning approaches are poised to tackle many challenges of building connectomes in a fraction of the time and cost, many state-of-the-art algorithms have been focused on task performance but not necessarily scalability. In a similar vein, these algorithms are often evaluated on small datasets, but not packaged in a reusable or reproducible way, thus making it difficult for other researchers to employ them on a much larger scale.

Efforts at JHU/APL are focused on improvements and adaptations of these state-of-the-art algorithms in combination with novel, efficient uses of cloud-based computing and Docker to operate at the scale of current and anticipated EM datasets. This operation is critically important to support our generation of ground truth data, proofreading efforts, and performer evaluation under the MICrONS program.

In building connectomes via automated approaches, we've addressed scalability at critical levels of the processing hierarchy. At the algorithmic level, APL has developed and adapted state-of-the-art algorithms for processing large volumetric data. In particular, APL has successfully implemented, modified, and trained deep learning U-Net models to perform both dense membrane and synapse segmentation. To-date, most existing deep learning techniques produce voxel-wise or supervoxel-wise labelings. While the latter method enables some degree of scalability, our approach provides dense segmentation at a rate that is orders of magnitude faster than naive approaches without sacrificing accuracy.

At the workflow level, APL has leveraged Docker and cloud-based solutions to enable efficient and repeatable processing of large volumetric datasets stored in the Block and Object Storage Service (BOSS). Through the use of Docker and Amazon Web Services (including their Elastic Container Service, Simple Queueing Service, and Batch), we're able to massively parallelize volume processing while maintaining high throughput. Combining the algorithmic and workflow accelerations, we're able to produce membrane and synapse segmentations for the entire Kasthuri 2015 (100x80x55 um3) dataset in approximately six hours using only eight K80 GPUs. These segmentations then enable faster, targeted ground-truth generation and proofreading under MICrONS.

Title: Single-subject source analysis from continuous resting state EEG

Authors: *A. C. TANG, W. R. FUNG, Y. HUA, L. QIN The Univ. of Hong Kong, Pokfulam, Hong Kong

Abstract: Resting state functional magnetic resonance imaging (rfMRI) studies have revealed organized patterns of brain activity, reflecting local and global synchronized activity within and across distinct functional brain regions. As fMRI measurement reflects changes in blood oxygen level, synchronized brain activity captured by rfMRI is of a different time scale from patterns of synchronization resulting from rapid changes in electroencephalograhy (EEG) associated with synaptic transmission. The relatively low cost and wide availability of EEG makes it a potential candidate for frequent and routine monitoring of human brain function. Here taking advantage of the millisecond temporal resolution of EEG, we used Second Order Blind Identification (SOBI) a blind source separation (BSS) method to uncover both local and global synchronized neuronal activity from continuous high-density EEG data (128 channels) collected during 5 min task-less resting period without using a shielded room. Across 9 participants (19 to 72 years of age), we were able to identify SOBI components with highly regular sensor-space projection maps reflecting (1) local synchronized neuronal activity along both dorsal and ventral visual pathways and in temporal and frontal cortices; (2) global synchronized neuronal activities spanning posterior-anterior parts of the brain. A subset of these components can be reliably observed across all participants while others show more individual differences. The most notable is the identification of the following component types: (1) components whose topography resemble those previously reported global network showing face-stimuli elicited P300 response; (2) components whose topography suggest a spatial origin of V4; (3) components whose topography suggest multiple spatial origins from the frontal lobes, including regions associated with

language processing. These maps raise the possibility of localizing synchronized ongoing neuronal activities to specific functional brain regions filling the gap from the rfMRI studies. The fact that such functionally distinctive maps can be obtained from 5 min EEG data suggests the feasibility of using highly portable EEG systems in frequent monitoring of brain activity from specific functional brain regions.

Title: Novelty reduces trial-to-trial variability in the latency of cortical neuronal responses

Authors: *G. OUYANG¹, Y. HUA², W. R. FUNG², C. ZHOU³, A. C. TANG² ¹Psychology, Ernst-moritz-arndt-Universität Greifswald, Greifswald, Germany; ²Lab. of Neurosci. for Educ., The Univ. of Hong Kong, Pokfulam, Hong Kong; ³Dept. of Physics, Ctr. for Nonlinear Studies, Inst. of Computat. and Theoretical Studies, Hong Kong Baptist Univ., Kowloon Tong, Hong Kong

Abstract: Under resting or task free conditions, the human brain maintains a highly variable ongoing activity, shown as oscillatory EEG signals recorded from the scalp. Such on-going activity contributes to trial-to-trial variation in the latency of the event-related potentials (ERPs) response to identical stimulation. In typical cognitive studies, such trial-to-trial variations are dealt with by averaging across trials of stimulus presentation and across different subjects to obtain the socalled grand average. Here by applying Second Order Blind Identification (SOBI) to singlesubject hd-EEG data, we first extracted neuronal sources, including both early sensory areas and higher order processing areas down the cortical processing stream. We then compared the latency variability in single-trial ERPs of these SOBI recovered cortical neuronal sources during a visual color oddball task, where the participants pressed a button in response to the low probability color stimulus (20% of 250 trials). For different time windows selected to capture the early and late temporal components of an ERP, we estimated single trial response latency by calculating the cross-correlation between a single trial and the averaged ERP waveforms. Variance tests revealed a significant difference between the high versus low frequency color stimuli conditions (ps < .01). Most surprising is the direction of this difference---the variability in LATE response to low frequency stimuli was significantly smaller than that of the high frequency stimuli despite the former having a smaller number of trials. In contrast, no significant variance differences were found for the EARLY ERP components. This result suggests that a major source of trial-to-trial variations may arise from top-down evaluation of the incoming

feed-forward signals and that novelty may recruit stronger attention to enhance learning, which manifests itself as increased response reliability in the top-down efferent signals broadcasted to multiple brain regions. This data set also offers additional opportunities to further test the hypothesis that top-down modulation of neuronal activity of the lower functional brain regions by higher functional regions underlies the greater variation in the late, as opposed to the early, ERP component of the early stage brain regions.

Title: Online unsupervised spike sorting using an artificial STDP neural network

Authors: M. BERNERT^{1,2}, *B. YVERT¹

¹U1205, INSERM Braintech Lab., Grenoble Cedex 9, France; ²CEA, Grenoble, France

Abstract: Extracellular neural recordings typically consist of the superposed activity of multiple neurons. To study ensemble dynamics, it is important to isolate the activity of single neurons. Automatic unsupervised spike-sorting is still a challenging problem, especially when largescaled neural recordings are considered. Moreover, applications such as brain-computer interfaces require real-time implementation. Most spike-sorting methods use four main steps: data filtering, action potential detection, feature extraction and clustering. However these methods often require supervision or offline processing. To overcome these limitations, we propose a fully unsupervised method based on a spike-timing dependent plasticity (STDP) artificial neural network, a type of network able to perform unsupervised learning. We considered a network constituted of three layers of neurons and one attention neuron, connected in a feedforward manner. The input signal, band-pass filtered, is continuously fed into the input layer. The spike trains of the output layer directly reflect the detected and sorted action potentials from the input signal. Each layer of the network has a specific role. The input layer fires at regular time steps, and the emitted spike train encodes the shape of the input signal within a sliding time window, thanks to input neurons encoding for different signal amplitudes at different delays. The attention neuron, which receives the input spike train, detects action potentials in the signal thanks to a short-term plasticity rule, and modulates the intermediate and output layer. The intermediate layer learns to recognize short signal shapes encoded by the input layer thanks to an STDP rule. Finally the output layer learns intermediate layer patterns thanks to an STDP rule, with the ability to adapt to the pattern size thanks to an intrinsic plasticity rule. We evaluated this method on several sets of artificially generated data with known truth and also on real extracellular recordings associated with intracellular recordings. On average we obtained comparable or better performances than the open-source spike-sorting software Osort and Wave_clus, especially in case of low SNR. Overall the proposed approach thus provides a robust online automatic and fully unsupervised spike sorting method.

Dept. of Neurosurg., Stanford, CA; ¹²EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

Abstract: Increasing evidence suggests that the activity of large populations of neurons is often well-described by low-dimensional dynamics. Measurements of these neural populations are often limited to recordings from separate populations of neurons observed in many separate experimental sessions. With this approach, it is typical for the recorded neurons to be completely non-overlapping across sessions. This makes understanding the dynamics of the aggregated neural population difficult, especially at the level of single trials. Here we introduce "dynamic neural stitching", an adaptation of LFADS (Latent Factor Analysis via Dynamical Systems, see

Pandarinath et al. SfN 2017) which infers common latent dynamics from separately recorded, single-trial neural population activity. LFADS learns one consistent dynamical system to describe all the data, and session-specific transformations that map from these (latent) dynamics to the neural activity observed in each individual session.

This approach is motivated by the assumption that in an experimental design where the subject is engaged in a similar behavior across recording sessions, groups of neurons recorded from the same brain region should share the same underlying dynamics. We tested this approach using 45 sequentially recorded spiking datasets (24 ch. Plexon V-probes) from macaque M1 and PMd during a center-out instructed-delay reaching task. We trained one multi-session LFADS model as well as 45 individual, single-session models for comparison. The multi-session model's latent states were considerably more informative about single-trial behavior, including cross-validated predictions of hand kinematics ($p < 10^{-6}$) and reaction times ($p < 10^{-6}$). The latent neural population state trajectories of the stitched model varied by reach direction but were highly consistent across recording sessions, implying that LFADS found a common low-dimensional latent state governing the population activity across recording sessions.

New multi-electrode and imaging technologies enable recording of ever-larger populations of neurons, but it is often practical to collect more cells over many sessions. Dynamic neural stitching enables neuroscientists to move beyond trial-averaged analyses of sequentially recorded datasets, and instead to infer common latent dynamics from the individual trials of each dataset. Understanding these dynamics may help to unravel the computations performed by neural circuits and to clarify the relationship between single-trial neural population state and behavior.

Abstract: Calcium imaging has become the preferred technique in neuroscience to simultaneously record the activity of thousands of cells. Yet most tools to analyze the recordings are rather rudimentary or require extensive knowledge of other disciplines, from machine learning to big data and network theory. Moreover, there is often a disconnection between the experiments and their analysis and outcome, usually taking place days apart and/or being done by different people.

We present NETCAL, a MATLAB-built, dedicated software platform to record, manage and analyze high-speed high-resolution calcium imaging experiments. Its ease of use, interactive graphical interface and exhaustive documentation is aimed to wet-lab researchers, but it will also meet the needs of any experienced data scientist through its plugin and scripting system. We have developed a large set of tools and incorporated state-of-the-art algorithms and toolboxes for large-scale analysis of network and population dynamics. Analyses include: automated cell detection (both static and dynamic); trace and population sorting through machine learning, clustering and pattern recognition; bursting dynamics; spike detection; network inference (from functional networks to causal relations); and many more. Several of these tools are also available in real-time, e.g. cells and spikes can be monitored during the actual recording, giving the researcher extensive feedback on the progress of the experiment.

We have tested and used the software in several different experimental preparations and laboratory equipment. For instance, NETCAL has been used to test the viability and performance of differentiation protocols from human induced pluripotent stem cells (hISPCs); to characterize the individual and collective behavior of dissociated cortical and striatal cultures from Huntington's disease (HD) mouse models; to reveal the communication between neurons and astrocytes in rat hippocampal cultures; and to detect propagating activity patterns in cortical cultures. Although NETCAL has been developed for calcium recordings in cultures, we have successfully tested and used it in other preparations, e.g., in-vivo calcium imaging and multi-

electrode arrays.

Our platform has been developed by scientists for scientists, to promote and foster the development of tools for the replication and validation of experimental results. The software is highly modular, and its implementation provides easy extendability to adapt it to the specific requirements of any research group.

Title: Detection of irregularly firing inspiratory neurons in the pre-Bötzinger complex based on spatio-temporal optical imaging data analysis

Authors: *F. MIWAKEICHI

The Inst. of Statistical Mathematics, Tachikawa-Shi, Japan

Abstract: Spontaneous synchronous neuronal activity is fundamental phenomena to maintain homeostasis. One of the essential brain function to sustain the life is respiration, and it has been known that spontaneous neural synchronization in the pre-Bötzinger complex (preBötC) generates inspiratory bursts which can be observed as local filed potential (LFP) signal. Recent development of imaging techniques, such as Ca^{2+} imaging system, enables us to simultaneously record multicellular activity to investigate neuronal circuitry. Cross-correlation analysis with a reference function defined from LFP signal for whole temporal domain has been used to detect neurons that involve inspiratory burst. Though this approach is simple and can be straight forwardly applied to the data, only the regularly firing (clock-like) neurons, which involves most of inspiratory burst, can be detected. The ratio of regularly firing neurons among the neuron in

the imaging data is about 10% and the other neurons are irregularly activated. Then question arises; what is the role of other neurons to generate respiratory rhythm? In order to elucidate the behavior of irregularly firing (non-clock-like) neurons, we applied cross-correlation analysis for each inspiratory burst with a sliding temporal window. Through this analysis we detected as many as seven times the number of the irregularly firing neurons than regularly firing neurons with discriminating the types of neuron, such as excitatory, glycinergic and GABAergic inhibitory neurons. We found that activation timing of regularly firing neurons were synchronized and kept the same time delay relative to the onset of the burst in LFP signal. On the other hand, the activation timing of irregularly firing neurons were also irregular. We also found that the number of firing neurons affected the amplitude of LFP signal for each inspiratory burst. We will further discuss the applicability of the causality analysis among the neurons in this poster.

Title: A fast image registration framework for light-sheet fluorescence microcopy of neural activities

Authors: *H. HUI¹, H. MENG¹, C. HU¹, X. YANG¹, J. TIAN² ¹Key Lab. of Mol. Imaging, CAS, Inst. of Automation, Chinese Acad. of Scienc, Beijing, China; ²Key Lab. of Mol. Imaging, CAS, Beijing City, China

Abstract: The ability of fast and single-neuron resolution imaging of neural activities enables light-sheet fluorescence microscopy (LSFM) as a powerful imaging technique in functional
neural connection applications. The state-of-art LSFM imaging system can record the neuronal activities of entire brain for small animal, such as zebrafish or C. elegans at single-neuron resolution. However, the stimulated and spontaneous movements in animal brain result in inconsistent neuron positions during recording process. In this work, we address the problem of real-time registration of neural positions in stacks of LSFM images. This is necessary to register brain structures and activities. To achieve real-time registration of neural activities, we present a fast rigid registration architecture by implementation of Graphics Processing Unit (GPU). In this approach, the image stack was preprocessed on GPU by mean stretching to reduce the computation effort. The present image was registered to the previous stack that considered as reference. A fast Fourier transform (FFT) algorithm was used for calculating the shift of the image stack. The calculations for image registration were performed in different threads while the preparation functionality was refactored and called only once by the master thread. We implemented our registration algorithm on NVIDIA Quadro K4200 GPU under Compute Unified Device Architecture (CUDA) programming environment. The experimental results showed that the registration computation can speed-up to 550ms for a full high-resolution brain image. The registration can be accelerated using more GPUs in the architecture. Our approach also has potential to be used for other dynamic image registrations in biomedical applications.

Title: LFADS: A deep learning technique to precisely estimate neural population dynamics on single trials

Authors: *C. PANDARINATH¹, D. J. O'SHEA², J. COLLINS⁵, R. JOZEFOWICZ⁵, S. D. STAVISKY³, J. C. KAO⁴, E. TRAUTMANN², M. M. CHURCHLAND⁶, M. T. KAUFMAN⁸, S. RYU⁹, J. M. HENDERSON¹⁰, K. V. SHENOY¹¹, L. ABBOTT⁷, D. SUSSILLO⁵ ¹Biomed. Engin., Emory Univ. / Georgia Tech., Atlanta, GA; ³Neurosurg., ⁴Electrical Engin., ²Stanford Univ., Stanford, CA; ⁵Google Brain, Mountain View, CA; ⁶Neurosci., ⁷Columbia Univ., New York, NY; ⁸Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY; ⁹Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; ¹⁰Dept Neurosurgy, R 227, Stanford Univ. Dept. of Neurosurg., Stanford, CA; ¹¹EE, BioE & Neurobio., Howard Hughes Med. Inst. -Stanford Univers, Stanford, CA

Abstract: Neuroscience is experiencing a data revolution in which simultaneous recording of many hundreds or thousands of neurons is revealing structure in population activity that is not apparent from single-neuron responses. This structure is typically extracted from trial-averaged data. Single-trial analyses are challenging due to incomplete sampling of the neural population, trial-to-trial behavioral variability, and fluctuations in action potential timing. We introduce Latent Factor Analysis via Dynamical Systems (LFADS; Sussillo et al. arXiv 2016), a deep learning method to infer latent dynamics from single-trial spiking data. LFADS uses a nonlinear dynamical system to model dynamics underlying observed population activity and to infer "denoised" firing rates for each neuron on a single-trial basis.

We tested the ability of LFADS to denoise single-trial spiking activity in motor cortical data with simultaneously recorded neural populations. In related work (O'Shea et al. SfN 2017) we extend LFADS to combine data from separately recorded populations to improve inference of underlying dynamics.

By denoising the observed spiking activity, LFADS enabled prediction of behavior with new levels of accuracy. We decoded reach kinematics from LFADS-denoised activity, and compared against alternative techniques on a dataset in which monkeys made straight and curved reaches. Denoising using LFADS outperformed smoothing spikes or Gaussian Process Factor Analysis (avg R2=0.91 for LFADS, v. 0.64/0.61 for smoothing/GPFA). We also compared performance as a function of population size and found that LFADS using ~35 neurons outperformed the alternatives applied to the full population of 202 neurons.

Further, LFADS uncovered known dynamic features of motor cortical activity on multiple timescales, e.g., 15-40 Hz LFP (Donoghue et al. J Neurophys 1998), and slow oscillations previously been characterized at the trial average level (Churchland et al. Nature 2012). LFADS revealed consistent dynamics on the single-trial level (~2300 individual trials, 108 reach conditions), and the inferred latent states were predictive of neurons that were held-out from model training (measured by likelihood of held-out neurons' spikes).

Finally, with its dynamical model, LFADS can infer when the observed data deviates from expected dynamics. When applied to M1/PMd data from a task in which unexpected perturbations occur mid-trial, LFADS inferred the presence, type and timing of the perturbations. In sum, LFADS accurately models neural population dynamics on single trials, opening the door to a detailed understanding their role in computation, and ultimately in driving behavior.

Abstract: To gain insight into the relationship between the activity of neurons and their connectivity in neocortical circuits, we are using imaging and computational approaches to coregister neurophysiological and neuroanatomical datasets in the primary visual cortex of the mouse. We use transmission electron microscopy camera array to acquire 3D high-resolution images of mouse V1 to reconstruct brain anatomy at the cellular level. We use two-photon calcium imaging to observe functional activities of neurons in the same area. To correlate brain structures and neuron activities in large scale, we are developing deep learning based approach to co-register EM and functional data. Our method uses a small chunk of manually co-registered EM and functional image as the training set. In the training phase, it takes small pair-wise patches of EM and functional data as input to a deep convolutional neural network (CNN), which outputs 1 or 0, indicating the small patch of EM and functional image match or not. In the testing period, we generated a pool of candidate spatial transformations between EM and functional data. Each transformation brings the two sets of data into the same canonical space, making them comparable. We then generate pair-wise patch samples for each transformation and use the trained CNN to predict whether they belong to class 1 (match) or 0 (non-match). We then selected the transformation that produces the maximum percentage of matched samples as the best registration. Our preliminary result on a small dataset has proved the effectiveness of the method. Like other Allen Institute products, data and tools developed will be made publicly available for the research community.

Title: Deep convolution neural networks and multi-scale inputs better classify suspicious breast masses

Authors: *A. J. LONSBERRY, S. PICKARD, R. QUINN

Mechanical Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: We demonstrate a computational system comprised of deep neural networks that is able to classify suspicious masses in images with 100% accuracy. Breast cancer screening, with mammography being one of the most employed early screening methods, affects millions of women. Although mammography as currently practiced is invaluable, improvements in its accuracy would be beneficial. According to Smith-Bindman et al., America has twice as many callbacks for questionable mammograms when compared to the UK, with 11% of screening mammograms assessed as abnormal. These callbacks result in women receiving further testing, such as invasive biopsies, and result in 3% of reassessed cases being confirmed as cancer (0.3% of total number of mammograms). This more aggressive callbacks was attributed by Smith-Bindman et al. in large part to fear of lawsuits and has resulted in an increase in sensitivity of mammography at the cost of specificity. The work here is poised to 1) increase the specificity of the mammography screening modality while not sacrificing sensitivity and 2) mitigate unnecessary callbacks and biopsies.

Deep learning neural networks have previously been applied to medical imaging diagnostics with good results. Jiao et al. developed a system capable of classifying suspicious masses as malign or benign with 97% accuracy. Our technique is able to perform the same task with 100% accuracy. This is achieved by using a residual network (Res-Net) (He et al.), a type of deep convolution neural network with a specialized structure. Res-Nets use shortcut connections across constitutional layers to mitigate problems with gradients shrinking to near zero or tending to infinity. In our work, we diverge from the common convolution neural network input structure, and rather than input one image at a time, input three images centered on the same location, but with different scales. The multi-scale input provides fine detail of the suspected tumor as well as surrounding tissue.

Title: Bayesian inference about the brain's effective connectivity using intracranial EEG data

Authors: *T. ZHANG, *T. ZHANG Statistics, Univ. of Virginia, Charlottesville, VA

Abstract: We use ordinary differential equations (ODEs) to model the human brain as a continuous time dynamic system consisting of biophysically interacting components, i.e., brain regions. In contrast to existing ODE models for fMRI and EEG data that focus on directional connectivity among only a few brain regions, we propose a high-dimensional ODE model motivated by statistical considerations to explore connectivity among many small brain regions recorded by intracranial EEG (ECoG). The new model is widely applicableto characterize various brain regions' oscillatory activity and their network of connectivity in a cluster structure. We develop a unified Bayesian framework to quantify the inadequacy in the proposed ODE model for the complex brain system, identify clusters and strongly connected brain regions, and map the brain's directional network where each network edge denotes a significant directional effect exerted by one brain region over another. We apply the proposed ODE model and Bayesian method to EGoG data sets, studying the brain network changes over time.

Title: Effects of global signal regression and head movement on connectivity analysis using resting state functional magnetic resonance imaging

Authors: *T. IIDAKA¹, T. KOGATA¹, E. BAGARINAO²

¹Dept. of Physical and Occup. Therapy, Nagoya University, Grad. Sch. of Med., Nagoya, Aichi, Japan; ²Brain and Mind Res. Ctr., Nagoya Univ., Nagoya, Aichi, Japan

Abstract: The functional network within the brain has been investigated with resting state (rs-) connectivity analysis in human participants. Changes in network connectivity in the brain have been reported in patients with neuropsychiatric disorders such as dementia, schizophrenia, and autism. Analysis of rs-connectivity using functional magnetic resonance imaging (fMRI) has been recognized as a powerful tool for developing disease-specific biomarkers. However, data obtained with rs-fMRI are confounded by signals originating from physiological and motionrelated artifacts, which may obscure result significance. To counter these confounding factors, global signal regression (GSR) has been used for data and the motion parameter threshold (MPT) for participants. However, how these methods affect the results of functional connectivity (FC) has never been clarified. In the present study, we systematically investigated the effects of GSR and MPT on FC analysis. Data were extracted from a multicenter database (Autism Brain Image Data Exchange) from five sites (all boys, including patients with autism (ASD) and controls (CTL), mean age: 10.8 years). Participants were selected and divided into three groups as per the manufacturer of the MRI scanner: group-G (General Electric, sites EMC and SDSU), group-P (Philips, site KKI), and group-S (Siemens, sites OHSU and UCLA). The number of participants was 89 in group-G (ASD/CTL, 44/45), 76 in group-P (38/38), and 79 in group-S (45/34). The rsfMRI data were preprocessed using SPM12 and DPARSFA, and signal changes in 90 regions, defined by the standard template, were extracted. The signal time courses were transformed into a 90 \times 90 FC matrix for each participant. The effects of GSR on mean and skewness of FC were tested collectively in ASD and CTL, and within each group. Excessive correlation (greater than 2 SD of the mean), which caused skewness of FC, was compared before and after GSR. Finally, the effects of head motion on the skewness of FC were investigated by excluding participants according to the MPT. The results showed that GSR significantly (p < 0.01) decreased mean FC to zero in both ASD and CTL, and in all groups. The significant (p < 0.05) difference observed in mean FC between ASD and CTL diminished after GSR. GSR significantly (p < 0.05) increased the number of regions with excessive correlation. Finally, the MPT significantly (p < p0.05) decreased the skewness of FC only after GSR application. These results indicate that GSR diminishes differences in FC between ASD and CTL, but does not eliminate excessive correlations. The effect of the MPT is relatively small and there is a tradeoff between data quality and sample size.

Title: Longitudinal graph analysis of functional connectivity of mild cognitive impairment and AD patients

Authors: *G. CASTELLANO¹, S. I. C. GUZMÁN¹, M. WEILER¹, M. L. F. BALTHAZAR² ¹Inst. de Fisica Gleb Wataghin, ²Departmento de Neurologia, Univ. of Campinas - UNICAMP, Campinas, Brazil

Abstract: As a contribution to the longitudinal research of Alzheimer's disease (AD), this study united the capabilities of graph theory and the resting state functional connectivity (RS-fMRI) technique. The main objective was to track changes in the topological configuration of functional connectivity networks of patients with AD and mild cognitive impairment (MCI). The images analyzed were of subjects from the neuropsychology and dementia outpatient clinic of a school-hospital in Brazil, who had two examinations. MR acquisitions were done on a 3T Philips Achieva scanner, while subjects avoided attention demanding activity. The interval between examinations was on average 52 ± 30 weeks. In the first examination there were 15 healthy controls (C) (12 women, 69 ± 6 years old), 22 MCI patients (14 women, 70 ± 6 years old), and 14 AD (9 women, 73 ± 8 years old). For the second examination, three participants changed diagnosis, so there were 14 C (11 women, 70 ± 6 years old), 21 MCI (14 women, 71 ± 6 years old), and 16 AD (10 women, 74 ± 8 years old). Image preprocessing included scrubbing of flagged volumes (Power et al., NeuroImage 105, 2015) besides the usual steps. For the graphs, 264 regions of interest represented the nodes (Power et al., Neuron 72, 2011); while the pairwise Pearson correlation coefficient of the extracted time series represented edges. Graphs were binarized with correlation thresholds. Selected graph metrics and their variance were calculated: degree, characteristic path length, clustering coefficient, and betweenness centrality. Also calculated were the small world coefficient and the local efficiency of 10 selected nodes. Mixed effects linear models were applied with fixed effects for diagnostic group and random intercepts for each individual. Later, education, time between acquisitions and confound variables age and a nuisance movement parameter were also tested. Contrary to similar studies, there were no significant results, only hints for the variance of some

metrics reflecting effects of the progression of the disease. The lack of results may be associated to the methodology for removing artifacts, a lack of statistical power, and the adoption of global metrics.

In conclusion, data from more observations is necessary, as well as improvements during acquisitions, quality control of the images, and the construction of graphs. The preferred metrics and tests should be local and nonparametric.

Title: The local functional connectivity of the seizure onset and peri-seizure onset areas

Authors: *H. P. ZAVERI¹, S. M. PINCUS³, I. I. GONCHAROVA², R. MUNBODH⁴, M. R. ALKAWADRI², J. L. GERRARD², R. B. DUCKROW², L. J. HIRSCH¹, D. D. SPENCER², S. S. SPENCER²

Abstract: Objective. To determine the band-related local functional connectivity (BRLFC) of the seizure onset area (SOA) and the peri-SOA.

Methods. This study was conducted on 18 unselected adult patients with intractable epilepsy undergoing icEEG monitoring for surgery. Intracranial EEG electrode contacts were located from post-implantation CT and MR images and registered to the MRI of a standard brain to allow interpretation of results from all patients in the same space. A 1 hr icEEG epoch, recorded during wake and removed in time from seizure occurrence, was studied. Coherence was estimated for all pairs of electrode contacts ipsilateral to the SOA in delta, theta, alpha, beta, gamma and a high frequency band. The BRLFC of each electrode contact was estimated as the average band-related coherence between it and all electrode contacts within a specified spatial window.

Results. The average BRLFC was significantly non-zero, and there was an inverse relationship between average BRLFC and distance from the SOA primarily in the beta, gamma and high frequency bands. The contacts ipsilateral to the SOA were separated into four sets based on radial distance to the SOA: (1) S: SOA contacts, (2) P: all contacts within 3 cm of the SOA but not including SOA contacts, (3) Q: all contacts from 4 to 7 cm of the SOA, and (4) R: all contacts from 8 to 12 cm of the SOA. The mean BRLFC for all contacts in each of these four

sets was calculated as well as the ratios of the mean values of BRLFC for S, P, Q, and R. The most pronounced significant (p < 0.05) differences in these values were observed between P and R in gamma BRLFC evaluated for a mid-radial distance window.

Conclusions. A graded relationship was observed between BRLFC and distance to the SOA, for specific frequency bands, such that electrode contacts with the greatest connectivity were in the SOA or in the immediate peri-SOA and those with the lowest connectivity were at a distance of several cm from the SOA.

Title: Graph Theory network analysis of functional connectivity in Mild Cognitive Impairment

Authors: *A. V. MEDVEDEV¹, R. S. TURNER²

¹Ctr. for Functional and Mol. Imaging, ²Neurol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Early detection of Alzheimer's disease (AD), which is critical for the effective treatment, calls for new functional biomarkers of the disease. Resting state functional connectivity (rsFC) is promising for the development of such biomarkers because it has been suggested to be able to detect pathological process earlier than cognitive tests. This premise is supported by the existing evidence that rsFC patterns experience significant changes in several neurological and psychiatric disorders (Seeley et al 2009; Cabral et al 2014). Resting state FC has been successfully studied using fMRI but there are serious limitations in its use in the elderly population. Electroencephalography (EEG) has shown promise as a possible new biomarker for AD and Mild Cognitive Impairment (MCI) (Moretti 2015). With the development of more accurate methods for source reconstruction and new software tools, it becomes possible to use scalp EEG to produce interpretable 3D images of the brain (Dubovik et al 2012). We recorded high density EEG signals in seven MCI subjects and seven age-matched healthy participants during the resting state (5 min). Data preprocessing included artifact removal with a special effort to remove myogenic activity using Independent Component Analysis (Olbrich et al 2011). rsFC was measured by imaginary coherence which is insensitive to volume conductance effects (Nolte et al 2004). The time courses of imaginary Fourier coefficients (FieldTrip toolbox, Oostenveld et al 2011) averaged within physiological frequency bands were subjected to source reconstruction using swLORETA (BESA, GmbH, Germany). The time courses of frequencyspecific 3D images were analyzed to derive rsFC maps and the global parameters of rsFC for controls and MCI subjects were analyzed with Graph Theory using CONN software (Whitfield-Gabrieli and Nieto-Castanon 2012).

Second-level analysis revealed significant group differences in Global Efficiency of brain networks within specific frequency bands. Thus, Global Efficiency within the alpha band (10-12 Hz) was significantly lower in MCI subjects especially in the parietal cortex. The network analysis in the beta band (14-28 Hz) revealed significantly lower Global Efficiency in the MCI group especially in the left hemisphere.

These data suggest that high density EEG reinforced by source reconstruction techniques is sensitive to detect the aberrant patterns of connectivity in MCI, a precursor of Alzheimer's disease. Thus, the global parameters of functional connectivity can be used for the development of new biomarkers for early diagnosis of MCI and AD as well as for quantitative assessment of treatments and rehabilitation strategies.
