Abstract: The purinergic P2X2 receptor (P2X2R) is an ATP-gated ion channel widely expressed in the nervous system. Here, we identified a putative Cdk5 phosphorylation site in the full-size variant P2X2aR (^{372}TPKH^{375}), which is absent in the splice variant P2X2bR. We therefore investigated the effects of Cdk5 and its neuronal activator, p35, on P2X2aR function. We found an interaction between P2X2aR and Cdk5/p35 by co-immunofluorescence and co-immunoprecipitation in HEK293 cells. We also found that threonine-phosphorylation was significantly increased in HEK293 cells co-expressing P2X2aR and p35 as compared to cells expressing only P2X2aR. Moreover, P2X2aR-derived peptides encompassing the Cdk5 consensus motif were phosphorylated by Cdk5/p35. Whole-cell patch-clamp recordings indicated a delay in development of use-dependent desensitization (UDD) of P2X2aR but not of P2X2bR in HEK293 cells co-expressing P2X2aR and p35. In *Xenopus* oocytes, P2X2aRs showed a slower UDD than in HEK293 cells and Cdk5-activation prevented this effect. A similar effect was found in P2X2a/3R heteromeric currents in HEK293 cells. The P2X2aR-

T372A mutant was resistant to UDD. In endogenous cells, we observed similar distribution between P2X2R and Cdk5/p35 by co-localization using immunofluorescence in primary culture of nociceptive neurons. Moreover, co-immunoprecipitation experiments showed an interaction between Cdk5 and P2X2R in mouse trigeminal ganglia. Finally, endogenous P2X2aR-mediated currents in PC12 cells, and P2X2/3R mediated increases of intracellular Ca^{2+} in trigeminal neurons were Cdk5-dependent, since inhibition with roscovitine accelerated the desensitization kinetics of these responses. These results indicate that the P2X2aR is a novel target for Cdk5-mediated phosphorylation, which might play important physiological roles including pain signaling.

Title: Intrinsic homeostatic plasticity in mouse and human peripheral nociceptors

Authors: *L. MCILVRIED[1], M. PULLEN-COLON[2], R. W. GEREAU, IV[3]
[1]Anesthesiol., Washington Univ. At St. Louis, Saint Louis, MO; [2]Anesthesiol., Washington Univ. In St Louis, Saint Louis, MO; [3]Anesthesiol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: The nervous system constantly undergoes experience-dependent plasticity. In response to a change in activity from fluctuations in the environment, homeostatic plasticity permits a compensatory shift of intrinsic excitability, allowing a return to a physiological, basal level. Stabilization of neuronal activity is critical for normal nervous system function, and homeostatic plasticity prevents neural circuits from becoming either hyper- or hypoexcitable. However, if this protective plasticity exists, then how does chronic pain develop? Homeostatic plasticity has been primarily studied in the central nervous system, so to first address this question, we recently tested whether this plasticity also occurs in peripheral nociceptors [i.e., small diameter dorsal root ganglia (DRG) neurons]. We hypothesized that mouse and human primary sensory afferents undergo adaptive changes in neuronal excitability due to intrinsic homeostatic plasticity. Using a combination of pharmacologic and optogenetic approaches, we find that chronic depolarization of mouse DRG neurons leads to a decrease in excitability of

small diameter neurons (putative nociceptors) as shown by decreased input resistance, increased rheobase and decreased number of action potentials in response to suprathreshold current injections. These effects rebounded as an increase in excitability with a 24 hour recovery. Preliminary data indicate that human DRGs show similar responses, and therefore also undergo homeostatic plasticity. Our results show that both mouse and human nociceptors are capable of homeostatic regulation of intrinsic excitability in response to sustained, pharmacological depolarization or sustained stimulation of activity. Primary afferent nociceptors are important for the development of pain, and it will be important to determine whether mechanisms of this plasticity are altered during chronic pain.

Abstract: There is a critical need for the establishment, validation and characterisation of human cell-based models in which to study nociceptive processing to aid in the development of novel pain therapeutics. We have therefore developed techniques for the ethical acquisition, culturing and functional analysis of human dorsal root ganglion (DRG) neurons. To date, we have successfully retrieved whole DRGs from organ donors, dissociated and established primary cultures of DRG cells, shipped cultured cells to both national and international consortium member laboratories, and electrophysiologically characterised DRG neurons in culture. Initial immunohistochemical analyses of immersion-fixed free-floating human DRG sections revealed a diversity of sensory neuron subtypes based on expression of NF200, Parvalbumin, CGRP, Somatostatin and substance P, which were each expressed by subsets of cells exhibiting distinct size distributions. Whole-cell patch-clamp recordings (conducted in 3 laboratories; St Andrews,

Metrion and Grunenthal) then demonstrated the functional viability of cultured DRG neurons along with their utility for physiological and pharmacological studies. Current-clamp mode recordings revealed that most DRG neurons generate single (44%) or multiple (28%) action potentials upon injection of square current pulses (n=54 cells). Analysis of action potential parameters revealed average half-widths of 3.6 ± 0.4 ms, and average amplitudes of 58 ± 3.6 mV (n=30 cells). Voltage-clamp mode recordings revealed fast, inactivating sodium currents, that varied in their TTX-sensitivity (21% cells completely TTX-sensitive, 21% completely TTX-resistant, 58% mixed; n=24 cells), transient and persistent voltage-gated potassium currents (23/23 cells), and both high and low voltage-gated calcium currents (10/10 cells). Current responses to the application of specific receptor agonists revealed heterogeneous expression of functional TRPV1 (capsaicin, 27/45 cells), P2X3 receptor (α,β-methyl ATP, 5/16 cells), GABA (GABA, 12/17 cells) and ASICs (low pH, 15/16 cells) receptors in cultured DRG neurons. Taken together, these data demonstrate that a mixed population of sensory neurons, including likely nociceptive afferents, can be successfully cultured from human DRGs and that these cells can be utilised for both electrophysiological and pharmacological studies which will reduce animal use in line with the principles of the 3Rs. This human cell-based model is likely to facilitate advances in our knowledge of the processing of sensory signals by human neurons, and aid in the development and validation of much needed, novel pain therapeutics.

Title: Nociceptor sensitivity in *Drosophila* larvae is controlled by RNA-binding proteins that regulate translation

Authors: K. HOFFMAN, R. STEWART, A. DYSON, *A. C. BELLEMER
Biol., Appalachian State Univ., Boone, NC

Abstract: Nociception refers to detection of noxious mechanical, chemical, or thermal stimuli by specialized somatosensory neurons called nociceptors. Sensitization of these nociceptor neurons in response to tissue damage or inflammation is at the root of many chronic pain syndromes. In *Drosophila melanogaster* larvae, the Class IV multidendritic neurons are activated by noxious thermal, mechanical, and UV stimuli to generate a stereotyped behavioral response termed nocifensive escape locomotion. This behavioral response can be investigated using powerful *Drosophila* genetic methods to identify and characterize the cellular and molecular mechanisms that shape nociceptor sensitivity. We have used a nociceptor-specific RNAi screen approach to identify widespread roles for RNA-binding proteins in regulating the sensitivity of nociceptors to noxious thermal and mechanical stimuli. Many of the genes that were found to produce defects in nocifensive escape locomotion when knocked down have been previously characterized as regulators of translation. Specifically, nociceptor-specific knockdown of multiple eukaryotic initiation factor genes caused insensitivity to noxious thermal and mechanical stimuli, while knockdown of the translational repressor gene, *pumilio*, produced hypersensitivity to noxious thermal and mechanical stimuli. These findings indicate that the regulation of protein synthesis is able to bidirectionally regulate the basal sensitivity of *Drosophila* nociceptors and also suggest the hypothesis that protein synthesis may be regulated during the sensitization of nociceptors in response to tissue damage or inflammation. Ongoing experiments will characterize the cellular mechanisms that translational regulators use to shape nociceptor function and also identify the molecular targets subject to translational regulation.

Title: A core signaling mechanism at the origin of animal nociception

Authors: E. E. ZAHARIEVA[1], O. M. ARENAS SABOGAL[2], C. VÁSQUEZ-DOORMAN[3], A. PARA[2], C. P. PETERSEN[3], *M. GALLIO[2]

Abstract: All animals must detect noxious stimuli to initiate protective behaviors, but the evolutionary origin of nociceptive systems is not well understood. Here, we show that a remarkably conserved signaling mechanism mediates the detection of noxious stimuli in animals as diverse as flatworms and humans. Planarian flatworms are amongst the simplest bilateral animals with a centralized nervous system, and capable of directed behavior. We demonstrate that noxious heat and irritant chemicals elicit robust escape behaviors in the planarian *Schmidtea mediterranea*, and that the conserved ion channel TRPA1 is required in peripheral neurons for these responses. TRPA1 mutant fruit flies (*Drosophila*) are also defective in the avoidance of noxious heat. Unexpectedly, we find that either planarian, or human TRPA1 can restore noxious heat avoidance to TRPA1 mutant *Drosophila*, despite the fact that neither is directly activated by heat - instead, a conserved cellular and molecular mechanism for channel activation is at the core of this remarkable across-phylum rescue. Together, our data reveal a core function for TRPA1 in signal transduction, demonstrate its conservation from planarians to humans, and imply that human nociceptive systems may share a common ancestry with those of most extant animals, tracing back their origin to a progenitor that lived more than 500 million years ago.

Title: The relationship between noxious stimuli, behavioral responses and pain perception in chronic pain patients

Authors: *H. B. HEITMANN[1], E. S. MAY[1], L. TIEMANN[1], P. SCHMIDT[1], S. TA DINH[1], M. M. NICKEL[1], T. R. TÖLLE[2], M. PLONER[1]

Abstract: Pain serves vital protective functions, which crucially depend on appropriate behavioral responses to noxious stimuli. However, pain has mostly been conceptualized as a perceptual phenomenon. Recent findings support a more action-oriented concept by showing that behavioral responses to noxious stimuli significantly shape the perception of pain in healthy human subjects. In chronic pain, perception is often decoupled from noxious input and behavioral responses are no longer protective but often unsuccessful or even maladaptive, suggesting fundamental changes of stimulus-perception-behavior relationships in chronic pain. However, direct and quantifiable evidence for these interrelations and their potential changes in chronic pain is lacking. We therefore applied a simple behavioral paradigm to investigate such relationships in 22 chronic pain patients and 22 age-matched healthy control subjects. Patients and controls performed speeded behavioral reactions and provided perceptual ratings of brief noxious and tactile stimuli to their right hand. As expected, intensity ratings increased and reaction times decreased with increasing stimulus intensity for both stimulus types in both patients and controls. In both groups, multi-level moderated mediation analyses revealed a significantly stronger involvement of behavioral responses in the translation of noxious stimuli into perception than in the translation of tactile stimuli. These results confirm previous findings and extend them to an older age group, providing further evidence for an action-oriented concept of pain. Moreover, we found that the mediation effect of behavioral responses in the stimulus-perception relationship was higher in chronic pain patients than in healthy controls, hinting at an even stronger role of behavioral responses for perception in chronic pain. Additional analyses will relate these findings to personality traits and disease-related parameters. This approach promises quantifiable insights into the relationships between noxious stimuli, behavior and pain perception that appear to be fundamentally altered in chronic pain. Eventually, a better

understanding of these complex interrelations might contribute to the development of new treatment strategies in chronic pain.

Title: Prefrontal gamma oscillations encode spontaneous fluctuations of chronic back pain intensity

Authors: *E. S. MAY[1], M. M. NICKEL[1], S. TA DINH[1], L. TIEMANN[1], H. HEITMANN[1], I. VOTH[2], T. R. TÖLLE[2], J. GROSS[3], M. PLONER[1]
[1]Dept. of Neurol. and TUM-Neuroimaging Ctr., [2]Dept. of Neurol., Technische Univ. München, Muenchen, Germany; [3]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Chronic pain is a major health care issue, whose neural basis is still incompletely understood. Previous work using functional magnetic resonance imaging has implicated the medial prefrontal cortex in chronic back pain, which has been associated with negative emotions and the affective value of sensory stimuli. In addition, studies using electroencephalography (EEG) revealed a role of prefrontal gamma oscillations in the encoding of the subjective intensity of tonic experimental pain in healthy subjects. However, the role of such higher frequency oscillatory brain activity in chronic pain has not yet been studied. In the current study, we asked 27 chronic back pain patients to continuously monitor and rate their current pain intensity while simultaneously recording EEG. In line with previous studies, behavioral data showed fluctuations of pain intensity within 10 minutes of recording. Time-frequency analyses of brain activity and cluster-based permutation statistics showed a positive relation between current pain intensity and the amplitude of prefrontal gamma oscillations (30-100 Hz, $p = 0.002$), but no associations between pain intensity and brain activity in theta (4-7 Hz), alpha (8-13 Hz) or beta (14-29 Hz) frequency bands. This relation was not present in a visual control condition controlling for sensory, motor and attentional components of the continuous pain rating procedure. These results indicate that chronic back pain intensity is encoded by prefrontal

gamma oscillations, revealing a potential frequency and spatially specific functional brain marker of chronic pain intensity. This finding extends previous work in healthy subjects, which showed that prefrontal gamma oscillations encode the subjective intensity of tonic experimental pain, while the objective stimulus intensity is reflected in sensorimotor alpha and beta oscillations. Thus, the current results are in line with a detachment of the neural processes underlying chronic pain from early sensory processes and a shift towards emotional-evaluative neural circuits.

Abstract: Chronic pain is a major healthcare issue whose causes are not fully understood and whose treatment is often unsatisfactory. Recent evidence has shown that the brain plays an important role in the development and maintenance of chronic pain. Magnetic resonance imaging has shown structural and functional changes in the brains of chronic pain patients at rest in different brain networks at frequencies below 0.1 Hz. Whether changes of brain networks also occur at higher frequencies assessed by electrophysiological recordings has remained largely unknown. We have recorded electroencephalography (EEG) during restful wakefulness in 20 chronic pain patients suffering from Fibromyalgia and 22 matched healthy controls. In accordance with previous findings, we observed a trend towards increased frontal brain activity at theta (4 - 8 Hz) frequencies in chronic pain patients. To assess potential changes of brain activity at the network level, we have performed graph theory-based network analyses of EEG

data at theta (4 - 8 Hz), alpha (8 - 13 Hz), beta (14 - 30 Hz) and gamma (60 - 100 Hz) frequencies. Specifically, we investigated the following graph measures: degree centrality, clustering coefficient, global efficiency, small-worldness, modularity and the global hub disruption index. Network analyses based on functional connectivity measured by the debiased weighted phase lag index were evaluated using permutation statistics and did not differ significantly between groups, neither at electrode nor source level. These results will be complemented by an extension of the analyses to a larger cohort of 100 chronic pain patients with respective controls and the amplitude envelope correlation as an additional measure of functional connectivity. As chronic pain affects many domains of sensory, cognitive and affective functioning we expect to find changes on a global network scale. These analyses promise to further the understanding of the brain mechanisms of chronic pain and could help to define brain- based biological markers of pain assessed by portable and affordable devices.

Title: Pain modulation; when expectations become the perception to maintain the status quo

Authors: M. LIM[1], A. MCINTYRE[2], C. O'GRADY[3], M. LYNCH[4], S. MATWIN[5], S. BEYEA[5], *J. A. HASHMI[4]
[1]Anesthesia, Pain Mgmt. and Perioperative Med., [2]Fac. of Computer Sci., [3]Physics and Atmospheric Sci., [4]Anesthesia, Pain Mangement and Perioperative Med., [5]Dalhousie Univ., Halifax, NS, Canada

Abstract: It is known that expectations induced with top-down visual cues can alter perceived pain intensity. Expectations are mental representations of internal models of our external realities. The internal model guides how new sensory inputs will be organized and interpreted

during the perceptual process. However, it is unclear how sensory decisions and brain activity map deviations in the associative rule that links top-down cues with bottom-up stimuli.
We hypothesized that learning a linear associative rule between cue and stimulus is preserved even when bottom-up stimulus intensity is altered and when top-down information in cues is missing.
16 healthy participants (8 women) were trained with probabilistic cues (0-100) that were linearly related with 10 incrementing heat stimulus intensities in a randomized order. The linear association between cue and stimulus was tested by inverting cue-stimulus association in events representing three conditions (A-C). A. values from a low cue range (0-40) and a high cue range (60-100) were coupled with a single low (45°) or high (47°) stimulus intensity respectively. B. values from a low cue range were coupled with a high stimulus intensity and C. top-down information in cue was absent and bottom-up stimuli were held at high or low intensity.
As hypothesized, pain ratings showed a linear relation with cues even when the stimulus intensity was held at two levels (condition A; $P < 0.007$). In condition B. pain was evaluated as significantly less painful ($P < 0.001$) when the high stimulus was coupled with cues selected from a low range versus a high range. In condition C. the evaluation of low and high stimuli in the absence of top-down cues was not significantly different ($P = 0.062$) from evaluations of these stimuli observed during the training phase. Neural responses mirrored the pattern of pain responses in conditions A and B. showing a linear relationship between cues and brain activations ($p<0.05$ corrected) with peak effects in dorsal ACC and right anterior insula.
Our findings demonstrate that pain is modulated by expectations that result from an internal model established through learning associative rules. Thus, even when bottom-up sensory inputs are significantly modified, the perceived pain is modulated to fit with the rules established in the internal model. The results offer new insights on the subjective nature of pain and show a bias in pain perception towards top-down information and past experiences.

Title: Brain networks of tonic experimental pain assessed by EEG

Authors: *M. M. NICKEL, S. TA DINH, E. S. MAY, L. TIEMANN, M. POSTORINO, M. PLONER
Dept. of Neurol. and TUM-Neuroimaging Ctr., Technische Univ. München, Muenchen, Germany

Abstract: Pain is a complex phenomenon which results from the integration of sensory and a broad variety of contextual processes. In the brain, the complexity of pain is reflected by activations of an extended network of brain areas displaying oscillations and synchrony at different frequencies. However, brain networks of pain have mostly been investigated in relation to brief experimental pain stimuli whereas the main clinical problem of chronic pain is characterized by longer-lasting pain. We have therefore recorded electroencephalography (EEG) during 10 minutes of tonic heat pain applied to the left and right hand in 39 healthy volunteers. To assess tonic pain-related brain activity at the network level, we performed graph theory-based network analyses of EEG data at theta (4-8 Hz), alpha (8-13 Hz), beta (14-30 Hz) and gamma (60-100 Hz) frequencies. Networks were constructed based on functional connectivity measured by the debiased weighted phase lag index on electrode level. The network measures degree centrality, clustering coefficient, global efficiency and small-worldness were compared between the tonic pain and a control condition using permutation statistics. We observed trends towards decreased small-worldness at alpha and gamma frequencies and a decreased global clustering coefficient at gamma frequencies during tonic pain. Additionally, in tonic pain conditions, a trend towards a local decrease in degree centrality was found at fronto-central electrodes at theta frequencies, which was consistent across the two hands. Thus, first analyses hinted at both global and local alterations of the functional network structure during the perception of tonic pain. These results will be extended by source level analyses and the application of complementary measures of functional connectivity, e.g. the amplitude envelope correlation. The analyses will broaden the understanding of the brain mechanisms of pain to the network representation of longer-lasting pain as a hallmark of chronic pain syndromes.

Title: Neurophysiological mediators of the perceptual, autonomic and behavioral components of pain

Authors: L. TIEMANN, V. D. HOHN, E. S. MAY, M. M. NICKEL, S. TA DINH, *M. PLONER
Neurol., TU Muenchen, Munich, Germany

Abstract: Pain is a complex phenomenon which translates sensory information into perception and autonomic and behavioral responses in order to protect the physical integrity of the individual. In the brain, the complexity of pain is reflected by patterns of pain-associated neural activity in different brain areas and at different latencies and frequencies. However, whether and how these different brain responses differentially contribute to the perceptual, autonomic and behavioral components of pain has remained largely unknown yet. In the current electroencephalography (EEG) experiment, we addressed this question by examining the neurophysiological responses evoked by noxious cutaneous laser stimuli of different intensities and relating them to perceptual (pain rating), behavioral (reaction time) and autonomic (skin conductance) pain responses recorded in 51 healthy subjects. Data were analyzed by means of multi-level mediation analysis which provides a unique opportunity to quantify the degree to which the relationship between objective stimulus intensity (independent variable) and subjective rating, reaction times or skin conductance (dependent variables) can be explained by different types of brain activity (mediators). The results show that the N1, N2 and P2 components of the well-known pain-evoked potential as well as activity in the theta frequency band (4-7 Hz) significantly mediated the effect of stimulus intensity on both pain ratings and reaction times. In contrast, responses at gamma frequencies (70-90 Hz) significantly mediated the effect of stimulus intensity on reaction times only, indicating a dissociation between the neurophysiological processes underlying the perceptual and behavioral components of pain. The neural mediators of skin conductance responses are currently being investigated. These results show how the present approach can comprehensively characterize the neurophysiological processes underlying the translation of noxious stimuli into the different components of pain. Beyond, the experiment showcases a novel approach to further the understanding of the functional significance of pain-associated EEG responses in health and disease.

Abstract: Despite evidence for structural and functional brain changes in chronic low back pain (cLBP) patients, the relation of these changes to the perception of clinical pain is still not clear. We previously investigated the role of primary somatosensory cortex (S1) functional connectivity (Kim et al. A&R 2015) in the brain processing of clinical pain and hyperalgesia in patients with chronic pain. In this study, we investigated functional connectivity between S1 and brain regions within the Salience Network, and how it is related to clinical pain processing within a large cohort of cLBP patients. BOLD fMRI data from 133 cLBP patients (age=40.3±11.8 yo, 73 F) and 54 healthy controls (HC, age=40.4±11.0 yo, 30 F) were used for resting connectivity analyses (Siemens 3T, TR=3s, 120 volumes). For cLBP, resting fMRI data were collected before and after individually-tailored low back pain exacerbation maneuvers (e.g. sit-ups, toe-touching, and twisting). Additionally, event-related fMRI runs with intermittent painful electrical stimulation applied to low back were used to localize the S1 subregion of the low back for seed definition. Clinical back pain in cLBP was significantly increased after pain exacerbation (34.0±21.9 vs. 55.2±23.0, $p<0.001$). Compared to HC, patients exhibited increased connectivity between salience network and a S1 cluster overlapping the low back representation (as determined by the experimental electrical pain fMRI data). Connectivity was increased relative to HC for cLBP both before and after clinical pain exacerbation. In turn, S1-seed based connectivity was increased to insula cortex and thalamus, compared to HC. Within the cLBP, clinical maneuvers increased S1 connectivity to the temporoparietal junction, dorsolateral prefrontal cortex and bilateral thalamus. Furthermore, a whole-brain linear regression analysis found that increased S1 connectivity to anterior insula, thalamus and midbrain was correlated with increasing clinical pain, closely linking back representation S1-specific connectivity with clinical pain perception. Our results of cLBP patients suggest that increased functional connectivity between the S1 representation of the low back and salience processing regions such as anterior insula as well as thalamus encodes clinical pain perception. Determination of the neural correlates of clinical pain has been elusive so far, and functional connectivity between body region-specific somatosensory and salience processing brain areas may serve as a key neurophysiological substrate for emergent clinical pain in chronic pain patients.

Title: Brush allodynia and mechanical hyperalgesia: Predictors and associations

Authors: Y. LIU[1,2], M. L. KEASER[1], A.-C. SCHMID[3], T. J. MEEKER[1], S. G. DORSEY[4], D. A. SEMINOWICZ[1], *J. D. GREENSPAN[1]

(EPFL), Geneva, Switzerland; [4]Dept Pain and Translational Symptom Sci., Univ. Maryland Sch. of Nursing, Baltimore, MD

Abstract: Introduction: Brush allodynia (BA) often, but variably occurs in many chronic neuropathic pain conditions. What leads to the development of BA in any given individual is unknown. Secondarily, it is not clear how strongly BA is related to mechanical hyperalgesia. The goal of this study was to determine: 1) what factors are associated with capsaicin-induced BA and mechanical hyperalgesia susceptibility, and 2) the extent to which a sensitizing provocation separately engages hyperalgesia and allodynia. **Methods**: Fifty-four healthy participants (24F) between 18-43 years (27.7±6.0) were evaluated before and after exposure to a sensitizing capsaicin-heat pain model (C-HP). The model consisted of topical application of 10% capsaicin cream, accompanied by a heat stimulus for 35 minutes provoking a moderate level of pain. Sensory testing included warmth detection thresholds (WDT), heat pain thresholds (HPT), and Mechanical Pain Ratings (MPR) of sharp probes of various intensities. Additionally, the following questionnaires were administered: Pain Sensitivity Questionnaire (PSQ), Beck Depression Inventory (BDI); State-trait anxiety (STAI), and the PILL to measure somatic awareness. **Results**: Predictors of brush allodynia: Lower WDT and HPT; higher ratings of punctate pain at low levels of stimulation (near threshold). Predictors of mechanical hyperalgesia: 1) *Hyperalgesia to lower intensity stimuli*: Lower HPT; higher ratings to all levels of punctate probe stimulation; higher scores on PSQ. 2) *Hyperalgesia to higher intensity stimuli*: higher scores on psychological measures of depression, anxiety, and somatic awareness. Associations between allodynia and mechanical hyperalgesia: Those with allodynia showed greater hyperalgesia than those without allodynia, most strongly at the first post-exposure time

point. In contrast, the area of allodynia did not correlate with the area of hyperalgesia at any time point. **Conclusions**: Greater sensitivity to heat and punctate mechanical stimuli near pain threshold significantly separated the BA susceptible from those not developing BA with the C-HP model. Greater baseline sensory sensitivity to painful stimuli predicted greater mechanical hyperalgesia for lower intensity stimuli, but not for higher intensity stimuli. Instead, psychological factors, rather than sensory sensitivity, were predictive of mechanical hyperalgesia at stronger levels of stimulation. These data suggest that factors driving sensitization-induced mechanical hyperalgesia differ at lower vs. higher stimulation levels, and only the former have overlap with allodynic factors.

Title: Functional diffusion tensor imaging (fDTI) of the human spinal cord during painful thermal stimulation

Authors: *S. C. MUELLER, J. C. LIN, J. W. YOUNGER
Psychology, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Introduction: The experience of pain involves both ascending nociceptive signals and descending inhibitory controls, both travelling through the spinal cord. These processes are difficult to measure in living humans, in part because non-invasive methods for imaging long axon activity are lacking. We are developing a modification of diffusion tensor imaging (DTI) for the measurement of task-related changes in axon activity via slow changes in spinal cord diffusion (fractional anisotropy; FA). We are first applying this technique to measuring spinal cord activity changes to pain stimuli. The tract of interest was the afferent spino-thalamic tract (STT), which is involved in relaying peripheral pain signals to the brain. We expected increases in mean FA after onset of the pain stimulus in the STT contralateral to stimulation, indicating increased spinal transmission of nociceptive messages.
Materials & Methods: We acquired structural (T2-weighted) and functional (diffusion weighted) images of spinal cords in 19 healthy males during a pain stimulation task. Participants received 4 blocks of the following: 5 minutes of baseline, 1 minute of thermal stimulus to the thenar eminence of the left hand (dermatome C6), and 4 minutes of recovery. Diffusion data was

registered to the T2-weighted image, and FA values from tracts of interest extracted. Generalized Estimating Equations (GEEs) were used to contrast baseline activity to 3 minutes post-pain-onset across the 4 blocks. GEEs were constructed for each tract of interest (STT ipsilateral and contralateral to the noxious stimulus). Activity was also tested above and below the C6 dermatome insertion point.
Results: GEEs indicated significant task-related decreases in FA in the contralateral STT. The task-related change required approximately 1 minute to peak, and 2 minutes to return to baseline. Changes were observed at spinal levels above the peripheral insertion point (C6), while activity below C6 remained stable.
Conclusion: FA values indicate the degree to which water diffusion in the spinal cord is restricted to one direction. A decrease suggests less restricted diffusion in the contralateral STT during painful stimulation, which may be due to morphological changes of glial cells. Notably, the task-related activity operated in a timescale (3 minutes) much different than that of blood-oxygen dependent (BOLD) measures (a few seconds). With further development, this technique may allow researchers to investigate normal and pathological pain transmission in the spinal cord.

Title: How'd you do? The impact of openness during competition on perceived pain in women

Authors: *A. B. SIMMONS, C. DE GUZMAN, J. J. SOLIS, J. R. VILLATORO, J. BOYETTE-DAVIS
Behavioral Neurosci., St. Edward's Univ., Austin, TX

Abstract: There are various influences on pain perception in women, including personality traits. Previous research has found that neuroticism and openness to experience are positively correlated with pain, but this did not account for levels of sex hormones, an important factor in pain perception in women. The current study investigated the impact of personality and testosterone levels in women experiencing a painful stimulus. Pain was induced in participants (n=22 women) using the cold pressor test (CPT) wherein participants placed their hand in water that was maintained at 2^0 C and rated the amount of pain perceived using a visual analog scale (VAS). Tolerance was captured as the amount of time participants kept their hand in the water. To further examine the influence of testosterone, half of the participants were led to believe that others exposed to the CPT were able to withstand the CPT-induced pain for the duration of the

test session; the other half were not provided with any such information, thereby creating competition and no-competition groups. The results indicated that when competition was present, participant VAS was significantly negatively correlated to the amount of time spent in the CPT (r= -.64, p= .03). Further, those scoring higher in openness spent more time in the CPT (r=.69, p=.04). These results were not found in the no-competition group. These data indicate that higher levels of openness when in a competitive environment increase pain tolerance, possibly in relation to changes in testosterone, clarifying previous research investigating personality traits in female pain perception.

Title: Physical pain enhances reward-related brain activation in medial prefrontal cortex

Authors: *C. WANG, J. GAO, X.-W. DONG
East China Normal Univ., Shanghai City, China

Abstract: Pain modulates motivation and motivation-related brain activities. For example, individuals in physical pain are motivated to escape from aversive states. However, it is unclear about the mechanism of how pain modulates motivation in humans. Animal studies indicate that the disturbed reward neural circuitry by chronic pain may responsible for motivation change. By using fMRI technology, the present study aimed to investigate the modulation of physical pain on brain activities in the reward neural circuitry. A total of 60 healthy university students were recruited and then were treated with either Capzasin (pain group) or hand cream (control group). During brain imaging, they played a card guess game in which they would receive monetary gain by a correct guess or monetary loss by an incorrect guess. Results showed that, the medial prefrontal cortex (MPFC) and bilateral nucleus accumbens (NAcc) were activated when individuals won during the card guess game in both groups (Fig. a). Interestingly, individuals in the physical pain group relative to those in the control group showed greater activation in the MPFC in the win condition (Fig. b), indicating that physical pain may increase the expectation of monetary reward. The MPFC-NAcc connectivity was reduced by physical pain (Fig. c). Moreover, individuals in pain group possessed a positive estimation of their performance (Fig. d) and such positive bias was correlated with subjective rating of pain intensity (Fig. e). Our

findings suggest that physical acute pain may increase reward-related MPFC activation and such facilitation of brain activity might be associated with a high expectation of reward and a positive bias of performance estimation. The study provides a potential mechanism of how pain modulates motivation, and sheds light on the consequences of pain on human cognition and behavior.

Title: Hippocampal subfield volumes remain time invariant in chronic pain and transition to chronic pain

Authors: *T. B. ABDULLAH, A. T. BARIA, L. HUANG, A. V. APKARIAN
Physiol., Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL

Abstract: The hippocampal formation is a complex, heterogeneous, structure which can be segregated into functional units along its longitudinal axis. The growing consensus asserts that the dorsal/posterio r component is associated with cognitive processes, while the ventral/anterior hippocampus is associated with emotional and stress related functions. Here we aimed to determine how the volume and functional connectivity of hippocampus subcomponents along the anteroposterior axis, as well as, along the neuroanatomical divisions of the hippocampal formation relate to different kinds of clinical pain. We collected T1 images and resting-state fMRI from 23 healthy controls, 22 chronic low back pain patients, 37 sub-acute persisting and 27 sub-acute recovering low back pain patients across 4 time points over a one-year period. We extracted whole hippocampal and subfield volumes using automated segmentation tools in FreeSurfer. All structural volumes were corrected for whole brain volume excluding ventricles. Functional images were motion corrected with ICA-AROMA and bandpass-filtered at 0.01 - 0.08 Hz. Functional connectivity was performed only in healthy controls, using a seed-based analysis with four regions of interests (ROIs) in bilateral anterior and poster hippocampi (antHC and postHC). Seeds were uniquely determined for each subject by FreeSurfer anatomical parcellation, and average time series from these regions were fit to all voxels in the brain (excluding hippocampal voxels) using a general linear model to generate functional connectivity maps. A two-way repeated measure ANOVA on subfield volume for time and pain-type yielded a significant time effect only in the right CA1-CA3 area ($F_{(3,315)} = 3.84$, $p < 0.01$), showing a general decrease in volume over one year which was not specific to any pain type. There was no significant condition-time interaction. Connectivity differences between ant/post HC indicated stronger antHC connectivity to ipsilateral parahippocamapl gyri, and stronger postHC to posterior cingulate cortex, precuneus, and visual cortices. Overall, our results indicate changes in hippocampal volumes are not implicated in transition or maintenance of chronic pain. Additionally, there is distinct functional differentiation of the antHC and postHC. How this differential hippocampal connectivity manifests in pain will be addressed. Title: Integration of bilateral nociceptive signals: When more is less

Authors: *S. NORTHON, *S. NORTHON, N. RUSTAMOV, S. BOIS, S. SCHREIBER, M. PICHE
Dept. de Chiropratique, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Integration of multiple concurrent somatosensory signals is an essential process to promote adapted behaviors in response to multiple stimuli from the environment. For instance, tactile inputs on fingers of both hands are integrated at early stages of sensory processing (response suppression, as measured with magnetoencephalography), which may promote coordinated bimanual tasks. To gain insight into cortical processing and integration of concurrent nociceptive signals, laser heat stimuli can be used to recruit nociceptors selectively. The most common measure of laser-evoked potentials (LEPs), namely the N2-P2, reflects activity in multiple brain regions involved in the central processing of nociceptive inputs. The aim of the present study was to examine the integration of bilateral nociceptive signals. Nineteen healthy right-handed participants (9 F, age: 25 ± 4) were recruited. Nociceptive stimuli were produced by a Nd :YAP laser system. Cortical activity was recorded with a 64-channel EEG system. Four counterbalanced blocks (20 trials each, 6 s inter-stimulus interval) were performed, during which stimuli were applied to the right or left hand or to both hands concurrently with attention to the right or left. The N2-P2 was measured at the vertex (Cz) and its amplitude was compared between the 4 blocks. N2P2 amplitude was not significantly different between the unilateral right vs left condition ($p=0.6$) and between the bilateral conditions with attention to the right or left ($p=0.22$). Also, the N2-P2 amplitude was decreased in bilateral conditions (attention to right or left) compared with their respective unilateral condition, (right: $p<0.001$; left: $p=0.013$). These results are consistent with a previous study on tactile integration and indicate that integration of concurrent bilateral nociceptive signals in the central nervous system is reflected by reduced N2P2 amplitude. This effect was not affected by spatial attention and may reflect a relative decrease of saliency for each stimulus.

Title: Pain sensation and thermal pain-evoked fMRI activity changes in chronic low back pain patients

Authors: *Q. YANG[1], L.-X. YANG[1,2], Y.-H. XU[1,2], L. CHEN[1,3,4]
[1]Shanghai Clin. Res. Ctr., Shanghai Inst. for Biol. Sciences, CAS, Shanghai, China; [2]Xuhui Central Hosp., Shanghai, China; [3]Dept. of Radiology and Radiological Sci., [4]Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstract: This study aims to characterize psychophysical measures of heat pain changes in chronic low back pain patients (CLBP); and to investigate CLBP's brain activities responded to thermal pain.

Methods

We recruited 101 CLBP and 100 healthy controls (CON) with their written informed consents. Each participant went through a psychophysical test prior to MRI scans. Participants reported their pain levels (numeric scale 0-10) from mild, moderate, to severe while ramping temperatures (baseline=32°C; ascending rate=0.5°C/s; 3 repeats) were delivered to their lower back skin with an ATS thermode (Medoc PATHWAY). Participants were scanned in a 3-T Siemens MRI system with a 32-channel head coil. T2*-weighted fMRI were acquired (EPI; TR = 2 s, voxel size = 3×3×5 mm^3, duration = 10 mins). During this scan, thermal stimuli (Fig. A; temperature = 43, 46 and 47°C; durations 8-23 s) were applied to the back of participants. Participants rated their pain with a finger-span device and a visual feedback.

Participants owned more than three white matter lesions (diagnosed by two radiologists), or had inadequate real-time pain rating (correlation < 0.55; Fig. B) were excluded. Finally, 53 pairs of CLBP (age = 53.4 ± 9.8 years; mean pain history = 5.3 years) and age-/gender-matched CON were included. Statistics of psychophysical tests were examined in MATLAB. Thermal stimulus-evoked fMRI changes between CLBP and CON were compared (SPM 8).

Results

Psychophysical analysis showed that CLBP reported significantly lower temperature for severe pain ($p < 0.01$, Fig. C) than CON. Additionally, the examination of temperature-rating for severe pain revealed that CLBP tended to rate higher for the lower temperature (dotted lines, Fig. D). Compared to CON, 10 brain areas in the CLBP exhibited significantly higher fMRI signals (Fig. E), including e.g. left insular (1), left orbitofrontal (2) bilateral cingulate (5, 6) and dorsolateral prefrontal (4, 8) cortex.

Conclusions

CLBP showed altered pain sensitivities for severe heat pain. CLBP had widespread changes in fMRI detected in pain-, memory- and cognition-related regions.

Title: An fMRI analysis of peripheral neuropathy pain before and after treatment with transcutaneous electrical nerve stimulation

Authors: *T. BODILY[1], J. PEACOCK[1], D. BUSATH[2], B. KIRWAN[3]
[2]PdBio, [3]Psychology, [1]Brigham Young Univ., Provo, UT

Abstract: Chronic pain is a widespread and costly pathology. Treatment regimens are typically only marginally successful in the long-term, especially when pain etiology is neuropathic. Transcutaneous electrical nerve stimulation (TENS) has been shown to be effective as an analgesic for some acute and musculoskeletal chronic pain conditions, but evidence regarding TENS efficacy in treating chronic neuropathic pain is unclear. The neural signature of chronic pain, thought to be localized largely in emotional and affective brain regions, is not well characterized for many chronic pain conditions, including peripheral neuropathy. Accordingly, we performed a treatment trial of two TENS protocols in subjects with peripheral neuropathies with pre- and post-treatment functional MRI scans.

Eighteen subjects were recruited from a pool of interested candidates by screening for compatible medication history, a minimum average pain level of 4/10, and a report of peripheral neuropathy symptoms. Subjects were randomly assigned to either of the two TENS treatment protocols and were given one thirty-minute treatment session. A double blind of therapist and subject awareness of treatment protocol was maintained throughout the duration of the study. Participants underwent three MRI scanning sessions--one immediately before the treatment, one immediately after, and one on the following day. Scan sessions included both structural and resting state fMRI. After removal of the blind, participants from one of the TENS protocols were invited to return for a crossover treatment with an MRI scan sequence parallel to the first treatment.

Both groups reported lower pain immediately after treatment, and pain levels in both groups returned to baseline by the following day. The crossover subjects did not experience a greater pain reduction from either treatment. Graph theoretical analysis of the resting state fMRI data revealed a decrease in global network efficiency across all subjects from pre- to post-treatment scans at liberal binarizing thresholds that returned to pre-scan levels on the following day. This decrease in network efficiency after treatment could have implications for understanding analgesic mechanisms and the effects of chronic pain on brain function.

Title: Decreased resting state network of fibromyalgia in theta band using graph filtration based on persistent homology

Authors: ***J. KIM**, M. CHOE, M. LIM, C. CHUNG
Seoul Nat Univ., Seoul, Korea, Republic of

Abstract: Fibromyalgia (FM), chronic widespread pain, exhibits spontaneous pain without external stimuli and is associated with alteration in intrinsic brain networks at rest. To understand the topological features of brain network in FM, we employed persistent homology which is a multiple scale network modeling framework without thresholding. Magnetoencephalography (MEG) activity was recorded in 19 healthy controls (HCs) and 18 FM patients at rest. The network features such as barcode, single linkage dendrogram and single linkage matrix were generated based on the proposed modeling framework in theta, alpha, beta, and gamma frequency. In theta band, the slope of decrease in barcodes showed steeper in HC, suggesting FM patients had decreased global connectivity. FM patients had reduced connectivity within default mode network, between middle temporal lobule and visual area, and between inferior temporal gyrus and cuneus in theta frequency. The longer pain duration was correlated with reduced connectivity between middle temporal lobule and visual cortex and between inferior temporal gyrus and visual cortex. Our results provided decreased intrinsic connectivity within default mode network and sensory network of FM patients in theta band. Our findings demonstrated that the aberrant resting state network would be associated with cognitive dysfunction and disrupted sensory processing without sensory stimuli in chronic pain. The persistent pain of FM may contribute to disruption of functional connectivity during resting state.

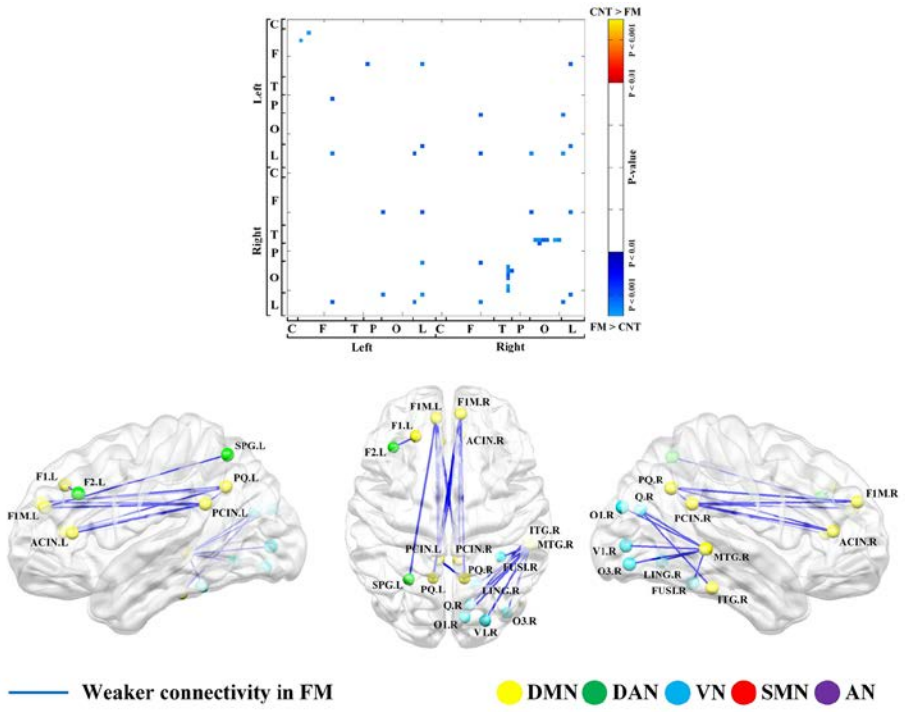

Figure 1. Local network properties based on persistent homology in theta band. Comparison of single linkage matrix (SLM) between fibromyalgia (FM) patients and healthy controls (HCs) (*upper*). Difference in the resting state network between FM and HC ($p < 0.001$) (*lower*).

Abstract: Prediction of pain states using brain imaging markers has been mostly limited to evoked experimental stimuli in healthy controls. Fewer efforts have been made towards the identification of brain-based predictive markers of different states in clinical pain. Chronic Low Back Pain (CLBP) is a good target to examine different states of clinical pain as back pain can be exacerbated by performing various physical maneuvers which evoke patients' clinical pain. In two independent studies with CLBP patients (total N=90), we used Arterial Spin Labeling (PCASL, 6 minutes, TR/TE=3800/15 ms, label duration=1500 ms, post label delay=1200 ms, at 3T) to characterize Regional Cerebral Blood Flow (RCBF) before and after a clinical back pain exacerbation procedure through painful maneuvers (Wasan, Loggia, et al., 2011). PCASL images were preprocessed as follows: motion correction, skull-stripping, tag-control subtraction, RCBF estimation in absolute values (mm/100 g of tissue/min), registration to T1 image, whole-brain RCBF normalization, non-linear transformation to common space (MNI152), and further spatial smoothing (FWHM=8 mm). Maneuvers successfully increased back pain intensity (pre-maneuver=29.4, SD=20.6, post- maneuver=50.5, SD=20.7, $p<0.0001$, on a 0-100 scale). Univariate GLM analysis (combined usable data from studies 1 & 2, N=78) showed that painful maneuvers increased RCBF in the thalamus, putamen, caudate, amygdala, hippocampus, posterior cingulate, supplementary motor area (SMA), preSMA, medial prefrontal (MPFC), pregenual anterior cingulate, inferior frontal gyrus (IFG) and ventrolateral prefrontal (VLPFC) (cluster-corrected, $Z=2.3$, $P<0.05$). Furthermore, in study 1 (N=55, training set), multivariate classification analysis (support vector machine with linear kernel) was applied to discriminate the low-pain (pre-maneuver) and high- pain (post-maneuver) state from RCBF data. Significant positive classifier weights were found in the thalamus, putamen, SMA, paracentral lobule, primary motor cortex (M1), IFG, MPFC, VLPFC, and mid-Insula. The accuracy of the classification in the training set was 70% (sensitivity=72.2%, specificity=67.3%, precision=69.0%, AUC=0.74). The classifier weight map calculated in study 1 was then tested in the independent testing dataset (study 2, N=23), and led to similar prediction results, with 73.9% accuracy (sensitivity=82.6%, specificity=65.2%, precision=70.4%, AUC=0.78). These results demonstrate the potential utility of multivariate machine learning based on cerebral blood flow information to predict clinical pain states.

Title: Neurometabolite changes in patients with complex regional pain syndrome: A magnetic resonance spectroscopy study

Authors: *Y.-H. JUNG[1], H.-J. KIM[2], S. JEON[2], J. KWON[2], Y. KIM[2], D.-H. KANG[2]
[1]Dept. of Neuropsychiatry, [2]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: The first aim was to investigate distinct neurometabolites in the right and left thalamus and insula of complex regional pain syndrome (CRPS) patients using proton magnetic resonance spectroscopy (MRS). Levels of N-acetylaspartate (NAA), N-acetylaspartylglutamate (NAAG), myo-inositol (mI), glutamine (Gln), glycerophosphocholine (GPC), glutathione (GSH), and alanine (Ala) relative to total creatine (tCr) levels were determined in 12 CRPS patients compared to 11 healthy controls using MRS. Levels of NAAG/tCr and Ala/tCr were higher in CRPS patients than in controls in the left thalamus. NAAG/tCr, mI/tCr, and Gln/tCr levels were higher, but NAA/tCr levels were lower in the right insula of CRPS patients. There were negative correlations between GSH/tCr and pain score in the left thalamus. The second aim was to assess neurometabolites affecting neuroinflammation in CRPS patients using [^{11}C]-(R)-PK11195 positron emission tomography (PET) and MRS. We found positive correlations of Lip13a/tCr and Lip09/tCr with the DVR of [^{11}C]-(R)-PK11195 in CRPS patients. There were positive correlations between plasma C-reactive protein (CRP) and GPC/tCr in the right thalamus in CRPS patients. There were positive correlations between CRP and Ala/Glx (Glu+Gln), GPC/Glx and mI/Glx, but negative correlations between CRP and Glx/tCr in the left thalamus in CRPS patients. There was negative correlation between CRP and mI/tCr in the left insula in CRPS patients. The third aim was to investigate whether distinct neurometabolites would affect depression, anxiety, suicidal ideation and anger in CRPS patients. In the right thalamus, there were positive correlations between Val/tNAA (NAA + NAAG) and the BAI and between GPC/Lip13a and the SSI and a negative correlation between Gln/NAA and the BDI. In the left thalamus, there were positive correlations between Ala/Gln and the BDI and SSI, between Glu/Gln and the BDI and SSI, between NAAG/Gln and the BDI, and between Ala/Lip13a and the BAI and a negative correlation between Gln and the SSI. In the right insula, there was a positive correlation between Ala/NAAG and the STAXI-T (trait anger) and a negative correlation between Cr/NAA and the STAXI-T. In the left insula, there was a negative correlation between Cr/Glx and the STAXI-T. The complex pathophysiological mechanisms

underlying CRPS include the involvement of the central nervous system, parasympathetic nervous system, neuroinflammation, oxidative stress, and antioxidants. Thus, the distinct metabolites may be essential to understand the core pathophysiology of CRPS, and combinatorial biomarkers have a strong diagnostic and prognostic potential for CRPS.

Title: Brain mechanisms moderating the relationship between depression and pain

Authors: *A. ADLER-NEAL[1], N. EMERSON[3], S. FARRIS[1], Y. JUNG[2], J. G. MCHAFFIE[1], R. C. COGHILL[4], F. ZEIDAN[1]
[1]Neurobio. and Anat., [2]Dept. of Radiology, Wake Forest Sch. of Med., Winston Salem, NC; [3]Neurosurg., Johns Hopkins Med., Baltimore, MD; [4]Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Rationale:
Pain and depression exhibit a co-morbid relationship. Depression is associated with heightened activation in the prefrontal (PFC) and insular cortices, brain regions associated with facilitating affective and sensory-discrimination of pain, respectively. However, the neural mechanisms moderating the relationship between depression and pain are unknown.
Methods: Seventy-six healthy, pain-free volunteers completed the Beck Depression Inventory (BDI) and fell below the cutoffs for clinically significant depression. Pseudocontinuous arterial spin labeling (PCASL) was used to acquire whole-brain cerebral blood flow images. Noxious

thermal stimuli were delivered to the right calf across four PCASL scans. Pain intensity and unpleasantness visual analog scale ratings (VAS) were collected after each scan. Heat scans consisted of alternating patterns of 49°C and 35°C. Neutral scans contained only 35°C stimuli. Separate regression analyses tested the relationship between BDI and pain intensity and unpleasantness ratings (SPSS 19). First and second-level repeated-measures ANOVAs [The Functional Magnetic Resonance Imaging of the Brain (FMRIB) Software Library] examined the main effect of pain (heat vs. neutral series) within and across individuals, respectively. Demeaned BDI scores, pain intensity, and pain unpleasantness ratings were entered as the first, second, and third regressors, respectively. The interaction between BDI and a) pain intensity and b) pain unpleasantness was modeled as the fourth and fifth regressor, respectively. Post hoc region of interest analyses examined significant interactions.

Results:

Greater BDI scores were associated with greater pain intensity (r=. 32; p=.006) and unpleasantness (r=.34; p=.003) ratings. Heat series produced greater pain-related activation in the primary somatosensory cortex (SI) corresponding to the stimulation site, thalamus, cerebellum, secondary somatosensory cortex (SII), and anterior/posterior insula, when compared to neutral series. Greater ventrolateral PFC (p=.006), anterior insula (p=.03), SII and posterior insula (p=.01) activation moderated the positive relationship between depression and pain intensity. Greater SI activation corresponding to the stimulation site (p=.014) and decreased orbitofrontal cortex (p=.003), anterior insula (p=.04), and rostral anterior cingulate cortex (p<.05) activation moderated the positive relationship between depression and pain unpleasantness. These results provide novel evidence that functionally distinct brain processes moderate the relationship between depression and pain intensity and unpleasantness.

Title: Effects of opioid-induced analgesia on electroencephalographic markers of pain perception

Authors: *J. I. EGANA[1,2], R. MONTEFUSCO-SIEGMUND[2], A. BLANCH[1], D. ROJAS-LIBANO[3], G. RIVERA[4]

Abstract: Chronic pain is a highly prevalent condition in modern medicine. Is the main cause of consultation, the principal cause of disability worldwide and represent enormous costs for all health systems. In most cases, chronic pain is a consequence of long exposures to untreated or subtreated acute pain. Efforts should be done in situation where acute pain is expected in order to prevent its transformation into chronic pain. Surgery is one of those situations. Nevertheless, chronic post-surgical pain (CPSP) is highly prevalent indicating that surgery-derived acute pain is not being correctly detected and/or treated. Mechanisms that account for acute to chronic pain transformation start acting rapidly after intense painful/nociceptive stimulation. That makes necessary to maintain adequate levels of analgesia during the surgery itself. Currently, there are no reliable intraoperative pain/nociception monitors. EEG is a powerful tool that has proved its utility for monitoring the brain under general anesthesia. Unfortunately most of the achievements have been developed in the study of unconsciousness and amnesia with little progress in the pain/nociception field. Before the EEG can guide medical interventions, the electrical activity associated with pain and analgesia should properly be characterized. Eight subjects were submitted to a 2 stages experiment while a 16+8 electrodes EEG was recorded. In the first stage they underwent a protocol of painful transcutaneous electrical stimulation of variable intensity. 3 consecutive stimuli of 4 different intensities, ranging from mild to moderate pain, were applied. Subject were instructed to report the amount on pain elicited by each of the stimuli in a 0-10 scale. During the second stage subjects repeated the previous protocol while they were exposed to increasing levels of analgesia. Analgesia was obtained by intravenous computer-controlled injection of remifentanil. Remifentanil is an ultrashort-acting synthetic opioid that allow quick effect and rapid recovery allowing rapid changes in analgesic effect. We report the effects of opioid-induced analgesia on pain-associated Event Related Potentials (pERP) and on induced oscillatory activity.

Title: Velocity of brain-state trajectory encodes salience and attention rather than pain

Authors: *R. JABAKHANJI[1], A. T. BARIA[1], M. A. FARMER[1], A. V. APKARIAN[1,2,3]
[1]Dept. of Physiol., [2]Dept. of Anesthesiol., [3]Dept. of Physical Med. and Rehabil., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Distinct perceptions are linked to distinct spatio-temporal patterns of activity. Different odors, for example, have been shown to elicit unique and reliable spatio-temporal activity patterns, or trajectories, which are thought to reflect not only stimulus properties, but also the subjective experience of stimuli. While distinct activity trajectories have been demonstrated in visual and olfactory systems, little is known about how these trajectories manifest in pain. Here we investigated the dynamics of fMRI brain activity trajectories in healthy subjects as they rated or passively underwent various painful and non-painful stimuli.
Fourteen subjects received block stimulation of painful thermal and visual stimuli in separate scans. Thirteen subjects received block stimulation of painful and non-painful vulvar touch in separate scans. Finally, 6 subjects received a thermal stimulus designed to elicit varying magnitudes of pain while the stimulus was held constant. Additionally, for a smaller subset of these scans, painful stimuli were passively experienced, and not rated. Each scan consisted of 6-12 stimulus blocks, each block lasting between 15-30 seconds. Functional images were preprocessed by ICA de-noising, regressing out signal related to motion, physiological artifact, white-matter, and average global activity. BOLD pattern dynamics related to each stimulus were then evaluated in activity space composed of the time series of these 480 regions, in which the location of a single data point represented the spatial activity pattern at a single point in time, and all data points temporally ordered represented the trajectory of brain activity. Thus, greater distance between 2 data points in this space indicated a greater dissimilarity in the brain activity patterns. Likewise, the distance between temporally adjacent data points indicated the velocity of the spatial pattern, or how quickly activity traversed along the trajectory. We observed primarily how the velocity of brain activity differed between the different thermal, somatosensory, and visual stimuli.
We found that activity velocity was slowed 1) in thermal painful compared to visual stimuli, 2) when pain was abolished under normally painful thermal stimuli, and 3) for both painful and non-painful vulvar touch. We also found that rating stimuli as they occurred further slowed activity velocity, and resulted in highly different activity patterns. These results indicate that fMRI activity velocity more likely encodes salience and attention, rather than perception of pain or stimulus properties alone. However, further analysis remains to be done on other activity trajectory features.

Title: Closed-loop pain relief control using fMRI multi-voxel decoder and reinforcement learning

Authors: *S. ZHANG[1], H. MANO[2], W. YOSHIDA[3], M. KAWATO[3], T. YANAGISAWA[4], K. SHIBATA[5], B. SEYMOUR[1,2,3]

Abstract: A major objective of technology-based therapeutics for chronic pain is to construct a smart 'closed-loop' automatic control system that is capable of adjusting its intervention according to brain activity related to pain intensity experienced. We demonstrated in our study the feasibility of such system in healthy human participants using fMRI, and explored the potential of brain-machine co-adaptation.
Firstly, in the decoder construction session, individual participant's functional brain images were recorded during fMRI scanning for decoder training, during which high and low levels of painful electrical stimuli were delivered in a sequence of random trials to elicit two levels of pain. Individual-specific, multi-voxel decoder was then trained for automatic classification of pain level experienced, using regions of interest identified in previous pain studies. Secondly, in the adaptive control session, the intensity of pain stimuli delivered was controlled by the participant's decoded pain from their brain activity in the previous trial. Specifically, after receiving pain, the decoder estimated in real-time the participants' probability of experiencing high pain from their brain images, which was used to determine the pain intensity level to be delivered in the next trial. To complete the control loop, the pain delivery system learned to

lower the overall level of pain delivered to the participant, which was accomplished with a basic reinforcement learning algorithm by rewarding the stimulation state that elicited lower decoded pain signal in the participant. Trial structure was otherwise identical to that of the decoder construction session, which made it a yoked control condition to the adaptive control session effectively, allowing investigation of whether any brain-machine co-adaptation processes took place.
Pilot results showed that such closed-loop system was achievable from an engineering perspective, and the pain delivery system could learn quickly to deliver low pain to participants, despite the probabilistic nature of the decoder. Despite the limited temporal resolution of fMRI scanning, the current system nevertheless demonstrates the use of machine learning techniques based on brain activity can be adopted in principle for closed-loop pain control systems.

Title: Pathological functional connectivity and pain catastrophizing converge on the salience and cingulo-opercular networks

Authors: *S. KRIMMEL[1], M. KEASER[2], J. HAYTHORNTHWAITE[3], D. A. SEMINOWICZ[4]
[1]Neural and Pain Sci., [2]Univ. of Maryland Baltimore, Baltimore, MD; [3]Johns Hopkins Univ., Baltimore, MD; [4]Dept of Neural & Pain Sci., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Migraine is a chronic pain disorder with substantial disease burden. A hallmark of chronic pain disorders is high levels of pain catastrophizing, which is associated with disease burden and maintenance. We acquired resting state functional MRI (rsfMRI) data in 21 episodic migraine patients (4-14 headache days per month) and 21 healthy controls matched on age, sex, race, education, and BMI. We determined resting state functional connectivity (RSFC) by extracting timeseries data from 264 nodes and used the extracted timeseries to create a full correlation matrix (264 x 264). To elucidate which functional connections and brain regions may promote pain catastrophizing, we correlated Pain Catastrophizing Scale (PCS) scores to the RSFC matrix ($p<0.05$, false discovery rate corrected for multiple comparisons). Consistent with existing literature on pain catastrophizing, we found migraine patients displayed higher PCS scores than controls. Additionally, we found PCS in patients correlated with RSFC in nearly all

brain networks, particularly to salience, cingulo-opercular, and default mode networks. Also, we identified differences in RSFC between patients and controls that was localized primarily to the salience, cingulo-opercular, and sensory networks. An overlap of these significant findings shows that the salience network and cingulo-opercular networks display both differences in RSFC between patients and controls and correlate to patient PCS scores. These findings support attention based theories of pain catastrophizing in chronic pain.

Title: Brain responses evoked by acupuncture and imagery

Authors: *J. CAO[1,2], J. PARK[1], K. JORGENSON[1], C. LANG[1], J. LIU[1], R. GOLLUB[1], S. ORR[1], J. KONG[1]
[1]PSYCHIATRY, MASSACHUSETTS GENERAL HOSPITAL, Charlestown, MA; [2]Insitution of Acupuncture moxibustion and tuina, Beijing Univ. of Chinese Med., Beijing, China

Abstract: Introduction: The use of imagery to treat illnesses is a widely accepted medical practice that has been used for long time, but the underlying mechanism behind its efficacy remains unknown. Acupuncture is a unique, invasive treatment modality. Studies have shown that the experience[1], as well as the visualization[2], of acupuncture needle stimulation provokes activation in overlapping brain regions such as the anterior insula (AI) and periaqueductal grey (PAG). In this study, we took advantage of the unique characteristic of acupuncture, and investigated fMRI signal changes evoked by acupuncture and video-guided acupuncture imagery treatment (VGAIT).
Methods: To date, 10 right-handed, healthy individuals have completed the crossover-designed

study. We investigated fMRI signal changes evoked by 1) VGAIT (watching a video of an acupuncture needle stimulating subject's acupoint, and imagining it being applied concurrently), 2) a VGAIT control condition (watching a video of a cotton swab touching subject's bodies and imagining it being applied concurrently), 3) real acupuncture, and 4) sham acupuncture (Streitberger needle). fMRI data were collected using a 3.0 T MRI scanner while subjects completed two 9-minute fMRI scans during which intermittent acupuncture, VGAIT and corresponding control conditions were applied. Two acupoints (right SP 6 and SP 9) were tested in this study. Data analysis was performed using SPM 12 with a threshold of $p< 0.005$ over 40 continuous voxels.

Results: Compared with the VGAIT control group, the VGAIT group showed fMRI signal increases at the bilateral dorsolateral prefrontal cortex (DLPFC), cerebellum, right PAG and temporoparietal junction. No significant fMRI signal decreases were observed. Compared with needle-stimulated acupuncture, VGAIT produced fMRI signal increases in the bilateral occipital cortex, hippocampus, PAG, pons, and cerebellum, and fMRI signal decreases in the right superior parietal lobule and left striatum. Actual acupuncture produced significant fMRI signal increases in the right superior temporal gyrus, dorsal lateral prefrontal cortex, and left posterior cingulate cortex compared with sham acupuncture.

Conclusions: Our results suggest that VGAIT can activate a widespread brain network, including PAG, a key region in the descending pain modulation system. This finding demonstrates the potential of VGAIT in pain management.

Title: Altered resting state oscillatory MEG power in multiple sclerosis patients with chronic pain

Authors: *J. A. KIM[1,2], R. BOSMA[1], K. S. HEMINGTON[1,2], A. ROGACHOV[1,2], J. C. CHENG[1,2], N. R. OSBORNE[1,2], J. OH[3,2], K. D. DAVIS[1,2]
[1]Krembil Res. Inst., Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]St. Michael's Hosp., Toronto, ON, Canada

Abstract: Objectives:
The mechanisms underlying pain associated with multiple sclerosis (MS) are not completely understood despite a high prevalence of patients whose quality of life suffers from the presence of chronic pain. In general, magnetoencephalography (MEG) and electroencephalogram studies have reported that MS patients have increased slow wave power in the theta and delta bands (Leocani et al 2000) and reduced alpha band coherence (Cover et al. 2006) compared to healthy controls. The latter findings suggest an alpha band-related abnormality in brain communication in MS. However, it is not known how chronic pain in MS impacts oscillatory brain activity, as measured using MEG. MRI studies have indicated that chronic pain is associated with structural and functional abnormalities in the dynamic pain connectome (Kucyi and Davis 2015; Bosma et al. 2017), a system that includes the default mode network, salience network, ascending nociceptive and descending modulation pathways. The goal of the current study was to use MEG to determine whether resting state brain oscillatory power is abnormal in the dynamic pain connectome in patients with MS and if this is related to chronic pain and its impact on quality of life metrics.
Methods:
Patients with MS and age-/sex-matched healthy control (HC) subjects were recruited for the study that was approved by the local institutional research ethics board and all participants provided informed written consent to the study protocol. Every participant underwent a 5 min MEG resting state data acquisition, a comprehensive psychophysics protocol, and completed questionnaires to assess pain, personality, clinical, psychological and quality of life issues. The brain power spectra information was derived from MEG data using linearly-constrained minimum variance beamformed time series of the resting state scan.
Results:
Whole brain power spectra in MS patients and HCs were similar over most frequency bands except the alpha band. Furthermore, the MS patients had altered alpha band power in specific nodes of the dynamic pain connectome that was related to their chronic pain and reductions in quality of life metrics that assessed the impact of pain (e.g., pain interference from the Brief Pain Inventory).
Conclusions:
These findings indicate that MS chronic pain affects resting state brain activity at slow-medium frequencies. This suggests that patients with chronic pain have altered baseline levels of activity which can lead to the manifestation of pain-related behaviour.

Title: Quantification of tonic thermal pain using EEG data and random forest models

Authors: *V. VIJAYAKUMAR[1], M. CASE[2], S. SHIRINPOUR[2], B. HE[2]
[1]Electrical Engin., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Pain is considered to be the product of a conscious, multi-dimensional response to stimuli perceived as nociceptive in nature. The current standard for pain assessment is self-report, which shows high degree of variability in chronic pain patients and can lead to sub-optimal treatment methods. Hence, developing an accurate pain assessment system which is generalizable across populations can increase the efficacy of clinical treatments. The aim of this study is to use electroencephalography (EEG) data collected from a subject pool in response to tonic thermal pain to build a classification model for predicting the pain score in the range of 1-10 in an unseen subject from the subject pool. The contribution of each frequency band to model accuracy is analyzed. Source imaging is then used to analyze the spatial correlates of two simultaneous temporal responses observed in a subject, which are quantifiably the best indicators of nociception: One which is shared by all subjects in the subject pool, referred to as a global pain signature, and one which is unique to each subject, referred to as a local pain signature. Twenty-five healthy subjects were recruited for this study. The threshold and tolerance levels of each subject were measured. During the experiment tonic low, medium, and high thermal pain stimuli between threshold and tolerance were administered to the subject. To rate their pain, they used a custom-made continuous pain rating device on a color bar. A random forest model is trained to predict pain scores using time-frequency wavelet representations of independent components obtained from the EEG data. Principal Component Analysis (PCA) is used to extract the spatial maps of the most consistent electrode activity, and sLORETA is used for source localization on these components.
The mean classification accuracy for predicting pain on an unseen test subject for a range of 1-10 is 89.45% using the leave-one-out classification paradigm, which is 6% higher than existing state of the art for multi-class pain prediction. The gamma band is the most important to both inter-subject and intra-subject classification accuracy. Global correlates of pain mostly localized to the posterior parietal lobe while local correlates predominantly localized to the anterior cingulate cortex, showing that there are observable spatial differences between two concurrent temporal

pain responses in a subject. Our results demonstrate the potential of this tool to be used clinically to help improve chronic pain treatment, and establish spatial biomarkers for future pain-related studies using EEG.

Abstract: Mindfulness meditation can be helpful in coping with chronic pain. Subjective accounts of strong analgesia in experienced meditators are supported by recent behavioral and neuroimaging findings. The process of pain chronification is sustained by widespread changes in the central nervous system. However, the way that long-term meditation practice can affect the brain in chronic pain patients has not been investigated. In this cross-sectional study, we used neuroimaging to examine the neuroplasticity of coping with pain in chronic pain patients who are experienced meditators. Mindfulness practitioners with chronic pain (at least 1000 hours of practice) and meditation-naïve patients with chronic pain were matched for age and gender; all participants completed an acute pain task (n=13 for each group) as well as structural diffusion tensor imaging scans (n=18 meditators and n=21 naïve patients). Prior to scanning, we determined a moderate pain level for each participant (7 on a 10-point scale). The acute pain task consisted of two runs using induced thermal pain, with five 20-second pain blocks each. Participants were instructed to “attend to the pain” in the first run and to “decrease and control the pain” (cope) in the second run. Whole-brain analyses revealed significant between-group differences in three regions (dorsal Anterior Cingulate Cortex, left Inferior Frontal Gyrus and the cerebellum) during coping with pain when compared to attending to pain. These findings are consistent with existing literature on acute pain perception in experienced meditators, which report decreased activations within sensory-discriminative regions of the pain matrix with increased meditation experience. Whole-brain analyses of axial diffusivity (AD) revealed higher AD in the superior and inferior longitudinal fasciculi in the meditation-naïve patients, possibly indicating stronger corticolimbic connections in the absence of meditation experience.

Title: Patient-clinician concordance in social mirroring brain circuitry during pain treatment: A hyperscanning fMRI study

Authors: *D.-M. ELLINGSEN[1], C. JUNG[1], K. ISENBURG[1], J. GERBER[1], I. MAWLA[1], R. SCLOCCO[1], R. R. EDWARDS[2], J. KELLEY[3], I. KIRSCH[4], T. J. KAPTCHUK[4], V. NAPADOW[1]
[1]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sc, Charlestown, MA; [2]Brigham and Women's Hosp., Boston, MA; [3]Endicott Col., Beverly, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: The patient-clinician relationship can modulate symptoms such as pain, but the brain basis for this is unknown. We simultaneously recorded functional Magnetic Resonance Imaging (fMRI hyperscanning) in patients and clinicians, who interact via video transfer, during clinician-initiated treatment of the patient's pain. We hypothesized concordant activation of circuitry involved in social mirroring, such as ventrolateral Prefrontal Cortex (vlPFC) and anterior Insula (aINS) in both patients and clinicians during pain treatment. Patients with chronic pain (fibromyalgia) and clinicians (acupunturists) were enrolled. Each patient was matched with a clinician participant (12 patient-clinician 'dyads'). The patient received a number of moderately painful cuff pressures to the left leg (15 s), while the clinician used a button box to control (real or sham) electroacupuncture stimulation to the patient's leg to treat the cuff pain. Both participants used a Visual Analogue Scale to rate self-pain (patients) or vicarious pain (clinicians) after each trial. Using MRI-compatible cameras, the participants were enabled to communicate non-verbally throughout the scan. fMRI preprocessing included motion correction, skull stripping, correction for magnetic field inhomogeneities, and registration to MNI152. After single-subject GLM analysis, we conducted a group GLM (whole-brain cluster-correction for multiple comparisons) followed by a group conjunction analysis, between patients and clinicians, of the [pain,treatment]>[rest] contrast. Patients reported decreased pain for both real and sham

treatment, compared to overt no-treatment, which was echoed by reduced ratings of vicarious pain by the clinicians. Patients (receiving pain+treatment) showed activation of posterior (pINS) and mid-anterior (m-aINS) Insula, secondary somatosensory areas (SII), Supplementary Motor Area (SMA), ventrolateral Prefrontal Cortex (vlPFC) dorsolateral prefrontal cortex (dlPFC), and Temporoparietal Junction (TPJ). Clinicians (observing pain+treating) showed activation in aINS, vlPFC, dorsomedial PFC, dlPFC, TPJ, Superior Temporal Sulcus (STS), and primary and secondary visual areas. A conjunction analysis showed activation of vlPFC, aINS, and TPJ for both patients and clinicians during pain and treatment, indicating concordant activation of circuitry important for social mirroring in interacting patients and clinicians.

Title: Expanding the Waxholm Space rat brain reference atlas using a data enriched magnetic resonance imaging template: New delineations of the auditory system, thalamus, and more

Authors: J. IMAD[1], A. E. WENNBERG[1], K. K. OSEN[1], F. CLASCÁ[2], G. CSUCS[1], C. COELLO[1], J. G. BJAALIE[3], *T. B. LEERGAARD[1]
[1]Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway; [2]Histology and Neurosci., Autonomous Univ. of Madrid, Madrid, Spain; [3]Univ. Oslo, Oslo, Norway

Abstract: Brain reference atlases are important resources for assigning anatomical location to experimental data, and for planning and interpreting experimental results. Three-dimensional atlases can also serve as templates for spatial co-registration (integration) and comparison of different types of brain images. The Waxholm Space atlas of the rat brain is a public resource based on high resolution magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) data. It features a coordinate system based on internal landmarks (Waxholm Space) and delineations of so far 79 brain structures (Papp et al., Neuroimage 97:374-386, 2015; Kjonigsen et al., Neuroimage 108:441-449, 2015). The atlas is shared via the Neuroimaging Informatics Tools and Resources Clearinghouse (www.nitrc.org), and has since its release been widely adopted by the community. A limitation is, however, that detailed anatomical delineations of several major brain regions are missing. In some instances, delineations are not easily introduced

due to low contrast in the underlying MRI / DTI templates, or complex features that are challenging to interpret in MRI / DTI data. To amend this, we have spatially registered images of serial histological sections stained for cyto-, chemo- and myeloarchitecture to the Waxholm Space rat brain template, and used these to aid the interpretation of boundaries of structures. We here outline our approach to defining brain structures in the Waxholm Space rat brain template, and present new delineations of the ascending auditory system, the thalamus, as well as several regions in the cerebral cortex and basal forebrain. The anatomical criteria underlying the delineations will be published, and the next version of the atlas delineations will be shared from www.nitrc.org.

Title: Cell type-specific and age-related changes in auditory cortical processing

Authors: D. LYNGHOLM, *S. SAKATA
SIPBS, Univ. of Strathclyde, Glasgow, United Kingdom

Abstract: Aging is inevitable and while the age-related deterioration of many brain functions including sensory, cognitive and motor functions are well documented, we know little about age-related changes in cortical processing at the neural circuit level. In particular, it remains unclear how cortical GABAergic interneurons contribute to age-related changes in cortical information processing. To address this issue, it is important to not only discriminate cell types, but also to delineate between central and peripheral effects of aging. In the present study, focusing on the auditory cortex, we investigate how the structure of spontaneous and auditory-evoked population activity changes with age and comparing two mouse strains to distinguish central and peripheral aging effects. We recorded neural ensembles in the auditory cortex of awake C57BL/6J mice, which have a mutation leading to early peripheral age-related hearing loss (ARHL). We observed an age-related decrease in multi-unit spiking activity, with a correlation between increased hearing threshold and increased spontaneous theta oscillations that is not apparent in age-matched CBA/J mice, which do not exhibit early ARHL. Combining electrophysiological and optogenetic approaches in both young and aged mice with and without early ARHL, we further investigate both cell-autonomous and circuit level changes in auditory cortical processing

involving GABAergic cells expressing either Parvalbumin or Somatostatin, thereby providing a deeper insight into the underlying mechanisms of age-related changes in auditory function.

Title: Diffusion tractography of the subcortical auditory system in a postmortem human brain

Authors: *K. R. SITEK[1], E. CALABRESE[2], G. A. JOHNSON[3], S. S. GHOSH[1]
[1]MIT, Cambridge, MA; [3]Radiology, [2]Duke Univ., Durham, NC

Abstract: The auditory system connects the sensory epithelium of the inner ear to the auditory cortex and is comprised of multiple intermediate subcortical structures. Research in animal models has revealed numerous functional subdivisions of auditory structures and structural connections between these structures. However, investigating the anatomy of the auditory system in humans has been much more limited in scope due to technical challenges of imaging subcortical regions. Here, we use high-field diffusion-weighted MR microscopy of a postmortem human brain stem acquired at the Duke Center for In Vivo Microscopy to identify pathways of the human subcortical auditory system. Diffusion data of the specimen, which included the medulla, pons, midbrain, and thalamus, were acquired at 7 Tesla in 120 unique diffusion directions with b=4000 s/mm^2 and 200 μm isotropic resolution. White matter tractography was performed using model-free reconstruction based on diffusion orientation distribution functions at each voxel. By creating seed regions of interest, we could clearly identify white matter pathways and connections between subcortical auditory structures. These include the lateral lemniscus tract between the brainstem and the inferior colliculus, fibers of the cochlear nerve, and medial geniculate-IC connections. In addition to the high sensitivity and angular resolution of the diffusion data, the high spatial resolution allows us to segment subcortical auditory structures into subnuclei and trace their specific connections throughout the auditory pathway. To our knowledge, this is the highest quality tractography study of the human subcortical auditory system. We can apply findings from this study to lower resolution in vivo human imaging data to improve mapping of the auditory system in other research and clinical populations.

Title: Noise induced hearing loss differentially reduces the dimerized pool of dopamine receptors and their interaction with N-ethylmaleimide-sensitive fusion (NSF-1) protein across auditory related brain regions

Authors: A. K. APAWU[1], A. DIXON[1], B. ADAMS[1], M. HALI[1], B. FYK-KOLODZIEJ[2], *A. HOLT[1]
[1]Anat. & Cell Biol, [2]Physiol., Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: While hearing loss, tinnitus, and hyperacusis have been associated with temporal and spatial changes in spontaneous neuronal activity, the neurochemical bases for these changes remain elusive. Not only have we reported deafness related changes in dopamine (DA) receptor (Drd) gene expression, but have also shown that these changes are brain region and time dependent. Furthermore, our work has revealed that the function of DA receptors in the inferior colliculus (IC) is both activity driven and class specific (Drd1 or Drd2). In the present work, we further examined the role of Drds in hearing by investigating the effect of noise exposure on Drd

localization, protein levels, and activity dependent interaction with the trafficking protein NSF-1. Adult male Sprague Dawley rats (n=14) were divided into normal hearing and noise exposure groups (16 kHz,106 dB, SPL, 1 hour; and 10 kHz, 118 dB SPL, 1/3 octave band, 4 hours). Receptor localization was examined in cryosections (40 µm) obtained from the IC and auditory cortex (AC) using immunocytochemistry. Following protein isolation, Drd1 and Drd2 levels were compared across groups using Western blot (7 µg/lane). Co-immunoprecipitation with and without calcium was used to determine activity dependent DA receptor/NSF-1 interactions.
In the IC, Drd1 labeling filled the somata while Drd2 labeling was patchy, within somata and dendrites. In animals with a permanent threshold shift (PTS) after noise exposure, somatic labeling for Drd1 appeared to be increased compared to controls while labeling for Drd2 appeared to decrease within somata, but not processes. While both Drd1 and Drd2 appeared to form dimers (~100 kDa) in the IC and AC, Drd1 primarily exists in the dimerized state. One day following the PTS, dimerized Drd2 was significantly decreased in the AC. The Drd1-NSF-1 interaction in the IC was calcium dependent in animals with a temporary threshold shift (TTS), at a time when hearing thresholds had returned to normal. In the AC, TTS resulted in increased NSF-1/Drd interaction in the presence of calcium.
These results suggest DA receptors in the IC and AC are affected by noise induced permanent and temporary hearing loss even if hearing returns to normal. The spatial differences in the effects of noise on dopamine receptor production, dimerization, and trafficking suggest functional differences in dopaminergic mechanisms between auditory brain regions.

Title: Genetic access to active neurons in the mouse auditory cortex

Authors: *G.-I. TASAKA[1], C. GUENTHNER[2], A. SHALEV[1], O. GILDAY[1], M. GROYSMAN[1], L. LUO[2], A. MIZRAHI[3]

Biol., Howard Hughes Med. Inst. - Stanford Univ., Stanford, CA; [3]Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Cortical circuits are often functionally heterogeneous and their responses can be sparse. In the auditory system, it is difficult to access specific local circuits encoding stimuli such as natural sounds as these shape neuronal responses in complex ways; for example, due to their rich frequency content, temporal structure and contextual effects. Here, we used a new method, called TRAP (*Targeted Recombination in Active Populations*) to identify and access functionally active circuits in the mouse auditory cortex (A1), *in vivo*. TRAP is based on a Fos-CreER^{T2} driver line allowing genetic access of temporarily active neurons. We developed and tested a new reporter mouse strain (called TB), which allows the expression of a fluorescent protein and tTA after the excision of a loxP-flanked transcriptional stop signal. The new reporter enables labeling of neurons as well as induction of other genes when these are expressed under the TRE promoter. We calibrated the FosCreER^{T2}xTB system to A1. We demonstrate near zero non-specific labeling in A1 and show up to 3-fold increase in the number of trapped neurons following sound exposure to natural sounds (but not pure tones). Efficient recombination is also shown in other regions of the auditory pathway. In vivo two-photon targeted patch recording from L2/3 neurons shows that TRAPed neurons respond significantly stronger to the trapping stimulus as compared to non-TRAPed neighbors or as compared to control TRAPed neurons. Next, we used this system to investigate plasticity of postpartum mothers. Pup ultrasonic vocalizations (USV) induced higher numbers of recombined neurons in mothers' A1 compared with naïve virgins. USV-TRAPed neurons in mothers were found to have a unique spiking signature suggesting that a newly recruited subpopulation of cortical neurons contribute to efficient encoding of USV. Our method will now be used as a substrate to elucidate the unique neural signature of parental plasticity across the auditory system.

Title: Mechanisms of changes in synaptic depression in response to different levels of activity at endbulbs of Held

Authors: *X. ZHUANG[1], W. SUN[2], M. A. XU-FRIEDMAN[1]
[1]SUNY UNIVERSITY AT BUFFALO, Buffalo, NY; [2]Dept. of Communicative Disorders and Sci., SUNY Univ. at Buffalo, Buffalo, NY

Abstract: Abnormal levels of auditory activity trigger an adaptation mechanism that changes the properties of endbulbs of Held, which are synapses formed by auditory nerve fibers onto bushy cells in the anteroventral cochlear nucleus. After exposure to an augmented acoustic environment, endbulbs of young mice reduce their synaptic depression, while after a week of ear occlusion, they show greater synaptic depression. It is important to understand the mechanisms underlying these changes, because abnormal auditory activity is associated with hearing problems including tinnitus and processing disorders. The most likely mechanism involves changes in presynaptic calcium, either changes in calcium influx, or in the efficacy of calcium driving neurotransmitter release. We tested these possibilities using voltage-clamp recordings of bushy cells in mouse brain slices. Bath-application of the slow chelator EGTA-AM blocked EPSCs more effectively in augmented endbulbs than in control endbulbs. This is consistent with decreased calcium influx or reduced coupling efficacy between calcium channels and the release apparatus, which could account for decreased synaptic depression. The fast chelator BAPTA-AM was less effective at blocking EPSCs in occluded endbulbs, which is consistent with tighter coupling or an increase in calcium influx and could account for increased synaptic depression. We also tested changes in coupling efficacy by quantifying the cooperativity following exposure to different sound environments and found no change. We plan to further assess calcium influx using calcium imaging. Another question is whether activity adjusts endbulbs only during development. We found that mature endbulbs (>postnatal 50 days) showed activity-dependent changes in synaptic depression similar to young endbulbs. This suggested there is no critical period for this phenomenon and endbulbs adjust their properties as auditory nerve activity changes throughout life. By understanding the mechanism of changes in synaptic depression, it may provide new ideas for treating disorders such as tinnitus and conductive hearing loss.

Title: Integrating in-vivo imaging and neuronal barcoding to link neural coding and network structure in mouse cortex

Authors: *A. VAUGHAN, C. J. STONEKING, A. M. ZADOR
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: In recent years, there has been considerable progress in understanding the mesoscale connectome of the mouse brain using neuronal barcoding (Kebschull et al., 2016). Parallel efforts have sought to develop high-throughput recordings of neural activity in order to understand the information geometry of sensory processing, decision-making, and motor control. To date, however, high throughput methods for each field - whole-brain connectomics and neural recording - have been fundamentally incompatible, leading to a piecemeal understanding of neural circuit form and function. Here, we describe a method that integrates GCaMP imaging with neuronal barcoding that enables the simultaneous resolution of both the activity and mesoscale connectivity of thousands of neurons simultaneously. Using GCaMP recordings of neurons in primary auditory cortex, we delineate the functional response properties of thousands of neurons using a suite of auditory stimuli. We then use neuronal barcoding to map the projections of these neurons, using a combination of mapSEQ (Kebschull et al., 2016) with in-situ sequencing (Lee et al., 2014; Chen et al., in prep). Linking these two datasets with high-resolution registration of in-vivo and ex-vivo data, we are able to identify and integrate the functional response properties and projection anatomy of thousands of neurons simultaneously. Using this approach, we generate an integrated view of diversity in neuronal activity as well as morphology, providing a unique holistic view into cortical structure and function.

Title: Reliable and persistent population encoding of sounds across layers in the auditory cortex of awake mice

Authors: *D. E. WINKOWSKI[1], *D. E. WINKOWSKI[1], Z. BOWEN[2], T. L. RIBEIRO[3], D. PLENZ[4], P. KANOLD[1]
[2]Biol., [1]Univ. of Maryland, College Park, MD; [3]Section on Critical Brain Dynamics LSN/NIMH, NIH, Bethesda, MD; [4]Sect Critical Brain Dynamics, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: The ability to detect and encode sensory stimuli hinges on the encoding capability of neuronal populations. Individual neurons in primary auditory cortex (A1) can show selectivity to stimulus features (i.e., sound frequency). However, the representation of sound information in populations of A1 neurons and the nature of populations activated by sound stimuli is unresolved. The theory of critical dynamics describes complex systems that operate at or near a critical point, i.e., balanced between order and disorder, where systems gain advantages in information processing and their dynamics become scale-invariant. This theory has been gaining traction in neuroscience since the identification of neuronal avalanches, intermittent spatiotemporal activity patterns with scale-invariant properties, e.g. their size and duration, are power law distributed.
Here, we tested whether sound processing in A1 neuronal populations of Layer 2/3 (L2/3) and Layer 4 (L4) is in line with expectations for critical dynamics. We characterized spontaneous as well as sound evoked activity in L2/3 and L4 in A1 of awake mice using in vivo 2-photon calcium imaging of neuronal populations. We explore the relationship between properties of sensory stimuli, single neuron responses, and population responses with respect to avalanches and compare our findings across cortical laminae. We investigate the spectral tuning properties of neurons participating in avalanches in order to probe the relationship between criticality and sensory coding. On the population level, we found that avalanche statistics varied with stimulus frequency and intensity of the presented sound. In L2/3, we found that avalanche patterns reliably represented sounds independent of level and contained stimulus information well after sound offset, revealing long-range spatiotemporal activity correlations not evident at single-cell or cell-pair level. Ongoing work is investigating whether this persistent encoding of stimulus information is inherited from L4 populations or whether this is an emergent feature of population activity in L2/3.
Our investigation will provide insight into how neural networks containing differing populations of neurons with varying firing rates stably encode information about sensory stimuli in the context of critical dynamics.

Title: Feedforward and feedback mechanisms governing auditory sensory gating in awake mice

Authors: *A. KHANI[1], F. LANZ[1], K. SCHALLER[2], C. M. MICHEL[1], C. QUAIRIAUX[1]
[1]Functional Brain Mapping Laboratory, Dept. of Basic Neurosciences, [2]Geneva Univ. Hospitals, Fac. of Med., Univ. of Geneva, Geneva, Switzerland

Abstract: In association with impaired performance in attention related cognitive tasks, EEG studies of schizophrenic patients repeatedly showed alterations in processing of auditory stimulation and in particular in auditory sensory gating and mismatch negativity. Sensory gating refers to the fundamental property of the brain that down-regulates neural response to a stimulus that is repeated after a short interval. Sensory gating is thought to reflect an inhibitory processing component of attention; however despite the long history of characterization of this phenomenon, the neural mechanisms are not clearly understood. One hypothesis is that sensory gating is governed by top-down influences from the prefrontal and cingulate areas on the bottom-up sensory processes.
We addressed neural mechanisms of sensory gating in head-fixed awake mice using either surface EEG or simultaneous multi-site intracerebral recordings from the inferior colliculus centralsis (ICc), auditory thalamus (medial geniculate nucleus; MGN), primary auditory cortex (Au1) and anterior cingulate cortex (ACC). We used paired tone paradigm with a wide frequency range (white noise) and a variable inter-stimulus interval (ISI). Analysis of global field power from surface EEG recordings revealed sensory gating up to 2s ISI and pointed to the activation of a large-scale auditory network propagating from the brainstem to the frontal cortices. Our intra-cortical recordings showed a robust attenuation of the LFP amplitude and spike rates of a subset of single neurons immediately after the second tone. The early sensory gating was also reflected in reduced gamma power in the ICc, MGN and Au1 suggesting a feedforward mechanism for attenuation of response from the ICc through MGN to Au1. On the other hand, a delayed increase in beta power in thalamus and delayed firing (~150 ms) of a subset of single neurons in the MGN and Au1 auditory cortex following the first tone suggest a top down mechanism involved in the regulation of sensory gating. This was further supported by a robust enhancement of the cross frequency phase-amplitude coupling between phases of low frequency (~15-20 Hz) LFP in the ACC and amplitude of gamma (~40-60 Hz) power in the ICc. Preliminary results of optogenetic manipulations suggest a causal role for top-down regulation of sensory gating. Taken together, our results suggest a differential contribution of both feedforward and feedback mechanisms in regulating sensory gating.

Title: Effect of ACh and general DREADD inhibition in tegmental areas on sensorimotor gating

Authors: *N. FULCHER[1], E. C. AZZOPARDI[2], C. DE OLIVEIRA[2], S. SCHMID[2]
[1]Neurosci., The Univ. of Western Ontario, London, ON, Canada; [2]Univ. of Western Ontario, London, ON, Canada

Abstract: Humans have intricate brains that deal with an abundance of stimuli emerging from the environment at all times. To prevent overwhelming our brains with sensory information, sensorimotor gating allows for the filtering of redundant information. Sensorimotor gating deficits are seen in an array of neurological disorders such as autism spectrum disorder, schizophrenia, and others. An established way to quantify sensorimotor gating is through prepulse inhibition (PPI) of the acoustic startle response (ASR). Here, we look to further understand mechanisms underlying PPI and its disruptions, to better comprehend how they are involved in affected neurological diseases.
The midbrain has been established as an integral brain region mediating PPI of the ASR. The acoustic pathway involved in PPI consists of: cochlear root neurons, the cochlear nuclei, the inferior (IC) and superior colliculi (SC), the laterodorsal (LDT) and pedunculopontine tegmental nuclei (PPT). The LDT and PPT neurons project to the startle mediating giant neurons of the PnC, which is a crucial part of the complex startle pathway. Lesions to the LDT severely attenuate PPI in rats, while lesions within the PPT disrupt PPI.
Designer Receptor Exclusively Activated by Designer Drugs (DREADDs) is an innovative chemogenetic technique that involves the delivery of viral constructs intracranially and allows drug injections to transiently activate/inhibit targeted classes of neurons. These viral constructs carry a specified DREADD receptor, promoter element, and fluorescent reporter that are introduced into the neuronal membrane. Here, we intracranially delivered bilaterally either the Cre-dependent inhibitory DREADD, or a control vector, into either the PPT or LDT of Cre-ChAT male and female adult Long-Evans rats. Subjects recovered for 3 weeks and received an i.p. injection of either the DREADD ligand clozapine N-oxide (CNO) or vehicle. Immunohistochemistry verified the effectiveness of transfection and quantified co-localization of the DREADD receptors with ACh markers.
Our findings suggest that DREADD-induced inhibition of ACh within the PPT or LDT does not

mediate PPI. Since both structures are composed of a heterogeneous collection of glutamate, ACh, and gamma-aminobutyric acid (GABA) neurons, future work will involve the inhibition of all three cell types in both regions to advance understanding of the potentially crucial role of the tegmental areas in sensorimotor gating. This work will help to develop better-suited drugs to enhance prepulse inhibition patients with deficits in sensorimotor gating.

Title: Behavioral state modifies excitation and inhibition in auditory cortical neurons

Authors: *N. EDWARDS[1], J. S. ISAACSON[2]
[1]Neurosciences, Uinversity of California, San Diego, LA Jolla, CA; [2]Neurosciences, UCSD, La Jolla, CA

Abstract: Factors such as arousal or attention are likely to modulate the processing of sensory information in cortical circuits. Indeed, recent studies indicate that changes in brain state are coupled to changes in the excitability of pyramidal cells in sensory cortices. While previous studies have relied on current clamp recordings to monitor changes in membrane potential, how changes in brain state alter excitatory and inhibitory input to cortical pyramidal cells is unclear. Here, we use whole-cell voltage clamp recordings from layer 2/3 pyramidal cells in the primary auditory cortex (A1) of awake mice to determine the effect of behavioral state on excitation and inhibition. We monitored pupil diameter as a measure of arousal while recording spontaneous and sound-evoked excitatory and inhibitory synaptic inputs. We find that increases in pupil diameter (increases in arousal) are coupled to decreases in both inhibition and excitation. However, brain state-dependent changes in inhibitory and excitatory input appear asymmetric. Ongoing experiments should provide insight into the synaptic and circuit mechanisms underlying behaviorally-driven changes in pyramidal cell excitability.

Title: Characterizing the organization and function of auditory cortex projection neurons

Authors: *P.-A. LIN, J. S. ISAACSON
Neurosciences, UCSD, San Diego, CA

Abstract: Sensory information processed in the primary auditory cortex (A1) is directed to a variety of spatially and functionally distinct targets including contralateral A1, inferior colliculus (IC), striatum, and thalamus. While these target regions play distinct roles in behavior and cognition, the properties of A1 neurons projecting to these structures and the information they convey are not well understood. We set out to determine whether individual A1 projection neurons serve as generalists that send redundant auditory information to several downstream regions, or as specialists that transmit particular aspects of auditory information to a single downstream region. To address this question, we used the retrograde tracer cholera toxin B (CTB) conjugated to different fluorescent dyes to simultaneously label and visualize multiple target-specific subpopulations of A1 projection neurons in the adult mouse brain. We find that neurons projecting to the inferior colliculus very rarely project to other targets. Furthermore, we find only a small subset of pyramidal cells targeting contralateral A1 that also project to the striatum. Taken together, our results indicate that the vast majority of A1 projection neurons act as specialists projecting to single downstream targets. We are currently using vivo calcium imaging in awake mice to determine the sound-evoked response properties of pyramidal cells that project to different targets.

Title: Sublaminar subdivision of mouse auditory cortex layer 2/3 based on functional connections

Authors: *X. MENG[1], J. P. Y. KAO[2], P. O. KANOLD[1]
[1]Biol., Univ. of Maryland, College Park, MD; [2]Ctr. for Biomed. Engin. and Technology, and Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The cerebral cortex is subdivided into 6 layers based on morphological features. In particular, the supragranular layers 2/3 (L2/3) are of interest because they reflect the first hierarchical cortical processing stage after sensory input is received in layer 4 (L4). In the auditory cortex (A1) sound frequency information is represented tonotopically in L4 but the frequency organization of supragranular L2/3 is more heterogeneous suggesting an interlaminar transformation of sound frequency representation. L2/3 contains morphological and genetically diverse population of neurons suggesting that the functional heterogeneity in L2/3 could be the result of cellular or circuit diversity.
We here investigated in mouse auditory cortex if L2/3 contains discrete subpopulations of cells with specific functional microcircuits. We use in vitro slice recordings coupled with laser scanning photostimulation (LSPS) to reveal the intracortical excitatory and inhibitory microcircuits impinging on L2/3 neurons. We then use hierarchical clustering on the excitatory and inhibitory laminar connection patterns. We find that multiple distinct classes of L2/3 neurons exist. The classes of L2/3 neurons are distinguished by their laminar patterns of inputs from within A1, their location within L2/3, and the amount of integration across the tonotopic axis. These results suggest that similar to higher mammals, rodent L2/3 is not a homogenous layer but that several parallel microcircuits exist.

Title: Optogenetic manipulation of inhibitory populations in auditory cortex during stimulus-specific adaptation

Authors: *T. S. YARDEN, A. MIZRAHI, I. NELKEN
Hebrew Univ., Jerusalem, Israel

Abstract: Neurons in primary auditory cortex exhibit stimulus-specific adaptation (SSA), the decrease in responses to a common (standard) stimulus that does not generalize fully to another, rare stimulus (deviant). We investigate the role of inhibition in shaping SSA using optogenetic manipulation of the activity of specific inhibitory populations in auditory cortex. We used a viral vector for conditional expression of the Arch opsin in transgenic mice, and performed *in vivo* two-photon targeted loose-patch recordings, targeting both pyramidal neurons and opsin-expressing inhibitory neurons. We show that the optogenetic effects on the opsin-expressing neurons were sometimes non-trivial, e.g. increasing the sensory response rather than decreasing it, or decreasing it more strongly at lower light intensities. Optogenetic effects depended on the protocol of sensory stimulation and on the intensity of light stimulation, and were different for spontaneous activity and for different phases of the sensory-evoked activity. In addition, we relate the manipulation of inhibitory neuron activity to the responses recorded in pyramidal neurons, showing the contribution of inhibition to the excitatory cortical activity during SSA

Title: GABAB receptors in cortical input layers mediate spike-timing dependent LTD of inhibition and regulate critical period plasticity

Authors: *E. D. VICKERS[1], C. CLARK[2], A. FRATZL[2], R. SCHNEGGENBURGER[2]
[2]Brain Mind Inst., [1]EPFL, Lausanne, Switzerland

Abstract: The tonotopic representation of pure tones in the input layers of primary auditory cortex depends on sound experience during a "critical period" (CP) of brain development. Parvalbumin (PV) - expressing cortical interneurons have been strongly implicated in CP plasticity. We have previously shown that PV interneuron output synapses onto input layer principal cells (PC) in auditory cortex exhibit bi-directional spike-timing dependent (STD) plasticity (SfN 2016 abstract: Vickers and Schneggenburger; 401.13/G11). Interestingly, long-term depression of inhibition (iLTD), observed with pre- (PV interneuron) before postsynaptic (PC) spike-timing orders, depended on $GABA_B$ receptor signalling, was converted into iLTP both by further brain development (P25 - P28), and by sound exposure during the CP (P11 - P14).
To investigate possible links between iLTD and CP plasticity, we knocked-out $GABA_B$ receptor expression in PCs of the input layers. For this purpose, we crossed $Scnn1a^{Cre}$ mice with floxed $GABA_BR1$ mice (Haller et al, 2004) and tdTomato reporter mice. This allowed us to perform paired whole-cell recordings from tdTomato+ PCs and their connected PV-interneurons. In PCs lacking $GABA_BR1$, we found that iLTD was eliminated at P18-20, revealing a specific role for postsynaptic $GABA_B$-receptors in the induction of iLTD. In addition, the baseline IPSCs amplitudes in PV-IN to PC pairs were significantly smaller in $GABA_BR1$ cKO mice.
We next wished to study the role of $GABA_B$ receptors in PCs of the input layers in CP band expansion. For this, we crossed $Scnn1a^{Cre}$ x $GABAB_R1^{lox/lox}$ mice with cfos-tTA x tetO-tdTomato mice. This enabled us to use 2-photon imaging of tdTomato in thalamocortical brain slices to quantify the band of neurons activated by 30 kHz tones. We found a band of cFos-labelled neurons in naive $GABAB_R1$ cKO mice. However, in $GABAB_R1$ cKO mice that had been exposed to CP sound conditioning for 6 days (P12-18), the band of cFos-labeled neurons was reduced in size and contained a lower density of labeled cells. Thus, we speculate that, following CP conditioning in the absence of postsynaptic $GABA_B$Rs, there is a misregulated strengthening of inhibition, maybe caused by the absence of iLTD, which then leads to suppressed tone-activation of PCs.

Title: Cortical circuits of GABAergic callosal projections

Authors: *C. ROCK, H. ZURITA, S. LEBBY, C. J. WILSON, A. J. APICELLA
Biol., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: A deep-rooted principle of cortical circuit organization is that excitatory neurotransmission is involved in both local and long-range processing, whereas inhibition is exclusively local. In favor of this, anatomical studies have shown that the majority of axons projecting via the corpus callosum are glutamatergic. However, a small but significant proportion of callosal axons are also immunoreactive for glutamic acid decarboxylase, an enzyme required for gamma-aminobutyric acid (GABA) synthesis and a specific marker for GABAergic neurons. In this study we tested the hypothesis that corticocortical parvalbumin-expressing (CC-Parv) neurons connect the two hemispheres of multiple cortical areas, project through the corpus callosum, and are a functional part of the local cortical circuit. Our investigation of this hypothesis takes advantage of viral tracing and optogenetics to determine the anatomical and electrophysiological properties of CC-Parv neurons of the mouse auditory, visual, and motor cortices. We found a direct inhibitory pathway made up of parvalbumin-expressing (Parv) neurons which connects corresponding cortical areas. Like other Parv cortical neurons, these neurons provide local inhibition onto nearby pyramidal neurons and receive thalamocortical input. Comparison of CC-Parv neurons to putative non-CC-Parv neurons shows a dissimilarity in both their morphological characteristics as well as their intrinsic properties. These differences in the intrinsic properties, such as instantaneous firing frequency, of CC-Parv neurons and putative non-CC-Parv neurons may reflect differential involvement in slow and fast gamma-band cortical oscillations, respectively.

Title: Restoring neuronal plasticity in the auditory cortex in adult mice by reducing thalamic adenosine signaling

Authors: *J. A. BLUNDON, N. ROY, B. TEUBNER, J. YU, S. HAN, S. ZAKHARENKO
St Jude Children's Res. Hosp, Memphis, TN

Abstract: Circuits in the auditory cortex are highly susceptible to acoustic influences during an early postnatal critical period. The auditory cortex selectively expands neural representations of enriched acoustic stimuli, a process important for human language acquisition. Adults lack this plasticity. Here we show in the murine auditory cortex that juvenile plasticity can be reestablished in adulthood if acoustic stimuli are paired with disruption of ecto-5'-nucleotidase-dependent adenosine production or A1 adenosine receptor signaling in the auditory thalamus. We used repeated two-photon imaging of Layer III/IV neuronal responses to sound stimuli in auditory cortex of awake mice to track neuronal best frequency during continuous sound exposure training. Neurons in adult mice with diminished or blocked thalamic adenosine signaling shift their best frequency towards the exposure frequency after only 24 hours of training. These mice also show long-term improvement of tone-discrimination abilities. We conclude that, in adult mice, disrupting adenosine signaling in the thalamus rejuvenates plasticity in the auditory cortex and improves auditory perception.

Title: Restoring auditory cortical map plasticity in adult mice by disrupting thalamic adenosine signaling

Authors: *N. ROY, J. A. BLUNDON, B. TEUBNER, J. YU, T.-Y. EOM, S. HAN, S. ZAKHARENKO
Developmental Neurobio., St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Circuits in the auditory cortex are shaped by acoustic influences during an early postnatal critical period. During this period, neural representations of frequently-occurring acoustic stimuli expand, a process which may be important for human language acquisition. Passive exposure to acoustic stimuli does not lead to cortical plasticity in adults. Here we show in mouse auditory cortex that the juvenile form of plasticity can be reestablished in adulthood if acoustic stimuli are paired with disruption of ecto-5'-nucleotidase-dependent adenosine production or A_1 adenosine receptor signaling in the auditory thalamus. This plasticity occurs at the level of cortical maps and individual neurons in the auditory cortex of awake adult mice and is associated with long-term improvement of tone-discrimination abilities. We conclude that, in adult mice, disrupting adenosine signaling in the thalamus rejuvenates plasticity in the auditory cortex and improves auditory perception.

Title: Synaptic and spiking responses to infant vocalizations in mouse paraventricular hypothalamus *In vivo*

Authors: *S. VALTCHEVA, R. C. FROEMKE
Skirball Inst., NYU Sch. of Med., New York, NY

Abstract: Experience-driven changes in neural circuits are believed to have important consequences for information processing and sensory perception. A fundamental question is how neural plasticity occurs under natural conditions, to promote the recognition of stimuli with behavioral significance. Motherhood is a dramatic natural experience (Dulac et al., 2014), but little is known about the underlying changes in neural circuits for parenting behavior. The neuropeptide oxytocin is synthesized by hypothalamic areas including the paraventricular nucleus (PVN), and is important for maternal behaviors including parturition, lactation, and parent-child bonding, perhaps in part by increasing salience of social information (Insel & Young, 2001). Indeed, many women experience oxytocin release and milk ejection simply in response to infant cries (McNeilly et al., 1983). Recently, we showed that oxytocin can enable maternal behavior by balancing synaptic inhibition with excitation in the auditory cortex (Marlin et al., 2015; Mitre et al., 2016). Therefore, cortical modulation and plasticity produced by

oxytocin signaling might enable long-lasting enhancements of social interactions and maternal care. However, beyond the necessity for lactation, mechanisms of oxytocin release in the brain leading to naturally-induced forms of plasticity are not well understood. Here, we aimed at identifying how social stimuli activate PVN oxytocin neurons in vivo, and if these responses were gated or changed after maternal experience. We performed in vivo cell-attached and whole-cell recordings from PVN neurons in awake head-fixed mice. We examined PVN neuronal responses to ultrasonic vocalizations (pup isolation calls) and pure tones. PVN neurons did not display frequency selectivity in response to pure tones but they showed reliable responses to pup calls. However, in virgin females these responses remained predominantly subthreshold. Our results suggest that PVN neurons can receive information about acoustic input, reflecting projections from central auditory areas. In absence of maternal experience, however, these responses are unreliable and less coherent, keeping the synaptic responses subthreshold and preventing spurious action potential generation and subsequent oxytocin release in naïve animals.

Title: Perceptual categorization of pup vocalizations in the auditory cortex of maternal mice

Authors: *J. SCHIAVO[1], R. C. FROEMKE[2]
[1]New York Univ., New York, NY; [2]Otolaryngology, NYU Med., New York, NY

Abstract: Learning requires generalization from specific exemplars to enable animals to respond reliably to different stimuli with the same behavioral significance. Perceptual categorization of vocalizations facilitates communication by grouping stimuli into discrete categories despite variability in acoustic features (such as pitch or tempo) between individuals. Little is known about the mechanisms underlying learned category formation at the single-cell and population level, as well as the link between categorical representations and generalization from learned categories. Here we take advantage of a natural behavior in adult mice: retrieval of nest-isolated pups based on distress calls (Ehret Nature 1987, Liu & Schreiner PLoS Biol 2007, Cohen et al. Neuron 2011, Marlin et al. Nature 2015). Naive virgin females initially do not behaviorally respond to these calls, while mothers and virgins co-housed with dams and litters can rapidly respond to distress calls by bringing the pup back to the nest. These ultrasonic vocalizations

(USVs) have distinct spectro-temporal features, occurring in bouts of 3-8 Hz with spectral peaks at 40-80 kHz. USV sequences are variable between and within individuals, however the behavioral significance is the same: to signal the mother. This behavior requires females to perceptually categorize USVs, and serves as a model to examine the neural mechanisms underlying category formation in the auditory cortex. Here we used behavioral measurement and 2-photon imaging to monitor changes in neural and behavioral categories. We assessed the categorical boundary for pup calls in the frequency and temporal domain by morphing pre-recorded USVs from P1-8 pups. First, we used these morphs to behaviorally assess response boundaries in maternal mice using a Y-maze. Mothers reliably approached speakers playing pre-recorded USVs, and approached speakers playing USVs modulated at the ethological rate when compared to time-warped USVs. Using 2-photon imaging in awake mice, we assessed neural response boundaries for pup calls in maternal and non-maternal females. Excitatory neurons in maternal auditory cortex responded invariantly to time-warped and pitch-shifted calls within the natural range, while excitatory neurons in naïve females did not respond invariantly to morphed calls in either domain. The behavioral and neural data thus far is indicative of distinct cortical differences in the processing of USVs between maternal and naïve females, providing an opportunity to further study how the brain shifts from a non-maternal to maternal state to enable parental behaviors.

Title: Cortical mechanisms of perceptual learning in juveniles

Authors: *M. L. CARAS, D. H. SANES
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: From riding a bike to learning a language, children are considered to be better skill learners than adults. One possible explanation for this superiority is that sensory systems display heightened plasticity during development, and thus may be more responsive to training. Developmental studies have documented differences between juvenile and adult learning, and have identified critical periods during which neural properties are particularly sensitive to

environmental experience. However, the neural plasticity that accompanies juvenile learning remains unexplored. To address this issue, we recorded telemetrically from left auditory cortex (ACx) of juvenile gerbils as they trained and improved on an amplitude modulation detection task. Neurometric and psychometric sensitivity were simultaneously tracked across days. As performance improved, juvenile ACx units displayed significant within-animal correlations between neural and behavioral thresholds. These data will be compared to similar recordings from mature adult animals to evaluate whether or not plasticity mechanisms differ.

Title: Network-level modifications induced by sound-reward or -punishment associations in mice auditory cortex

Authors: *J.-F. LEGER[1], X. LIU[1], A. LOURDIANE[1], C. VENTALON[1], L. BOURDIEU[1], Y. BOUBENEC[2], S. A. SHAMMA[3,4]
[1]CNRS- Ecole Normale Superieure, Paris, France; [2]Lab. des Systèmes Perceptifs, Ecole Normale Superieure, Paris, France; [3]Univ. of Maryland, Washington, MD; [4]Lab. des Systèmes Perceptifs, Ecole Normale Supérieure, Paris, France

Abstract: Behavioral training on a task associating a sound with a reward or a punishment leads to extensive changes in the tonotopic map of the rodent auditory cortex (e.g. Rutkowsky & Weinberger, PNAS 2005, Shepard et al., eNeuro 2016). However, the corresponding changes in specific populations of neurons remain poorly described due to the difficulty of tracking the activity of defined neurons and populations throughout the learning process. We have used chronic two-photon calcium imaging with GCamp6f expression in layers 2/3 of the mouse primary auditory cortex to identify these changes after the animals learned a water-rewarded or electric shock-punishment operant sound recognition task. The tasks consisted in placing the animal in a shuttle box, presenting a target sound, and requiring the animal to switch its position in the box to either receive a water reward or escape an electric shock. This design was chosen to allow for direct comparison between the changes induced by positive and negative sound-meaning valence, without modification of the motor response in the tasks. Animals readily

learned the tasks and reached expert levels within 4 days (sound / electric shock association) to 10 days (sound / water reward association), succeeding in learning the two tasks sequentially. Calcium imaging performed before and after each learning period revealed profound modifications of individual cell responses, in particular with an average increase of the responses to the target sound, as well as the modifications induced at the cortical auditory network level.

Title: Categorical memory representation in ferret auditory and frontal cortices

Authors: *P. YIN[1], J. B. FRITZ[1,2], S. A. SHAMMA[1,2,3]
[1]Inst. For Syst. Research, Univ. Maryland, College Park, MD; [2]Electrical and Computer Engin. Department, Univ. of Maryland, College park, MD; [3]Sensory Perception Laboratory, Ecole Normale Superieure, Paris, France

Abstract: Categorization can arise by grouping of sensory stimuli sharing perceptual similarity or by training in which sensory stimuli are assigned to behaviorally relevant classes associated with learned responses. Neuronal category representations have been previously identified in vision in prefrontal, inferotemporal and parietal cortices, but a clear demonstration in audition has been elusive. In previous work, we showed that ferrets could be trained to classify auditory stimuli distributed along continuous feature dimensions (e.g. frequency or amplitude modulation) into classes based on behavioral meaning (Go or No-Go). Here we explore how these categories become represented in different fields of ferret auditory cortex (A1 and secondary areas in dPEG) and frontal cortex (FC), when animals were passively listening to sounds or actively engaged in task. To investigate the underlying mechanisms of category representation, we distinguish between “category-selective coding” and “sensory-selective coding”. Specifically, we expect stimuli from the same category to evoke shared response patterns across the neural population despite potentially large sensory differences between them, e.g., in perceived pitch or modulation. Two metrics based on the Euclidean distance of the population response between stimulus pairs were computed to evaluate these categorical effects: (a) categorical index (***CI***) - defined as the difference between the mean distances of the pairs the stimuli from different categories and of the pairs the stimuli from same category; and (b) the proportion of variance

explained by the categories (η^2). This analysis revealed that categorical information (Go *versus* No-Go) was observed in all three regions during task performance. Furthermore, the dynamics of this representation reveals that the categorical information emerges earliest in FC neurons, followed in dPEG, and then in primary A1. These results are consistent with the findings from visual system and provide insight into how the primary and secondary auditory cortices are differentially involved in classifying acoustic inputs during active auditory memory retrieval.

Title: Representations of tones in core fields of auditory cortex depend on their associated, upcoming behavioral outputs during the performance of auditory tasks

Authors: *Y. HUANG, M. BROSCH
Leibniz Inst. For Neurobio., Magdeburg, Germany

Abstract: Representations of sensory stimuli in sensory cortex depend on a variety of factors that are crucial for converting the stimuli into appropriate behavioral outputs during goal-directed tasks. However, an understanding of the effects of behavioral outputs themselves on sensory representations has been elusive. Here, by conducting a study in two nonhuman primates in which they performed two auditory tasks, we show that tone representations in core fields of auditory cortex depend on the upcoming behavioral outputs associated with the tones. The tasks were performed on the same set of stimuli and had a symmetrically rewarded go/no-go structure. The tasks and the stimuli were designed in such a way that the same tones could be associated with different behavioral outputs, i.e., making a bar release (*go response*) or withholding a bar release (*no-go response*), in different tasks. The same tones could also be irrelevant to making the appropriate behavioral outputs in the tasks. Neuronal activity evoked by the same tone differed when it was associated with an upcoming go or no-go response. The differences were observed in the spike activity of ~25% of the 420 multiunts and in the local field potentials at ~85% of the 570 sites recorded in core fields of auditory cortex. In both the spike activity and local field potentials, such differences emerged mainly because of increased activity evoked by

the tone when it was associated with a no-go response and barely changed activity when it was associated with a go response, relative to that when it was irrelevant to making an appropriate behavioral output. Our results suggest that tone representations in core fields of auditory cortex can change to reflect whether an upcoming go or no-go response should be made to the tones, i.e., auditory cortex can attach behavioral meaning to the tones.

Title: Maladaptive central auditory gain enhancement and disrupted loudness perception following acoustic trauma

Authors: *B. D. AUERBACH[1], K. RADZIWON[1], G.-D. CHEN[1], M. GHOBADI[2], E. T. ESFAHANI[2], R. SALVI[1]
[1]Ctr. for Hearing and Deafness, [2]Mechanical and Aerospace Engin., Univ. at Buffalo, Buffalo, NY

Abstract: The central auditory system displays a remarkable ability to adapt its response properties to changes in sound level. This includes compensatory increases in neuronal gain that can partially restore sound detection following long-term hearing loss. A price of this plasticity, however, is the potential for maladaptive sound encoding in response to abrupt or extreme changes in auditory input. To explore this issue, we examined the relationship between central auditory gain changes and behavioral measures of loudness following acoustic trauma. Simultaneous recordings from multiple levels of the central auditory system demonstrated that noise-induced gain enhancement gradually emerged along the ascending auditory pathway, culminating in excessive amplification of sound-evoked activity in the auditory cortex. In chronic recordings from behaviorally trained animals, we found this cortical hyperactivity to be strikingly correlated with changes in loudness perception. These results show that sound-evoked activity undergoes progressive amplification at successive stages of auditory processing following hearing loss and that excessive neural gain can result in maladaptive changes to sound intensity coding and loudness perception. These results have particular relevance to hyperacusis,

a common auditory perceptual disorder associated with hearing loss where moderate, everyday sounds are perceived as intolerably loud or painful.

Title: ER-mitochondria crosstalk is regulated by NCS and is impaired in Wolfram syndrome

Authors: *B. DELPRAT, C. DELETTRE
Inserm U1051, Montpellier, France

Abstract: Communication between endoplasmic reticulum (ER) and mitochondria plays a pivotal role in calcium (Ca^{2+}) signalling, energy metabolism and cell survival. Dysfunctions of this crosstalk lead to metabolic and neurodegenerative diseases. Wolfram syndrome (WS) is a fatal neurodegenerative disease due to mutations of the ER resident protein WFS1. However, clinical phenotype of WS resembles mitochondrial disorders. Here we show that WFS1 forms a complex with a Neuronal Calcium Sensor protein (NCS) and inositol 1,4,5-trisphosphate receptor (IP3R) to promote ER-mitochondrial Ca^{2+} transfer in response to stimuli that generate inositol-1,4,5-trisphosphate. In addition, we report that NCS localizes to mitochondria-associated membranes and regulates mitochondrial respiratory chain. Moreover, we demonstrate that WFS1 prevents the degradation of NCS by the proteasome. In agreement, NCS expression is reduced in WFS1-null patient fibroblasts, which show reduced ER-mitochondria interactions and Ca^{2+} exchanges. Importantly, NCS overexpression not only reactivates ER-mitochondrial Ca^{2+} transfer, but also induces a significant rescue of the dysfunctional mitochondrial phenotype observed in WFS1 deficient cells. Our results describe an unexpected key role of NCS in ER-mitochondria crosstalk and reconcile the ER expression of WFS1 with the mitochondrial phenotype, underlining a novel pathogenic mechanism for WS and opening new insights into the biogenesis of other neurodegenerative diseases.

Title: Dyslexia: Evidence for a multifactorial basis

Authors: *M. G. FEITOSA[1], M. R. D. PRESTES, 70910-900[2], M. M. F. SANTANA, 70910-900[3,4], N. G. S. N. RIBEIRO[1]
[1]Inst. de Psicologia, Univ. De Brasília, BRASÍLIA, Brazil; [2]Hlth. Dept., Governo do Distrito Federal, BRASÍLIA, Brazil; [3]Ctr. Universitário do Distrito Federal, BRASÍLIA, Brazil; [4]Brasilia Children's Hosp., Brasília, Brazil

Abstract: According to the Phonological Theory, phonological deficit is a direct cause of dyslexia. According to the Auditory Deficit Theory, a change in the processing of acoustic stimuli is a direct cause of the change in the course of phonological development in dyslexics and, in turn, of the difficulty in learning to read and write. Since the speech stimulus is an acoustic signal, alteration in auditory temporal processing may lead to difficulty in processing of consonants characterized by rapid formant transitions. Alteration in perception of short sounds and rapid transitions can lead to difficulties in speech perception, impairing the construction of the mental representations of speech stimuli. Studies on categorical perception of speech in a voiced /unvoiced (V/U) perceptual continuum have shown altered perception of speech by dyslexics. And studies on the frequency of different types of orthographic errors have pointed out that voiced/voiceless exchanges are the most frequent type of error in both dyslexics and oralized deafs. Objective: To assess the underlying picture of the voiced/voiceless exchanges presented by dyslexics, and possible relationships between dyslexia symptomatology and alterations in auditory processing and speech perception. Methods: A group of Brazilian typical readers aged 9 to 15 years (N = 17), and two groups of dyslexics with (N = 17) and without (N = 09) V/U exchanges were studied. Groups were compared regarding measures of reading, writing, phonological awareness, minimum-pairs auditory discrimination, auditory temporal processing, and speech perception in an experiment of identification of stimuli that differed in onset time, forming the Portuguese perceptual continuum /bala-pala/. Results: The group of dyslexics without V/U exchanges did not differ from the group of typical readers in the occurrence of V/U exchanges, and in the total number of errors in the dictation task. In the other measures, the typical reader group presented superior performance to that of both groups of dyslexics. The groups of dyslexics with and without persistent V/U exchanges differed in the ability of auditory temporal resolution and in phonological awareness at the syllable level. Significant correlations

were observed between consistency in the classification of stimuli along the /bala-pala/ continuum and measures of reading, writing, phonological awareness, and auditory temporal processing. Conclusion: Evidence supports the proposition that dyslexia has a multifactorial basis, since both the auditory perceptual alteration and the phonological awareness alteration exerted influence on the symptoms of dyslexia.

Title: Gata3 haploinsufficiency causes sensitivity to noise damage

Authors: *J. DUNCAN
Western Michigan Univ., Salt Lake City, UT

Abstract: Human *GATA3* haploinsufficiency leads to HDR (hypoparathyroidism, deafness, and renal dysplasia) syndrome. The development of the parathyroid, inner ear, and kidneys in humans appear extremely sensitive to levels of GATA3 and deviation of these levels leads to defects. Deafness in these patients appears to be moderate during childhood and progresses to severe in most patients. There has been some indication that in older mice with *Gata3* mutations there is a loss of inner ear hair cells while other auditory areas of the CNS appear normal. *Gata3* haploinsufficient mice were found to have relatively normal inner ear innervation, as well as normal innervation of the auditory and vestibular nucleus by the vestibular cochlear nerve. These mice also appear to have relatively normal hair cell and supporting cell development in the organ of Corti at birth. While these mice have normal numbers of cells and morphology of the organ of Corti and cochlear duct hearing was also tested by ABR. At 21 days mice had moderate hearing loss that continued throughout the lifespan. However when exposed to prolonged loud broad frequency sound the haploinsufficient mice had profound hearing loss and hearing did not return to normal. This is in contrast to control mice exposed to the same broad frequency sound. The control mice had a slight drop in hearing threshold that quickly returned to normal. While mice haploinsufficient for *Gata3* have moderate hearing loss, their hearing is quickly and permanently damaged by loud noise.

Title: Cortical auditory response adaptation and cross-frequency coupling in normal and impaired listeners

Authors: *U. MALINOWSKA[1], P. J. FRANASZCZUK[3], N. E. CRONE[4], D. F. BOATMAN[2]
[1]Neurol., [2]Johns Hopkins Sch. of Med., Baltimore, MD; [3]Human Res. & Engin. Directorate, US Army Res. Lab., Aberdeen Proving Ground, MD; [4]Neurol., Johns Hopkins Hosp., Baltimore, MD

Abstract: Introduction. In auditory cortex, the rapid decrease in neural activity that occurs with stimulus repetition is known as adaptation and is thought to facilitate listening in background noise. Stimulus repetition also increases cross-frequency coupling in auditory cortex, potentially reflecting sensory gating at the network level. We hypothesized that rate of adaptation and cross-frequency coupling correlate with listening performance in background noise.
Methods. We analyzed electrocorticographic (ECoG) recordings from 10 adult epilepsy patients with electrodes implanted over lateral, left temporal cortex. All had normal hearing; five demonstrated impaired speech recognition in noise. Tone and speech stimuli were presented in a passive auditory oddball paradigm. Time-frequency matching pursuit analysis was used to identify sites with significant increases in high-gamma (70-150 Hz; HG) power. Adaptation rates were computed for frequently repeated stimuli, fitting single-trial responses with a decaying exponential to derive time constants. Cross-frequency phase-amplitude coupling (PAC) of theta (4-7 Hz) and HG was measured by computing phase-locking values across consecutive repetitive trials. PAC changes as a function of stimulus repetition were identified by Pearson correlation coefficients.
Results. Patients with intact speech in noise abilities showed adaptation of high gamma power for repetitive tone and speech stimuli. Average adaptation rates were 2.23 repetitions for tones (0.8-5.75/patient) and 2.38 repetitions for speech (1.06-6.44/patient). For normal listeners, correlation analysis also revealed significant repetition-related increases in PAC for tones

(r=0.78, p=0.02) and even stronger increases for speech (r=0.9, p=0.002). For patients with impaired speech in noise listening abilities, the average HG adaptation rate for tones was 1.88 repetitions (0.8-10.5/patient), comparable to normal listeners. However, the average adaptation rate for speech was 4.02 repetitions (3.01-6.99/patient) almost twice that of normal listeners. Impaired listeners also showed no significant increases in PAC for tones (r= 0.06, p=0.98) or speech (r=-0.44, p=0.27).
Conclusions. In contrast to normal listeners, impaired listeners showed slower adaptation rates and no repetition-related increases in cross-frequency coupling in auditory cortex for tones or speech. These results suggest that slower adaptation and abnormal local network processing may contribute to listening difficulties in background noise.

Title: Effects of short term synaptic plasticity on stimulus specific adaptation in auditory cortex: A modeling study

Authors: *D. BEEMAN[1], P. KUDELA[2], D. BOATMAN-REICH[3], W. S. ANDERSON[2]
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Neurosurg., Johns Hopkins Univ., Baltimore, MD; [3]Neurol. and Otolaryngology, Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Neural responses decrease with stimulus repetition, a phenomenon known as adaptation or repetition suppression. In auditory cortex, adaptation is stimulus-specific (SSA) in that it does not generalize to novel or different sounds and is often measured using an 'oddball paradigm' in which the subject listens to a weighted random sequence of short tone pips at two different frequencies, with one more probable than the other. Auditory evoked potentials (AEPs) are recorded from cortical surface (ECoG) electrodes.
The neural mechanisms underlying SSA in human auditory cortex remain poorly understood. In this modeling study, short term synaptic depression and facilitation were evaluated as a potential neural substrate for SSA in auditory cortex. Model simulations based on the same experimental parameters as the ECoG recordings yielded AEPs consistent with those derived from the ECoG

recordings.
An existing layer 4 primary auditory cortex model consisting of 2304 multicompartmental pyramidal cells and 576 basket cells was extended to include 288 inhibitory Martinotti cells. Synaptic depression was applied to interlayer excitatory synapses of the pyramidal and basket cells, with facilitating excitatory synapses on the Martinotti cells.
SSA arises from two time constants associated with the plasticity model, which was implemented in GENESIS 2.4. After a fit of the model parameters to measurements in mouse auditory and somatosensory cortex, we were able to replicate and explain the significant features of the AEP experiments.
As in a typical experiment or simulation, 300 short tone pips at 1000 and 1200 Hz are presented at 1 sec intervals with probabilities of 0.82 and 0.18. A thalamic input model applies tones targeted at rows along a tonotopic axis with a 1 mm spacing between octaves. Thus, two mostly distinct groups of neurons are strongly excited. On average, frequent tone stimuli will follow each other at 1 sec intervals. The probability of two sequential infrequent tones is low, and the average interval between these stimuli is much larger.
In the synaptic depression model, the synaptic weight is a product of two depression factors, each with a depression increment and a time constant for weight decay back towards the original value of 1.0. One of these, with a time constant of about 1.5 sec, gives less depression if the interval between input spike pulses is long. Consequently, sequential stimuli of the frequent tone will maintain some depression between pulses, but responses to the more widely separated infrequent stimuli will have recovered from the depression. This is seen in the amplitudes of simulated AEPs for frequent and infrequent tones.

Title: Mechanistic identification of stimulus relay from the medial auditory thalamus necessary for delay and trace eyelid conditioning

Authors: *L. C. HOFFMANN, S. J. ZARA, M. D. MAUK
Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX

Abstract: The essence of neural processing is transforming inputs into useful output. Identifying and characterizing inputs is therefore a fundamental initial step toward understanding any particular instance of neural processing. How discrete, stimulus-driven responses are transformed into persistent neural responses that last well beyond stimulus offset, a process often connected to the substrates of working memory (Fuster & Alexander 1971; Funahashi, Bruce & Goldman-Rakic, 1989; Zhou & Fuster 1996), is an important example. Trace eyelid conditioning requires persistent activity that is conveyed to the cerebellum for learning to occur (Kalmbach et al. 2009; Kalmbach, Ohyama & Mauk 2010). To begin identifying where and how this persistent activity is generated, we have tested the hypothesis that the medial auditory thalamic nuclei (MATN) are a necessary component of a pathway connecting the activity elicited by auditory conditioned stimuli (CS) to the task-related persistent activity that is necessary for learning. Using tetrode recordings of medial prefrontal cortex and reversible MATN inactivation with muscimol, we show that the MATN are necessary for trace ELC and corresponding persistent activity in prefrontal regions necessary for the task. Using electrical stimulation of MATN, we further show that CS-duration input from MATN is not sufficient for acquisition of trace conditioning, while inputs that bridge CS and US support learning. Results suggest trace eyelid conditioning is supported through persistent activity that is driven directly or indirectly by MATN.

Title: Hearing sensitivity and participation restriction in adults with longstanding unilateral chronic otitis media

Authors: *R. S. TSCHIEDEL[1], S. C. L. BRAGA[2], L. S. SÁ[2], M. V. S. MEDEIROS[1], R. C. GRANJEIRO[2], M. A. G. FEITOSA[1]
[1]Univ. of Brasilia, Brasilia, Brazil; [2]Distrito Federal Dept. of Hlth., Brasilia, Brazil

Abstract: Chronic otitis media (COM), a characteristic disease of developing countries, can cause a decrease in auditory sensitivity. This perceptual barrier, often initiated in childhood and adolescence, can extend throughout adult life due to several factors. Hearing impairment resulting from COM can lead to negative implications for daily activities that demand auditory perception, even when the involvement is unilateral. The objective of this study was to assess the

level of auditory sensitivity, perceived hearing difficulty, and auditory participation restriction among adults with a longstanding unilateral COM history. Twenty-six adults with unilateral COM, whose symptoms started until the age of 18, were evaluated. All were followed up at a public Otorhinolaryngology outpatient clinic in the Brazilian capital and were recruited from the waiting list for otologic surgery. Procedures included interview, puretone thresholds for 500, 1000, 2000 and 4000 Hz, and administration of the Hearing Handicap Inventory for Adults questionnaire (score 0 to 100).In the sample aged 18-54 years, 54% had the symptoms of COM initiated until 6 years of age, and 46% between 7 and 18 years of age. These participants had on average symptoms of COM for 33 years, and 65% of them had undergone at least one otologic surgery. In all, the ear with COM presented alteration in the peripheral auditory system, and in 69% there was involvement of the inner ear associated with alteration in the middle ear, and in 99% reduction in the auditory sensitivity (mean = 46dB). Sixty-five percent presented some level of participation restriction (HHIA ranged from 18 to 80), and for 69% the perceived hearing difficulty was classified as medium or large. Both, participants with a mean auditory sensibility threshold between 21 and 40dB, and participants with an average threshold between 41 and 69dB, presented levels of restriction of absent to severe participation. Correlation analysis using Kendal tau showed that perceived hearing difficulty correlated with HHIA score ($\tau = 0.34$, $p < 0.05$) and the consequent level of participation restriction ($\tau = 0.83$, $p < 0.01$). Results also showed that HHIA score cannot be explained based solely on auditory sensitivity, and other factors should be investigated. Adults with unilateral COM may present a long time of hearing deprivation, even though they have undergone otologic surgery, and each individual perceives differently the reduction in auditory sensitivity.

Title: Selective synaptic contacts promote retinotopic detection of visual looming in the *Drosophila* central brain

Authors: *M. B. REISER, M. MORIMOTO, A. NERN, G. M. RUBIN, E. ROGERS, A. WONG, P. GHORBANI, N. A. SMITH, M. DREHER, R. PAREKH, D. BOCK
HHMI / Janelia, Ashburn, VA

Abstract: Lobula Columnar (LC) neurons provide an anatomical connection between early visual processing areas and central brain regions in flies. Each LC cell class projects to distinct central brain structures called optic glomeruli. LC neurons exhibit retinotopic tiling of a visual neuropil with their dendrites, but their axonal projections in the glomeruli do not show any obvious retinotopic organization. These cells have been thought to encode visual features, and this apparent loss of retinotopy provided further evidence for this proposal. We have focused on a single LC type, the LC6 neurons, which are responsive to visual looming stimuli, and can induce takeoff behavior in flies upon ontogenetic activation. Since the LC6 glomerulus is not innervated by the known neurons of escape pathways, we investigated the targets of LC6 projections. Using the imaged expression pattern of collections of genetic driver lines we have identified at least 5 downstream target neuron types of LC6, and then used the split-GAL4 technique to develop refined genetic driver lines for each cell type. We established the functional connectivity of LC6s to each downstream neuron type by using optogenetic depolarization of LC6 neurons while measuring intracellular calcium responses in the downstream neurons. We then used 2-photon calcium imaging to measure the visual response properties of several LC6 target neurons. While the target neurons retain the sensitivity to visual looming, we find that different downstream cell types appear to respond selectively to looms presented in distinct, restricted, parts of the visual field. In light of the previous evidence observed with light microscopy, that the optic glomerulus does not contain any retinotopic organization, these new imaging results suggested that retinotopy might be achieved through selective synaptic contacts in the glomerulus. To examine this hypothesis, we took advantage of the Bock Lab's newly acquired serial section TEM imaging volume of an entire female Drosophila brain. We began tracing visual projections into the central brain and were able to identify the LC6 neurons as well as their targets. Several target neurons and all of their LC6 inputs were traced. We observe selective connectivity between the target neurons and their visual inputs, suggesting that distinct patterns of visual information are accessible within optic glomeruli.

Title: A visual projection neuron class links the detection of translational motion to the control of forward walking

Authors: *M. ISAACSON, J. ELIASON, A. NERN, M. B. REISER
Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: The perception of visual motion is useful for animal navigation and moving object detection, and flies are a prominent model system for elucidating the neural mechanisms behind this computation. In flies, directionally selective neurons in the optic lobe compute local motion and project retinotopically into motion-direction-specific layers in the Lobula Plate. Several large visual projection neurons have been extensively studied that integrate Lobula Plate local motion information across a large field-of-view of the fly eye and project this information to the central brain. However, the Drosophila visual system also features small-field visual-projection neurons which have received little attention. Here we present the results of studying one such cell type, which we call Lobula Plate Columnar Type 1 (LPC1), in tethered flies positioned in the center of an LED visual arena capable of delivering all types of rotational and translational motion stimuli. We found that regressive translational motion, which specifically caused flies to cease forward walking, no longer had this effect upon silencing LPC1, yet LPC1 silencing did not affect optomotor reactions to rotational visual motion. We then used 2-Photon imaging to measure visual stimulus evoked calcium responses in the axon terminals of LPC1s, and found that this cell type responds strongly to regressive motion presented to its corresponding eye, but this response is abolished when the opposite eye simultaneously received progressive motion -- a computation that can differentiate between the visual consequence of translational motion and rotational self-motion. Optogenetic activation of LPC1 caused the fly to cease forward walking while also not affecting turning behaviors produced by rotational motion stimuli, demonstrating that the control of forward locomotion and turning are largely decoupled in the fly nervous system. These results identify a population of cells that integrate visual translational motion information from both eyes, a computation that may contribute to the behavioral reactions to moving objects.

Title: Simple integration of inputs computes directional selectivity in *Drosophila*

Authors: *E. GRUNTMAN[1], S. ROMANI[2], M. B. REISER[3]
[1]Janelia Res. Campus, Ashburn, VA; [2]HHMI Janelia Res. Campus, Ashburn, VA; [3]HHMI Janelia Res. Campus, Ashbrun, VA

Abstract: The detection of visual motion is a fundamental neuronal computation that serves many critical behavioral roles, such as encoding of self-motion or figure-ground discrimination. For a neuron to extract directionally selective (DS) motion information from inputs that are not motion selective it is essential to integrate across multiple spatially distinct inputs. This integration step has been studied for decades in both vertebrate and invertebrate visual systems and given rise to several competing computational models. Recent studies in Drosophila have identified the 4th-order neurons, T4 and T5, as the first neurons to show directional selectivity. Due to the small size of these neurons, recordings have been restricted to the use of calcium imaging, limiting timescale and direct measurement of inhibition. These limitations may prevent a clear demonstration of the neuronal computation underlying DS, since it may depend on millisecond-timescale interactions and the integration of excitatory and inhibitory signals. In this study, we use whole cell in-vivo recordings and customized visual stimuli to examine the emergence of DS in T4 cells. We record responses both to a moving bar stimulus and to its components: single position bar flashes. Our results show that T4 cells receive both excitatory and inhibitory inputs, as predicted by a classic circuit model for motion detection. Furthermore, we show that by implementing a passive compartment model of a T4 cell, we can account not only for the DS response of the cell, but also for its dynamics.

Title: Circuitry of the lobula giant movement detector 2 neuron

Authors: *E. COCKS, C. RIND
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Serial Block Face Scanning Electron Microscopy (SBF-SEM) can reveal novel information on neuronal circuitry. One example is the discovery of the complex circuitry of the locust visual system, specifically the Lobula Giant Movement Detector 1 and 2 (LGMD1 and 2) neurons. The neurons are part of a larger network involved in jumping, escaping and hiding in response to an approaching object. The system is of importance, as it can be used as a model of sensory-motor integration. However, the LGMD1 has been the main focus of analysis so far and not much is known about the connectomics of the LGMD2. In order to study this with SBF-SEM, the brain of an adult locust (*Locusta migratoria*) was processed with an adapted heavy metal staining protocol. The samples were embedded in hard resin and the blocks trimmed and prepared for SBF-SEM. From a block 500 slices at 60nm thickness were taken and analysed in Microscopy Image Browser and Amira. Reconstructions of the LGMD2 dendrites show single afferent neurons (AN) from the medulla, connecting with the LGMD2 more than once. ANs each synapse onto both the large (~7µm) and small (~2µm) diameter branches, in a ~18-20µm area. ANs synapsed multiple times with the same and different neighbouring ANs at each of these two locations. Also seen, and only through 3D reconstruction, is that the ANs, found to synapse multiple times in one region on the LGMD2, followed a similar path to one another through the neuropil, when no longer synapsing. ANs have previously been shown to synapse on multiple occasions on the same branch, and on multiple branches of the LGMD1. The reconstructions show a similar pattern for the LGMD2. Multiple synaptic connections in a small area of the LGMD2 from a single AN allows for rapid signal integration over the LGMD2 dendrites, explaining how a locust can process a visual stimulus and initiate a motor response in less than a tenth of a second. The precise computation of looming by the LGMD1 relies on the multiplication, in the neuron, of two signals, one excitatory and the other inhibitory. The inhibitory signal is spatially removed from the excitatory one and this matches the structure of the LGMD1 dendritic tree, which has one main dendritic tree for excitatory input (branch A) and two smaller dendritic fields (sub-branches B and C) for inhibitory input. The LGMD2 does not have these sub-branches so how is looming signalled? Labelling of inhibitory synapses in the neuropil, using immunogold, in combination with SBF-SEM, could be a way to find and map another mechanism of inhibition that occurs in the input network of the LGMD2. Revealing how the combination of excitatory and inhibitory inputs also shapes the LGMD2's response to looming objects.

Title: Electron microscopy-based reconstruction of the motion information processing circuits in the fruit fly brain

Authors: *K. SHINOMIYA[1], G. HUANG[1], T. ZHAO[1], S. XU[2], S. PLAZA[1], L. SCHEFFER[1], I. A. MEINERTZHAGEN[3,1]

Abstract: The visual system of the brain of *Drosophila melanogaster* has been studied as a model system in the field of electron microscopy (EM)-based connectomics. Regardless of its modest size, the optic lobe houses complex circuitry, which processes diverse modalities of visual information in parallel. In this study, we reconstruct motion information processing circuits in the optic lobe applying a sparse reconstruction strategy using the focused-ion beam aided scanning EM (FIB-SEM) technique for imaging. The dataset covers the entire optic lobe, including three synaptic neuropils, the medulla, lobula and lobula plate. The neuropils, consisting retinotopic columnar units, are interconnected by neuronal processes through the second optic chiasm. We imaged the optic lobe neuropils with FIB-SEM with an isotropic resolution (8nm x 8nm x 8nm). Neurons in the three-dimensional grayscale image stack were segmented on computer, and synaptic areas (both pre- and post-synapses) were also auto-predicted. It has been known that motion information is detected by T4 cells projecting from the medulla to the lobula plate, and T5 cells projecting from the lobula to the lobula plate. T4 and T5 cells detect moving light (ON)- and dark (OFF)-edges respectively, with inputs from their upstream neurons. Motion information from the two pathways is integrated into lobula plate neurons. Using information of predicted synapses, we traced and reconstructed neurons that receive inputs in the lobula plate to comprehensively identify the neurons participating in motion information processing. As a result, we reconstructed the entire motion information processing circuit in the optic lobe completely from the photoreceptors to the projection neurons to the central part of the brain. We confirmed that many lobula plate tangential cells (LPTCs), lobula plate interneurons (LPi) and other newly found neurons are engaged in motion information processing, with projections from the T4 and T5 cells. In the lobula plate, four directions of stationary motion (backward, forward, upward and downward) are processed in four distinct layers. We also revealed that T4 and T5 cells processing motion of one direction inhibit LPTCs responsible for the opposite direction in a neighboring layer, mediated by inhibitory LPi cells. This connectomics approach is expected to accelerate high-throughput reconstruction of neuronal circuits that serve as the anatomical basis for further functional analyses, both within the optic lobe and in the central brain.

Abstract: A classic problem in visual neuroscience, how the visual system detects image motion, has recently undergone resurgent interest in the fruit fly Drosophila. The problem has long been analyzed using mathematical models, of which the Hassenstein-Reichardt elementary motion detector (EMD) or Barlow-Levick model are both widely canvassed. Both models compare two visual inputs separated in time and space and simulate motion detection well. However, the exact neural mechanism underlying the detection of direction by motion-sensing cells is still understood only imperfectly. Here we reconstructed a comprehensive connectome of the circuits of fly's visual motion-sensing T4 cells using a superior electron microscopy technique. We uncover complex T4 inputs and reveal that putative excitatory inputs cluster at T4's dendrite shafts, while inhibitory inputs localize to the bases. Our results suggest new candidate circuits for motion detection, including previously unidentified inhibitory pathways. We furthermore mapped synaptic circuits of ~30,000 connections between nearly all medulla cell types, and also reconstructed the morphologies of, and mapped over 240,000 synaptic connections between, all 983 neurons within the mushroom body, the fly's learning and memory center. The unprecedented level of detail of synaptic circuits should enable modeling studies not previously possible and suggests many experiments to explore their physiological and behavioral significance. That many of the new pathways and neural circuitry were not anticipated by decades of extensive anatomical, experimental and theoretical studies argues strongly for the value of EM connectomics studies.

Title: The effect of locomotion-induced octopamine release on motion detection circuits in *Drosophila*

Authors: *J. KOHN, R. BEHNIA
Columbia Univ., New York, NY

Abstract: To survive in ever-changing environments, an animal must be able to detect relevant stimuli. Neuromodulation affords anatomically rigid networks the ability to tune their sensitivity to various stimuli in a state-dependent manner. However, the mechanisms underlying the modulation of neural circuits are relatively unknown. Motion-detecting circuits in *Drosophila* are well-characterized and provide a powerful model system to study the effects of behavioral state on circuit output. These circuits consist of connections between photoreceptors in the eye and lobula plate tangential cells (LPTCs) in the optic lobe, which are direction selective. Locomotion modulates LPTCs by increasing their response amplitude and shifting their sensitivity toward faster moving stimuli (Maimon *et al.* 2010, Chiappe *et al.* 2010). This process is dependent upon the release of octopamine (OA), a neuromodulator equivalent to mammalian norepinephrine (Suver *et al.* 2012). We investigate the neuronal targets of OA in these circuits, how the action of OA leads to the shift in sensitivity of the outputs towards faster-moving stimuli, and explore potential cellular and circuit mechanisms underlying this modulation.

Title: Flight control and color vision in *Drosophila*

Authors: *K. D. LONGDEN, M. B. REISER
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Learning and memory experiments have demonstrated that *Drosophila* has color vision and can discriminate different wavelengths of light, even when they are isoluminant. This capacity for color vision is supported by the expression of five rhodopsins in the compound eyes, each with a distinct wavelength sensitivity profile, and by dedicated circuitry that has been characterized in detail. Meanwhile, how naïve flies use for this capacity for color vision remains a mystery. Here, we have investigated how color vision can influence three forms of flight control prior to learning. To do this, we developed a novel ultraviolet and green projector system to display wide-field visual stimuli. We measured the flight control responses of tethered flies by optically recording changes in wing stroke amplitude. First, flies can stabilize the horizon even when the intensities of the different wavelengths are matched so that they provide no luminance contrast. This is achieved by combining wavelength-sensitive phototaxis and color-blind motion vision to stabilize the scene. Second, during looms the steering responses are color-blind, but the wing beat frequency varies with the intensity of ultraviolet light. Third, during flight towards an attractive object, a single vertical stripe, the responses are color blind. Together, our results show how the wavelength of light can influence multiple aspects of flight attitude and control, and allow the operation of color vision circuitry to be investigated in the context of natural behaviors.

Title: Characterization of feed forward inhibition in a looming detection circuit

Authors: *H. WANG[1], R. B. DEWELL[1], F. GABBIANI[1,2]
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Dept. of Electrical Engin., Rice Univ., Houston, TX

Abstract: The lobula giant movement detector (LGMD) in the locust optic lobe is among the best-studied looming sensitive neurons. It receives feed-forward excitatory inputs through a fan-shaped dendritic field, called field A and inhibitory inputs through two additional dendritic fields, called B and C. The excitatory inputs encode the angular velocity of the approaching

object, while the inhibitory inputs are thought to encode its angular size. Current experimental data are consistent with the LGMD effectively multiplying these two inputs resulting in a firing rate that gradually increases, peaks, and then decays towards collision. The medullary neurons providing inhibition to the LGMD have not yet been physiologically characterized. Hence, our current understanding of feed-forward inhibition is based on anatomy, pharmacology and modeling. Multiunit recordings from the medulla were paired with intracellular LGMD recordings during visual stimuli to characterize the inhibitory inputs to the LGMD. Previously, we examined their sensitivity to contrast polarity, directional selectivity, receptive field size and the response profile. In this work, the inhibitory neurotransmitters released onto dendritic field C were examined. To our surprise, puffing of multiple transmitters, including GABA and Histamine, significantly reduced the firing rate of the LGMD in response to looming stimuli. For the same stimuli, the recorded medullary neurons showed a firing rate profile resembling that of the LGMD, which gradually increases, peaks and then decays towards the end of the simulated approach. An angular size linear model fits the instantaneous firing rate of the recorded medullary neurons with a R^2 value of 0.71. This indicates that the firing rate of medullary neurons providing inhibitory input to the LGMD most likely encodes angular size of the approaching object, in agreement with the earlier hypothesis that a logarithmic exponential transform implements multiplication of angular size with a negative exponential of speed within the LGMD neuron.

Title: Electroretinographic study of vision in the stink bug Halymorpha halys compound eyes

Authors: J. STRICKLAND[1], A. B. LALL[2], *V. D. SHIELDS[1]
[1]Fisher Col. of Sci. and Mathematics - Biol. Sci., Towson Univ., Towson, MD; [2]Biol., Howard Univ., Baltimore, MD

Abstract: The brown marmorated stink bug, *Halymorpha halys*, has become an agricultural nuisance in the United States. According to the Environmental Protection Agency, this polyphagous feeder creates damage and yield loss in a wide range of crops. The insect utilizes a

suckering mechanism for the removal of sap from desirable food sources. The affected crops are often left unappealing to consumers. The typical methods utilized for prevention of damage and ultimately loss have been non-biological pesticides, which are designed to kill or cause adverse effects to living organisms. However, more recent control measures have included the design of olfactory and visual traps. The incorporation of visual traps as an alternative to common non-biological pesticides are beneficial to both human health and other living organisms. To utilize visual traps, it is first necessary to know the visual characteristics of the compound eyes of this insect. Electroretinograms (ERGs) elicited by light stimuli were recorded from the corneal surface of the eyes by a standard method. Our results indicate that the ERG was a negative monophasic waveform consisting of an initial phasic component followed by a maintained component that lasted for the duration of the flash, with no off-response at the end of white light stimulus. The eye responded over a six log unit change in white light illumination, as indicated by the V/logI curves, and the response latency was long (40-60 ms) in dim illumination and short (20-30 ms) in bright illumination. Visual spectral sensitivity of the eye was obtained by determining the number of photons needed for eliciting a criterion amplitude ERG response (0.2, 1.2, and 2.4 mV) across the spectrum at 13 different stimulus wavelengths from 420 nm to 640 nm. The spectral sensitivity had a maximum around 540 nm. The waveform of the ERG response elicited by short wavelength stimuli (blue) differed from those obtained with long wavelength stimuli (green or red). These waveform responses are being further evaluated by studies obtaining ERG responses under different chromatic adaptation conditions. Our data suggest the presence of a dominant spectral mechanism in the green region of the spectrum as is common among insects. The presence of a secondary spectral mechanism in the short wavelengths is being investigated by chromatic adaptation experiments.

Title: Linear relation between orientation structure and spatial resolution in visual cortex

Authors: *E. KOCH, J. JIN, J. M. ALONSO, Q. ZAIDI
Biol. and Visual Sci., SUNY Optometry, New York, NY

Abstract: Visual information is topographically mapped in the primary visual cortex according to multiple stimulus parameters such as orientation and spatial frequency. While the representation of each parameter is well known, the cross-parameter structure remains poorly understood. We recently proposed an Excitation-Normalization (EN) model to explain the topographic relation between orientation tuning and orientation preference (Koch et al, 2016). This model also predicts a strong relation between local orientation homogeneity and spatial frequency resolution. Here we tested the prediction for spatial resolution by performing horizontal penetrations with multielectrode arrays through cat primary visual cortex. We simultaneously measured orientation and spatial frequency tuning with random sequences of single gratings that included 8 orientations, 4 phases and 10 spatial frequencies presented separately to contralateral and ipsilateral eyes. For each cortical site, we calculated a homogeneity index of local orientation preference (LHI, 1: no local change, 0: rapid local change), the circular variance of orientation tuning, the high spatial frequency cutoff at 50% response amplitude (SF50), and the ocular dominance. As predicted by the EN model, our results revealed a strong linear relationship between SF50 and LHI ($r=0.7099$, $p<0.0001$, $n= 55$), with spatial resolution systematically increasing as the multielectrode entered a cortical iso-orientation domain. The SF50 was also correlated with orientation selectivity ($r=-0.5767$, $p<0.0001$, $n=55$) and ocular dominance ($r=0.4604$, $p<0.001$, $n=55$), with non-oriented monocular-neurons showing lower spatial resolution than orientation-selective binocular-neurons, as recently found in macaques (Nauhaus et al, 2016). We also found a strong relation between ocular dominance and binocular mismatch in spatial resolution ($r=0.7246$, $p<0.0001$, $n=45$), with neurons being binocularly-matched in spatial resolution when they are also binocularly-matched in response strength. Finally, ocular dominance was correlated with LHI ($r=-0.3313$, $p=0.003$, $n=75$) as expected from the alignment of pinwheel centers with monocular regions. Our results reveal pronounced relations across different stimulus parameters in cortical topography as would be expected from a specialization of different map domains in different functions. We conclude that, just as the weak cross-orientation suppression of pinwheel centers allow processing of multi-orientation patterns more efficiently (Koch et al, 2016), the enhanced spatial resolution of binocular domains may help maximize the spatial resolution of binocular vision.

Title: Emergent functional connectomes are systematically activated within overlapping micro-organization of spatial frequency and orientation maps in the visual cortex

Authors: *S. MOLOTCHNIKOFF[1], V. BHARMAURIA[2], N. CHANAURIA[3], L. BACHATENE[4]
[1]Sci. Biologiques, Univ. de Montreal, Montreal, QC, Canada; [2]York Univ., North York, ON, Canada; [3]Sci. Biologiques, Univ. de Montréal, Montréal, QC, Canada; [4]Dept. of Nuclear Med. and Radiobiology, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Orientation tuning and spatial frequency tuning are characteristic properties of visual neurons across species. Although the orientation maps are well established and investigated across species, debate still persists on the existence of the spatial frequency maps in the cortex. However, recently, investigators using optical imaging (Nauhaus et al. 2012; Ribot et al. 2013), two-photon imaging (Nauhaus et al. 2012) and single neuron electrophysiology (Molotchnikoff et al. 2007) have shown and suggested that spatial frequency is micro-organized and overlapped with orientation maps in the visual cortex. Here we investigated the functional circuits (connectomes) within ensembles of neurons (recorded using tungsten microelectrodes in anesthetized cats) while spatial frequency and orientation tunings of neurons were simultaneously tested. First, the orientation tunings of neurons were computed by randomly presenting oriented sine-wave drifting gratings in steps of 22.5°, and then the functional circuits were revealed using cross-correlograms (CCG) between these simultaneously recorded neurons at each orientation (Bharmauria et al. 2016). Thereafter, the spatial frequency was systematically changed and the functional connectomes were revealed within above ensembles while the orientation was kept constant (0° or 90°). Indeed, as reported before (Bharmauria et al. 2014, 2016), a salient network was activated within an ensemble in relation to the specific spatial frequency, suggesting that a unique functional connectome is important for spatial frequency encoding. Further, it was divulged that neurons that shared orientation and spatial frequency tuning exhibited significantly more connections than those neurons that did not share the properties. This suggests that spatial frequency and orientation tuning maps may be simultaneously micro-organized and functionally superimposed while an ensemble encodes both properties at the same time.

Title: Functional specialization of ON and OFF pathways for slow-global and fast-local change in the visual world

Authors: *R. MAZADE, J. JIN, C. PONS, J. ALONSO
Biol. and Vision Sci., State Univ. of New York Col. of Optometry, New York, NY

Abstract: Visual information is processed in the brain by ON and OFF pathways that respond to light and dark stimuli. In the visual cortex, OFF visual responses are stronger, represent visual space more accurately, and respond more linearly to luminance contrast than ON responses. Here, we demonstrate that these ON-OFF cortical asymmetries reflect a functional specialization to signal different spatial (global vs. local) and temporal (slow vs. fast) properties of visual scenes. To quantify the ON/OFF cortical representation of spatiotemporal space, we performed horizontal penetrations through cat primary visual cortex with multielectrode arrays (32-electrode Neuronexus, 0.1 mm electrode spacing, n=5 animals) and measured visual responses to dark and light targets presented with different sizes (1 to 23 deg/side), durations (16 to 133 msec), backgrounds (light, dark, mid-gray) and mean luminance (0.024 to 239 cd/m^2, attenuated with neutral density filters). Our results demonstrate that cortical responses are 25% stronger to darks than lights when stimuli are fast and spatially local (e.g. 16 msec, 7 deg target; dark=106.5±3.5 vs. light=80.1±2.3 spk/s; $p<0.001$, Wilcoxon test) but they are 30% stronger to lights than darks when stimuli are slow and large (e.g. 133 msec, 23 deg target; light=85.4±2.1 vs. dark=60.5±1.6 spk/s; $p<0.001$, Wilcoxon test). In addition, we demonstrate that responses to darks show pronounced size suppression (e.g. 16 msec, 7 vs. 23 deg target; 106.5±3.5 vs. 85.1±2.4 spk/s; $p<0.001$, Wilcoxon tests) and temporal suppression (e.g. 7 deg target, 16 vs. 133 msec duration; 106.5±3.5 vs. 70.6±1.9 spk/s; $p<0.001$, Wilcoxon tests), two properties that are important to segregate local moving targets in visual scenes. Conversely, responses to lights are robust when the stimulus is large and show no size suppression (e.g. 7 vs. 23 deg target; 80.7±1.1 vs. 82.6±1.1 spk/s; $p=0.69$, Wilcoxon test) or temporal suppression (e.g. 16 vs. 133 msec duration; 78.1±0.8 vs. 81.9±0.8 spk/s; $p<0.001$, Wilcoxon test). We demonstrate that these

pronounced spatiotemporal asymmetries between darks and lights are present over a wide range of luminance conditions (0.1 to 239 cd/m^2) and only disappear under very low mesopic luminance (e.g. 7 vs. 23 deg dark targets at <0.1 cd/m^2; 8.1±1.2 vs. 18.7±0.9 spk/s; $p<0.001$, Wilcoxon test). Our results suggest that ON and OFF visual pathways are specialized in processing different spatiotemporal properties of visual scenes (ON for slow-global change and OFF for fast-local change), a finding that could explain why reflexes triggered by scene movement are ON dominated in many animals (e.g. optokinetic reflex for image stabilization).

Title: Optical blur affects differently on and off visual pathways

Authors: *C. PONS, R. MAZADE, J. JIN, J. ALONSO
Biol. Sci., State Univ. of New York, New York, NY

Abstract: The eye focuses objects at the plane of fixation leaving large surrounding regions of the scene optically blurred. Image regions that are optically blurred are dominated by low spatial frequencies, which are thought to be less effective at driving ON than OFF visual pathways (Kremkow et al., 2016), however, the effect of optical blur on ON-OFF response balance has not been experimentally studied. Here we measured how ON and OFF responses are affected by optical blur in cat visual cortex, by inducing blur with either contact lenses (-10, 0, +10 diopters) or spectacles (-10, -5, -3, 0, +3, +5, +10 diopters), while using an artificial pupil of 3 mm in all conditions. To quantify the effect of optical blur, we measured changes in receptive field size mapped with light and dark spots and the strength of responses to these stimuli. Our results indicate that the cortical effects of optical blur depend both on the contrast polarity of the stimulus (dark or light) and the polarity of the optical blur (positive or negative). When tested with contact lenses, positive blur made visual responses stronger and cortical receptive fields larger. However, while the response enhancement could be relatively similar for darks and lights (darks: 26.5%, $p<0.0001$, lights: 20.65%, $p<0.0001$, Wilcoxon tests, -10 to +10 diopter), the receptive field enlargement was more pronounced for lights (lights: 17.83%, $p<0.0001$, darks: -0.02%, $p=0.85$, lights-darks: 17.85%, $p<0.0001$, Wilcoxon tests, 0 to +10 diopter). When tested with spectacles, optical blur also made visual responses stronger. However, the effect was dependent on receptive field size, as it would be expected from changes in image magnification

that result from positive (enlargement) and negative (shrinkage) optical power. Spectacles inducing positive blur enhanced the responses of neurons with receptive fields larger than the stimulus while spectacles inducing negative blur enhanced the responses of neurons with smaller receptive fields, and both response enhancements reached saturation at focus. Our results indicate that positive blur (and the associated image magnification) strengthen both OFF and ON visual responses but enlarge more ON than OFF receptive fields. The larger spatial distortion of ON receptive fields could explain why cortical retinotopy is more precise for OFF responses (Kremkow et al., 2016, Li et al., 2016) and why myopia progression is associated with ON visual deficits (Pardue et al., 2008). The saturation of the blur/response function at focus could also provide a mechanism to finely adjust eye optical power to maximally stimulate the smallest receptive fields available in the retina of different animals.

Title: 100 thalamic afferents per cortical point are sufficient to accurately map on and off retinotopy in cat visual cortex

Authors: *E. ZABEH[1], J. JIN[2], R. LASHGARI[1], J. ALONSO[2]
[1]Brain Engin. Res. Ctr., IPM, Tehran, Iran, Islamic Republic of; [2]SUNY Col. of Optometry, New York, NY

Abstract: The thalamocortical pathway is the main route of sensory information to the cerebral cortex, however, we still do not have accurate estimates of how many thalamic afferents converge at each cortical point. Even in cat visual cortex (the animal model with most detailed thalamocortical quantification), the estimates can range from 1000 (Peters and Payne, 1993) to less than 10 (Ringach, 2004; Paik and Ringach, 2011). To provide more realistic estimates of thalamocortical convergence, here we calculated the number of afferents needed to accurately represent ON-OFF retinotopy within a 1-2 mm horizontal track of cat visual cortex. ON-OFF retinotopy was first measured with multielectrode arrays and stimulus spike-trigger-averaging (Neuronexus, 32 electrodes separated by 0.1 mm) and then simulated with a weighted sum of thalamic receptive fields. The simulation used initial random values for receptive field position/size/polarity, and axonal synaptic-weight/cortical-spread that were constrained within physiological ranges (e.g. matched sizes of thalamic/cortical receptive field subregions, average thalamic receptive field scatter per cortical point: 2.5 receptive field centers, equal number of ON and OFF afferents, Jin et al., 2011). After randomizing the initial values, thalamocortical

connections were pruned using a joint-sparse-regression algorithm (Deng et al., 2013) that minimized afferent number without compromising simulation accuracy. The relation between the initial afferent number and simulation accuracy followed a power law that reached r^2: 0.9 with < 100 afferents (average correlation between simulation and data for 80 initial afferents pruned to ~ 65: r^2= 0.98 for OFF, r^2=0.97 for ON, r^2=0.90 for ON-OFF, 10 simulations). When using <100 initial afferents, the simulation accuracy was higher if both excitatory and inhibitory thalamocortical connections were allowed rather than forcing all connections to be excitatory (e.g. r^2 = 0.9 vs. 0.77, for 60 initial afferents). This difference could be reduced but was still maintained when more afferents were used (e.g. r^2 = 0.94 vs. 0.92, for 400 afferents pruned to ~ 125). Reaching a simulation accuracy of r^2 > 0.9 required ~ 40% inhibitory connections for <100 initial afferents (e.g. 41% ON, 40% OFF for 80 afferents) but the percentage was reduced to ~ 34% when the afferent number increased (e.g. 31% OFF, 36% ON, for 400 afferents pruned to ~ 125). We conclude that ON and OFF retinotopy can be accurately mapped in cat visual cortex with a developmental process that uses an excess of thalamic afferents at initial stages, which is pruned to ~100 afferents per cortical point with 30-40% of inhibitory connections.

Title: Untangling cortical maps in mouse primary visual cortex

Authors: *D. L. RINGACH[1], L. JIMENEZ[2], E. TRING[3], J. T. TRACHTENBERG[4]
[1]Neurobio. & Psychology, [2]Psychology, [3]Neurobio., [4]UCLA, Los Angeles, CA

Abstract: Local populations of neurons in mouse primary visual cortex have receptive fields with varied tuning preferences. We show this seeming disorder can be untangled: the similarity of tuning between neurons is correlated better with the overlap of their receptive fields in space rather than with their distance in the cortex. Our findings are consistent with the hypothesis that salt-and-pepper maps in mouse V1 arise in part due to the lateral dispersion of clonally related neurons (Ohtsuki et al, Neuron, 2012).

Title: 2-P imaging of visual cortex layer 6 corticothalamic feedback in the behaving mouse

Authors: ***S. AUGUSTINAITE**, B. KUHN
Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: Layer 6 (L6), the deepest lamina of cerebral cortex, is one of the key structures regulating behavior state related information processing within the cortex and various subcortical areas. However, very little is known about the functional significance of different L6 circuits in vivo. L6 experiments in the behaving animals still remain challenging due to hard access of the recording / imaging site, complexity of neuronal circuits and heterogeneity in neuron morphology. Here, we focus on primary visual cortex L6 feedback projections to visual thalamus (lateral geniculate nucleus) which regulate visual signal transmission from retina to cortex. We developed a method to study this corticothalamic feedback in vivo with 2P microscopy. With

this method, we can reliably image retrogradely labeled corticothalamic and other excitatory L6 neurons in a head-fixed mouse. Up to a few hundred individual neurons can be recorded simultaneously for several hours and/or repeatedly recorded during different days, while monitoring mouse behavior state. This allows us to study the role of corticothalamic feedback in visual signal processing during different behavior states, ranging from full alertness to sleep.

Title: Distinct patterns of stimulus selectivity, spontaneous activity, and connectivity of L6 callosal projection and thalamic projection neurons in primary visual cortex of the awake mouse

Authors: *Y. LIANG, W. SUN, R. LU, N. JI
Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: The corpus callosum is the major commissural pathway connecting the two cerebral hemispheres in the mammalian brain. In contrast to other cortical regions, within mouse primary visual cortex (V1), callosal connections are dominated by infragranular neurons. Little is known about the properties of these callosal projection neurons or their relationship with the corticothalamic (CT) neurons in layer 6 (L6). Developing an understanding of the physiological roles of these neurons requires dissection of their functional specificity and connectivity. By combining retrograde labeling, in vivo two-photon calcium imaging, and rabies virus-based input mapping, we determined the sensory response properties and upstream monosynaptic connectivity of L6 neurons mediating the callosal cortico-cortical (CC) pathway in V1 of the awake mouse. Distinct from the L6 CT neurons, a smaller percentage of CC neurons are orientation selective (OS), with the OS CC neurons possessing similar orientation tuning properties to those of OS CT neurons. Interestingly, a small fraction of callosal CC neurons, but not CT neurons, show spontaneous activity that is suppressed by the presentation of visual stimuli. Rabies-virus-assisted monosynaptic tracing indicates that callosal CC neurons receive more long-range cortical inputs than CT neurons, consistent with the observation that CC neurons have less confined receptive field than CT neurons. Providing evidence that there is a distinct segregation in the function and connectivity between callosal CC and CT L6 neurons, our results support the notion that L6 is more implicated in corticocortical pathways than what was thought previously.

Title: Integrated circuit analysis of layer 2/3 pyramidal cells in mouse visual cortex

Authors: *S. WEILER, T. ROSE, M. HÜBENER, T. BONHOEFFER, V. SCHEUSS
Dept. Synapses-Circuits-Plasticity, Max Planck Inst. Neurobio., Martinsried, Germany

Abstract: Neocortical pyramidal cells (PCs) display functional specializations defined by their connectivity as well as their molecular, anatomical and electrophysiological properties. PCs in layers 5 (L5) and 6 (L6) have been classified into different subtypes based on their *in vivo* functional response properties and corresponding connectivity patterns as well as genetic and electrophysiological characteristics (Velez-Fort et al. *Neuron* 2014, Kim et al. *Neuron* 2015). For layer 2/3 (L2/3) PCs no unique genetic markers corresponding to individual functional subtypes have been discovered so far (e.g. Zariwala et al. *Front Syst Neurosci* 2010). However, L2/3 PC have been shown to project functionally target-specific to higher visual areas (Glickfeld et al. *Nat Neurosci* 2013).
Here, we ask whether L2/3 PCs differ in their connectivity patterns in mouse primary visual cortex (V1) and whether this is related to differences in L2/3 PC stimulus preferences. To address this question, we characterize the excitatory and inhibitory cortical inputs of the same L2/3 PCs using laser-scanning photostimulation (LSPS) by UV glutamate uncaging in brain slices. The majority of L2/3 pyramidal cells receive strong excitatory input from layer 4 (L4) (77/106 PCs, exc. L4 input >50% of total input) and strong local inhibitory input from L2/3 (67/106 PCs, inh. L2/3 input >50% of total input) and varying degrees of additional input from the other layers (e.g. 19/106 PCs, exc. L5 input >25% of total input). Furthermore, the spatial overlap between excitatory and inhibitory synaptic input within a given L2/3 PC varies, e.g. L5 excitatory input is mostly unbalanced by L5 inhibitory input.
In order to explore the functional implications of the different input patterns we developed an *in vivo* / *in vitro* approach: First, we characterize the visual response properties (orientation/direction selectivity, temporal/spatial preferences, ocular dominance and spontaneous activity) of individual neurons expressing genetically encoded calcium indicators (GECIs) with *in vivo* 2-photon calcium imaging. Subsequently, we retrieve the same neurons in brain slices for circuit analysis with LSPS.
In conclusion, L2/3 PCs appear to be a heterogeneous group based on their connectivity patterns, and we currently explore if this is reflected in their visual stimulus preferences.

Title: Neocortical layer 5 is composed of cell type specific microcolumnar circuits

Authors: *S. SAKAI[1,2], H. MARUOKA[2], N. NAKAGAWA[2], S. TSURUNO[2], T. YONEDA[2], T. HOSOYA[2]

Abstract: Neocortex contains various types of excitatory and inhibitory neurons, each with specific axonal projection patterns, gene expression, cell morphology and electrophysiological properties. Understanding the structure of microcircuits composed of these neuronal types is a key to investigate neocortical information processing. Layer 5, an output layer of neocortex, contains two major types of projection neurons. Subcerebral projection neurons (SCPNs) project axons to extracortical targets including the pons, superior colliculus and spinal cord, while cortical projection neurons (CPNs) project axons to other cortical areas. We have previously reported that SCPNs form periodic columnar clusters termed microcolumns and that SCPNs in the same microcolumns show similar visual responses (Maruoka et al., J Neurosci 2011). These observations suggest that SCPN microcolumns function as functional units in layer 5. It has been unknown, however, whether CPNs and inhibitory neurons in layer 5 form microcolumnar functional units similarly to SCPNs. We conducted three-dimensional analysis of the spatial arrangement of major neuronal types in layer 5. Each neuron type was specifically labeled using retrograde tracers, transgenic mice expressing marker proteins or immunostaining. After brain samples were fixed and cleared, large areas of the cortex were imaged by two-photon microscopy. Both SCPNs and CPNs showed thin columnar arrangement in a wide range of cortical areas. These SCPN and CPN microcolumns were interdigitated with each other. We performed in vivo calcium imaging to investigate the activity of the cell type specific microcolumns. Columnar correlations of spontaneous activity and visual response preference were analyzed. Our result indicates that the neocortical layer 5 is composed of cell type specific microcolumnar circuits.

Title: Involvement of gap junctions in the function of microcolumns in neocortex

Authors: *N. NAKAGAWA, T. YONEDA, H. MARUOKA, S. SAKAI, T. HOSOYA
Lab. for Local Neuronal Circuits, RIKEN Brain Sci. Inst., Wako-Shi, Saitama-Ken, Japan

Abstract: Gap junctions mediate electrical coupling between neurons and promote neuronal circuit formation. Recently we found that subcerebral projection neurons (SCPNs), one of the major types of excitatory neuron in layer 5, selectively couple with radially aligned SCPNs in the first postnatal week. The coupling was cell-type-specific; SCPNs rarely coupled with cortical projection neurons, another major type of excitatory neuron. The coupling disappeared during the next week, suggesting its involvement in the development of neuronal circuits but not in the adult brain functions.In a wide range of cortical areas, SCPNs form radial clusters termed microcolumns with a diameter of 1-2 cells, suggesting that the gap junctions preferentially couple SCPNs in individual microcolumns. Our recent analyses revealed that SCPNs in individual microcolumns exhibit correlated activity in the adult stage in vivo. These results raise the possibility that the gap junction network is involved in the construction of microcolumnar neuronal circuits that promote correlated activity in adults.To test this hypothesis, we conducted forced expression of mutant connexin (DNCx) that suppresses electrical coupling in a dominant-negative manner. DNCx expression partially but significantly suppressed electrical coupling between SCPNs in the early postnatal stage. Our preliminary results suggest that DNCx expression impaired correlated activity in the adult stage without altering the microcolumnar organization or basic neuronal activities. These results suggest that electrical coupling between SCPNs promote the development of microcolumnar circuits that enable correlated activity, and thereby establishing the behavior of microcolumns as functional units in neocortex.

Title: LGN input to fast-spike interneurons in layers 4 and 6 of awake rabbit visual cortex

Authors: *Y. I. BERESHPOLOVA[1], X. HEI[1], C. R. STOELZEL[1], J.-M. ALONSO[2,1], H. A. SWADLOW[1,2]
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Biol. and Visual Sci., SUNY Optometry, New York, NY

Abstract: Fast-spike interneurons in layer 4 (L4) of rabbit visual cortex (V1) receive monosynaptic input from the LGN and convey a fast, sensitive, and broadly tuned feed-forward inhibition onto local targets. Layer 6 (L6) also receives a distinct, albeit weaker input from the LGN, and contains fast-spike interneurons. To understand better the role of these interneurons in the thalamocortical circuit, we examine the rules governing thalamocortical connectivity and sensory response properties of putative fast-spike interneurons (suspected inhibitory interneurons, SINs) in both input layers of awake rabbits. We found that L6 SINs, like those of L4 (Zhuang et al., 2013), were very broadly tuned to stimulus orientation/direction, had complex receptive fields (RF) with extensively overlapping ON and OFF zones, responded in a similar, non-linear manner to drifting visual gratings (F1/F0 ratios < 1), showed similar tuning for spatial/temporal frequency, and had high spontaneous firing rates. However, visual responses of L6 SINs were much less sensitive to visual stimuli (higher C50 values: 25.86 ± 2.95 % vs. 10.83 ± 1.94 %, $p < 0.001$, Wilcoxon rank-sum test), responded less robustly to drifting visual grating (lower F1 values: 11.54 ± 1.56 spikes/s vs. 32.97 ± 3.73 spikes/s, $p < 0.001$, Wilcoxon rank-sum test), and were less reliable (higher Fano factors: 2.18 ± 0.34 vs. 1.33 ± 0.08, $p = 0.025$, Wilcoxon rank-sum test) than those of L4 SINs. Cross-correlation analyses of LGN neurons and L4/L6 SINs showed a high connection probability that was strongly related to the degree of retinotopic overlap, with little dependence on matching either (a) the preferred sign of the LGN cell (on-center or off-center) and the SIN (on-dominated or off-dominated), or (b) the sustained/transient response classification of the LGN/SIN paired cells. In both rabbits (Swadlow and Gusev, 2002) and rats (Bruno and Simons, 2002), L4 fast-spike interneurons receive a strong, highly convergent/divergent input from neurons in the topographically aligned thalamic region. Our results show that this is also true for fast-spike interneurons in both L4 and L6 of the visual cortex. Although L6 SINs of V1, like those in L4, are well-suited to convey a broadly

tuned feed-forward inhibition onto their local targets, their responses to visual stimuli are considerably less sensitive, less reliable, and less responsive to changing stimulus conditions.

Title: A circuit for spatial integration and its modulation by running in four classes of V1 neurons

Authors: *M. DIPOPPA, M. CARANDINI, K. D. HARRIS
Univ. Col. London, London, United Kingdom

Abstract: A prominent feature of neurons in primary visual cortex (V1) is selectivity for the size of visual stimuli, known as size tuning. In pyramidal (Pyr) neurons of mouse V1, size tuning is thought to be imposed by somatostatin-expressing (Sst) interneurons, whose responses integrate Pyr input over a wide cortical area. Size tuning, moreover, depends on locomotion, which can profoundly affect sensory responses in multiple neuronal classes of V1. We sought to understand the interplay between these phenomena by measuring the activity of Pyr, Sst, Parvalbumin (Pvalb), and Vasoactive Intestinal Polypeptide (Vip) cells, and describing their interactions with a simple circuit model.
We imaged the visual responses of superficial V1 neurons with the calcium indicator GCaMP6 using a 2-photon microscope, identifying Pyr, Sst, Vip and Pvalb neurons in transgenic mice. We measured size tuning both for cells whose receptive field was centered on the visual stimulus and for the remaining off-center cells. In contrast with a previous report, well-centered Sst neurons did exhibit size tuning, similarly to the other cell classes. Only off-center Sst neurons increased monotonically their responses with stimulus size. Additionally, locomotion increased only responses to small stimuli in Vip neurons and only responses to large stimuli in Sst neurons.
To capture these observations we devised a rate model based on the recurrent connections of these neurons classes and on feedforward excitation from thalamus. In the model, the visual responses of each class is estimated as the sum of average responses from local Pyr and thalamic

cells subtracted or divided by the average responses of functionally connected interneuron classes. The inputs are integrated over a cortical area of finite size with two-dimensional Gaussian functions.
The model provided accurate quantitative fits to the data of all cell types, but only if we incorporated the following constraints of the functional connections between V1 cell classes: (1) a broad spatial integration of inputs from Sst neurons to Pyr neurons; (2) thalamic visual input that impinges not only on Pyr and Pvalb neurons but also on Sst cells (perhaps through Pyr neurons in deeper layers); (3) a divisive effect of Sst cells onto Vip cells; (4) a subtractive effect of Vip cells onto Sst cells; (5) thalamic visual input that becomes stronger with locomotion (perhaps due to stronger thalamocortical synapses). We conclude that a relatively simple rate model with reasonable assumptions can capture the apparently complex size- and locomotion-dependent responses of multiple classes of V1 neurons.

Title: Functional organization of presynaptic networks in primary visual cortex

Authors: *L. F. ROSSI, K. D. HARRIS, M. CARANDINI
Univ. Col. London, London, United Kingdom

Abstract: Neurons in the primary visual cortex (V1) are tuned to retinotopic location, orientation and direction of motion. Such selectivity stems from the integration of inputs from hundreds of presynaptic neurons distributed across cortical layers. Yet, the functional principles that organize such presynaptic networks have only begun to be understood. Is the presynaptic network uniform in space, or are there anisotropies, perhaps related to the postsynaptic neuron's orientation preference? Does dendritic morphology contribute to such anisotropies? How does the stimulus preference of a postsynaptic neuron relate to the activity of its presynaptic partners?
To answer these questions, we used monosynaptic rabies virus tracing and two-photon

microscopy in mouse V1. We bred mice expressing the calcium indicator GCaMP6 in all excitatory cortical neurons, and we electroporated a pyramidal neuron in L2/3 (starter neuron) with plasmids coding for the rabies glycoprotein oG, the avian receptor TVA and the fluorescent protein dsRed. Then we extracellularly injected an EnvA-dG-dsRed rabies virus, which could only infect the TVA tagged starter neuron and then spread to its presynaptic partners. Finally, we imaged the activity of the starter cell, its presynaptic neurons and the surrounding excitatory population across layers 2-5 in response to sparse noise or drifting gratings, while the mouse was free to run on a treadmill. We also acquired high resolution z-stacks to reconstruct the morphology of the starter neuron and the position of its inputs.
For each starter neuron, we identified on average 132±41 local V1 presynaptic partners (range of 38-334, n = 8), distributed between L1 and L5 and most abundant in layers 2/3 and 4. The connection probability to neighboring neurons decreased laterally with a space constant of 128±16μm. The resulting distribution of presynaptic spanned 46±3 degrees in azimuth and 26±1 degrees in elevation of the visual field. In comparison, the density of dendrites fell laterally with a space constant of 83±17μm.
Many presynaptic neurons (53±7%) displayed activity-dependent fluorescence changes: 32±2% of these neurons (17±3% of the total) responded significantly to drifting gratings, as did the majority of the starter neurons (6/8). Our preliminary analysis shows that the tuning of neurons in each presynaptic network is heterogeneous and is not necessarily aligned to the orientation preference of the corresponding starter neuron.
We are currently investigating further the relationship between visual properties of the starter neurons and the functional organization of their presynaptic networks.

Abstract: Introduction: Individual neurons in cortex receive inputs from hundreds of neurons. How the response properties of a single cortical neuron relates to those of its presynaptic partners remains poorly understood. **Methods:** We performed single-cell-initiated, monosynaptically-restricted, retrograde transsynaptic tracing with modified rabies viruses expressing GCaMP6s to trace the presynaptic networks of individual neurons in layer 4 of mouse visual cortex. We then performed in vivo calcium imaging of the postsynaptic neuron and of its presynaptic network during visual stimulation. **Results:** This technique labelled hundreds of presynaptic cells connected to individual layer 4 neurons in primary visual cortex, with the majority of presynaptic neurons being located nearby in primary visual cortex. Using in vivo calcium imaging, we characterized the response properties of the starter neuron and its presynaptic network to a diverse set of visual stimuli. We found that presynaptic networks connected to individual layer 4 neurons could be classified into different functional groups based on their response properties. In addition, we compared the functional response properties and anatomical locations of presynaptic neurons belonging to individual layer 4 neurons with previous data regarding individual layer 2/3 postsynaptic neurons. **Conclusion:** These results reveal the existence of diverse network organization principles belonging to the presynaptic networks of individual layer 4 pyramidal neurons in mouse visual cortex.

Title: Functional organization of intrinsic and feedback presynaptic inputs in the primary visual cortex

Authors: *Y. WEN, Q.-F. ZHANG, H. LI, A. GUO, M.-M. POO
Inst. of Neuroscience, SIBS, CAS, Shanghai City, China

Abstract: In the primary visual cortex (V1) of mammals with highly developed visual systems, neurons are often organized according to their preferred stimulus orientation into a highly ordered map. However, whether and how the various presynaptic inputs to V1 neurons are organized relative to the neuronal orientation map remains unclear. To address this issue, we constructed genetically encoded calcium indicators targeting axon boutons, and used them to directly map the organization of axon boutons of V1 intrinsic and V2-V1 feedback projections in adult tree shrews. Both connections are spatially organized into maps according to the preferred orientations of the axon boutons. Dual-color calcium imaging showed that V1 intrinsic inputs are more precisely aligned to the orientation map of V1 cell bodies than V2 feedback projections. Such spatially organized axon bouton maps could provide substantially clustered inputs to dendrites of V1 neurons and facilitate the establishment of V1 cell body map.

Title: Local interneurons form an organizing nidus for feature-selective subnetworks in mouse visual cortex

Authors: *G. S. PALAGINA[1], S. M. SMIRNAKIS[2]
[1]Neurol., Boston VA Res. Inst., Boston, MA; [2]Brigham and Women's Hospital, Harvard Med. Sch., Boston, MA

Abstract: Sensory stimuli are encoded by the joint firing of neuronal groups rather than single isolated neurons. However, the rules by which these groups encode information remain poorly

understood. A leading hypothesis is that similarly tuned interconnected pyramidal cells form multicellular encoding units yoked to a similar purpose. The existence of such units likely reflects on the profile of the spontaneous population bursts in neocortical networks. We studied the population activity of pyramidal cells and interneurons in layer 2/3 of the mouse area V1 over the course of visual cortical maturation (postnatal days 7-45). We recorded spontaneous events and visually evoked neuronal responses over several hours using two-photon calcium imaging. The sizes of spontaneous population bursts in layer 2/3 formed scale-free distributions obeying a power law. This was also true for the degree of functional connectivity (a measure of pairwise synchrony) across layer 2/3 neurons. These findings are consistent with the hierarchical small-world network architecture, where cliques of highly interconnected cells ("small worlds") communicate with each other via a restricted number of links between "hub" cells. To detect candidate "small world" cliques we focused on the groups of pyramidal cells that: (a) had significant functional connectivity between each other (displayed high synchrony), and, (b) generated calcium events that showed a consistent temporal relationship with the events of specific local interneurons in the context of ongoing spontaneous activity. This approach was guided by the intuition that neurons whose synchronous firing represents a "conceptual unit" ought to be inhibited together. We thus identified cliques of pyramidal neurons temporally "linked" to one or more local interneurons. These cliques were already present before eye opening, but did not remain static during postnatal development: both clique size and member overlap with other cliques decreased over time, as pyramidal neurons became progressively more selective, "linking" to fewer local interneurons. Notably, pyramidal neurons in a clique shared functional properties (tuning for orientation and direction of motion) between each other and with their partner interneuron. Our findings suggest that spontaneous population bursts in the V1 are shaped by "small-world" networks of pyramidal neurons that share functional properties and work in concert with one or more local interneurons. We propose that such groups represent a fundamental neocortical unit of computation at the population level.

Title: Thalamic influence on the statistical wiring of visual cortical receptive fields and maps

Authors: A. J. VALIÑO[1], J. R. BROTONS-MAS[1], F. T. SOMMER[2], J. A. HIRSCH[3], S. SALA[1], *L. M. MARTINEZ[1]
[1]Inst. De Neurociencias De Alicante. CSIC-UMH, Sant Joan d'Alacant, Spain; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA; [3]USC, Los Angeles, CA

Abstract: Neurons in the primary visual cortex (V1) of most mammals respond only to a restricted set of stimulus orientations. Furthermore, in some species but not in others, V1 cells with similar orientation preferences tend to cluster together in an orderly fashion giving rise to the renown cortical orientation preference maps (OPMs). Over the years, contrasting models emphasizing the role of feedforward vs. intracortical connectivity have been proposed to explain the emergence and function of this salient feature of cortical organization. Still highly debated, both types of developmental models have, nonetheless, in common that they largely neglect the potential role that the thalamus (lateral geniculate nucleus, LGN) plays in this process. Recently, we have demonstrated that the retinothalamic circuit is optimized to increase the resolution of the retinal output on its way to V1 through a straight process of information upsampling and interpolation occurring at the level of the LGN (Martinez et al., 2014). Here, we use a similar approach to show that the probabilistic, convergent connectivity from retina to LGN required to increase visual resolution significantly transforms the thalamic representation of the retinal mosaics generating partially segregated thalamic domains of On- and Off-center receptive fields cells arranged in locally correlated clusters of dipoles with different orientations. We further demonstrate that this new thalamic structure has the same properties as those previously shown in cortical orientation maps and suggest that it might be essential for their emergence and stability: First, our results revealed that the structure of the emergent cortical maps perfectly correlates very well with the arranging of the thalamic ON and OFF domains. Second, the periodicity and stability of the cortical orientation map depend critically on the biological constraint imposed by the upsampling and interpolation procedure performed in the LGN. Finally, the retinothalamic rewiring allows to maintain large values of thalamocortical convergence, and still conserving the stability of the map, without requiring complex developmental rules or very precise patterns of spontaneous or visually driven feedforward activity.

Title: Signatures of colorvision in the functional architecture of the primary visual cortex

Authors: *M. SCHOTTDORF, J. LIEDTKE, F. WOLF
MPI DS, Goettingen, Germany

Abstract: Color vision was lost in mammals during the nocturnal bottleneck when our ancestors were small, dark-dwelling animals between 205 to 65 Million years ago (Ma). Among modern mammals old world monkeys and great apes (re-)invented trichromacy 30-40 Ma. The newly developed color vision inserted new pathways into cortical functional architecture, potentially perturbing the layout of orientation domains in the primary visual cortex (V1) through non-orientation selective cytochrome oxidase blobs. How much impact color vision had on the overall functional architecture of V1 remains unclear because most studies are phenomenological and little is known about theoretically expected effects. Here we assess the experimental signatures of two distinct and paradigmatic model types to fill in this gap.
The first one is a coordinated optimization model of visual cortical maps, in which the coupling between the layouts of orientation and color are expanded (Reichl et al. PLoS CB 2015, Bressloff et al. PRL 2002). We find that this type of interaction leaves a strong signature in the pinwheel configuration, detectable with the measures of the common design (Kaschube et al. Science 2010, Schottdorf et al. PLoS CB 2015). The second model is a phenomenological model to incorporate non-orientation selective regions into a layout of orientation domains by geometric distortions. Models of this type leave the measures of the common design invariant, but generate higher order layout correlations.
In summary, we discovered a set of quantitative, specific and measurable predictions from both models that can in principle be falsified given the precision of available data. By defining these most informative measures we provide a solid foundation for a future comparative studies across mono-, di- and trichromatic mammals that will help to clarify whether there is any signature of colorvision in the functional architecture of V1.

Title: Mapping visual cortical processing networks with infrared neural stimulation

Authors: *M. M. CHERNOV[1], R. M. FRIEDMAN[2], A. W. ROE[3,4]
[1]Neuroscience, Oregon Natl. Primate Resource Ctr., Oregon Hlth. and Sci. Univ., Beaverton, OR; [2]Div. of Neurosci., Oregon Hlth. & Sci. Univ. - ONPRC, Beaverton, OR; [3]Zhejiang Univ., Zhejiang, China; [4]Neurosci., Oregon Hlth. and Sci. University- ONPRC, Beaverton, OR

Abstract: Microelectrodes for brain mapping have been the gold standard for over a century. However, the technique suffers from several drawbacks, such as poor spatial precision and technical issues that arise when this type of stimulation is combined with state of the art recording methods, such as electrophysiology or MRI. Over the past two decades, significant progress has been made into optical alternatives to electrophysiological techniques. One such method is infrared neural stimulation (INS), which uses short (on the order of 10^{-4} s) pulses of 1875 nm light to create focal thermal transients that lead to generation of action potentials in both the CNS and peripheral nerves (Wells et al. 2005, Opt. Lett., Cayce et al. 2014, Neuroimage, Chernov and Roe 2014, Neurophotonics). Because light at this wavelength is quickly absorbed by water in tissue, the stimulation is essentially confined to the radius of the illuminating spot produced by light from an optical fiber and spreads a few hundred microns into tissue. The high spatial precision of the method, its minimally invasive nature (stimulation can be contact-free) and its compatibility with a variety of imaging modalities including intrinsic optical imaging (IOS) and MRI, as well as electrophysiological recordings make it an excellent tool for the study of functional connections in cortex.
We are interested in using INS as a probe to reveal the organization of functional connections in primate sensory cortices when used in combination with IOS and other imaging methods. Previously, we have found that ocular dominance (OD) eye columns in visual cortex can show enhanced activation following INS (Cayce et al. 2011, Neuroimage). In this study, we use focal (~200-micron diameter illumination spot) INS to reveal short-range projections between functional domains in primary visual cortex, including OD columns, orientation domains and blobs when applied combination with relevant visual stimuli. We report that focal INS leads to patches of activation that line up with the location of functional domains. Moreover, we show that the strength of these connections is modulated by visual input. We conclude that INS is a useful tool for *in vivo* functional dissection of cortical circuits.

Title: Organization of orientation and spatial frequency preferences in V1: Two-photon imaging of awake monkey

Authors: *Y. SHAO[1,2], S.-C. GUAN[3], N.-S. JU[2], L. TAO[2], C. YU[3,4,5], S.-M. TANG[2,4]

Abstract: Both intrinsic and fluorescence optical imaging have revealed highly organized functional maps of orientation and spatial frequency preference in cat and monkey V1. Here we use two-photon calcium (GCaMP5) imaging of awake, fixating monkey to investigate the response properties of layers 2 and 3 (depths of 150 um and 300 um) V1 neurons. The visual stimulus consists of Gabor gratings at 12 orientations (-45-120 deg), 6 spatial frequencies (0.25-8 cpd) at 90% contrast and drifting at 2 cycles/sec. We recorded from 1475 layer-2 and 1194 layer-3 neurons (orientation OSI > 0.5, ANOVA $p < 0.05$) at two sites (both within a window of 850x850 um at 3-deg parafovea). We found that orientation and spatial frequency maps are largely orthogonal at both sites and both depths, confirming previous results. We also found a systematic decrease of both orientation and spatial frequency tuning bandwidths (half-width at half maximum) as we move away from pinwheel centers. Both layers 2 and 3 contain highly orientation selective neurons, with roughly 9% of the neurons with orientation bandwidths less than 15 degrees and 31% of the neurons with bandwidths less than 30 degrees. Both layers 2 and 3 contain mainly medium frequency neurons (with optimal frequencies between 1-4 cpd), which make up roughly 80% of both layers. However, we observed a significant peak spatial frequency response shift to lower spatial frequencies as we move from layer 3 to 2, with only 5% of layer 3 neurons but over 9% of the layer 2 neurons peaking at less than 1 cpd. Thus while orientation selectivity remain largely invariant as we move from layer 3 to 2, spatial frequency tuning moves to lower spatial frequencies, indicating the role of the laminar V1 structure in shaping lower spatial frequency processing.

Title: A new visuotopic cluster in macaque posterior parietal cortex revealed by wide-field retinotopy

Authors: *S. RIMA, B. R. COTTEREAU, Y. HÉJJA-BRICHARD, Y. TROTTER, J.-B. DURAND
Cerco, Toulouse, France

Abstract: The visuotopic organization of macaque posterior parietal cortex (PPC) is investigated with functional imaging (fMRI) and wide-field retinotopic mapping. A new cluster of 4 visuotopic areas is revealed at the confluence of the parieto-occipital and intra-parietal sulci, in a location that has previously been defined histologically and anatomically as the posterior intra-parietal (PIP) region. This PIP cluster groups together 2 newly identified areas (PIP1/2) and 2 recently described areas (CIP1/2). it is bordered by other visuotopic areas: V3A/DP laterally, V6/V6A medially and LIP anteriorly. Together, these results show that monkey PPC is endowed with a dense set of visotopic areas, as its human counterpart. The fact that these areas can be robustly mapped with fMRI and wide-field stimulation offers both a new framework for invasive investigations in monkey PPC and a promising avenue for direct comparisons with human PPC.

Title: Functional parcellation of lateral prefrontal cortex in macaques

Authors: *R. RAJIMEHR[1], H. XU[1], D. Y. TSAO[2], R. DESIMONE[1]
[1]MIT, Cambridge, MA; [2]Caltech, Pasadena, CA

Abstract: Prefrontal cortex in primates plays a crucial role in high-level cognitive processes such as working memory, rule-based learning, abstract categorization, attentional control, and decision-making. Prefrontal cortex has been divided into distinct regions based on cytoarchitectonics and connectivity patterns. The visually-responsive regions are located in lateral prefrontal cortex. Here we used a data-driven approach to functionally parcellate lateral prefrontal cortex in macaque monkeys based on fMRI responses to a naturalistic movie stimulus. In this approach, all vertices/points of lateral prefrontal cortex were first represented in a high-dimensional activity space. Vertices were then projected into a low-dimensional space using a

combination of principal and independent component analyses. Hierarchical clustering of vertices revealed spatially distinct clusters that corresponded to areas FEF+45, 46, and dorsal prefrontal. Clustering analysis also showed patches in premotor cortex, including a patch in ventral premotor cortex that appeared to be the 'mirror-neuron' region. The ventral premotor cluster showed higher response to body movements and action scenes in the movie, and it was selectively connected to non-frontal regions involved in action representation. Our approach provides a new look at the functional organization of prefrontal cortex during natural vision.

Abstract: Spontaneous cortical activity is structured at multiple scales, showing phenomena such as oscillations, propagation of activity, resting-state networks, and area-specific intrinsic time scales. Most of these phenomena rely on inter-area interactions. Moreover, patterns of cortical interactions and dynamics are layer- and cell-type-specific. Thus, macroscopic

interactions as well as microscopic cortical organization need to be taken into account for modeling multi-scale cortical dynamics.
We present a spiking model of all vision-related areas in one hemisphere of primate (macaque) cortex. Each area is represented as 1 mm^2 of cortex, with the full density of neurons and synapses, avoiding distortions of the dynamics due to downscaling [1]. Individual neurons are described as integrate-and-fire nodes. The local circuits cover layers 2/3, 4, 5, and 6, each with an excitatory and an inhibitory population. The model, comprising 4 million neurons, is implemented in NEST and simulated on the JUQUEEN supercomputer.
Model construction follows an integrated bottom-up and top-down approach. Axonal tracing data and statistical regularities define the connectivity. A constant density of synapses along with a gradient of decreasing neuron density from eulaminate to limbic areas yields a gradient in indegrees (the numbers of synapses per neuron). Synapses are statistically mapped to the soma locations of target neurons based on morphological reconstructions, leading to non-negligible feedback onto layer 4 neurons. Slight adjustments of the connectivity based on mean-field theory stabilize the network at realistic firing rates [2]. The result is a full population-level connectivity matrix for macaque visual cortex.
Spiking activity of the model fluctuates on multiple time scales. For intermediate cortico-cortical synaptic weights, the network shows metastable activity and its functional connectivity resembles that of empirical fMRI data. Intrinsic time scales are short in primary visual cortex and longer in more limbic areas, akin to experimental observations. Time scales are influenced by both the gradient in indegrees across areas and inter-area interactions. Activity propagates mainly in the feedback direction, similar to non-sensory-driven brain states. Granger causality analysis reveals strong feedback influences from layer 5 to layer 6. The consistency of the model with a wide range of observations renders it a promising basis for further enhancing our understanding of cortical dynamics.

Title: Dorsal visual cortex in macaques resembles that of New World monkeys: A reassessment of its topography based on sub-millimeter retinotopic fMRI mapping

Authors: *Q. ZHU[1], ***Q. ZHU**[1], W. VANDUFFEL[1,2,3]
[1]Lab. for Neuro- and Psychophysiology, KU Leuven, Leuven, Belgium; [2]Dept. of Radiology, Harvard Med. Sch., Boston, MA; [3]A.A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: The visuotopic organization of third tier visual areas in macaque monkeys is still heavily debated. One prominent model (Gattass et al., 2015; Kaas et al., 2015) proposed that V3 extends along most of the anterior V2 border, containing a split upper and lower visual field (VF) representation mirroring that of V2. Although this simple organization holds for V3v, V3d is more complex, with often a reported gap dividing it in two parts. Rostral to V3d, another third tier area (V3A) is described with both an upper (more caudally) and lower (rostral) VF representation, and a lower vertical meridian (VM) representing its anterior border with V4d. Another model (Angelucci and Rosa, 2015), however, considered V3d and the upper quadrant representation of V3A as part of area DM. The lower quadrant representation of V3A, on the other hand, is considered as a continuation of V3v. Together they form a complete representation of the VF similar to VLP of New World monkeys (marmosets). To evaluate these models, we acquired retinotopy maps from 3 awake rhesus monkeys using high resolution phase-encoded retinotopic fMRI mapping (0.6 mm isotropic voxels). To better detect fine grained VF transitions, we superimposed isopolar angle and isoeccentricity contour lines on field sign maps (Sereno et al., 1994). Furthermore, population receptive field (pRF) sizes (Dumoulin and Wandell, 2008) were calculated to quantitatively test the two models. Our results show that rostral to V2d there are two separated mirror field sign maps with a gap, exactly as described above for V3d. However, the more dorso-medial area shares a horizontal meridian with V2d, as V3d, and a lower VM with another area, while the more ventro-lateral area bends away from V2d, and contains a representation of both the upper and lower VF, very similar to DLP as described in New World owl monkeys (Sereno et al., 2015). This more ventral area, has the same non-mirrored field sign as V3v with which it forms a continuous band, but it is distinct from VLP because of the upper VF representation. The pRF size in this macaque counterpart of DLP is also significantly larger than that found for V3d and V3v -the two latter areas have the same pRF sizes. Therefore, DLP cannot be considered as another part of V3d, as proposed by the first model, nor the continuation of V3v, as proposed by the second model. Its pRF size, however, is similar to that of V4d and V4v, suggesting that DLP is a fourth tier area, consistent with the observation of Zeki and Baizer et al. that multiple VFs are represented in V4d (Zeki, 1971;

Baizer and Maguire, 1983). In summary, the retinotopic maps of dorsal visual cortex is more similar in Old and New World monkeys than generally appreciated.

Title: Transient oscillatory feedback from ipsilateral IPS in response to a visual target

Authors: *K. YUASA[1,2,3], H. TAKEMURA[1,2,3], I. MOTOYOSHI[4], K. AMANO[1,2]
[1]CiNet, NICT, Osaka, Japan; [2]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [3]JSPS, Tokyo, Japan; [4]Dept. of Life Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: A number of experimental and theoretical studies suggest a fundamental role of intra-cortical feedback loops in visual processing (Hochstein & Ahissar, 2002; Lamme, 2001). Recent studies proposed that feedforward and feedback signals have been associated with different frequencies of neural oscillations based on macaque electrophysiology (van Kerkoerle et al., 2014) and human MEG (Michalareas et al., 2016). While these characteristics were mostly studied for late sustained responses, early transient responses are also crucial for visual processing. Here we investigated temporal property and stimulus dependency of feedforward and feedback signals in the early response to visual stimulus onset.
Twenty healthy participants viewed a monochromatic checker disc that was presented for 500 ms at one of four possible locations (upper-left, upper-right, lower-left, and lower-right) with respect to the central fixation dot. The stimulus contrast was either 100% or 30%. For each condition, MEG signals were recorded repeatedly over 216 trials with an inter-trial interval of 1000-1500 ms. The source activities were estimated by means of dSPM for twelve region-of-interests (ROIs; V1, V2v, V3v, hV4, VO/PHC, V2d, V3d, V3a/b, LO, TO, IPS0, and IPS/SPL) that were identified via surface-based fitting of retinotopy atlas (Wang et al., 2015). For every pair of ROIs, we applied a granger causality analysis in the time-frequency domain, and looked at feedforward and feedback interactions across cortical areas.
The analysis revealed strong feedforward signals from V1 to the other visual areas and feedback signals from the IPS/SPL to the other visual areas ($p<0.05$). Both were clearly observed in the beta band at 100-160 ms after the stimulus onset. The feedback signals were significantly larger in the ipsilateral hemisphere than in the contralateral hemisphere with respect to the stimulated visual field ($p<0.05$). While the evoked response increased with the stimulus contrast ($p<0.05$),

we did not find a significant contrast dependency in the amplitude of the feedforward and feedback signals ($p>0.05$).
Given the retinotopic organization of IPS, it has been suggested that some top-down modulation in the primary visual cortex is regulated by IPS (Silver & Kastner, 2009). Indeed, the parieto-occipital network in the contralateral hemifield has been considered critical for the control of spatial attention (Kastner et al., 1999; Saalmann et al., 2007). While dominant feedback from the ipsilateral IPS is apparently inconsistent with the previous studies, it may suppress signals in the ipsilateral visual field where the target is absent for efficient visual processing.

Title: Dynamic lateral interactions in monkey area V4

Authors: *R. XIA[1], S. GUAN[2], D. L. SHEINBERG[3]
[2]Dept. of Neurosci., [3]Neurosci., [1]Brown Univ., Providence, RI

Abstract: The primate visual system has long been thought as a feedforward hierarchical machine with independent filtering nodes. Less is known about the dynamics and the role of lateral interactions within a visual region. To investigate the pattern of these recurrent interactions, we carried out multi-electrode recordings in monkeys' intermediate visual area V4 when monkeys were looking at visual stimuli or performing feature-based attention tasks. We found that the pairwise coherence between local field potentials was strongly modulated by task events. Despite the large variation in such modulations, our decoding results indicated that the synchrony pattern contained information about both visual and attentional features. Furthermore, Granger causality analysis showed asymmetric interactions between foveal and peripheral neurons. We found that the signal flow from peripheral channels to foveal channels were increased during full-screen visual presentation, whereas small central visual stimuli induced a larger increase of Granger influences from foveal channels to peripheral channels. In contrast, the local interactions within foveal and peripheral groups, but not the cross-group interactions, were enhanced during the feature attention-modulated delay period. Put together, our results suggested a task-related, receptive field-specific interaction pattern. In order to further probe the recurrent functional connectivity in V4 during visual attention tasks and also causally test its physiological and behavioral roles, our ongoing project involves multi-channel optogenetic

stimulation and simultaneous recordings. We hope that our data will provide more insights to the understanding of the dynamical, highly interactive visual network.

Title: Bidirectional visual processing: Distinct dynamics and interactions between V4 and inferior temporal cortex in challenging scenarios

Authors: *S. GUAN[1], R. XIA[2], D. SHEINBERG[2]
[1]Dept. of Neurosci., [2]Neurosci., Brown Univ., Providence, RI

Abstract: The feedforward hierarchical framework of the ventral stream greatly advances our understanding of visual objection recognition. However, there are as many feedback/horizontal projections as the feedforward ones, whose roles in visual recognition are largely unknown. This current study aims to investigate the visual processing beyond the feedforward sweep in a naturalistic setting. To engage the feedback/horizontal mechanisms, we probe the visual system using full screen natural images with two manipulations: 1) the images are either familiar (after months' exposure) or novel, and 2) the images are overlaid with different levels of occluding noise. Our behavioral data shows that recognition requires longer image presentation time when higher level of noise is added, and familiarity helps recognition in high noise conditions, which suggests the possible involvement of feedback processing. To find the neural correlate, we did simultaneous multi-channel electrophysiological recordings in areas V4 and inferior temporal cortex (IT) in a macaque monkey. We found that V4 and IT respond differentially to our image manipulations: 1) occluding noise only scales down the averaged population firing dynamics in V4, whereas it flattens the dynamics in IT, by reducing the early peak and increasing the late-phase response; 2) familiarity reduces the averaged population firing rate earlier and to a larger extend in IT than in V4; 3) population decoding results shows that occluding noise largely scales down the image information contained in V4, whereas it reduces the early phase of IT's information to a smaller extend but leave the late phase unaffected; 4) functional connectivity analysis using local field potential Granger causality suggests that feedforward information flow from V4 to IT is largely reduced by noise, whereas the feedback information flow from IT to V4

is not affected by noise, and emerged later than the feedforward flow. Taken together, we our results provide evidence for the bidirectional visual recognition processing in a challenging naturalistic scenario.

Title: Distinct intrinsic connectivity patterns for dorsal and ventral regions of lateral intraparietal area (LIP) of macaque monkeys

Authors: *M. RUESSELER[1], B. AHMED[1], J. BENNETT[1,2], J. E. T. SMITH[1], A. J. PARKER[1], K. KRUG[1]
[1]Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom; [2]Dept. of Informatics, Univ. of Sussex, Falmer, Brighton, United Kingdom

Abstract: Neurons in parietal area LIP respond to visual stimuli and serve to integrate visuo-motor information to an attended saccade location. Dorsal (LIPd) and ventral (LIPv) regions can be distinguished based on myelination, cytoarchitecture and inter-areal connectivity. Here, we examine the intrinsic pattern of local connections of LIPd/LIPv by analysing the distribution of labelled cells following focal tracer injections.
Using structural MRIs under Brainsight (Rogue Research Inc) control, we injected (~80 nL) retrograde tracer into LIP of four male Rhesus macaques (*Macaca mulatta*). Three animals received LIPd injections (Cholera-Toxin b (CTb) N=2; Fluorogold (FG) N=1); one received a CTb injection into LIPv. From a 1:5 series of 50 µm parasagittal sections, we marked labelled cell bodies with Neurolucida (Microbrightfield Ltd). Cell density was quantified by smoothing cell locations with a Gaussian spread (sd = 100µm); distinct clusters of high-density label were identified (contours at >90% of max density). For two animals with CTb injections in LIPd, we generated a 2D spatial map of cell density distribution. A polynomial described the distribution of labelled cells separately for superficial and deep layers in each section (fitted R^2 >=0.9): locations of cells were projected onto this line to measure the variation in density of labelled cells along the dorso-ventral extent of LIP. Consecutive parasagittal sections were aligned based

on nearest neighbour density distributions of labelled cells.
Injection in LIPd gave a widespread pattern of labelled cells within LIPd, for all layers. Along the dorso-ventral extent, the density distribution formed a longitudinal patch of labelled cells centred on the location of the injection site. Along the medio-lateral axis, a small number of large but distinct patches of labelled cells were found about 2 to 3 mm away from the injection site. Within single sections, cell density analysis indicated a more fine-grained organization, with distinct smaller clusters of labelled cells with the majority of intercluster distances between 0.5 and 1mm. In stark contrast, in LIPv only one cluster of labelled cells was found after tracer injections in LIPd. Conversely, data from the single animal with an injection in LIPv revealed a more widespread pattern of retrogradely labelled cells spanning both LIPv and LIPd.
The widespread connectivity pattern found within LIPd suggests that a number of distant visual field locations might contribute to receptive/response field properties of cells. The restricted point-to-point projection from LIPv to LIPd might relate to the structure of the visuotopic map previously shown to exist in LIPv.

Title: Foveal, elliptical and horizontal - Population receptive fields in the visual word form area are tuned optimally for word reading

Authors: *E. H. SILSON[1], R. C. REYNOLDS[2], D. JANINI[1], C. I. BAKER[3], D. J. KRAVITZ[4]
[1]Lab-Brain & Cog, [2]Scientific and Statistical Computing Core, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Lab. Brain and Cognition, NIH, Bethesda, MD; [4]Dept. of Psychology, The George Washington Univ., Washington, DC

Abstract: Our ability to identify words is optimal at fixation and deteriorates rapidly with increasing eccentricity. In cortex, word reading is thought to be subserved by a specialized region, the visual word form area (VWFA), in left ventral occiptotemporal cortex. Despite early assertions of position invariance, recent work demonstrates position sensitivity within VWFA (Rauschecker et al., 2012; Le et al., 2017).
Here, using a population receptive field (pRF) model that allows for estimates of elliptical and orientated pRFs, we investigated the pRF properties of VWFA. Specifically, we tested the

prediction that pRFs in VWFA would be 1) foveally centered, 2) highly elliptical and 3) horizontal - the ideal parameters for recognizing word forms in languages that read left-right. Importantly, we contrast the pattern of VWFA pRFs with those exhibited by two control regions in which we do not predict this specific pRF combination: the parahippocampal place area (PPA), and early visual cortex (EVC) V1-V3.
Thirteen participants completed eight pRF runs. In each run, a bar aperture revealing scene fragments traversed the visual field, whilst participants fixated centrally. Our VWFA definition was taken from the group average in Stevens et al (2017), whereas PPA and EVC were identified functionally in each individual.
We computed distributions of eccentricity, aspect ratio, and orientation theta in each participant and region, respectively. First, consistent with our predictions, the distribution of eccentricity within VWFA peaked within the first two degrees of visual angle, which was significantly more foveal than that of either PPA or V1. Second, VWFA showed significantly more elliptical pRFs than either PPA and V1; VWFA showed a distribution skewed significantly towards greater ellipticities. Third, unique to VWFA, pRF orientations were tightly distributed around horizontal. To confirm this specific pRF combination in VWFA, we further identified and measured VWFA pRFs in an additional six participants at high-resolution ($1.2mm^3$). The patterns of results were indistinguishable from our group-based approach. As with the group-based ROIs, pRFs in individually defined VWFAs were foveal, elliptical, and horizontal. Our data suggests two possibilities. First, pRFs in VWFA are randomly tuned to these characteristics and that guides the formation of the VWFA. Second, and more likely, is that learning to read shapes pRFs in VWFA, making them ideal for word reading. What form the pRFs in this region take in children prior to reading, in dyslexic individuals, or readers of languages not written from left to right are critical questions for the future.

Title: Multi-electrode recordings in human lateral occipital cortex

Authors: *E. PREMEREUR[1], T. DECRAMER[2], W. VAN PAESSCHEN[1], P. JANSSEN[1], J. VAN LOON[3], T. THEYS[4]

Abstract: The lateral occipital complex (LOC) is a set of areas in human occipito-temporal cortex responding more to objects as opposed to non-object control stimuli, but the correspondence between LOC and the macaque inferotemporal areas is poorly understood. We had the unique opportunity to implant a 96-channel Utah array in human LOC, in a patient requiring surgery for epilepsy, at MNI coordinates -50 (mediolateral), -77 (anteroposterior), 6 (dorsoventral). An LOC localizing fMRI experiment performed after array extraction showed stronger activations during presentation of non-scrambled versus scrambled objects at the implantation site. Multi-unit (MUA) and local field potential (LFP) activity was recorded on four consecutive days, and the LOC localizer task was presented to the patient on three out of four days (day 1, 2 and 4). During the LOC localizer task, we presented images of stimuli, stimulus-outlines and scrambled controls for both, as in previous fMRI experiments, while monitoring the position of both eyes using an infrared tracker (Iscan). We found significant stimulus-induced gamma (25-150 Hz) responses (shapes compared to baseline) on all channels (n = 95) in all three sessions (permutation test, $p < 0.01$). Moreover, 92 (day 1), 55 (day 2) and 79/96 (day 4) channels showed significant differences in gamma response between scrambled and non-scrambled objects. Receptive field testing showed significant gamma responses during ipsi- and contralateral stimulus presentation on virtually all channels (permutation test, $p < 0.01$). We obtained qualitatively similar results when restricting the analysis to the high-gamma band (80-120 Hz). Furthermore, we measured significant MUA spiking responses during visual stimulation compared to baseline on 19 channels, and significant differences in MUA response between non-scrambled and scrambled stimuli on 9 channels (day 1). MUA latencies were around 175 msec, with a peak response at 200 msec. As a final test, we recorded neural activity during foveal presentation of disparity-defined convex or concave stimuli on a stereoscope during binocular eye movement control. We found an increase in gamma power on 92 channels (permutation test, $p < 0.01$) during stimulus presentation compared to baseline. Importantly, 11/95 channels on day 1 and 7/95 channels on day 2 showed a significant preference in gamma response to convex versus concave stimuli, which was preserved across positions in depth (ANOVA, significant main effect of stereo; no significant interactions), indicating higher-order disparity selectivity. Taken together, these results suggest that human LO may correspond more to macaque area TE than to area TEO.

Title: Cortical thinning of functional regions in the ventral temporal cortex is associated with increased myelination

Authors: *V. S. NATU[1], J. GOMEZ[2], M. BARNETT[1], B. JESKA[1], Z. ZHEN[1], S. COX[1], K. GRILL-SPECTOR[3,4]
[1]Dept. of Psychology, Stanford University,, Stanford, CA; [2]Neurosciences Program, Stanford Univ. Sch. of Medicine, Stanford, Stanford, CA; [3]Stanford Univ., Stanford, CA; [4]Stanford Neurosciences Institute, Stanford Univ., Stanford, CA

Abstract: The human brain undergoes substantial anatomical changes from childhood to adulthood including decreases in gray matter volume, cortical thinning (Sowell et al., 2004), and increases in white matter volume (Giedd et al., 1999). However, the mechanisms underlying these developments, especially the thinning of cortex, are unknown. We tested two main hypotheses of cortical thinning: pruning and growth. Pruning suggests that cortical thickness (CT) decreases due to reduction in tissue volume from childhood to adulthood. Thus, pruning predicts higher T_1 relaxation rate, measured with quantitative MRI (qMRI), and higher mean diffusivity (MD), measured with diffusion MRI (dMRI), in adults than children. In contrast, growth associated with increased myelination, predicts lower T_1 and lower MD in adults than children. We tested these hypotheses using fMRI, qMRI, and dMRI in 27 children (ages 5-9, *N*=12; ages 10-12, *N*=15) and 30 adults (ages 22-28). We identified face-, body-, character- and place-selective regions in ventral temporal cortex (VTC) of each participant and measured in each region CT, T_1, and MD, as well as T_1 and MD in the neighboring white matter. We observed four main findings: First, CT significantly decreased from childhood to adulthood in all category-selective regions (Fs>27.67, ps<0.001). The cortex thinned on average by 0.8±0.18 mm, with the least thinning in the right place-selective region. Second, in regions that we observed significant reduction in CT, we also found significant reduction in T_1 from childhood to adulthood ($F_{2,492}$=12.75, p<0.001). Third, both T_1 and MD of white matter neighboring the face-, body- and character-selective (but not place-selective) regions showed significant age-related reductions (Fs>35.22, ps<0.001). Fourth, analysis of T_1 and MD by cortical layers showed that greatest developmental changes occur close to the gray-white matter boundary and the developmental shifts in T_1 curves by layer is similar to the developmental changes observed in

cortical thickness. Together, our data (i) reveal differential development of tissue properties across human VTC, and (ii) provide strong evidence that cortical thinning is associated with increased myelination in deep cortical layers and adjacent white matter, rather than pruning. As developmental changes in CT are prevalent throughout the brain, our results have important implications for interpreting the mechanisms of CT during typical and atypical development.

Title: Functional magnetic resonance imaging (fMRI) - Guided single unit recordings reveal weak higher-order disparity selectivity in macaque area TEO

Authors: *A. ALIZADEH, R. VOGELS, P. JANSSEN
Katholieke Univ. Leuven, Leuven, Belgium

Abstract: Binocular disparity provides a strong, unambiguous cue for depth perception in primates. Several cortical areas in both the dorsal and the ventral visual pathways are involved in the processing of depth from binocular disparity. Previous functional magnetic resonance imaging (fMRI) studies in monkeys (Van Dromme et .al, PLoS Biol. 2016 Apr 15;14(4):e1002445. doi: 10.1371) revealed stronger activations in the posterior part of the inferotemporal cortex (area TEO) in response to higher-order (curved and slanted) disparity stimuli compared to zero-order (flat) stimuli. The current study was carried out to investigate the higher-order disparity selectivity in area TEO at the single-cell level. In two monkeys, we targeted the fMRI activation elicited by curved surfaces in area TEO during a passive fixation task. The search test consisted of 32 second-order stimuli in addition to 8 first-order stimuli (2 vertical and 2 horizontal linear disparity gradients, square shape, 4 of which were 8.4° and the other 4 were 18.75° in diameter). We tested for disparity selectivity (including monocular controls) and selective cells were additionally tested with preferred and non-preferred stimuli at 5 different positions in depth (mean disparity from -0.5 to 0.5 deg). In total, we recorded from 123 TEO neurons showing significant visual responses to the stimuli of the search test presented at the fixation point. A small fraction of all visually responsive neurons (20 neurons, 16%) exhibited significant selectivity for disparity-defined curved and slanted stimuli, which could not be explained by the monocular responses. Moreover, the weak disparity selectivity of TEO

neurons emerged very late after stimulus onset (150 ms). Only four neurons (3% of all visually responsive neurons) preserved their selectivity across positions in depth when tested with second-order (curved) stimuli. .Disparity-selective TEO neurons usually had small receptive fields (average RF size = 32 deg^2) centered on the fovea. Our results suggest that the fMRI activations observed in TEO overestimates the neuronal selectivity for disparity-defined curved surfaces. The weak disparity selectivity we measured in TEO may represent feedback signals from higher-order areas in the ventral visual stream.

Title: Categorization in monkey inferior temporal cortex determined by image features, not acquired knowledge

Authors: *X. YUE[1], M. YETTER[2], L. G. UNGERLEIDER[3]
[2]Natl. Inst. of Mental Hlth., [1]NIH, Bethesda, MD; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Our visual system represents visual objects according to categories. One of most basic categories is the animate vs. inanimate division. Based on results from recent studies (Livingston et al., 2015; Perrinet & Bednar, 2015) and our earlier study (Yue et al., 2014), we hypothesized that animate vs. inanimate categorization is: 1) encoded by multivoxel activity patterns; and 2) influenced to a large degree by the unique image-based features that distinguish animate from inanimate stimuli. Using a slow event-related design, we acquired fMRI scans in three fixating rhesus macaques in response to a large set of visual stimuli, including 47 sub-categories with 20 images per sub-category. We employed curved and rectilinear Gabor filters to quantify curved and rectilinear image-based features. As hypothesized, we found that multivoxel activity patterns measured with support vector machine classification encoded animate vs. inanimate categories in the monkey inferior temporal cortex; multiple dimensional scaling failed to categorize individual exemplars in the animate vs. inanimate division. This result suggests that animate vs. inanimate categorization is represented in the brain in a high dimensional space, and is not a 2-dimensional representation. Moreover, curved and rectilinear features explained a significant amount of variance in the fMRI activity patterns that encoded animate vs. inanimate categories. Our results thus support our hypothesis that animate vs. inanimate categorization in the inferior temporal cortex is influenced to a large extent by the unique image-based features (such as curved and

rectilinear features) that distinguish animate vs. inanimate stimuli. The results argue against the notion that categorization stems from acquired semantic knowledge of the characteristics that distinguish object categories, and instead suggest that the unique image-based features that distinguish animate vs. inanimate stimuli give rise to the formation of categorization in the macaque inferior temporal cortex.

Title: Principles of object representation in two object networks in IT cortexprinciples of object representation in two object networks in IT cortex

Authors: *P. BAO[1], L. SHE[2], M. MCGILL[3], D. Y. TSAO[2]
[1]Biol., [3]Computation and Neural Systems, [2]Caltech, Pasadena, CA

Abstract: Understanding the neural mechanism of object recognition is one of central challenges in visual neuroscience. Last year at SFN, we reported discovery of a new “object network” in macaque IT cortex consisting of three connected, discrete patches of cells with highly consistent response selectivity to a set of objects (Bao & Tsao, 2016). Here, we further probed the coding scheme used by neurons in this object network. For comparison, we also probed neurons in a body network. We performed extracellular recordings in both the object and body networks while monkeys kept fixation for juice reward and viewed a stimulus set consisting of realistic objects and their silhouettes. A large proportion of neurons in both the object and body networks showed indistinguishable responses to the real objects and their silhouettes. This suggests that we can reasonably reduce the real object image space to a much simpler silhouette space. To explore how neurons code the silhouette space, we recorded responses of cells in the middle body patch and anterior object patch to 2000 silhouette images randomly sampled from a 30 dimensional (30-d) space, extracted from a large set of object silhouette images by principal components analysis. We then fed the same image sets (real objects, silhouettes of real objects, silhouette images sampled from 30-d space) into a trained deep network, Alexnet, and fitted actual neuronal responses to the 2000 random silhouettes to a linear combination of artificial neurons’ responses from AlexNet. We found this linear model could effectively predict responses of

neurons to the real object silhouette images as well as to the original images, with correlation between predicted and actual neuronal responses as high as the noise ceiling. Overall, these results show that we can model the object code used in the macaque object and body networks with high precision, and that at least within these two networks, this code largely based on silhouettes of objects.

Title: The role of disparity columns in segmentation

Authors: ***J. K. HESSE**[1], D. Y. TSAO[2]
[1]Biol., [2]Caltech, Pasadena, CA

Abstract: Segmentation is a process crucial for interacting with objects in the world, as one needs to know what regions of visual space constitute the objects that we interact with and where the borders are that belong to them. We set out to find out whether there exist specialized regions that are responsible for segmentation. Disparity columns in V3 found by Adams and Zeki (J Neurophys, 2001) contain alternating clusters of cells tuned to far and near disparity, respectively. Since disparity information is an important cue for interpreting 3D objects and surfaces, we hypothesized that disparity columns might play a role in segmentation, too. We performed tangential recordings along the fundus of the lunate sulcus and found that, besides clusters of cells tuned to near and far, disparity columns also contain clusters of cells tuned to the border-ownership of a disparity-defined square. We found that these cells encoding disparity-defined borders also carried significantly more segmentation-related information for squares defined by other modalities, such as luminance, texture, motion and illusory contours.
Our results suggest that disparity-columns in V3 may serve a broader role rather than just computing disparity and may be responsible for segmenting the visual scene into surfaces corresponding to objects.

Title: Coding of 3d-surfaces by neurons in the primate caudal intraparietal sulcus (CIPS)

Authors: *L. CHANG[1], D. Y. TSAO[2]
[1]Div. of Biol., CALIFORNIA INSTITUTE OF TECHNOLOGY, Pasadena, CA; [2]Caltech, Pasadena, CA

Abstract: The central function of the visual system is to infer events happening in the 3-d world. One key step of this inference is to extract depth/disparity information from 2-d inputs. Previous fMRI studies identified an area in the parietal lobe, CIPS (caudal intraparietal sulcus), which responds selectively to images defined by variations in disparity (Tsao et al., 2003). Electrophysiology revealed that neurons in this area are tuned to 3-d features such as tilt and slant of surfaces (Tsutsui et al., 2001, Rosenberg et al., 2013). However, the full mechanism by which CIPS neurons encode 3-d structure remains unclear. We targeted CIPS for electrophysiology recording, guided by fMRI scans using stereo images. Tilting surfaces similar to a previous study (Rosenberg et al., 2013) were first presented to determine the preferred orientation of the recorded neuron. Surfaces with depth varying as a sinusoidal function along this orientation or along an axis orthogonal to this orientation were synthesized and presented. We found CIPS neurons displayed diverse tuning to this stimulus set. To further explore the effective features coded by each neuron, the sinusoidal stimuli at the preferred spatial frequency and orientation were sectioned into smaller segments. As a result, the new stimulus set contained different kinds of shapes (slanting surfaces, convex or concave surfaces) at varying locations. We found two types of behavior in the recorded neurons. Type 1 neurons preferred the same feature at different locations, while type 2 neurons preferred different features at different locations. Further analyses revealed that responses of type 2 neurons could be explained by a receptive field structure analogous to simple cells in V1: instead of coding different polarity in light intensity as in V1 simple cells, the type 2 neurons code different polarity in depth/disparity at different 2-d spatial locations.

Title: Receptive fields of adjacent neurons in primate prefrontal and parietal cortices

Authors: *P. VISWANATHAN[1,2], A. NIEDER[1]
[1]Inst. of Neurobiology, Univ. of Tuebingen, Tübingen, Germany; [2]IMPRS for Cognitive and Systems Neurosci., Tuebingen, Germany

Abstract: The basic organization principles of the primary visual cortex (V1) are commonly assumed to also hold in the association cortex such that neurons within a cortical column share functional connectivity patterns and represent the same region of the visual field. Adjacent neurons within these cortical columns show nearly identical receptive field (RF) locations and stimulus tuning properties. We examined this principle in the prefrontal cortex (PFC) and ventral intraparietal area (VIP) of two rhesus monkeys by mapping the visual receptive fields of neurons recorded at the same electrode. By first creating high-resolution RF maps for the neurons that selectively responded to the position of a moving bar stimulus and comparing those of neuron pairs, we found that the spatial characteristics of visual receptive fields between adjacent neurons differed considerably, with increasing heterogeneity from VIP to PFC. To further examine how the fine-scale specificity of connections between adjacent neurons might explain the relationship between their receptive fields, we performed cross-correlation analysis of their spike trains. In addition to receptive field incongruences, putative inhibitory interneurons and pyramidal cells were differentially connected in the two areas, with inhibitory interactions much more prevalent between PFC neuron pairs than those in VIP. These findings suggest that local receptive field topography vanishes with hierarchical distance from visual cortical input and argue for increasingly modified functional microcircuits in non-canonical association cortices that contrast V1.

Title: Voxel-to-voxel encoding models of connectivity between visual areas

Authors: *M. MELL, T. P. NASELARIS
Med. Univ. of South Carolina, Charleston, SC

Abstract: In the human brain, vision is accomplished collectively by a multitude of interconnected but distinct cortical areas. We are still in the early stages of our understanding of the way that connections between these areas enable visual perception. In particular, we know very little about the functional differences between feedforward, feedback, and within-area connections. We developed a voxel-to-voxel encoding model approach to quantify the spatial patterns and predictive accuracy of the three types of connections across visual brain areas. In an fMRI experiment we measured BOLD responses to natural images in seven visual areas treated in our study as an ordered, hierarchical sequence: V1, V2, V3, V4, V3A, V3B, and the lateral occipital complex (LO). We then constructed encoding models that predicted the activity variation in one voxel as a function of the activity variation in other voxels. For each voxel, we constructed seven distinct encoding models. Each model predicted the target voxel's activity as a function of activity in one of the seven visual areas (including the visual area occupied by the target voxel). Models that connect lower to higher visual areas (e.g., V1 to LO) were considered feedforward. Models connecting higher to lower areas (e.g., LO to V1) were considered feedback. Models connecting voxels in the same areas were considered internal. For each type of encoding model we measured cross-validated prediction accuracy. Several interesting trends emerged from this analysis. First, we found that for purely linear feedforward encoding models prediction accuracy decayed rapidly across the visual hierarchy from V1 to LO. Prediction accuracy for linear internal encoding models also decayed rapidly. However, for linear feedback models prediction accuracy showed little or no decay across cortical areas, and was roughly matched to the accuracy of the internal model. When nonlinear encoding models (implemented as a shallow neural network) were applied, the asymmetry in the pattern of prediction accuracy between feedforward and feedback models was preserved; however, the prediction accuracy for the internal models was markedly improved, and remained stable across visual areas. A preliminary interpretation of these results is that connectivity in the feedforward direction is nonlinear at each stage (as in a deep neural network), compounding the failure of purely linear, or nonlinear but shallow models, across the cortical hierarchy. Connections in the feedback direction appear not to accumulate nonlinearities at each stage, explaining why the performance of purely linear models was independent of distance along the cortical hierarchy.

Title: The effect of ocular dominance and binocularity on population receptive fields' properties

Authors: *P. B. DE BEST, N. RAZ, N. LEVIN
fMRI unit, Neurol. Dept., Hadassah Hebrew Univ. Med. Ctr., Jerusalem, Israel

Abstract: *Introduction:* In the seminal Hubel & Wiesel (1959, 1962) work in cats, ocular dominance and binocularity effects on visual perception were assessed. **Ocular dominance**, the tendency to prefer visual input from one eye to the other was found to be the main factor contributing to receptive field differences between the eyes. **Binocular** stimulation resulted in a stronger response than monocular stimulation, a phenomenon known as binocular summation. Herein, we use the population receptive field (pRF) method to study the neural representation of monocular and binocular vision to better understand the origin of these phenomena.
Methods: Thirteen subjects were scanned in a 3T Siemens Skyra magnetic resonance imaging (MRI) scanner while viewing drifting bar stimuli and performing a fixation task. Both eyes (binocular condition), the dominant eye and the non-dominant eye (two monocular conditions) were stimulated in separate sessions. The pRF size and amplitude were compared between the three conditions along the eccentricity axis. Binocular summation ratios were calculated by dividing binocular by mean monocular amplitude and pRF size.
Results: To evaluate viewing condition and experimental order effects (e.g. running the binocular condition first or last), analysis of variance (ANOVA) was performed. A main effect for the tested eyes condition (dominant, non-dominant or binocular) was found in V2 at 5-6^{o} eccentricity. Post-hoc tests indicated that pRF size was significantly larger for binocular than for non-dominant eye conditions. In addition, significant interactions between condition and order were found in lower eccentricities, suggesting that binocularity may be affected by prior exposure to monocular stimulation.
It was also found that binocular amplitudes were significantly higher than monocular amplitudes, indicating a binocular summation effect. This effect occurred consistently, and varied between 1.1 and 1.3 among visual areas and across eccentricities. In contrast, pRF size summation only occurred at high eccentricities in V2, and probably resulted from the significant effect on pRF size described above.

Conclusions: Our results suggest that binocular pRF sizes in early visual areas are derived from the dominant, and not the non-dominant eye but no significant difference between the dominant and non-dominant eye in regard to the pRF size was found. Interactions with experimental order indicate that binocular pRF size may be influenced by prior exposure to monocular stimulation. The found summation ratios indicate that binocular amplitude summation occurs, despite a lack of pRF size differences between binocular and monocular conditions.

Title: Visual field map clusters in higher-order visual processing: Organization of visual field maps within the human lateral occipital cortex

Authors: *A. A. BREWER[1], B. BARTON[2]
[1]Cognitive Sci., UC Irvine, Irvine, CA; [2]Univ. of California Irvine, Irvine, CA

Abstract: Over the last ten years, the lateral part of the occipital pole has often seemed to be the Wild West of visual field mapping, with a variety of claims regarding retinotopic organization staking out this region. Studies have variously proposed that the lateral occipital cortex between V3d dorsally and hV4 ventrally and posterior to hMT+ has no retinotopic organization (Ishai et al., 2000; Kanwisher et al., 1997; Halgren et al., 1999), bears only a gradient of 'eccentricity bias' (Malach et al., 2002), or, ventral to LO-2, shows sensitivity to retinal position suggestive of underlying retinotopic representations (Sayres & Grill-Spector, 2008). More recent studies have begun to demonstrate VFMs in some sections of lateral occipital cortex, with somewhat contradictory reports of 2 dorsal VFMs (LO-1, LO-2; Larsson & Heeger, 2006) with non-orthogonal (15.3° offset) eccentricity and polar angle gradients and a shared polar angle border with hMT+/TO VFMs (Amano et al., 2009), or 2 dorsal VFMs now with orthogonal gradients (LO-1, LO-2) and a shared eccentricity border with hMT+/TO VFMs and 2 ventral VFMs organized into a cloverleaf cluster (phPIT; Kolster et al., 2010). Our results resolve these conflicting reports and extend the orthogonal VFM measurements by demonstrating that the lateral occipital cortex is home to 6 VFMs bilaterally, LO-1, LO-2, LO-3, LO-4, LO-5, and LO-6, which together form the lateral part of the occipital pole visual field map cluster. The peripheral eccentricity representations of the LO maps reverses anteriorly into the peripheral eccentricity representations of the hMT+/TO visual field map cluster. Reliability measurements of these VFMs reveal that these cloverleaf clusters are remarkably consistent and functionally differentiable. Our findings add to the growing number of measurements of widespread sensory

cortical field maps (CFMs) organized into cloverleaf clusters (e.g., Barton et al., 2012), indicating that CFMs and cloverleaf clusters may both be fundamental organizing principles in cortical sensory processing.

Title: Visual field map clusters in high-order visual processing: Organization of V3A/V3B and a new cloverleaf cluster in the posterior superior temporal sulcus

Authors: *B. BARTON, A. A. BREWER
Univ. of California Irvine, Irvine, CA

Abstract: The cortical hierarchy of the human visual system has been shown to be organized around retinal spatial coordinates throughout much of low- and mid-level visual processing. These regions contain visual field maps (VFMs) that each follow the organization of the retina, with neighboring aspects of the visual field processed in neighboring cortical locations. On a larger, macrostructural scale, groups of such sensory cortical field maps (CFMs) in both the visual (Brewer et al., 2005; Wandell et al., 2005; Kolster et al., 2010) and auditory systems (Barton et al., 2012) are organized into roughly circular cloverleaf clusters. CFMs within clusters tend to share properties such as receptive field distribution, cortical magnification, and processing specialization. Here we use fMRI and population receptive field (pRF) modeling to investigate the extent of VFM and cluster organization with an examination of higher-level visual processing in temporal cortex and compare these measurements to mid-level visual processing in dorsal occipital cortex. In human temporal cortex, the posterior superior temporal sulcus (pSTS) has been implicated in various neuroimaging studies as subserving higher-order vision, including face processing (e.g., Hoffman and Haxby, 2000), biological motion perception (e.g., Grossman and Blake, 2002), and multimodal audiovisual integration (e.g., Beauchamp et al., 2004). In human dorsal occipital cortex, the transverse occipital sulcus (TOS) contains the V3A/B cluster, which comprises 2 VFMs subserving mid-level motion perception and visuospatial attention (Press et al., 2002; Smith et al. 1998). For the first time, we present the organization of VFMs in pSTS in a cloverleaf cluster. This pSTS cluster contains four VFMs bilaterally: pSTS-1:4. We characterize these pSTS VFMs as relatively small at ~125 mm^2 with relatively large pRF sizes of ~2-8° of visual angle across the central 10° of the visual field. V3A

and V3B are ~230 mm^2 in surface area, with pRF sizes here similarly ~1-8° of visual angle across the same region. In addition, cortical magnification measurements show that a larger extent of the pSTS VFM surface areas are devoted to the peripheral visual field than those in the V3A/B cluster. Reliability measurements of VFMs in pSTS and V3A/B reveal that these cloverleaf clusters are remarkably consistent and functionally differentiable. Our findings add to the growing number of measurements of widespread sensory CFMs organized into cloverleaf clusters, indicating that CFMs and cloverleaf clusters may both be fundamental organizing principles in cortical sensory processing.

Title: The fMRI contrast response function to natural images is enhanced according to local subjective importance

Authors: *W. ZUIDERBAAN[1], S. O. DUMOULIN[2]
[1]Utrecht Univ., Utrecht, Netherlands; [2]Spinoza Ctr. For Neuroimaging, Amsterdam Zuidoost, Netherlands

Abstract: INTRODUCTION
Our visual percept is not solely based on the sensory information that we receive from the light falling on our retina, but is also influenced by our knowledge of the world. There is no consensus about how this interaction influences the neural signal in early visual areas. Current theories implement this knowledge of the world as a perceptual hypothesis that is compared with the sensory input. According to different inference theories, the perceptual hypothesis can either be suppressing or boosting the sensory information represented by early visual areas. In our study we investigated the effect that the knowledge-based perceptual hypothesis has on the neural signal in early visual cortex and how this interacts with the responses to the sensory-driven image feature contrast.
METHODS
We measured the responses using 7T fMRI to different sets of stimuli: standard mapping stimuli, 45 natural images and a full-field stimulus (100% contrast).
The mapping stimuli were used to estimate the region of visual space a voxel responds to: the population receptive field (pRF, Dumoulin et al, 2008). We used a 2D Gaussian in the visual

field to represent the pRF.
We used the pRFs to quantify both the amount of RMS-contrast (sensory-driven property) and the amount of subjective importance (knowledge-based property) in the pRF.
To show how the neural responses are modulated by the RMS-contrast inside the pRF, we derived the contrast response function (CRF) by plotting the fMRI response amplitude against the RMS-contrast of all pRFs within a given visual field map.
The natural images were taken from the 'Berkeley Segmentation Dataset and Benchmark' database (Martin et al, 2001). In this dataset, for every image observers labeled the subjective important parts of the image. We use these manual labels to define and quantify our measure for the perceptual hypothesis in the pRF. Last, we show how the CRF is modulated by the amount of subjective importance inside the pRF.
RESULTS
Based on the inherent variations of contrast in the natural images we show that we can derive the contrast response function (CRF). Furthermore, we show how the CRF is modulated by the perceptual hypothesis as we defined it by subjective importance. The CRF was boosted in visual areas V1-V2-V3 when the responses were elicited by parts of the image of high subjective importance.
DISCUSSION
Thus, the sensory-driven image representation of a scene in early visual areas is boosted by the knowledge-based perceptual hypothesis. This result argues against most conventional implementations of predictive coding.

Title: High-resolution 7T fMRI reveals auditory and imagery information in non-stimulated visual cortex

Authors: *M. BENNETT[1], L. S. PETRO[1], A. A. MORGAN[1], F. DE MARTINO[3], L. MUCKLI[2]

Abstract: Introduction Feedback outnumber feedforward connections in human early visual cortex. Vetter, Smith and Muckli (2014) showed that complex auditory scenes played to blindfolded subjects can be classified from V1, V2 and V3 using multivariate techniques. This raises questions about what the information represents and its relation to other non-feedforward input to visual cortex (Meyer, 2012; Smith, & Muckli, 2010). Here, we use high-resolution 7T functional brain imaging and multivariate classifiers to study auditory information and mental imagery in the early visual cortex of blindfolded subjects. **Methods** Five blindfolded subjects took part in a 7T fMRI experiment. Subjects either listened to one of three sounds (forest, traffic, people) or were cued to engage in mental imagery of one of the scenes for 12 seconds. We used polar angle and eccentricity retinotopic mapping to localise V1, V2 and V3. We ran a multivariate searchlight analysis (Kriegeskorte, Goebel, & Bandettini, 2006) in which the activity pattern from a cluster of voxels centred on every voxel in the early visual cortex was entered into a support vector machine classifier. Thus, each voxel was labelled with decoding accuracy based on nearby information. The information profile across entire V1 cortical depths was also analysed. **Results** Results suggest that both auditory and imagery information can be classified from non-stimulated visual cortex. There seems to be some commonality in the location of the patches of early visual cortex that can classify auditory and imagery information. While several possibilities remain open at this stage, there is a hint that during auditory stimulation information seems to be localised more to deeper layers of V1 (see figure 1). **Conclusions** Our data suggest that feedback to early visual cortex occurs - even in the absence of feedforward stimulation. Moreover, non-visual sensory input reaches the visual cortex at the earliest levels and seems to be localized in a similar way as feedback based on mental imagery.

Title: Development differentially sculpts receptive fields across human visual cortex

Authors: *J. GOMEZ[1], V. S. NATU[2], B. L. JESKA[2], M. A. BARNETT[3], K. GRILL-SPECTOR[4]

Abstract: A fundamental property of neurons in the visual system is that they have receptive fields that process visual information in spatially restricted regions of visual space. How RFs develop in humans, however, is unknown. While high-level visual areas involved in reading and face recognition show a protracted development in humans, it is unknown if this development is associated with changes to receptive fields, and if so, at what stages of the visual hierarchy they occur. To answer these questions, we estimate the population receptive field (pRF) of all voxels in the visual system in 26 typical children (5-12 years) and 26 adults (22-27 years) and compared across age groups. Participants took part in two fMRI experiments: (1) retinotopic mapping with bars containing black and white checkerboards to delineate retinotopic areas and estimate pRFs, and (2) a functional localizer containing faces, words, bodies, places, and objects to map high-level regions. In the ventral stream, we find no significant difference across age groups in polar angle, eccentricity, pRF size, or visual field coverage in areas V1-VO1 (Figure 1A). In contrast, we found differential development of pRFs of face- and word-selective regions across hemispheres. In the right hemisphere, pRFs and coverage in face-selective cortex become more foveally biased from childhood to adulthood, while word-selective cortex becomes less so. In the left hemisphere, this pattern is reversed (Figure 1B). We link this pRF development to behavior, collecting measurements of fixation patterns on faces and words outside the scanner. We find an increased foveal bias on words and faces in adult relative to child participants (Figure 1C). These results thus suggest a differential development of pRF and visual field coverage in face and word selective regions across hemispheres, which may importantly be driven by changes in viewing experience across development.

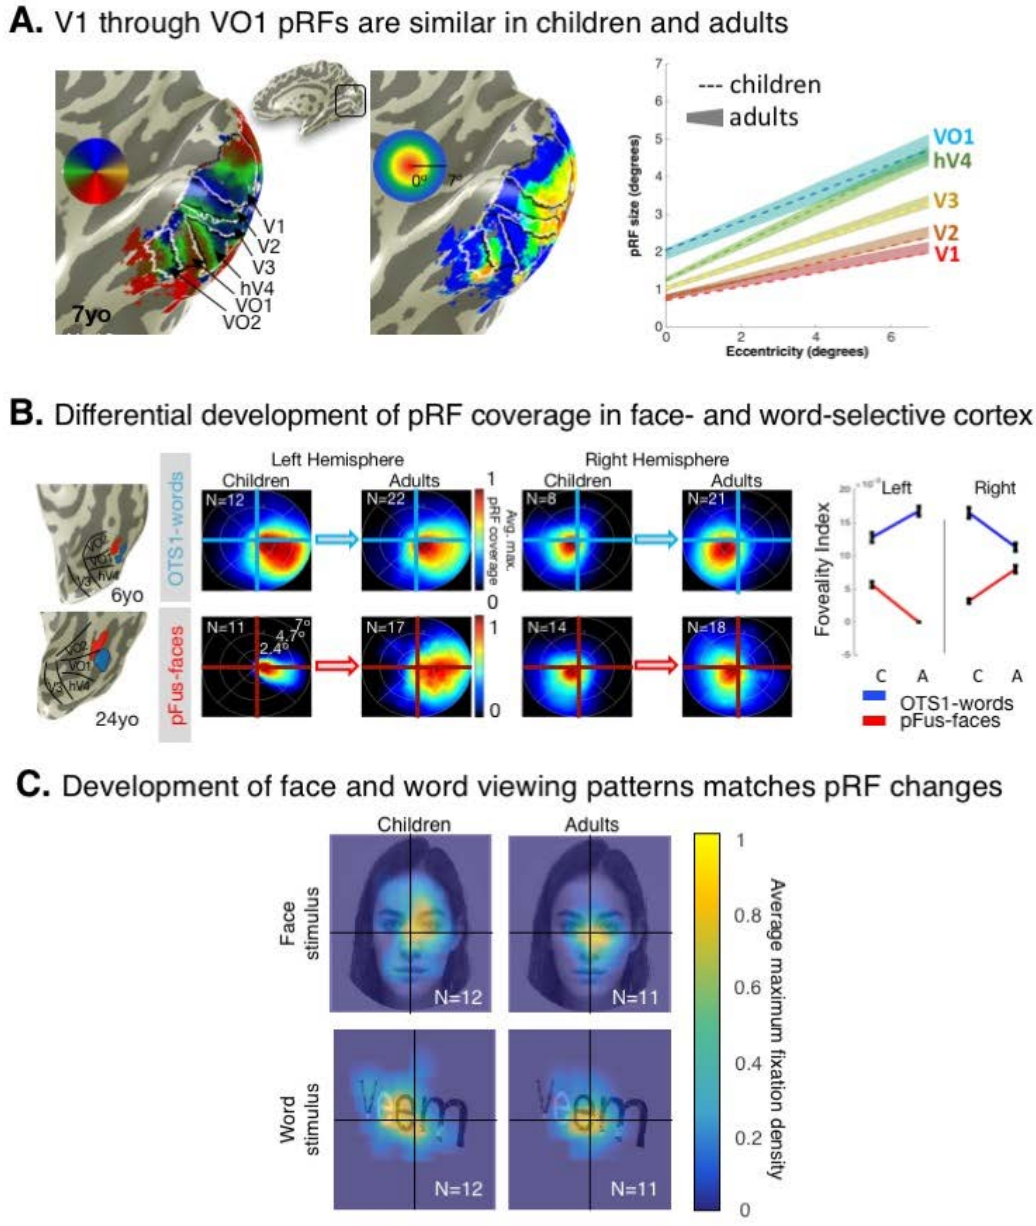

Figure 1. (A) Example pRF phase and eccentricity fits on the cortically inflated surface of a 7 year old child. On the right, average pRF eccentricity vs. size relationships across all children (dotted lines) and adults (shaded standard error of the mean). **(B)** Visual field coverage of face- and word-selective cortex (example fROIs shown on left) averaged across subjects. Foveality index calculated by multiplying coverage map by a mexican-hat filter positively weighting foveal coverage. C=children, A=adults. **(C)** Eye tracking experiment performed outside scanner in which fixations on stimuli are smoothed and averaged across subjects. Fixations are more central and punctate in adults.

Title: Retinotopic organization in the default mode network

Authors: *T. KNAPEN[1], D. VAN ES[2], M. BARENDREGT[2]
[1]VU Amsterdam, Amsterdam, Netherlands; [2]Cognitive Psychology, Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: The brain's default mode network (DMN) comprises a set of brain regions that consistently show decreases in Blood Oxygenation Level Dependent (BOLD) signal during task engagement, at times when most other cortical areas show BOLD signal increases. Despite being a well-known property of the DMN, the nature and function of DMN deactivations remains unclear.
Here we demonstrate that a fundamental neuroanatomical principle, retinotopy, exists within the human DMN. Specifically, BOLD decreases in the lateral parietal node of the DMN are specific to the appearance of a visual stimulus in a circumscribed region of retinotopic space. We estimated population receptive fields (pRFs) of negative amplitude from BOLD time courses in the DMN, and show that this region contains a coherent retinotopic map along the cortical surface. Moreover, this description of spatial preferences in the DMN, combined with ongoing activation patterns, allows us to reconstruct (decode) the position of a visual stimulus with a fidelity comparable to the known retinotopic maps of the intraparietal sulcus.
Our results indicate that retinotopically specific activations and deactivations synergistically subserve the processing of visual information. As DMN regions have been shown to contain pRFs that selectively activate for social information, it is likely that representations in retinotopic and other reference frames coincide in these regions. This overlap would allow local computations to integrate multiple levels of information processing.

Title: Separate resting state networks for grasping and visually guided reaching in macaques

Authors: *R. S. GREULICH[1], R. ADAM[2,3], S. EVERLING[2,4], H. SCHERBERGER[1,5]
[1]German Primate Ctr., Goettingen, Germany; [2]Robarts Res. Inst., [3]Grad. Program in Neurosci., [4]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada; [5]Fac. of Biol. and Psychology, Univ. of Göttingen, Göttingen, Germany

Abstract: Grasping allows primates to handle food and tools in a very specialised way. Tract tracing studies in nonhuman primates have highlighted three cortical areas as central nodes in the grasping network: anterior intraparietal area (AIP), ventral premotor area (F5), and the hand area of primary motor cortex (M1) (Davare et al., 2011). Although the anatomical connectivity between these cortical areas is known, their functional connectivity is less well understood. Furthermore, neurons were found which responded to grasping in the visual area V6a and the medial intraparietal area (MIP) (Galletti et al. 2003, Gamberini et al. 2011). Area V6a and MIP are part of the dorsal stream and are involved in the processing of visually guided reaching movements (Baccalá and Sameshima, 2001).
Here, we aim to expand our understanding of the functional connectivity within and between the cortical grasping and reaching networks in macaques using resting-state functional MRI. We applied a seed based functional connectivity analysis for each region-of-interest individually (AIP, F5, M1, V6a, MIP) and compared the resulting correlation maps.
First, we found that AIP, F5, and M1 individually reveal similar resting-state networks. These areas are part of the grasping network, which extends over large parts of the parietal lobe and includes somatosensory and motor areas. Area V6a and MIP also revealed comparable resting-state networks, which covered posterior frontal areas around the frontal eye field and extending to the temporal lobe.
These findings reveal two distinct networks, one traditionally attributed for grasping and one for visually guided reaching, with only slight overlap between the two.

Title: A preference for mathematical processing outweighs selectivity for Arabic numbers in the inferior temporal gyrus

Authors: *M. GROTHEER[1], B. L. JESKA[1], K. GRILL-SPECTOR[1,2,3]
[1]Dept. of Psychology, [2]Stanford Neurosciences Inst., Stanford Univ., Stanford, CA;
[3]Neurosciences Program, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: A region in the inferior temporal gyrus (ITG), referred to as the 'number form area' has been shown to respond more strongly to Arabic numbers than other visual stimuli, suggesting that it is involved in the visual encoding of numbers. However, other studies report that this region activates during mathematical tasks on auditory stimuli, suggesting that it may be involved in mathematical rather than visual processing. To address this debate, we conducted three fMRI experiments (N=15), in which we varied stimuli and task to determine how these factors affect ITG responses. In Experiment (Exp) 1, we measured responses to visually different stimuli (numbers, letters, false numbers and letters, Fourier scrambled numbers and letters, and objects), during a non-mathematical task (1-back on stimulus identity). In Exp 2, we measured responses to well-controlled character-like stimuli (colored number and letter morphs) during different tasks (adding, reading, and remembering stimulus color). In Exp 3, we measured responses to visually dissimilar stimuli (colored numbers, hands, and dice) during different tasks (adding and remembering color). Results show that those voxels in the ITG showing a preference for numbers vs. other visual stimuli in Exp 1, show higher responses to mathematical processing (adding vs. color or reading) in Exps 2 and 3, but not higher responses to numbers vs. other stimuli in Exps 2 or 3. Likewise, those voxels in the ITG showing higher responses to mathematical processing (adding vs. color or reading) in Exp 2, also show higher responses to mathematical processing (adding vs. color) in Exp 3 using different stimuli, but do not show a preference for numbers in any of the experiments. Finally, a classifier approach revealed that mathematical task can be successfully decoded (>85% accuracy in both Exps 2 and 3) from distributed ITG responses, but decoding accuracy for numbers was poor (<65% in Exp 1, at chance in Exp 2 and <45% in Exp 3). Together, these results suggest a need to rethink the function of the "number form area" as the context of a mathematical task rather than the processing of number stimuli produces reliable local and distributed ITG activations. We

propose that the ITG ascribes numerical content to the input, irrespective of the nature of the stimulus.

Title: A neural basis for biased competition in the developing visual system: An fMRI study in school-aged children

Authors: *N. KIM, M. A. PINSK, S. KASTNER
Princeton Univ., Princeton, NJ

Abstract: Attention functions develop significantly in childhood. Prior research investigated age-related differences in performance on various attention tasks and found different developmental trajectories for exogenous and endogenous attention and for sustained, selective, and executive attention. However, neural mechanisms underlying attention functions during development remain unclear. Here, we used hypotheses derived from biased competition model (Desimone and Duncan, 1995) to explore the neural basis of visual attention in elementary school children. An important role of attention is to select or ignore components of sensory input to optimize behavior. According to the biased competition model, multiple stimuli that are present simultaneously compete for neural representation due to the limited processing capacity of the visual system. The neural competition can be influenced in several ways including bottom-up and top-down factors. To examine sensory competition in the developing visual system, we presented multiple color patches either simultaneously or sequentially while children (age 6 to 12) were engaged in an irrelevant fixation task. We hypothesized that, as previously shown in the adult brain, multiple stimuli would compete with one another when presented simultaneously and thus mutually suppress neural responses in multiple areas of the visual processing hierarchy. We quantitatively evaluated the degree of sensory competition in multiple topographically organized areas, as identified with the help of a probabilistic functional brain atlas. Our results on sensory competition will provide a basis for investigating how top-down and bottom-up factors influence neural competition, thereby providing a neural basis for the filtering of unwanted information during the selection process. The results of these studies may have implications for a better understanding of neurodevelopmental disorders such as attention deficit disorder.

Title: Optical infrared vestibular stimulation evokes physiological eye movement and cardiovascular responses

Authors: *W. JIANG[1], D. RICE[3], G. P. MARTINELLI[4], G. R. HOLSTEIN[5], S. RAJGURU[2]
[1]Biomed. Engin., Univ. of Miami, Miami, FL; [2]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL; [3]Univ. of miami, Miami, FL; [4]Dept. Neurol., [5]Depts Neurol, Neurosci, Anat/Cell Bio, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Infrared neural stimulation has been demonstrated to modulate the pattern of neural signals transmitted from the angular motion sensing semicircular canals of the vestibular system to the brain. The goal of the present study was to investigate the physiological effects of pulsed infrared stimulation (pIR) focused on individual vestibular end organs in the rat. A surgical approach was developed to target specific semicircular canals and otolith organs and pIR (1863nm, 250pps, 200µs) was directed to vestibular endorgans using custom-designed 200 and 400 µm optical fibers. The evoked bilateral eye movements were measured using a video-based, two-channel eye tracking system (ISCAN Inc, Woburn, MA) and changes in blood pressure and heart rate were recorded as a measure of activation of the vestibular sympathetic reflex pathway. The activation of vestibulo-ocular motor pathways by frequency modulated pIR evoked significant characteristic bilateral eye movements. The eye movements continued through 30+ minutes of continuous pIR stimulation. Simultaneously, a significant drop in blood pressure and heart rate were recorded with low frequency sinusoidal pIR stimulation. The results compared well with our previous observations that sinusoidal galvanic vestibular stimulation and tilt can be used to activate central vestibular neurons of the vestibulo-sympathetic reflex pathway. To identify the vestibular endorgans activated by pIR, histology and micro-computed tomography were performed. Following the experiments, the radiation energy was increased to a level likely to induce tissue damage. The cochlea and vestibular end organs were harvested to visualize the damage and determine the beam path. In other animals, high-resolution microCT was used to image the inner ear structures and the location of the optical fiber fixed in place following experimentation. Overall, the results demonstrate selective stimulation of vestibular endorgans by pulsed infrared optical stimuli and suggest potential applications in inner ear.

Title: Localization of central vestibular neurons activated by pulsed infrared stimulation of individual vestibular end organs

Authors: ***G. R. HOLSTEIN**[1], D. RICE[3], W. JIANG[3], S. RAJGURU[4], G. P. MARTINELLI[2]
[1]Depts Neurol, Neurosci, Anat/Cell Bio, [2]Dept. Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Biomed. Engin., Univ. of Miami, Miami, FL; [4]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL

Abstract: The vestibulo-sympathetic reflex (VSR) pathway is important for modulating blood pressure upon changes in head position with regard to gravity, as occurs when humans rise from a supine position and when quadrupeds climb or rear. We have demonstrated that sinusoidal galvanic vestibular stimulation (sGVS) and tilt can be used to activate central vestibular neurons of the VSR pathway. Changes in blood pressure were recorded in response to these stimuli, and the activated vestibular neurons were identified by cFos labeling and retrograde tract tracing. Maps of the activated VSR neurons indicate that the cells are located almost exclusively in parvocellular medial vestibular nucleus (MVN), the caudal region of MVN, and throughout the caudal half of the spinal vestibular nucleus (SpVN). However, both sGVS and tilt activate the vestibular nerve globally.
The goal of the present study was to identify the specific locations and densities of VSR neurons activated by stimulation of individual vestibular end organs in rats. To achieve this, pulsed infrared laser stimulation (pIRs) at 1863nm, 100-250pps, and 250µs was directed through the round window toward vestibular end organs in rats using customized optical fibers. Changes in BP and heart rate and evoked eye movements were recorded in response to pIRs of semicircular canal cristae and otolith maculae. Cells that were activated by pIRs were identified by cFos/DAB immunohistochemistry. Labeled cells in the vestibular nuclei were counted in skip-serial sections through the caudal vestibular nuclei that were separated by at least 100 µm. The cell counts from each rat were mapped onto 16 representative rostro-caudal Bregma levels. Results indicate that posterior canal stimulation activates primarily (but not exclusively) ipsilateral neurons in both

parvocellular MVN and SpVN. Although VSR neurons were observed between Bregma -11.16 and -12.84, the highest density of VSR neurons activated by posterior canal stimulation was concentrated at Bregma levels between -11.52 and -12.12. This distribution is contrasted with the maps of activated VSR neurons resulting from global vestibular nerve stimulation, and from pIRs of individual otolith organs.

Title: Probing the role of the efferent vestibular system using direct monosynaptic viral tracing

Authors: M. A. MATHEWS[1], *A. J. CAMP[2], A. J. MURRAY[3]
[1]Univ. of Sydney, Sydney, Australia; [2]Univ. of Sydney, Sydney University, Australia; [3]Sainsbury Wellcome Ctr. for Neural Circuits and Behaviour, Univ. Col. London, London, United Kingdom

Abstract: *Background:* Many sensory modalities adopt efferent circuitry in the central nervous system (CNS) to modulate peripheral targets. Unlike other sensory modalities, the functional role of the efferent vestibular system (EVS), originating in the brainstem efferent vestibular nucleus (EVN) and terminating on vestibular hair cells and afferent fibres at the periphery, remains elusive. Previous work has focused on the anatomy, morphology, physiology, synaptic mechanisms, and peripheral responses to EVN activation, with few studies directly investigating a behavioural function. Moreover, a lack of understanding regarding EVN circuit dynamics makes it impossible to link vestibular efferent activity to behaviour. *Objective:* Here, we sought to determine the central context within which the EVN is activated by tracing the monosynaptic inputs to this group of neurons, and expand on the work presented at the previous Neuroscience meeting. *Methods:* We used monosynaptic rabies tracing to determine the direct inputs to EVN neurons. In mice (n =3) expressing Cre under the control of the choline acetyl transferase (ChAT) promotor we expressed the rabies glycoprotein (G) selectively in EVN neurons. Following G expression, we injected glycoprotein-deficient rabies (RABVG) virus expressing a fluorescent protein into the horizontal and posterior semicircular canals in the inner ear of the same animal. Histological analysis was performed to identify the direct inputs to EVN neurons. *Results:* We observed >50 direct inputs from diverse regions throughout the brainstem, cerebellum, and forebrain including from structures in the telencephalon and diencephalon. *Conclusions:* The identification of direct monosynaptic inputs to mouse EVN neurons with

rabies virus will allow us to expand hypothesis regarding EVN function. In addition, this method will allow us to manipulate EVN neurons, or their inputs, via electrical, chemical or optogenetic methods providing a means to systematically explore the context-dependent central modulation of peripheral vestibular function.

Title: Decoding body-centered representations of translational motion in 3D from neural activity in the rostral fastigial nucleus

Authors: *C. MARTIN, J. X. BROOKS, A. M. GREEN
Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: Many of our daily behaviors (e.g., postural control, locomotion, reaching) rely on estimates of our body motion. Vestibular signals are essential for such estimates but to contribute appropriately they must be transformed from a head- to a body-centered reference frame. Recently, we extended previous work to examine whether cells in the rostral fastigial nucleus (rFN) reflect this transformation fully in 3D. Consistent with such a transformation, many cells exhibited spatial tuning shifts for changes in head-re-body orientation in both horizontal and vertical planes. However, tuning properties were broadly distributed between head- and body-centered with most cells reflecting only a partial transformation. This suggests that despite evidence in the rFN for the precise matching of vestibular and neck proprioceptive signals required to distinguish head from body movement (Brooks and Cullen, 2009) explicit estimates of body motion are unlikely to be encoded by most individual cells. The goal of the current study was to investigate the facility with which fully body-centered representations in 3D could be decoded from populations of rFN cells and whether specific tuning properties affected this capacity. To this end, we generated a synthetic population of 500 cells with preferred tuning spanning 3D space and having distributions of spatio-temporal tuning properties similar to those of our recorded neurons. We then examined the ability to decode fully body-centered motion representations along 13 axes in 3D space across changes in head-re-body orientation of ± 90° in

the yaw, pitch and roll planes. We show that fully body-centered representations can be decoded through a simple linear combination of the tuning functions of small groups (5-7) of these cells. Furthermore, with changes in decoding weights such representations can exhibit a broad range of temporal properties ranging from lagging translational velocity to leading acceleration. Two key properties of rFN cells were crucial to this capacity. These include: 1) a near absence of "gain-fields"; 2) tuning shifts that follow a very specific theoretically predicted trajectory in 3D space. Collectively, these observations suggest that despite the broad distribution of tuning properties, rFN cells reflect a late or "output" stage in the head-to-body reference frame transformation. We propose that the maintenance of partially transformed responses with different spatio-temporal properties facilitates the creation of downstream body motion representations with a broad range of dynamic characteristics, consistent with the functional requirements for tasks such as postural control.

Title: Noise correlations between neurons in early vestibular pathways are negligible during both active and passive self-motion

Authors: *A. DALE[1], J. CARRIOT[2], M. J. CHACRON[2], K. E. CULLEN[2,3]
[2]Physiol., [1]McGill Univ., Montreal, QC, Canada; [3]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Vestibular sensory information is encoded by the primary afferents of the VIIIth cranial nerve and transmitted to the brainstem vestibular nuclei. To fully understand how self-motion signals are decoded by central processing stages, correlated variability (i.e., noise correlations) among ensembles of neurons must be taken into account (e.g., Cohen and Kohn 2011). Notably, with shared afferent input among nearby vestibular nuclei neurons (Sato et al. 1989), as well as evidence of gap junctions between them (Condorelli et al. 2000), one might predict that noise correlations play a role in early vestibular processing during everyday activities. However, to date, this question remains open. Here, we computed cross correlations between the activity of pairs of vestibular nuclei neurons as well as their afferent inputs during 1) sinusoidal passive stimulation at frequencies from 0.5-4Hz, 2) passive stimulation with active-like trajectories, and 3) active movements. We first show that the resting discharges of both

peripheral afferent and central vestibular only neurons exhibit negligible noise correlations over windows ranging from 1-50ms. We next considered the effect of self-motion stimuli resulting from different behavioral contexts. We found that neuronal activities displayed insignificant noise correlations during passive sinusoidal stimulation which maximally drives vestibular sensory neurons. Furthermore, noise correlations remained negligible during more natural passive vestibular stimulation. Finally, we tested vestibular only neurons during voluntary self-motion when their responses are cancelled by purported cerebellar inputs to the vestibular nuclei. We found that over durations spanning synchronous firing to whole movements, the responses of vestibular nuclei neurons remained independent from one another. As such, we conclude that if anatomical connections tend to correlate activity between neurons, then additional factors must be present to cause trial-to-trial variabilities of neuronal responses to be de-correlated. We hypothesize that this independence between neuronal responses allows subsequent stages of vestibular processing (e.g., thalamus or cortex) to best average out the variability in their inputs in order to achieve improved stimulus coding.

Title: Cerebellar re-encoding of self-generated head movements

Authors: ***G. P. DUGUÉ**[1], M. TIHY[1], B. GOURÉVITCH[2], C. LENA[3]
[1]IBENS, Paris, France; [2]Dept. Cognition & Behavior, Inst. De Neurosci. Paris-Saclay (neuropsi), Orsay, France; [3]Inst. de Biologie de l'Ecole Normale Superieure, PARIS, France

Abstract: Head movements are primarily sensed in a reference frame tied to the head, yet they are used to calculate self-orientation relative to the world. This requires to re-encode head kinematic signals into a reference frame anchored to earth-bound landmarks such as gravity, through computations whose neuronal substrates remain to be determined. Here, we studied the encoding of self-generated head movements in the caudal cerebellar vermis, an area essential for

graviceptive functions. Multi-unit recordings were obtained from caudal cerebellar units in freely moving rats, while head kinematics was monitored using a miniature digital inertial sensor. This sensor provided the same type of information as the animal's vestibular organs (a measurement of the instantaneous head angular velocity and acceleration).The gravitational component of acceleration was isolated offline using an orientation filter algorithm. The kinematics of natural head movements in our conditions was characterized by 1) a multi-peaked power spectrum of angular velocity signals up to 20 Hz, 2) a predominance of the effect of gravity in the lower frequency range of acceleration (< 2 Hz) and 3) the relative absence of translational acceleration in the total acceleration signal (i.e. most of the non-gravitational acceleration signal was generated by rotations). We found that, contrarily to peripheral vestibular inputs, most caudal Purkinje cells exhibited a mixed sensitivity to head rotational and gravitational information (with a negligible contribution of non-gravitational acceleration information), and were differentially modulated by active and passive whole-body movements. The presence or absence of visual cues did not seem to condition the units' responses to head movements. We analyzed in greater details the units' receptive fields and found that they were tuned to a preferred head rotation whose direction depended on head tilt. In a subpopulation of cells, this tilt dependent rotation-coding scheme underlay a tuning to angular velocity about an axis defined relative to gravity. These cells thus exhibit a transformed angular velocity signal which is mapped to an external, earth-bound reference frame, and could provide the appropriate substrate for computing gravitationally-anchored head direction signals.

Title: Temporal whitening of naturalistic self-motion stimuli by early vestibular pathways

Authors: *D. E. MITCHELL[1], A. KWAN[2], J. CARRIOT[3], M. J. CHACRON[2], K. E. CULLEN[2]
[1]Dept. of Physiol., [3]Physiol., [2]McGill Univ., Montreal, QC, Canada

Abstract: Understanding how the brain generates appropriate behavior and accurate perception in response to incoming sensory signals remains a fundamental challenge in neuroscience. The common wisdom is that neural coding strategies are adapted to the statistics of the sensory signals found in the natural environment. Specifically, early sensory pathways are thought to

efficiently process natural stimuli by matching both their tuning properties and neural variability to the statistics of their natural stimuli, thereby removing redundancy and thus maximizing information transmission. If this is the case the resulting neural response is independent of frequency (i.e. “whitened”). To date, however, there has been no experimental demonstration that such a match exists. Here we show for the first time how whitening is achieved by sensory pathways. Specifically, we examined how neuronal variability and tuning are balanced to optimize coding of naturalistic self-motion in early vestibular pathways. We recorded from vestibular neurons during naturalistic self-motion and found that whitening occurs sequentially, beginning at the level of the sensory periphery, and is then further refined centrally. We found that, while the tuning of afferents was largely sufficient to explain their contribution to whitening, this was not the case for central neurons. Indeed, the exceptionally whitened responses of central neurons could only be accounted for when we considered their resting discharge variability as well as their high-pass tuning. Our analysis then further revealed that this combination of resting power and variability is well matched to offset naturalistic stimulus statistics in order to temporally whiten neural responses, thereby maximizing information transmission. These findings overturn the prevailing view that whitening of neural responses is achieved through tuning alone by demonstrating that neural variability is a fundamental feature of the neural code.

Title: Neonatal excitation-inhibition imbalance introduces long-lasting changes to neuronal recruitment in vestibular circuits for spatial navigation

Authors: *O. W. CHUA, Q. F. JIANG, K. L. K. WU, Y. S. CHAN
Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, China

Abstract: A critical period exists during the first 2 postnatal weeks for development of GABAergic transmission in the rat vestibular nucleus (VN). Perturbation of GABAergic transmission in the VN with bicuculline, a $GABA_A$ blocker, during this period abolished efficient spatial navigation behaviour in adults. Post-critical period treatment at P21 had no effect. We hypothesized that the behavioural deficits are the result of long-lasting changes in MVN circuitry. The number of parvalbumin-expressing neurons and perineuronal nets was increased in rats treated with bicuculline at P1 as compared with controls. We further found that there was a decrease in amplitude/frequency of sIPSCs and change in firing pattern of projecting vestibular neurons in adult rats with bicuculline treatment at P1. Since the anterodorsal thalamic nucleus (ADN) integrates vestibular input to generate head direction signal for navigation, we examined neuronal activation in the ADN in these rats after natural vestibular stimulation. It was found that *c-fos* expression pattern in the ADN of P28 rats after wobble rotation was deranged. Taken together, the data show that neonatal disruption of excitation/inhibition balance in the VN leads to long-lasting derangement of MVN circuitry and its output thereby impacting vestibulo-thalamic neuron recruitment in rats and navigational behaviour. Our findings will inform strategies to promote rewiring of brain circuits for rehabilitation.

Title: Vestibular compensation: possible role of extracellular matrix

Authors: *K. MATESZ[1,2]
[1]Univ. of Debrecen, Fac. of Dent., Debrecen, Hungary; [2]Dept. of Anatomy, Histology and Embryology, Oral Anat. Div., Univ. of Debrecen, Debrecen, Hungary

Abstract: Peripheral lesion of the vestibular system (VS) evokes postural and visual deficits accompanied by impaired vegetative function. Depending on the species, most of the symptoms regain spontaneously during the process of vestibular compensation (VC). In amphibians, the sectioned vestibular nerve regenerates, the re-growing axons establish functional synapses. In contrast, the injured vestibular nerve of mammalian species does not regenerate but functional

recovery from the vestibular symptoms is possible. Over the last few decades, the role of extracellular matrix (ECM) on the plasticity and regeneration of CNS has been emphasized. Our hypothesis is that different molecular composition of ECM in the perineuronal nets (PNNs) of vestibular neurons, the condensed ECM around the neuronal cell bodies and dendrites, is responsible for the different restoration capacity of VS in non-mammalian and mammalian species. Therefore, we examined the expression of ECM during the VC in the PNN of the vestibular nuclei in frog and rat. On anesthetized frogs the vestibular nerve was transected and reunited, in the rats unilateral labyrinthectomy was performed to destroy the vestibular sense organs. The animals were sacrificed at different survival times and on the brainstem section the expression of hyaluronan (HA), chondroitin sulfate proteoglycans (CSPGs), tenascin-R and link proteins were detected by using histochemical and immunohistochemical reactions. In the non-operated frog and rat conspicuous molecular differences were shown in the PNNs. During the VC, the time course of bilateral destruction and subsequent reorganization of PNNs showed species differences and corresponded to the restoration of static symptoms. Our results suggest that the permissive HA-rich, but CSPG-free PNNs of frog vestibular nuclei may be associated with the high degree of plasticity and regenerative potential of VS in amphibians. In contrast, the strong expression of the CSPGs in the PNNs of the rat vestibular nuclei seems to be against the plasticity of VS in mammalian species. This contradiction can be resolved by the very quick and dynamic quantitative and qualitative changes in the expression of ECM molecules in the rat PNNs presented in our experiments. It is tempting to assume that in the non-lesioned rat the condensed PNNs are needed to stabilize the synaptic contacts, whereas their postlesional disruption has beneficial effect on the synaptic reorganization in order to compensate the lost vestibular input. On the other hand, the loose ECM network in the PNN may allow the in-growth of non-vestibular axon terminals as a possible factor of VC.

Title: Malformation of the vestibular inner ear leads to abnormal vestibular nuclei development

Authors: S. J. LILIAN[1], H. E. SEAL[1], A. POPRATILOFF[1], J. C. HIRSCH[1], *K. D. PEUSNER[2]

[1]Anat. and Regenerative Biol., [2]George Washington Univ. Sch. of Med. and Hlth. Sci., Washington, DC

Abstract: Many developmental disorders affecting the inner ear are manifested clinically as delayed motor development and challenges in maintaining posture and balance, indicating that central vestibular circuits are affected. How central vestibular wiring is changed in pediatric cases with inner ear abnormalities is poorly understood. We hypothesize that the malformed vestibular inner ear transmits abnormal signals to developing vestibular nuclei, the first brain centers processing the input. We expect abnormal signals to influence the development of the entire vestibular neural circuitry from brainstem vestibular nuclei to vestibular cerebral cortex. Our lab has implemented the chick embryo, a well-established animal model for studying normal development, as a novel model to study vestibular brain development in congenital disorders. Existing genetic mutant mouse models show high variability in inner ear pathology, possibly resulting in many variable brain abnormalities. We find that surgical rotation of the developing inner ear, or otocyst, 180 degrees in two-day-old chick embryos results in an abnormal inner ear with one of two forms. The predominant defect is a large sac with truncated or absent canals, while the less frequent pathology is an inner ear with one or more small canals. These defects are similar to those commonly reported in pediatric cases of congenital vestibular inner ear disorders. Thus, the chick offers a reproducible model with phenotypic outcomes like those found in children with congenital vestibular inner ear disorders. After hatching, chicks with rotated otocyst show abnormal vestibular behaviors, including head tilt, stumbling while walking, delayed righting reflex, and a tendency to close one or both eyes.
To understand the consequences of this peripheral manipulation on brainstem vestibular centers, we began by counting vestibular nuclei neurons in the chick tangential nucleus after otocyst rotation. The tangential nucleus was selected because its principal cells are distinctive vestibular second-order projection neurons readily identified in the lateral medulla oblongata. We find significant reduction in the number of neurons in the tangential nucleus on the rotated side. Using the chick model, we will test fundamental neuronal mechanisms operating during the emergence and maturation of vestibular signal processing and compare the results to those reported in normal chicks (Peusner, 2014). Understanding the role of vestibular sensory input on brain development may help to reveal the aberrations in central vestibular neuronal networks, and lead to advances in treating children with malformed vestibular inner ears.

Title: Primary projections of the VIIIth nerve in two species of snakes, the western diamondback rattlesnake (Crotalus atrox) and amazon tree boa (Corallus hortulanus)

Authors: *R. M. LONG[1], M. S. BOTHE[2], C. GUTIERREZ-IBANEZ[1], T. KOHL[2], H. LUKSCH[2], H. STRAKA[3], D. R. WYLIE[1]
[1]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [2]Tech. Univ. of Munich, Freising, Germany; [3]LMU Munich - Biocenter Martinsried, Planegg, Germany

Abstract: Detection of angular and translational body motion derives from sensory transformations within otolith and semicircular canal organs. Signals are transmitted to the brain by the VIIIth nerve with an anterior branch that carries afferents from the saccule, utricle, anterior and horizontal canals and by a posterior branch that carries afferents from the posterior canal, lagena and various papillar organs. The central projection of individual organs has been described in various vertebrates, however, these studies generally examined only one organ at a time. Here we used an *in vitro* approach with fluorescent tracers to simultaneously trace the respective termination pattern of afferent fibers from each semicircular canal in two species of snakes (*C. atrox, C. hortulanus*). Brains were isolated and each semicircular canal nerve branch was stained separately with Dextran-Tx Red, Dextran Fluorescein, or Neurobiotin 350. Brains were incubated in cold Ringer's solution at 9°C for 48 hrs, fixed, sliced into 50 µm sections and imaged with fluorescence microscopy. Afferents from the different endorgans terminated throughout the rostrocaudal extent of the vestibular complex in rhombomere 1-8, including a cluster of efferent cell bodies ventromedially in r4. Afferents in the posterior branch terminated within the dorsal region of the lateral, medial and descending vestibular nuclei, as well as the tangential and cochlear nuclei. Afferents in the anterior branch terminated in ventral and medial areas of the vestibular nuclei, with a noticeable differential termination pattern of horizontal and anterior canal afferents. Dense terminal labelling from the horizontal and anterior canals was seen, respectively, in the ventrolateral and medial areas of the vestibular nuclei. In contrast, only few afferents terminated as mossy fibers within the cerebellum. The latter derived from the two vertical but not the horizontal canal. The overall pattern of the vestibular afferent projections in snakes is similar to that of other vertebrates suggesting an evolutionarily conserved central topography.

Title: Vestibular nucleus and reticular formation neurons with converging limb and labyrinthine inputs differentially discriminate vestibular signals

Authors: *D. M. MILLER, C. D. BALABAN, A. A. MCCALL
Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The CNS processes multiple inputs, including from the vestibular periphery and peripheral proprioceptors, to effect balance control. Neurons that receive vestibular inputs in the vestibular nuclei (VN) and pontomedullary reticular formation (pmRF) have recently been shown to respond to convergent proprioceptive inputs from the hindlimb in conscious cats. However, it is presently unknown whether dynamic vestibular and limb proprioceptive signals are processed differentially in either of these two areas. We have modeled the firing of VN and pmRF neurons during vestibular stimulation and hindlimb movement and determined if vestibular or limb movement signals could be used to predict the histologic location of a given neuron. Single-unit recordings were obtained in conscious cats from neurons in the caudal VN (n=77 neurons) and the pmRF (n=60 neurons). Sinusoidal whole body rotation in the roll plane

was used as the search stimulus. Neurons modulating with the search stimulus were subsequently recorded during 10° ramp-and-hold roll body rotation, 10° ramp-and-hold hindlimb movement and to both stimuli delivered simultaneously. Composite response histograms were fit by an additive model of low and high pass filtered limb and body position signals using least squares non-linear regression. The R^2 values for goodness of fit for the VN and pmRF additive models were 0.91 ± 0.03 and 0.65 ± 0.17, respectively. Forward stepwise logistic regression (Wald criterion) was used to estimate coefficients in order to categorize neurons as belonging to either the pmRF or the VN using the set of parameters from the additive model. This logistic regression analysis revealed that 2 predictors - high pass vestibular roll gain (EAR UP) and low pass vestibular roll gain (EAR DOWN) - discriminate VN neurons from pmRF neurons with a sensitivity of 74% and specificity of 50%. pmRF neurons were more likely to have rectified high pass roll gain responses while VN neurons were more likely to have higher gain responses to low pass roll position signals. The present findings support the notion that neurons in vestibulospinal and reticulospinal pathways have complimentary functional roles in postural control. While neurons that integrate limb proprioceptive and vestibular signals in an additive manner likely govern corrective limb movements in response to postural perturbations through modulation of corrective reflexes, pmRF neurons may be more likely to be involved in modulating muscle activity during dynamic tasks (such as walking).

Title: Peripheral and central processing during vestibular unisensory integration in humans

Authors: *P. A. FORBES[1,2,3], G. P. SIEGMUND[4], A. KWAN[5], D. E. MITCHELL[6], A. C. SCHOUTEN[7], K. E. CULLEN[5], J.-S. BLOUIN[2]
[1]Dept. of Neurosci., Erasmus Med. Ctr., Rotterdam, Netherlands; [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Delft Univ. of Technol., Delft, Netherlands; [4]MEA Forensic Engineers & Scientists, Richmond, BC, Canada; [6]Dept. of Physiol., [5]McGill Univ., Montreal, QC, Canada; [7]Delft Univ. Tech., Delft, Netherlands

Abstract: Effective sensory integration arising from simultaneous biological events is essential to understanding and engaging with our surroundings. In the vestibular system, this integration typically results in subadditive responses, and can occur during multisensory (canal-otolith) and

unisensory (canal-canal) integration. Subadditive unisensory integration occurs due to a static-boosting nonlinearity in the input-output relationship of vestibular nuclei neurons, a process thought to expand their dynamic linear range. Understanding how vestibular unisensory integration modulates motor output in humans is critical for developing experimental, clinical and virtual/altered-reality applications that combine different forms of vestibular stimuli. In this study, we explored how electrical and motion vestibular stimuli are integrated to generate human neck muscle responses with the aim to determine at what neural stage integration occurs. We first applied electrical vestibular stimulation (EVS) as a stochastic signal (0-75 Hz) to seated subjects who were rotated about a vertical axis at 1 Hz with increasing peak amplitudes (0-150 °/s). Bilateral EMG of the sternocleidomastoid was collected to determine whether combined stimuli modified the electrically- and motion-evoked vestibulocollic reflex (VCR). We observed that the electrically-evoked VCR decreased across the stimulus bandwidth with increasing motion velocity. The timing of attenuation varied within the motion cycle and was similar in phase to the motion-evoked VCR: leading input velocity by ~40-60°. To further examine this relationship, we varied the frequency of motion from 0.4 to 4 Hz. Our results suggest that the phase of attenuation matched the dynamics of first and second order vestibular neurons, indicating that integration occurred prior to convergence on the motoneuron. To confirm that electrical and motion stimuli combine linearly at the afferent level, we then recorded macaque afferent responses during equivalent electrical and motion (1 Hz) stimuli used in humans. Afferent responses to the electrical stimulus were not altered by simultaneous whole-body motion. Instead, afferent activity could be predicted by the sum of each response, suggesting integration occurs at the vestibular nuclei. Finally, a model simulating the static-boosting nonlinearity of vestibular nuclei neurons replicated human neck muscle responses. Taken together, these results reveal that vestibular contributions to neck muscle activity evoked by electrical and motion stimuli undergo similar nonlinear integration within vestibular nuclei that occur during unisensory vestibular stimulation.

Abstract: Our previous work studied one manner of testing tandem walking and the Romberg on foam with head still and head moving in pitch and showed moderate ROC values, sensitivity and specificity. Using larger sample sizes, (controls, n= 355; patients, n=140) we again tested Romberg on foam with eyes closed and feet together, with head still, head moving in yaw and in pitch at 0.3 Hz, controlled with an oscillating tone. We also tested subjects on tandem walking with eyes closed (controls, n = 291; patients, n=92). Logistic regression was performed for estimation of area under the curve (AUC), where cut offs for best combinations of sensitivity/specificity were determined. P <.05 was considered significant. Trial durations of Romberg pitch and yaw trials in controls were significantly shorter than head still trials but did not differ from each other, and trial durations decreased gradually and significantly with age. ROC values were moderate, depending on the exact cut of the age range, but were approximately 0.75. Tandem walking was tested with eyes closed, but instead of counting the number of correct consecutive steps the total number of correct steps out of ten was counted, on three consecutive trials. Subjects seemed to improve slightly on the second trial but fatigued on the third trial. Therefore, the first trial seems to be a good indicator of performance. ROC values were moderately high, better for younger subjects, < age 60, than subjects > age 60: ROC=0.8 younger subjects but ROC=0.72 older subjects. Kinematic data may provide additional insight but are not useful for screening.

Title: Reduction of motion sickness through targeting histamine N dash methyltransferase in the dorsal vagal complex

Authors: *H. L. XU, L. CHANG, Z. JIANG
Inst. of Nautical Med., Nantong Univ., Jiangsu, China

Abstract: Abbreviations: CNS, central nervous system; DVC, dorsal vagal complex; GFP, green fluorescent protein; HNMT, histamine N-methyltransferase; MS, motion sickness; SSS, saccharin sodium solution.

Abstract

To investigate the role of histamine N-methyltransferase (HNMT) activity in the development of motion sickness (MS) in the dorsal vagal complex (DVC) to inform the development of new drugs for MS, Beagle dogs and Sprague-Dawley rats were rotated to simulate MS. HNMT expression in the brain stem and DVC was measured. In addition, the effects of systemic application of tacrine, a HNMT inhibitor, on the development of MS were observed. Moreover, we microinjected a histamine receptor H1 inhibitor, promethazine, into the DVC to verify the involvement of DVC histaminergic neurotransmission in MS development. Finally, lentiviral vectors were microinjected into the DVC to determine the effects of altered HNMT expression on MS development. We found: 1) HNMT expression in the medulla oblongata of dogs and rats insusceptible to MS was higher than susceptible animals. 2) Tacrine dose-dependently promoted MS in both animals. 3) Blocking histaminergic neurotransmission in the DVC with promethazine inhibited MS. 4) Rotatory stimulus induced an elevation in HNMT expression and vestibular training elevated basal level of HNMT in the DVC during habituation to MS. 5) *In-vivo* transfection of a lentiviral vector packaged with HNMT gene increased HNMT expression in the DVC and reduced MS. 6) Microinjection of a lentiviral vector driving interference of HNMT gene expression *in vivo* significantly inhibited HNMT expression in the DVC and exacerbated MS. In conclusion, HNMT expression in the brain stem is inversely correlated with MS development. Increasing HNMT expression or stimulating its activity in the DVC could inhibit MS.

Title: Vestibular dysfunction impairs visuospatial working memory independently of other co-morbid depression, anxiety, fatigue and sleep disturbance

Authors: *S. SURENTHIRAN[1], L. J. SMITH[2], D. T. WILKINSON[2], R. BICKNELL[2], M. BODANI[2]

[1]Balance Centre, Neurosci. Unit, Medway Maritime Hosp., Gillingham, United Kingdom; [2]Sch. of Psychology, Univ. of Kent, Canterbury, United Kingdom

Abstract: Background Beyond the acute effects of vertigo and unsteadiness, disease or injury to the human vestibular system is commonly accompanied by subjective reports of memory loss and problems concentrating. The co-morbid presence of psychiatric illness, fatigue and difficulty sleeping, coupled with the lack of comprehensive, validated neuropsychological assessment, has left questions unanswered about the origin and nature of these underlying memory and attentional impairments. **Methods** 100 patients diagnosed with primary vestibular disorder (mostly vestibular migraine) at their initial neuro-otology appointment completed validated neuropsychological assessments of depression, anxiety, depersonalisation, fatigue, sleep, memory and attention. Vestibular pathology was characterised using a range of behavioural and physiological assessments. Statistical analyses first calculated the prevalence of cognitive and other comorbid impairments. A series of structural equation models then tested whether vestibular function exerted a direct influence on cognition, or influenced performance indirectly via psychiatric, fatigue/ sleep mechanisms. All models were adjusted for age-related effects on cognition. **Results** The majority of patients presented with a combination of anxiety, depression, sleep disturbance, fatigue, working memory impairments and problems sustaining attention. Most importantly, balance function, assessed via balance platform (a measure of unassisted posture), influenced visuospatial memory performance independently of any age, psychiatric or fatigue/ sleep-related effects. **Conclusion** The present findings identify new clusters of impairment in vestibular patients and highlight a direct effect of vestibular dysfunction on short-term visuospatial memory. We suggest that the most likely anatomical route is via the vestibulo-thalamo-cortical pathway which passes vestibular signals to several areas associated with working memory and visuospatial processing including the hippocampus, parietal cortex, frontal cortex and basal ganglia, From a clinical perspective, the results suggest that psychiatric treatments may do little to reduce co-morbid cognitive symptoms since they arise independently of psychiatric co-morbid factors and directly from the vestibular dysfunction.

Title: Resolving the paradox of active versus passive self-motion sensation: A unified internal model theory

Authors: *J. LAURENS[1], ***J. LAURENS**[1], D. E. ANGELAKI[2]
[1]Neurosci., [2]Dept of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: We present a theoretical framework that reconciles two segregated and seemingly conflicting lines of research on how the brain estimates self-motion during active and passive head movements. On one hand, brainstem and cerebellar neurons have been shown to implement an internal model of self-motion to accurately estimate rotations and translations from ambiguous and often inaccurate sensory vestibular signals during unpredicted, externally-generated ('passive') head and trunk movements. On the other hand, neurons in these same areas show reduced or no responses during self-generated ('active') head movements, a finding that suggests that the sensory consequences of motor commands are subtracted from sensory signals. Remarkably, the computational processes underlying sensory prediction during active motion and their relationship to internal model computations established during passive movements have never been modeled.
Here we show that the same internal model of self-motion described previously for passive vestibular stimuli should also process efference copies of motor commands in order to generate accurate sensory predictions. We provide support for this hypothesis by constructing a Kalman filter that incorporates motor commands into a previously-established Bayesian model of passive self-motion estimation. The Kalman filter computes sensory prediction dynamically based on internal estimates of head motion and motor commands, and converts sensory prediction errors into feedback signals that update the internal motion estimates. We simulate active and passive head rotations, translation, and combined head and trunk rotations, and find that the simulated feedback signals match neuronal responses recorded in the brainstem and cerebellum during active and passive rotation of the head and trunk, and translation of the head. We also predict neuronal responses to active and passive tilt, and long-duration active rotations and translation. We conclude that a single internal model of head motion, likely implemented by brainstem and cerebellar neuronal networks, can process motor commands and sensory afferent signals optimally, and that the Kalman model can provide valuable insights into the underlying neuronal computations as well as accurate quantitative simulations.

Title: Correlation of postural instability during virtual reality immersion to virtual sickness symptoms

Authors: *E. SON, K. ROH, J. KIM, J. KIM, S. HONG, S. KIM
Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Virtual sickness refers to motion sickness-like symptoms elicited by immersion in virtual reality (VR) environment. VR technology can render 3D environment and is used in various industrial and medical applications and entertainment. However, a portion of users are deterred from VR by virtual sickness. Sensory conflict and postural instability theories are two main explanation given for virtual sickness. In this study, we aimed to investigate postural instability during VR experience and examine its correlation with subjective virtual sickness symptoms. Forty young subjects performed postural tasks adapted from modified clinical test of sensory integration test (standing on firm and foam surfaces) under four visual conditions (eyes open without VR, eyes closed, with VR goggles on, or while viewing a virtual reality scene). Postural instability was measured using center of gravity (COG) sway velocity, and subjective symptoms were measured using visual analog scale(VAS) and simulator sickness questionnaire(SSQ). The subjects showed a wide range of subjective symptoms related to virtual sickness measured using VAS and SSQ. Immersion in VR caused increased COG sway velocity compared to eyes open or closed conditions. COG sway velocity is increased sequentially from the eyes open, closed, goggle only and VR. COG sway velocity is also increased in foam surface conditions compared to firm surface. The effect of goggles was comparable to eyes closed conditions in both firm and foam surfaces ($P>0.5$). Postural instability was correlated with total and subscale (nausea, oculomotor, disorientation) scores of SSQ. Significant correlation with all subcales and total scores of SSQ was observed during VR only in Firm surface condition. In summary, even normal healthy subjects experienced variable levels of motion sickness during postural tasks in the VR immersion condition. Correlation of subjective symptoms with Increased postural sway during VR immersion supports the theory of postural instability contributing to virtual sickness.

Title: The neural encoding of active self-motion by the primate cerebellum-evidence for an internal model that accounts for gravity

Authors: *I. MACKROUS[1], J. CARRIOT[2], K. E. CULLEN[3]
[1]Physiol., McGill, Montreal, QC, Canada; [2]Physiol., [3]McGill Univ., Montreal, QC, Canada

Abstract: During daily activities, our sensory system is activated by self-generated and external events. We have shown that cerebellar output neurons robustly encode passively applied motion in the horizontal plane, while they are attenuated during comparable self-generated head motion. However, the complex trajectory of natural head motion poses a particular challenge for the vestibular system because of the presence of the gravity. This is because the sensory periphery does not provide an explicit representation of gravity. Here we asked whether an estimate of gravity is included in the internal model used to compute the difference between self-generated and external self-motion by studying the neuronal responses of cerebellar output neurons (rostral Fastigial nuclei, rFN) during active motion. Based on their responses to passive motion, neurons could be divided in three groups: 1) GIA selective cells that respond similarly to tilt and translation, 2) tilt-selective cells that showed greater responses to tilt, and 3) translation-selective cells that showed greater responses to translation. We then recorded the responses of each individual neuron during conditions in which monkeys actively changed their head orientation (tilts) or made active head translations. Notably, the responses of the GIA and the tilt-selective cells were attenuated during active head tilts (80%). Furthermore, translation-selective cells showed a ~80% attenuation in their neuronal response during active compared to passive translation, and were also insensitive to active tilts. Thus, changes in head orientation relative to gravity were not encoded at the rFN level by any cell type during active motion. This finding implies that the generation of the required cancellation signal is based on an internal model of the expected sensory consequences that accounts for gravity. To further test whether the cancellation signal was specific to the active motion, or instead a more general gating mechanism, we also recorded neural response during passive translation while the monkeys made simultaneous voluntary head tilt motion. When submitted to concomitant stimuli, neuron's response to the active tilt stimulus was attenuated while cells' responses provided a precise estimate of the passive translation motion. Thus, taken together our findings demonstrate the output of a sophisticated computation, in which the influence of gravity is taken into account. Specifically, we propose a new model, which includes an estimate of the influence of gravity during voluntary motion, to explain how the brain differentiates between self-generated and passively applied head movements.

Title: Inter-hemispheric control of vestibular thresholds

Authors: *N. BEDNARCZUK, M. CASANOVAS-ORTEGA, A.-S. FLURI, A. M. BRONSTEIN, Q. ARSHAD
Dept. of Neuro-otology, Div. of Brain Sci., Imperial Col. London, London, United Kingdom

Abstract: Neural mechanisms underpinning vestibular cortical control are subject to inter-hemispheric interactions, which in turn can modulate both low and higher order vestibular functions. However, whether inter-hemispheric interactions can influence vestibular thresholds remains unknown. Hence, we investigated whether individual differences in hemispheric dominance, as assessed using a validated, objective biomarker, could predict changes in vestibulo-ocular (VO) and vestibulo-perceptual (VP) thresholds following alterations in cortical excitability using trans-cranial Direct Current Stimulation (tDCS). Twenty right-handed normal subjects were recruited, with ten subjects receiving cathodal stimulation (experimental condition), whilst the remaining ten received anodal stimulation (control condition). Stimulation was applied with a current of 1.5mA for 15min over the left posterior parietal cortex (P3, 10-20 international EEG system), with the reference electrode placed on the ipsilateral shoulder. Hemispheric dominance was quantified by assessing the degree of vestibular-nystagmus suppression in response to cold-water (30 ^{o}C) caloric irrigations in both ears after tDCS. To measure vestibular thresholds, participants were rotated in a vibration-free, motorised chair with an initial velocity of 0.3^{o}/s and an incremental acceleration of 0.3 ^{o}/s^{2}. Rotations occurred in complete darkness with amplified white noise to mask auditory cues, and were stopped as soon as subjects pressed the direction-specific button, indicating motion perception. Simultaneously, eye movement recordings were obtained using electro-oculography. Analysis of this data provided VO thresholds, which reflect the time taken from onset of chair rotation to the first nystagmic beat, and VP thresholds, which represent the time taken from rotation onset to the participant's button-press. After cathodal stimulation, the average VO thresholds became symmetrically raised, whilst average VP thresholds remained largely unchanged. Importantly, we observed a significant, positive correlation between individuals' hemispheric dominance and the degree of asymmetry present between right and left VO thresholds. Hemispheric dominance was also predictive of an individual's degree of change in VP thresholds following cathodal tDCS, but only for rightward and not leftward rotations. We provide a novel demonstration of the importance of inter-hemispheric interactions in modulating vestibular thresholds following alterations in cortical excitability using tDCS.

Title: High-level motor planning assessment during performance of complex actions in humans and humanoid robots: A computational approach

Authors: ***T. C. HAUGE**[1], G. KATZ[2], D.-W. HUANG[2], G. DAVIS[2], J. A. REGGIA[2], R. J. GENTILI[3]

Abstract: Most past work on cognitive-motor processes underlying upper-extremity motor control and learning has examined the sensorimotor level while considering relatively simple movements. However, complex cognitive-motor planning is needed to generate actions of daily living that are composed of different sub-actions. Therefore, in addition to kinematic analyses that can assess sensorimotor processes, there is a critical need to develop formal methods for representing and analyzing complex action sequences to better understand high-level motor planning. Here we describe a general computational method for comparing complex tasks performed by humans and humanoid robots. Our approach is based on sequence comparison methods that are employed in linguistics and genomics, but now the atomic elements (nodes) represent the individual actions forming complex action sequences. Such an approach allows one to examine qualitatively (graphical representations) as well as quantitatively (clusters of similar trials; similarity metrics) the structure of complex actions. For assessment purposes, the proposed approach was tested on data that were collected during a complex imitation learning task, in which human participants as well as a humanoid robot learned a disk-drive dock maintenance task, based on a demonstration recorded in a virtual human-operated environment. Once learning was complete, the humanoid robot was able to generalize the task to novel initial states by inferring the demonstrator's intentions. Then, human participants had to imitate the same task demonstrated in a video with minimal instruction. The results revealed that for most trials, human participants were able to successfully imitate the demonstrated goal of the task. However specific differences between the demonstration, humans, and humanoid robot actions were

observed suggesting that different strategies were employed for achieving the same goal. Specifically, our computational method was able to detect: i) identical and modified sequences; ii) unique sequences performed by humans, iii) the distribution of trials among sequences and iv) levels of similarity between actions performed by the human demonstrator, the human participants, and the humanoid robot. We conclude that this is a promising tool for analyzing high-level motor planning in humans during cognitive-motor control and learning of complex actions as well as for informing human-robot interaction studies.

Title: Postural control that precedes to the forelimb reaching in the cat

Authors: *K. TAKAKUSAKI[1], M. TAKAHASHI[1], S. MIYAGISHI[1], T. DREW[2]
[1]Asahikawa Med. Univ., Asahikawa/Hokkaido, Japan; [2]Dept. of Neurosci., Montreal Univ., Montreal, QC, Canada

Abstract: Appropriate postural control precedes the onset of the purposeful action so that the subject achieves goal-directed movements. Such a feed-forward postural control is often called as the anticipatory postural adjustment (APA). Although evidence was accumulated on the mechanisms of cortical control of APA, there have been few studies that have specifically asked how APA ensure goal-directed movements. To understand this issue, postural control associating with forelimb reaching was examined in four unrestrained cats weighing from 2.2 to 3.3 kg. Cats were trained to stand by their four-limbs toward the panel which contained several holes (targets) at various positions. The cats were then asked to reach either of their forelimbs to one of the targets and catch food pellets inside of the holes. The cat movements were monitored by video-tracking systems, and ground reaction forces impinging on each limb was measured by force transducers so that changes in center of vertical pressure (CVP) against left-right and anterior-posterior coordinates were examined. Forelimb reaching movement was divided into three phases. The first phase was the onset of APA which was typically identified by a loading of the forelimb to be lifted. With this, CVP moved toward ipsilateral to the forelimb side. This was

immediately followed by the second phase which was characterized by the period of unloading of the forelimb until the forelimb was apart from the surface. During this phase, the cat poked up one's head together with leaning trunk toward contralateral side of the forelimb. During such a postural alteration, the CVP was rapidly shifted contralateral side of the forelimb. It takes approximately 0.25 - 0.3 seconds for the first and second phases. The third phase was a period for reaching movement until the forelimb touch the target after the plantar was lift from the surface. This phase took approximately 0.2 - 0.3 seconds. Although CVP was altered in conjunction with forelimb reaching, CVP position at reaching the target was mostly equal to the CVP position at the end of the second phase. When position of the target was changed from the original position to either the left or right, CVP positions of the second and third phases was altered in relation to the target position. These findings suggest that APA provides the final stage of posture that can be optimized to ensures the achievement of voluntary forelimb reaching. Therefore, this process requires motor programs that depend on cognitive spatial information of one's body and the target. It can be postulated that the APA is mediated by descending motor systems other than the lateral corticospinal tract such as the cortico-reticulospinal pathways.

Title: Effect of practice on the control of reach extent

Authors: *J. C. STEWART, A. HETHERINGTON, D. BRUEMMER, T. ICHIYANAGI, J. ROCKTASHEL, M. O'DONNELL, C. SIMMONS, T. M. HERTER
Univ. of South Carolina, Columbia, SC

Abstract: The systematic scaling of reach kinematics to targets that vary in distance has been well-described. To control reach extent, individuals generally utilize a control pattern that includes both anticipatory planning and feedback based adjustments. However, the stability of this control pattern over days of practice is not known. The purpose of this study was to determine the effect of three days of practice on the control of reach extent for reaches to targets presented in 3-dimenionsal space. Twenty-four young, right-hand dominant adults (mean age

23.4 ± 2.7) performed reach movements to 3-dimensional targets that varied in distance (7, 14, 21 cm) and direction (ipsilateral, contralateral workspace) over 3 days of practice; 12 individuals reached with the dominant, right arm and 12 individuals reached with the nondominant, left arm. Position data was captured with a sensor on the index finger and used to extract kinematic variables of reach performance (movement time, endpoint error, velocity, acceleration) and the reach control pattern (planning-variance in reach distance explained by peak acceleration magnitude; feedback based adjustments-variance in reach distance explained by acceleration duration). Reach performance improved over practice (increased peak velocity, decreased movement time, decreased error) in both Right and Left arm groups ($p<0.05$) across target directions. Both groups showed a control pattern that include both planning and feedback adjustments; the overall control pattern was similar to ipsilateral and contralateral targets. Over days of practice, the Left arm group showed a significant increase in the use of planning and adjustments in both directions ($p<0.05$), however, the magnitude of changes was relatively small (increase in percent variance explained ranged from 3 to 7%). The Right arm group did not show any significant changes in the reach control pattern in either direction with practice. Consistent with previous work, reach performance improved with practice for measures of both reach speed and reach accuracy, even for this relatively simple task. The change in the control pattern seen with the left arm but not the right arm may be related to dominance. The right arm was the dominant arm in all participants; this arm may have a more stable control pattern than the nondominant, left arm for the control of reach extent due to overall greater frequency of use in everyday activities. Future work will investigate the effect of practice on the control of reach extent in individuals with reach control deficits.

Title: Visual feedback may establish an implied context for reaching behavior

Authors: *S. G. PENNY, N. VAIDYANATHAN, M. BERNIKER
Mechanical and Industrial Engin., Univ. of Illinois At Chicago, Chicago, IL

Abstract: It is known that reaching movements can be influenced by altering visual feedback, but could visual feedback itself be biasing how reaches are controlled? Efficient reaches (i.e. those that minimize work or energy) should move the hand along curved paths, but studies

consistently find straight reaches. Does the visual feedback of standard reaching tasks implicitly cue subjects to perform a "visual capture" reach, moving the visual cue along a straight path to the target and disregarding any inherent preferences for efficiency? We hypothesized that if this were true, even a brief display of visual cues would bias how subjects reach. To test this, we had subjects participate in one of two reaching experiments: visual feedback is either introduced or removed halfway through testing. In experiment 1, continuous visual feedback of the hand and target location were provided during reaches for the first half of the trials, and then both hand location and targets were extinguished for the remainder of the trials. In experiment 2, feedback of neither the hand nor the targets were provided for the first half of the experiment, but were then revealed for the second half. To aid subjects during the extinguished visual feedback portion, the target number and an "error bar" (indicating the unsigned distance to the target) were displayed. In experiment 1, we found that subjects made straight movements while the visual feedback was provided, and continued to make straight reaches after visual feedback was removed. In experiment 2, subjects made curved movements while no feedback was provided, but immediately switched to straight movements once presented with the feedback. Our findings suggest that visual feedback may influence the planning of reaches, resulting in straight movements even after feedback is extinguished.

Title: Local generalization curves after force field adaptation

Authors: *A. REZAZADEH[1], M. BERNIKER[2]
[1]Dept. of Mechanical & Industrial Engin., [2]Mechanical and Industrial Engin., Univ. of Illinois At Chicago, Chicago, IL

Abstract: To understand how we learn, we often examine the ability to generalize. Thus, to study motor learning many studies probe the ability to make unpracticed reaches after adapting to a force field. This is often executed using reaches that are different (i.e. far away) from those practiced. Recent findings suggest that the ability to generalize is more limited and local than previously assumed; however, this evidence does not account for potential changes in limb inertia across reach directions. To address this, we designed a force field study to examine the extent of generalization while controlling for limb impedance. Subjects practiced reaches in a curl field to one of eight targets and were then tested in all directions using no-vision error-clamp trials. We computed generalization curves for each direction by pooling the data across all eight

reaches in order to correct for changes in limb impedance. These results provide a thorough evaluation of the localized ability to compensate for a force field and speak directly to how new motor behaviors are represented.

Title: Are straight reaches the result of visual feedback?

Authors: *N. VAIDYANATHAN[1], S. PENNY[2], M. BERNIKER[1]
[1]Mechanical and Industrial Engin., Univ. of Illinois At Chicago, Chicago, IL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: While biologically relevant goals such as minimizing forces or joint torques dictate curved hand trajectory, reaching studies consistently find straight point-to-point hand paths. It is well documented that visual feedback affects how subjects reach, but could this influence explain the lack of curvature experimentally found? To address this question we reproduced an influential study (Morasso 1981) that argued point-to-point reaches are planned to move the hand's coordinates along straight paths, while moving the limb joints along indirect paths to their target. In the first protocol subjects were provided feedback of their hand location as well as targets. In a second protocol, feedback of the hand's location was replaced with a circle centered on the target, whose radius was equal to the subject's distance to the target; therefore, subjects were shown their distance to the target, but not their exact hand location. In a third protocol, feedback of both the hand and the target location was extinguished, and subjects were provided with the target number, and an error bar, indicating the unsigned distance to the target; here, subjects had to rely on the remembered target locations. As prior studies have shown, when the standard visual feedback of hand and target was provided, subjects moved their hand along relatively straight paths. But as visual feedback was attenuated subjects moved their hands along progressively curved paths. To help explain these changes and also to comprehend the strategies involved in reaching movements, a secondary analysis of the subject's limb orientation - involving the path of elbow and shoulder angles was performed. We suggest that as visual feedback is attenuated, and reaches rely less on the visual cues provided, the planning of reaches may prioritize limb dynamics over hand coordinates. Therefore, this experimental paradigm may unmask previously unexamined features of the control and planning of movement.

Title: Modeling a shuffleboard machine that regulates motor noise like a human

Authors: *J. P. CUSUMANO[1], C. J. SMITH[2], J. B. DINGWELL[3]
[1]Dept. of Engin. Sci. & Mechanics, [2]Engin. Sci. & Mechanics, Penn State Univ., University Park, PA; [3]Kinesiology, Univ. of Texas At Austin, Austin, TX

Abstract: In recent work with human subjects playing a virtual shuffleboard game, we showed that the analysis of trial-to-trial fluctuations near the task's goal equivalent manifold (GEM) sheds light on how humans exploit motor redundancy to achieve repeatable, accurate performance while coping with intrinsic physiological noise (John et al., PLoS Comput. Biol. 2016). Our model-based, dynamical approach yields a coordinate-independent characterization of the combined geometrical and temporal structure of motor variability in repeated trials, showing how goal-level task error arses from the interplay of motor noise, passive sensitivity properties of the GEM, and inter-trial error correction. However, our variability analysis uses models built from experimental end-effector data (for shuffleboard, the position and velocity of the puck at release), so it is difficult to directly relate the resulting abstract measures of performance (e.g., geometric stability, correlation) to the underlying neuro-biomechanical system generating it. To bridge this gap between experimental methods and first-principles, we formulated a physics-based model of a two-link shuffleboard machine driven by a motor with state-dependent torque, with pseudo-random noise in the motor output representing human physiological noise. We show how the shuffleboard GEM and its sensitivity properties transform between the space of end-effector variables and the space of internal torque parameters. Multi-trial simulations show that inter-trial error regulation that only aims to keep the system near a generic operating point with mean-zero goal-level error does not result in a variability structure like that observed in human shuffleboard players, whereas “GEM aware” error regulating controllers do. In particular, the dynamical anisotropy observed in human subjects experiments, in which inter-trial error regulation acts much more strongly in directions transverse to the task manifold than along it, is recovered in the model with GEM aware controllers. Furthermore, we show that the fluctuation analysis previously applied to human subjects, which uses only directly observable end-effector data, accurately characterizes the system dynamics as described in the space of its intrinsic motor variables.

Title: Task dependent modulation of implicit visuomotor adaptation

Authors: *D. E. PARVIN[1], J. R. MOREHEAD[2], A. R. STOVER[1], R. B. IVRY[1]
[1]UC Berkeley, Berkeley, CA; [2]Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA

Abstract: Implicit sensorimotor adaptation is thought to be driven by discrepancies between 'predicted' and 'actual' feedback, or sensory prediction errors (SPEs). It has been suggested that this process is automatic and obligatory, even when detrimental to task success (Srimal *et al.*, 2008; Mazzoni & Krakauer, 2006). One explanation for this apparent immunity to task success is that sensory predictions are generated relative to the efferent motor command, irrespective of the context in which this command was generated. To explore whether implicit adaptation is truly independent from the task conditions, we developed a task that allowed us to manipulate the task context without altering the actual movements or the ostensible sensory prediction errors introduced by altered feedback. Specifically, we used multiple redundant feedback cursors to show a participant's hand position in a center-out planar reaching task (Kasuga, Hirashima & Nozaki, 2013). The redundancy of the feedback allowed separate groups of participants to perform reaching movements with the same visuomotor mapping but under different task instructions specifying the task-relevant cursor. After the learning block, we probed implicit adaptation and generalization by having the participants moved their unseen hand directly to the target location without visual feedback. In all baseline conditions, each of the three cursors had a constant rotation of -45º, 0º and 45º, and participants were instructed to hit the target with the 0º cursor. For the learning blocks, we created conditions based on the overall rotation of the three cursors and the rotation of the task-relevant cursor, the one they were instructed to hit the target with. In the first group, we kept the overall cursor rotation as in baseline, but changed the task-relevant cursor to the 45º one. In the other two groups, we rotated the overall cursor feedback by 45º, resulting in cursors with rotations of 0º, 45º and 90º. In the second group and third group, the task-relevant cursor was at 0º and 45º respectively. The aftereffects depended on the rotation of the task relevant cursor, rather than the overall rotation of the three cursors. These results indicate that the motor system intelligently modulates the influence of putative error signals for learning in the context of redundant feedback. This is consistent with either a modulation via visual attention, or of a dedicated selection system for visuomotor binding (Reichenbach et al 2014) which links the hand representation in visual and motor systems.

Title: Gaze patterns provide a read out of strategy use in visuomotor adaptation

Authors: *A. J. DE BROUWER, M. ALBAGHDADI, J. R. FLANAGAN, J. P. GALLIVAN
Queen's Univ., Kingston, ON, Canada

Abstract: Sensorimotor adaptation is thought to reflect the resultant combination of two separate, but interacting processes: the implicit adaptation of an internal model, and the use of an explicit, cognitive strategy. Current evidence suggests that explicit strategies underlie faster adaptation (i.e., savings) when re-exposed to the same perturbation a second time. Interestingly, previous research indicates a link between gaze behavior and the explicit process (Rand & Rentsch, 2015). Here, we systematically examined gaze behavior over the time course of adaptation and re-adaptation to a visuomotor rotation, and directly tested the idea that gaze fixations provide a read out of the state of explicit adaptation during learning. Two groups of participants performed two sessions (separated by 24 h) of fast center-out reaching movements while adapting to an instantaneous 45° rotation of the visual feedback of the hand cursor. Participants in the intermittent report group were asked to verbally state the direction they would move their hand in before starting the movement (see Taylor et al., 2014) on one quarter of the trials. Participants in the non-report group were not required to report their aiming direction. We found that gaze fixation angles preceding the reach movement were bimodally distributed for 18 out of 21 participants in the intermittent report group and for 13 out of 21 participants in the non-report group. One peak was located at the visual target location, and the second peak was closely aligned to the explicit component, as measured in verbal reporting trials in the intermittent report group. Notably, in the non-report group, we observed faster adaptation and greater savings in participants that naturally fixated an internal aimpoint, indicating the implementation of an explicit strategy. Together, these results suggest that gaze fixations, prior to reaching, can be used to probe cognitive strategies during sensorimotor learning and utilized as a substitute for verbal reporting measures, which may influence adaptation.

Title: PMd reach-related activity expresses a response component related to the strength of evidence used to choose a target before, during and after the movement

Authors: *C. MONTANEDE[1], J. F. KALASKA[2]
[1]Neurosciences, Univ. of Montreal, Montreal, QC, Canada; [2]Neurosciences, Univ. De Montréal, Montréal, QC, Canada

Abstract: Monkeys pointed to either a Blue or Yellow target in opposite directions according to their estimate of whether a multi-colored checkerboard-like Decision Cue (DC) had more B or Y squares (Choose-and-Go (CG) task; Coallier and Kalaska 2014). The DCs presented in different trials had different total numbers and differences in numbers (color bias) of B and Y squares. Neurons in dorsal premotor cortex (PMd) often showed a graded rate of increase in activity before reach movement onset as a function of the strength of the color bias in the DCs (Coallier et al 2015). We also noted that some PMd neurons continued to show color bias-dependent differences in activity during the movements and while holding the arm over the targets. Here, we confirm that latter property in a new monkey. We recorded activity of 59 PMd neurons near the genu of the arcuate sulcus in the CG task. We tested the responses for the effects of chosen target direction (PD, oPD), and the color bias (4-100 squares) and predominant color (B, Y) of DCs (repeated-measure 3-way ANOVA, $p<0.01$). Most neurons showed a significant main effect of direction (Reaction Time epoch: 43/59; Movement Time epoch: 50/59; Target Hold epoch: 44/59). Many also showed a significant main effect of color bias (systematic increase or decrease of discharge rate in both directions as a function of bias; RT: 13/59; MT: 24/59; TH: 31/59). A partially overlapping set of neurons showed a significant interaction between direction and bias (significant differences in activity as a function of bias that differed for the 2 reach directions; RT: 7/59; MT: 10/59; TH: 9/59). Far fewer neurons showed a significant main effect of predominant color (0/59; 7/59; 4/59) or direction-color interaction (3/59; 2/59; 2/59). Similar trends were seen for the same neurons in CG task variants in which a delay was imposed between the presentation of the DCs and a later GO signal, or in which the monkey saw the DC first for 1-2s before being shown the 2 targets. Response differences were much less prominent when trials were sorted according to reach reaction time rather than color bias. The effect of

color bias was much weaker in a set of neurons recorded in primary motor cortex close to the central sulcus (e.g., main effect – RT: 7/26; MT: 7/26; TH: 3/26). These findings suggest that PMd reach-related activity expresses a response component that covaries with the strength of evidence (color bias independent of predominant color) on which the monkey made its target choice for the entire duration of the trial, not just before movement onset. This component may reflect various factors such as the level of confidence of the monkey in its target choice, reward expectations or error detection.

Title: Reinforcement learning leads to increase in exploration variability

Authors: *S. UEHARA[1,4], F. MAWASE[1], A. S. THERRIEN[2,5], K. M. CHERRY-ALLEN[1], A. J. BASTIAN[2,5], P. CELNIK[1,2,3]

Abstract: Exploration is thought to serve a critical role in motor learning, allowing us to find the optimal motor solution to perform a new task. In particular, exploration seems to be critical in reinforcement learning processes because it allows the motor system to determine which movements lead to the most reward. Indeed, previous studies have shown that exploration variability influences performance in reinforcement-based learning tasks (Wu et al. 2014; Therrien et al. 2015). However, it remains unclear whether the process of reinforcement learning can also lead to changes in exploration. Here we show that exploration variability is integral to reinforcement learning, but that reinforcement learning also shapes exploration.
In Experiment 1, we evaluated the magnitude of exploration variability while participants learned a new goal-directed finger pointing movement using only binary feedback about their movement success (vision of their movements was occluded). As a proxy for exploration variability, we measured trial-to-trial changes in pointing angle as a function of whether the preceding trial resulted in success or failure. The magnitude of movement angle change after

each failure trial was used as the measure of exploration. We found that exploration gradually increased and persisted at high levels even after the pointing movements matched the predetermined target angle (i.e. the optimal motor solution was found). Participants who were unable to reach the target angle showed smaller exploration variability throughout the training. In Experiment 2, we investigated whether the increased exploration benefited performance in a subsequent exposure to the same task. A new group of participants performed the same motor task twice, with a washout phase in between the two learning phases. We found that participants showed faster learning in the 2nd phase, which was accompanied by greater exploration from the beginning of the 2nd phase. To control for potential directional biases in pointing angle after the 1st phase, we conducted a third experiment that was identical to Experiment 2, but in the 2nd phase participants learned pointing movements in the opposite direction to movements made in the 1st phase. We found that, similar to Experiment 2, learning of the task in the 2nd phase was faster than that in the 1st phase. This faster learning was also proportional to the magnitude of motor exploration.
These findings indicate that the motor system may flexibly regulate exploration variability during reinforcement learning, which facilitates learning of similar tasks. This indicates a bidirectional influence between exploration and reinforcement learning.

Title: Are physically interacting partners mutually optimal?

Authors: *N. BECKERS, A. KEEMINK, E. VAN ASSELDONK, H. VAN DER KOOIJ
Univ. of Twente, Enschede, Netherlands

Abstract: Physically interacting partners have shown to improve motor performance, coordinate actions or select Nash equilibria in non-cooperative motor games. However, it remains unclear how humans change and shape their control policies during two-person physical interaction in cooperative movement tasks. Diedrichsen showed that feedback control changed optimally with task goals in bimanual reaching; a perturbation applied to only one hand was compensated optimally by both hands. In bimanual motor control the central nervous system has direct knowledge of the dynamics and task goals of both hands, allowing an optimal *centralized* control

strategy. However, physically interacting partners can only indirectly infer the dynamics of their partners through sensorimotor interaction to construct a control policy. In addition, partner dynamics are not time-invariant. If one partner changes control policy, this changes the dynamics the other partner interacts with. Since the control policy that is optimal for one interaction dynamics is unlikely to remain optimal for another, changed, interaction dynamics, the other partner will most likely reoptimize his/her control policy. Importantly, each partner only optimizes for their *own* cost function and inferred (closed-loop) partner dynamics. If this process occurs in physically interacting partners, partners will ultimately become *mutually optimal* with respect to each other's *separate* task goals, dynamics and control policies. However, if both partners manage to estimate the dynamics, state and cost function of their partners the mutually optimal controllers could select a control policy approaching a centralized controller, as in the bimanual case. Our objective is to test whether two physically interacting partners indeed change control policies such that they are mutually optimal controllers. Using a dual-interface robotic setup we couple two partners with a virtual spring. Both partners simultaneously perform reaching movements to the same target. A force field is then introduced for one of the partners to evoke reoptimization of control policies. By matching the measured force responses during catch trials to computational models with either two mutually-optimal controllers or an optimal centralized controller, we intend to test whether interacting partners select mutually optimal strategies, a centralized strategy or exploit a different strategy altogether. This work is useful in unraveling the mechanisms of physical interaction and to develop optimal human-robot interaction paradigms.

Title: Preparatory activity in motor cortex and supplementary motor area does not reflect the instantaneous probability of choosing to move

Authors: *A. J. ZIMNIK, A. H. LARA, M. M. CHURCHLAND
Dept. of Neurosci., Columbia Univ., New York City, NY

Abstract: When deciding which movement to execute, activity in monkey motor and premotor areas can wax, wane, or vacillate in ways that reflect the instantaneous likelihood of making a particular choice. But does such activity relate directly to the decision process, or result from a strategy to prepare movement as soon as a choice becomes likely? To dissociate these possibilities, we employed a task where the decision of when to reach evolved over the course of seconds, guided by internal estimations and external cues. In contrast, the physical location of the reach target was certain upon stimulus onset. Neural activity reflecting the evolving likelihood of executing a choice should wax and wane with the measured probability of choice execution. Conversely, activity reflecting motor preparation should change rapidly upon stimulus onset but remain relatively constant with time. To achieve the desired dissociation, only one target was available on a given trial, but the decision of when to move had to take into account two factors: a monotonically increasing reward and a sensory cue conveying the fluctuating probability that the target might become unavailable. The monkey's probability of choosing to move appropriately reflected these two factors and could be predicted (R^2 = 84%) via an economic model. We recorded from motor cortex (primary and premotor cortex, 152 neurons) and from supplementary motor area (SMA, 242 neurons) and concentrated on activity during the decision period. We analyzed the top 2 principal components, which accounted for ~25% of the variance and were selective for target location. We expected these components to reflect the time-varying probability of choosing to move, such that activity selective for a particular direction would be stronger when the probability of moving in that direction was higher. Yet this was not the case. Selective activity emerged immediately upon target onset and remained strong regardless of whether the probability of moving was low or high. This observation is consistent with activity reflecting motor preparation; selectivity is fully present once the reach direction is known. We used regularized regression to ask whether there exist other components that correlate with the probability of choosing to move. Such components were present but captured little variance (4.9% and 3.8% in SMA and motor cortex). Our results are consistent with two possible interpretations of decision-period activity in motor and premotor areas. First, such activity may primarily reflect movement preparation, and lie downstream of the decision process. Second, such activity may reflect the decision of what movement to make but not when to make it.

Title: Relative sensitivity of subjects' performance to total, net and relative evidence in three color-quantity estimation tasks

Authors: *S. DUROCHER, J. MILOSZ, O. IERFINO, J. KALASKA
Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: Many studies of two-alternative perceptual- and action-related decisions based on noisy signals (“evidence”) suggest that subjects optimize the decision process by sequential sampling of evidence to alter the value of a decision variable until it exceeds a decision threshold. One large class of models assumes that the decision variables are altered by the difference in momentary evidence (“net evidence”; NE) for each choice whereas another class assumes that the variables are modulated only by the absolute evidence for their respective choice (“total evidence”; TE). NE models have been extensively supported by studies in which subjects identify the coherent motion direction of a subset of dots in random-dot motion (RDM) stimuli. However, in nearly all cases, the net coherent motion was in only 1 of the 2 directions so that NE and TE is essentially identical. In contrast, two recent studies in which subjects identified the brighter of two visual stimuli over a wide range of different absolute and relative brightness showed a significant influence of the absolute brightness (i.e., TE) on subjects’ performance (Liston & Stone 2013; Teodorescu et al 2015). We tested to what degree subjects were sensitive to NE vs TE in 3 tasks in which they estimated whether there were more Blue (B) or Yellow (Y) squares in a multi-colored checkerboard (Decision Cue; DC) (Coallier & Kalaska 2014). We used 252 DCs with a wide range of different combinations of Y & B squares; the total number (TE) of B or Y squares in each DC ranged from 0 - 100 of each, as did the net difference in squares (NE). In Task 1, subjects estimated the predominant color of a DC presented in the center of a monitor, and then pointed to either a B or Y target positioned on opposite sides of the DC. In Task 2, a solid B or Y Color Cue in the center of the monitor indicated to which of two DCs on opposite sides of the cue to point; the two DCs had mirror-symmetrical B and Y NE. In Task 3, they saw two monochromatic (either B or Y) DCs with variable numbers of evidence squares and they pointed to the DC with the larger number of squares. While there were some differences in the overall RT durations and error rates in the 3 tasks, subjects’ RTs were poorly related to TE across all tasks. Moreover, unlike many RDM studies, overall performance was better related to the normalized NE in each DC, rather than NE per se. One potential factor is that

RDM direction discrimination is a signal-detection problem (is there a motion bias in the noise?) whereas our task requires an estimate of the relative numbers of easily detected signals (are there more B or Y squares?); judgements of relative numerosity are strongly dependent on normalized evidence (ratio difference of quantities).

Title: Mechanisms underlying motor planning under uncertainty

Authors: *L. ALHUSSEIN, R. B. SINGH, M. SMITH
SEAS, Harvard Univ., Cambridge, MA

Abstract: Mounting evidence suggests that uncertainty in tasks requiring goal-directed movements evokes activity in sensorimotor brain areas that reflects multiple possible actions. These actions are thought to indicate distinct motor plans, but the mechanisms by which they are combined into the final observed movement are still unclear. In an experimental setting, the influence of uncertainty on motor planning has been studied in a paradigm where subjects are first presented with two potential targets, and one of them is later cued, but often only after movement onset has occurred. To compensate for this uncertainty, subjects tend to produce intermediate movements between the two targets. Two prominent hypotheses have attempted to provide a mechanistic explanation for how subjects plan these intermediate movements. One idea, the motor averaging hypothesis, states that given multiple potential targets for an action, the uncertain initial motion represents an average of the motor output associated with movements to each potential target. An alternate idea, the optimal planning hypothesis, suggests that the initial motion should instead be planned to optimize for success. This would be accomplished with an initial motion that provides the opportunity for in-flight corrections to be as effective as possible once the final cue is available. A number of previous studies have failed to disambiguate these two hypotheses. To address them, we designed a task for which motor averaging and optimal planning make dramatically different predictions. We used the basic two-target trial paradigm to introduce uncertainty in motor planning. However, we created a dynamic environment that added resistance to specifically increased the effort required for making in-flight corrections to only one of the two potential targets, without interfering inflight corrections to the other target or direct movements to either target. Optimal planning would predict that subjects modify the initial movement to reduce in-flight corrections to the first/resisted target to allow successful corrections against the levied resistance to be feasible. In contrast, the motor averaging

hypothesis would predict that initial movements follow the averaged movement path between the targets, as direct movements to either target do not face interference. While both motor averaging and optimal planning are feasible approaches for motor planning under uncertainty, we hypothesize that the motor system employs optimal planning to maximize task success. The results of this experiment may significantly contribute to the ongoing debate regarding the influence of uncertainty in task goals on motor planning.

Title: Arm reaching movements are affected by the uncertainty in the targeet location during standing in stroke individuals

Authors: *R. B. GARBUS[1], S. R. ALOUCHE[2], A. G. NARDINI[3], S. M. FREITAS[4]
[1]Univ. Cidade De São Paulo, Santos, Brazil; [2]Univ. Cidade de Sao Paulo, Sao Paulo, Brazil; [3]Univ. Cidade de São Paulo, São Paulo, Brazil; [4]Univ. Cidade De Sao Paulo, Sao Paulo, Brazil

Abstract: Individuals with mild stroke present motor impairments that can affect the performance of arm reaching during standing. Uncertainty in target location has been described to affect these arm movements in healthy individuals and in stroke individuals only in sitting position. Therefore, the aim of this study was to examine the effects of the target uncertainty on the arm reaching during standing in stroke individuals. Nineteen individuals with stroke divided in two groups (9 on the right and 10 on the left side) and eighteen healthy individuals for control group stood in upright position to perform reaching movements with their ipsilateral arm to the brain lesion. Reaches were performed towards a target shown in a monitor and were presented in one of three heights (center, eye level, 10 cm upper or lower to the center target). There were the certain (the participant know where the target was, 60 trials) and uncertain condition (i.e. the target moved for the upper or lower position or remained in the center, 60 trials). The order of trials was randomized.
They were instructed to reach and touch the center of the target as fast as possible after the target changes its color. Time spent from this color stimulus until participants' movement initiation (time of movement onset, TIM), time spent to complete the task (movement time, MT) and accuracy (constant error, CE) were compared among target heights, experimental conditions and groups using Analysis of Variance (ANOVA). For the TIM, ANOVA revealed a condition effect

(p<0.001), individuals spent more time to reach under the uncertainty condition and was 130 ms greater for the stroke group (p<0.001).
For the MT, ANOVA revealed effects of target height (p=0.002) and group (p=0.016).
There was an interaction between height and group (p=0.018), indicating that the effect of height was observed only for stroke group. For the CE, there was an interaction between condition and height (p=0.002) and a triple interaction between condition, height and group (p=0.004). The CE was greater in higher targets for the stroke group and in lower target for control group. The uncertainty in target location affected mainly the TIM for both groups, indicating that the knowledge of the target location is important to plan the reach. The stroke individuals spent more time to initiate their movements and were less accurate for higher targets. The uncertainty in target location affects the arm reaching movements during standing in stroke individuals.

Title: Deciding while acting - an investigation of decision-making during ongoing action control

Authors: J. MICHALSKI, *P. E. CISEK
Univ. of Montreal, Montreal, QC, Canada

Abstract: Studies of decision-making, in both psychology and neuroscience, have focused almost exclusively on situations in which subjects must first make a choice and then report it with an action. Such “decide-then-act” paradigms have led to theories in which the brain weighs the costs and benefits of different options, selects one, and then prepares and executes the associated action. However, in our daily lives, we often make decisions while we are already acting (consider almost any sport), and the choice is between an action that is being executed and a new potential action that has become available. Given that the human brain evolved primarily to guide real-time behavior, our theories of decision-making must be able to address decisions made in real-time, during “decide-while-acting” paradigms. The affordance competition

hypothesis (Cisek 2007, Phil. Trans. B) suggests that the brain is continuously processing information about potential actions that are available in the environment, even while performing one of them, and decisions evolve as a competition between these simultaneous action representations. While this hypothesis is supported by a variety of neural and behavioral studies, it has never been tested in scenarios of continuous activity, in which the choice is between continuing one action versus switching to another, as in real-time behavior.
Here, we present an experimental paradigm for studying decision-making during ongoing action control. In the "continuous tracking" task, human subjects use a hand-held cursor to track a target that moves around on the horizontal plane. As long as subjects track the target, they earn rewards (points translated into monetary payments) at a rate that gradually decreases over time and is correlated with the gradually fading luminance of the target. At certain moments, a new target choice is presented somewhere on the screen with a luminance that indicates either a higher or lower reward rate. The subjects can ignore that target and continue tracking the current one, or they can switch to the new target choice, which then starts to move and becomes the tracked target. The placement and timing of appearance of the new target choices is designed to face subjects with decision scenarios that are analogous to situations already well-studied in "decide-then-act" paradigms. For example, we examine how the choice preference curve (with respect to the relative reward value of the new target versus the current tracked target) shifts as a function of the relative biomechanical costs of the tracking movement versus the switching movement, akin to earlier studies in static paradigms (Cos et al. 2011, 2012, 2014, J Neurophysiol).

Title: Molecular changes in the sensorimotor cortex during learning and recall: Tracking and manipulating PKMzeta

Authors: *J. T. FRANCIS[1], P. GAO[2]
[1]Univ. of Houston, Houston, TX; [2]SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Procedural learning and memories, such as those associated with learning how to ride a bike, are believed to be supported by plasticity and reorganization of the sensorimotor cortex. Several studies utilizing a rodent reaching task, as that used in the current work, have shown that procedural learning is accompanied by enhanced synaptic strength and structural modification in the sensorimotor cortex at distinct layers (e.g. layers II/III and V). However, an investigation that causally links these changes with synaptic molecular machinery and behavior has been elusive. This study aims to fill this gap in our current understanding by tracking changes in task performance as well as layer specific modifications in a key molecule, atypical protein kinase M zeta (PKMzeta), that has been shown necessary and sufficient for the maintenance of long-term potentiation (LTP). Our results demonstrate that PKMzata levels decrease in S1 during an early pause in learning on day 3, and peak in S1 and M1 once performance has reached an asymptote on day 9. In addition, continued daily practice after day 9 is accompanied by sustained higher levels of PKMzeta. Past this correlation, we utilized genetic and pharmacological methods to causally perturb PKMzeta during and after learning. We found results indicating the importance of PKMzeta both during learning and in maintaining the procedural memory engram.

Title: Post-stroke interhemispheric cortical connectivity during active motor states of the paretic and nonparetic limb

Authors: ***J. A. PALMER**[1], L. A. WHEATON[2], P. GURUPRASAD[1], M. R. BORICH[1]
[1]Emory Univ., Atlanta, GA; [2]Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Introduction: Following stroke, atypical interhemispheric (IH) interactions have been observed in stroke survivors with poor motor recovery and may affect post-stroke function. Using synergistic transcranial magnetic stimulation (TMS)-electroencephalography (EEG), our laboratory found differences in IH connectivity between stroke survivors and controls during active but not resting motor states. However, the relationship between IH connectivity and post-stroke strength and impairment of the paretic upper extremity has not been investigated. The

purposes of this study were to (1) investigate the relationship between IH connectivity during paretic (P) and nonparetic (NP) active motor states with P arm motor behavior and, (2) compare the magnitude of IH connectivity in stroke survivors vs. neurologically-intact older adults during P vs. NP muscle activation. **Methods:** Participants with chronic stroke (n=17) and no history of stroke (n=14) completed clinical and neurophysiologic testing using synergistic TMS-EEG. Upper Extremity portion of the Fugl-Meyer (FMUE) assessment and grip strength were assessed. TMS was used to determine M1 resting motor thresholds (RMTs) for the P and NP abductor pollicis brevis (APB). TMS testing was performed during a submaximal contraction of the ipsilateral 1) P and 2) NP APB to evaluate transcallosal inhibition. EEG was recorded during the delivery of 50 suprathreshold (150% RMT) TMS pulses for each condition. IH connectivity was calculated as the post-TMS (0-300ms) imaginary part of coherency (IPC) value between electrodes (C3, C4) within the beta frequency range (15-30Hz). Relationships between IPC vs. FMUE score and P grip strength during each condition were evaluated. We compared IPC in stroke vs. control groups during P vs. non-dominant and NP vs. dominant APB activation. **Results:** We observed a negative relationship between IPC values vs. UEFM ($r=-0.47$, $p=.03$) and P grip strength ($r=-0.48$, $p=.03$) during NP, but not P APB activation. There was a group by condition interaction ($F=5.13$, $p=.03$). In the stroke group, IPC was less during NP ($p=.04$) and greater during P APB activation ($p=.04$) compared to controls. IPC was greater during P vs. NP APB activation ($p=.02$). **Conclusions:** Results indicate that IH connectivity during NP muscle activation was associated with motor behavior poststroke. IH connectivity was abnormal in stroke group during both P and NP muscle activation. Measures of inhibitory neuronal network behavior during NP muscle activation may index salient measures of adaptive corticomotor changes following stroke and potentially offer valuable insights into mechanisms influencing functional recovery.

Title: Context-dependent brain dynamics during grasping and dexterous manipulation

Authors: *P. MCGURRIN[1], J. FINE[2], K. SCREWS[3], M. SANTELLO[2]
[1]Sch. of Life Sci., [2]Sch. of Biomed. and Hlth. Systems Engin., [3]Sch. for Engin. of Matter, Transport, and Energy, Arizona State Univ., Tempe, AZ

Abstract: Unique sensorimotor processes underlie dexterous manipulation requiring predetermined (constrained) versus self-selected (unconstrained) contact points. The former context involves executing a near-identical motor plan across manipulations via retrieval of previously-learned manipulative forces, whereas the latter requires feedback of digit placement at object contact to drive modulation of digit force distribution to compensate for across-trial variability in digit placement. Our recent work has demonstrated that disrupting the cortical sensorimotor network through non-invasive brain stimulation has differential behavioral effects on constrained versus unconstrained grasping. However, the offline stimulation used in our previous work did not allow us to examine corresponding spatial and temporal features of neural activation. To investigate context-dependent activity of this sensorimotor network, we used electroencephalography (EEG) to quantify spatiotemporal cortical dynamics during unconstrained and constrained grasping. We hypothesized that distinct grasp type-dependent cortical activation and connectivity underlie these grasp contexts due to their unique sensorimotor requirements. Subjects performed a visually-cued grasp and lift task using a precision (thumb-index) grasp, with separate blocks for unconstrained and constrained trials. In all trials subjects were asked to lift an object with an asymmetrical center of mass while minimizing tilt. We combined EEG data with subject's structural MRIs to perform cortical source analysis. Time-frequency analysis of predefined source regions revealed significantly ($p < .01$) greater power in alpha and low beta band power in unconstrained versus unconstrained grasping over left prefrontal, sensorimotor, and parietal regions 400 ms prior to and following the 'go' cue. In addition, Granger connectivity analysis revealed significantly different connectivity from prefrontal and precentral to postcentral regions, as well as parietal to frontal regions. Increases in alpha and beta power have been previously linked to prediction of sensorimotor events. Here we speculate that higher power in these frequency bands is due to increased uncertainty in sensorimotor predictions. Namely, across-trial variability in digit placement during unconstrained grasping necessitates increased reliance on feedback in order to generate correct digit forces to maintain stable performance. These results are the first to establish unique activity of nodes in the fronto-parietal grasping network during tasks requiring differential weighting of feedforward vs. feedback mechanisms.

Title: Two representations of the diaphragm in the primary motor cortex

Authors: *L. B. HELOU[1], R. P. DUM[2], P. L. STRICK[3]
[1]Systems Neurosci. Institute, Univ. of Pitt, Pittsburgh, PA; [2]Neurobiology, Ctr. for Neural Basis of Cognition, Systems Neurosci. Inst., Univ. Pittsburgh, Pittsburgh, PA; [3]Neurobio., Systems Neurosci. Institute, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The diaphragm is a multi-functional muscle. It is the primary muscle for automatic and volitional inspiration. In addition, it is critically involved in vocalization and swallowing, and plays a key role in creating the optimal trans-abdominal pressure gradient for other actions such as posture, micturition, defecation, and vomiting. We used retrograde transneuronal transport of rabies virus from the diaphragm to define the distribution of neurons in M1 that are involved in the control of this multi-functional muscle. We injected rabies virus (CVS-N2c strain, 700-900 uL, 1 $x10^{10}$ pfu) into the costal portion of the diaphragm muscle in cynomolgous monkeys (n=3). We set the survival time (~96 hrs) to be long enough to enable retrograde transneuronal transport of virus to infect neurons in M1. Transport to the cortex required retrograde transport from the muscle to phrenic motoneurons in the spinal cord (1^{st} order neurons); retrograde transneuronal transport from phrenic motoneurons to spinal interneurons and neurons at other sites (e.g., reticular formation) (2^{nd} order neurons); and then another stage of retrograde transneuronal transport from these 2^{nd} order neurons to output neurons in layer V of M1 (3^{rd} order neurons). In all three animals we also observed a small number of labeled neurons in layer III. This indicates that the survival time was long enough to allow transneuronal transport to 4^{th} order neurons. Notably, the labeled neurons in M1 were located in two spatially separate groups. One group was located in the axial body representation of M1 which lies between the arm and leg representations. The second group was located more laterally in the face area of M1. To date, these data represent the most complete picture regarding the neural substrate in M1 that subserves diaphragm motor control in primates. Moreover, the lateral group of neurons appeared to overlap the location of laryngeal representation in M1 that was identified in another study from our laboratory (Cerkevich and Strick, SfN, ’15). Thus, our observations raise the possibility that coordination of laryngeal and breath control during vocalization may be achieved, in part, by co-localizing the cortical control of the two systems in M1.

Title: Deconstruction of corticospinal circuits for goal-directed motor skills

Authors: *X. WANG
Neurbiology, Boston Children's Hosp., Boston, MA

Abstract: The corticospinal tract (CST) is the most important voluntary motor control system in humans, but how it transforms cortical commands into accurately executed sequential multi-joint movements in motor skills remains an unresolved issue. By using a retrograde labeling system in mice, we defined the requirement of both total and region-specific CSNs in the accurate execution of sequential movement steps in a skilled forelimb task. In vivo imaging CSN activity during task performance revealed the sequential activation of topographically ordered functional ensembles with moderate local mixing. Region-specific manipulations indicate that CSNs from caudal or rostral forelimb area (CFA or RFA) control reaching or grasping, respectively, and both are required in the transitional pronation step. These region-specific CSNs terminate in different spinal cord levels and locations, therefore preferentially connecting with the premotor neurons of muscles specially engaged in different steps of the skilled motor task. Together, our findings provide a logic for spatially ordered, parallel corticospinal circuits that orchestrate goal-directed motor skills by transforming descending cortical signals into distinct muscle activation patterns.

Title: Cortical and reticular contributions to response preparation and initiation

Authors: *A. N. CARLSEN[1], D. MASLOVAT[2], N. M. DRUMMOND[1], A. LEGUERRIER[1], J. HAJJ[1], V. SMITH[1]
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Over the past decade many studies have investigated response preparation through the use of a startling acoustic stimulus (SAS) presented during reaction time (RT) tasks. A common finding is that RTs are dramatically reduced when a startle reflex is induced, often resulting a mean premotor RTs of <70 ms. One hypothesis explaining this "StartReact" response is that details of the motor plan are stored in brainstem centres (e.g. reticular formation) and triggered by startle reflex activation which bypasses normal cortical processing. For example, in patients with hereditary spastic paraplegia with degraded coricospinal pathways, it has been shown that a SAS leads to normalized reaction times, providing support for a subcortically-mediated response pathway. However, other studies involving a SAS have provided evidence that at least some aspects of the prepared response and/or response initiation drive in SAS-speeded RT trials involve contributions from primary motor cortex (M1). For example, when single pulse transcranial magnetic stimulation (TMS) was used to disrupt cortical processing by inducing a cortical silent period, it delayed RTs for both non-SAS and SAS-triggered trials. The present study used a TMS silent period and EMG-EMG coherence analysis to investigate whether different response types involve differential contributions from cortical and reticular centres to the preparation and initiation of movements. In a series of experiments, participants performed targeted single degree of freedom movements with different muscles and task requirements. Experiments 1 and 2 employed TMS to induce a cortical silent period on some trials just prior to initiation of wrist flexion and extension movements. On select trials a SAS unexpectedly preceded the go-signal, whereas on other trials both TMS and a SAS were presented in the same trial. Results from Experiments 1 and 2 showed significant differential RT effects of the TMS between control and SAS trials, as well as between flexion and extension movements in control trials. In Experiments 3 and 4, EMG-EMG coherence was analyzed on control and SAS trials while participants performed RT tasks involving different effectors. Results from these experiments showed significant differences in coherence between movement types in those

frequency bins typically associated with reticulospinal drive. Together the results from these studies suggest that motor actions are represented in a distributed network of cortical and subcortical brain structures, and that the relative contribution of each area depends on the functional and/or anatomical requirements of the task to be performed.

Title: Variability in corticospinal excitability during digit force planning for grasping in humans

Authors: *N. RAO[1], P. J. PARIKH[1,2]
[1]Hlth. and Human Performance, Univ. of Houston, Houston, TX; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Variability in motor responses affects the ability to perform motor tasks and learn new motor skills. Motor variability occurs due to the neuromuscular noise during movement execution. Recent work suggests that the central mechanisms during preparation of a motor task may also contribute to motor variability. Specifically, the variability in the firing rate of primate neurons within primary motor (M1) and premotor dorsal cortices during movement preparation contributed to the control of reach trajectory in a motor task. However, how the central mechanisms during movement preparation contribute to motor variability in humans remain unknown. In this study, we sought to determine whether the variability in the corticospinal excitability (CSE) during movement preparation contributes to the control of digit forces during two motor tasks in humans. We delivered single-pulse transcranial magnetic stimulation (TMS) over M1 to assess CSE. Nine healthy young subjects were visually-cued to grip an object at a specific location using the index finger and thumb by exerting either a low grip force (LF; 1N) or a grip force equal to 10% of their maximum voluntary contraction (HF). TMS was delivered at one of the eight latencies from the 'task' cue in a random order: 500, 750, 1000 ('go' cue), 1100, 1200, and 1300 ms. We found a difference in the variability in CSE between LF and HF tasks at 1200 ms after the presentation of the 'task' cue. Interestingly this force magnitude-dependent difference in CSE variability was observed for the first dorsal interosseous and abductor pollicis

brevis muscles, which were directly involved in the exertion of digit force. Similar force magnitude-dependent change in CSE variability was not observed for the abductor digit minimi and flexor carpi radialis (control) muscles. Our findings suggest that the force planning related modulation in the variability of CSE may represent the variability in activity of neuronal population within M1 and/or it may arise from variability in the inputs from neuronal population outside M1. Future work will assess the contribution of M1 and premotor areas to the variability in CSE during the planning of motor tasks.

Title: The relationship between cortical and muscle activity during a motor-cognitive interaction task

Authors: *J. R. LUKOS[1], M. ALAM[2], J. C. BRADFORD[3], D. P. FERRIS[4]
[1]Space and Naval Warfare Systems Center, Pacific, San Diego, CA; [2]Space and Naval Warfare Syst. Ctr. Pacific, San Diego, CA; [3]Army Res. Lab., Aberdeen Proving Ground, MD; [4]Univ. of Michigan, Ann Arbor, MI

Abstract: In contrast to cognitive and motor tasks being done in isolation, performing these tasks simultaneously can affect overall performance. The goal of this study was to better understand the underlying neural processes associated with locomotion under variable cognitive and physical loads. We measured EEG and muscle activity while participants walked on a treadmill with an empty backpack (unloaded condition) or a heavy backpack (40% body weight, loaded condition) at 1 m/s for 1 hour. While walking, subjects also performed a visual oddball task between bouts of isolated walking where 12% of images were targets. We recently found that the EEG revealed differences between target trials during seated, loaded, and unloaded conditions at the electrode level [1] and cortical source level [2], particularly in regions of the brain associated with motor activity. These findings suggests that cortical resources initially dedicated to the cognitive task while seated were reallocated to the motor task while walking. Here, we investigate the effect of changes in physical demand in the muscle activity. We looked at the normalized peak muscle activity for the Tibialis Anterior (TA), Soleus, Rectus Femoris (RF) and Biceps Femoris (BF) muscles during the loaded and unloaded conditions across time for six subjects. We found that the TA and RF exhibited greater muscle activity during the loaded than unloaded condition ($p<0.05$; see Table). Not surprisingly, these preliminary results suggest that walking with a heavy load requires more muscle activity than walking with no load.

Further investigation linking the gait activity to EEG will help to identify which cortical areas contribute to these muscle activity changes.

Title: The role of different motor cortex subregions in goal directed action in mice

Authors: *K. MORANDELL[1], D. HUBER[2]
[1]Univ. of Geneva, Geneve, Switzerland; [2]Basic Neurosci., Univ. of Geneva, Geneva, Switzerland

Abstract: Mammalian motor cortex consists of several interconnected subregions thought to play distinct roles in voluntary forelimb movements, yet their respective role in decision making and motor execution is not clear. Here we performed transient optogenetic inactivations of the caudal forelimb area (CFA) and a rostral forelimb area (RFA) in mice, after they were trained to perform a vibrotactile discrimination task and report their choice by pushing or pulling a joystick after a delay period. We found that choice and motor execution are temporally segregated processes in this behavioral paradigm. CFA and RFA are both necessary during the sensory period for correct choice, while during the delay period neither area alone, but only combined inactivation was able to affect choice. Deficits in movement execution were limited to the execution period and restricted to CFA inactivation. Our findings suggest the existence of transient and partially distributed representations of choice and motor execution across different subregions of motor cortex.

Title: Modulation of different interneurone networks during proactive and reactive inhibition

Authors: ***V. RAWJI**[1], R. TIBOLD[3], T. FOLTYNIE[2], M. JAHANSHAHI[2], J. C. ROTHWELL[4]
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, Birmingham, United Kingdom; [2]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom; [3]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London Inst. of Neurol., London, United Kingdom; [4]Inst. Neurol, London, United Kingdom

Abstract: Introduction
Behavioural inhibition is subdivided into reactive (RI) and proactive inhibition (PI), the former becoming active using external cues and the latter an ingrained type of inhibition, serving to facilitate reactive stopping. Recent studies applying Transcranial magnetic stimulation (TMS) in different directions and with specific pulse widths have shown that different inputs into the motor cortex (M1) are differentially modulated depending on behavioural demands. The functional role of these different inputs into M1 with respect to mechanisms of behavioural stopping has not yet been elucidated.
Methods
We employed TMS during either the conditional and normal stop signal task to probe RI and PI in 14 healthy individuals. TMS was applied in two ways: a postero-anterior direction and antero-posterior with 120μs and 30μs pulse widths respectively (PA-120/AP-30). These parameters have been shown to selectively recruit the aforementioned inputs into M1. TMS was applied at different phases of the go (preparation to stop) and stop processes and MEPs recorded from the right FDI muscle, to reflect PI and RI respectively.
Results
During the go trials (PI), PA and AP MEPs were differentially modulated: AP inputs were reduced when PI was implemented, whereas PA inputs were enhanced. This difference reached statistical significance ($p=0.02$, $t=2.464$). For RI we found that stopping the left hand inhibited MEPs more than when the right hand was stopped, for both PA and AP inputs. However, this was statistically significant for PA MEPs only ($p=0.001$, $t=3.941$). Interestingly, we found that the probability of successfully inhibiting increased with the number of preceding go trials, which

was also inversely proportional to PA MEP size.
Discussion
AP and PA inputs into M1 are differentially modulated by behavioural inhibition: preparation to stop specifically inhibits AP inputs whereas stopping is mediated predominantly by PA inputs. We also suggest that the go process is not a global one, and modulates different M1 inputs in varying ways. Finally, we show a physiological predictor of stopping efficacy, and that this too is input specific.

Title: Imitation depends on an intact representation of abstract trajectory shape in dorsal premotor cortex

Authors: *A. L. WONG[1], S. A. JAX[2], L. L. SMITH[2], L. J. BUXBAUM[2], J. W. KRAKAUER[1]
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Imitation is an important means of learning skills, but how imitation occurs is not well understood. In part, this is because “imitation” conflates distinct interpretations: achievement of the same task goal, reproduction of the same end posture, and replication of the same kinematic motion. We propose that the latter definition is critical: copying the shape of the trajectory described by the motion of the end-effector in space. In line with this, we recently showed that people generate such trajectory shape representations when planning curved reaches around barriers.
Imitation deficits have been observed bilaterally in patients with apraxia due to left frontoparietal strokes. However, much of this work focused on patients with parietal lesions and actions cued by actors. This has led to two major assumptions about imitation. First, imitation is thought to depend on representing the relative configurations of body parts (body schema); however, bilateral imitation deficits despite unilateral lesions suggest that trajectory shape may be represented in an effector-independent manner. Second, parietal cortex is assumed to perform the computations required for imitation; while this is consistent with fMRI studies of imitation and neurophysiological evidence that activity in parietal cortex modulates with the trajectory taken to hit a target, contrasting neural evidence suggests that neurons in premotor cortex encode movement kinematics of complex trajectories. Thus it is unclear whether trajectory shape is represented in parietal or premotor cortex.

To address these questions, we asked patients with left-hemisphere strokes to imitate movement trajectories. We observed that patients had impaired imitation abilities relative to controls. Deficits were comparable regardless of whether the movement was cued by an actor or a cursor, suggesting an impaired processing stage for representing abstract trajectory shapes in extrinsic space. This could not be attributed to low-level motor impairments: patients imitated point-to-point movements as well as controls. Imitation ability was also uncorrelated to performance when reporting which trajectory shape was observed, suggesting a dissociation between producing trajectory shapes and perceiving stimulus paths. Finally, a voxel-based lesion-symptom mapping analysis found that imitation deficits were associated with lesions in left dorsal premotor cortex (PMd) but not parietal cortex, suggesting that PMd is critical for processing trajectory shapes for movement planning. Together, these findings suggest that imitation critically depends upon the planning of movement shape, which relies upon PMd.

Title: Transfer learning in convolutional neural networks as a tool to analyze animal behavior imaging data

Authors: *A. ARAC[1], S. CARMICHAEL[2], P. GOLSHANI[3]
[1]Neurol., UCLA, Los Angeles, CA; [2]UCLA Sch. Med., Los Angeles, CA; [3]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: To fully understand the principles of motor control or how motor control recovers after brain injuries, motor output must be quantified and analyzed. This approach helps distinguish such effects as compensation vs true recovery and to begin to relate activity in brain circuits to motor output patterns. A key step in such a process is the use of automated animal behavioral experiments. Automated animal behavioral experiments result in large volumes of high quality data. High-speed video-recording is usually used, and an extensive analysis of imaging data, while providing unforeseen insight and information, can be challenging and time-consuming. Thus, there is a huge need for automated analysis methods. The ideal methods would be easily adaptable for different sets of data (object detection, image classification, or segmentation). In addition, these ideal methods would be unbiased, and would require minimal

subjective decision making. Deep learning algorithms such as convolutional neural networks have great promise in automation of image analysis, being used in face detection, object recognition, and self-driving cars. However, one requirement for these networks to achieve high accuracy is the need for large training datasets (millions of images) as the performance of these networks improve significantly when trained with large datasets. This may limit their use in biomedical research given that each type of experimental data has their own training datasets, and creating these training datasets as the ground-truth images can be as challenging. Here, we present use of transfer learning approach. We take an already trained convolutional neural network (i.e. AlexNet, Inception-v3) on ImageNet dataset, and re-train this network with our experimental data. This approach has significant advantages as the already-trained network has variables optimized to detect different features of the images, and good results can be achieved by using relatively small numbers (hundreds to a few thousands) of images from experimental data. We have shown proof-of-concept analysis for paw detection when the mouse is performing a skilled reaching task. To do this, we have created a system where the mouse is head-fixed for future two-photon imaging or electrophysiology experiments, and is performing a reaching task to a food pellet, we image the paw movements with two cameras. We detect the paw by using the convolutional neural networks trained with transfer learning approach, and obtain 2D trajectories. We combine these 2D trajectories to obtain the 3D kinematics of the paw movement. Transfer learning approach can provide an automated, unbiased image analysis of the animal behavior.

Title: Consistency between task-related neural sub-spaces within and between subjects: Potential for universal neural decoders?

Authors: *C. E. VARGAS-IRWIN[1], J. HYNES[1], J. B. ZIMMERMANN[1,2], J. P. DONOGHUE[2,1]

Abstract: The activity of networks of neurons addressing similar computational challenges should reflect common information processing motifs. We hypothesize that for motor cortical areas driving upper limb motion, the common structure of the end effector will result in encoding features that remain consistent between subjects. In order to test this hypothesis, we use spike train similarity space (SSIMS) analysis to generate low dimensional embeddings that capture the intrinsic relationship between network states. Comparing these state spaces allows us to quantify the similarity between encoding schemes across different networks. In the present work we compare SSIMS maps generated using activity in primate primary motor cortex of monkeys performing a planar center out reaching task. The resulting state spaces consisted of eight clusters associated with different reaching directions. Instead of being distributed in a uniform circle, the clusters were arranged in a more complex asymmetric shape that was consistently observed across different datasets. We demonstrate that using simple normalization techniques and matching the directions of maximum variance, it is possible to combine neural state spaces from different sessions and even different subjects into one cohesive whole. This can be accomplished using the intrinsic properties in each neural dataset and with no a priori knowledge of the different trial conditions. The resulting combined space can be used as a basis for decoding models applicable across sessions and subjects, demonstrating a remarkable degree of convergence between the neural state spaces analyzed. Our results show that SSIMS captures intrinsic features of motor control processes applicable to multiple subjects performing the same task. This finding suggest that it should be possible to train 'universal' neural decoders that can be applied to new subjects out of the box.

Title: Motor learning for corticospinal and corticobulbar pathways

Authors: *S. PARK[1], A. CASAMENTO-MORAN[1], M. L. SINGER[2], A. E. ERNSTER[2], B. YACOUBI[1], I. A. HUMBERT[2], E. A. CHRISTOU[1]

Abstract: The use of visual feedback is critical for motor learning. It remains unknown whether the use of visual feedback for motor learning differs for effectors controlled by different descending pathways. Here, we compare motor learning of the ankle joint and tongue because they represent the corticospinal and corticobulbar pathways, respectively. Twelve young adults (19.63 ± 2.11 years, 6 females) practiced a tracking task (combination of four frequencies at 0.02, 0.37, 0.5, and 1 Hz) with ankle dorsiflexion and with tongue elevation for 100 trials. The participants practiced each effector (ankle or tongue) in different days and the order of the effector was counterbalanced. Following practice, participants performed the same tracking task with simultaneous contractions of the tongue and ankle (dual tracking task; transfer) with three different visual feedback conditions (no visual feedback, visual feedback only for ankle, visual feedback only for tongue). We recorded the force output from the tongue and ankle and quantified the force accuracy (RMSE) from each effector. When there was no visual feedback of the motor output or target (testing memory of the practiced task), the performance of the dual task was similar for the ankle and tongue. In contrast, the RMSE was lower for the ankle than the tongue regardless whether participants received visual feedback about the ankle or tongue ($P <$ 0.02). These results provide novel evidence that learning a motor task that requires integration of visual feedback is better for the corticospinal pathway (ankle joint) than the corticobulbar pathway (tongue).

Title: Effects of pseudoexperience on the understanding of hemiplegic movements: An fMRI study by physical therapists as subjects

Authors: *R. WATANABE, N. KATSUYAMA, N. USUI, M. TAIRA
Cognitive neurobiology, Tokyo Med. and Dent. Univ., Bunkyo-ku Sendagi, Japan

Abstract: The fronto-parietal cortical network is suggested to play a fundamental role in the understanding of observed actions (action observation network, AON).
Previous studies have shown that AON is more activated in the observer with actual experience of observed action than without. However, it is not known whether the pseudoexperience of observed movement also have the same effect on the AON as the actual experience. Physical

therapists (PTs) routinely observe the hemiplegic movements of stroke patients in clinic. Thus, they are thought to have pseudoexperience of the hemiplegic movements in the treatment, such as careful touching and observing of the hemiplegic bodies, even though almost none of them experienced hemiplegia.
In the present study, in order to understand the effect of pseudoexperience, we measured cortical activity of 19 PTs and 19 non-PTs using functional MRI (fMRI). Two conditions were prepared, such as observing movies of the stroke patients clasping and unclasping 1) with the hemiplegic hand and 2) with the non-hemiplegic hand. Immediately after the fMRI scan, participants again observed all the movies and were asked to assess the patients feeling to their own hemiplegic movements by the questionnaire. In fMRI measurements, the AON in the PTs was more activated than in the non-PTs during observing the
hemiplegic movements. Furthermore, the anterior/middle cingulate cortex (aMCC) which is thought to relate to negative affect was also more active, and the left aMCC increased its connectivity to the right supramarginal gyrus which is thought to relate to body representation, in psychophysiological interaction analysis. In addition, behavioral test indicated that the PTs assessed more accurately patients' feelings of difficulty associated with hemiplegic movements than the non-PTs. These findings suggest that even the pseudoexperience also have the same effect on the AON as the actual experience, and may help for better understanding of the observed movements through activation of the AON. Furthermore, the better understanding of difficulty of hemiplegic movements, the pseudoexperience may affect limbic system through modulating own body representations.

Title: An open database of cat neuronal activity

Authors: I. A. NALL[1], I. BRAVERMAN[1], J. T. GOODROAD[1], F. FLORES[1], F. JOHNSON[1], A. RIVARD[1], *I. N. BELOOZEROVA[2]

Abstract: The cat is one of the best researched higher vertebrates. It is a model animal for studies of several common diseases. Except for the frontal lobes, cat brain is quite similar to the brain of primates. It is well studied but yet little understood. To promote understanding of the brain in general, we have created an open database of cat brain neuronal activity during various behaviors to allow all interested parties to search and analyze available cat brain data.
We formed a back-end system that utilizes the existing front-end functionality of WordPress, an open-source content management system, which is based on PHP scripting language and also uses an attached SQL relational database management system. We have merged that SQL with our custom MySQL database to act as our main data repository. With our interface and general functions, such as file-uploading, being handled by WordPress, we focused on modifying the system to make it better tailored to our requirements. We created a series of custom plugins, themes, scripts and widgets to allow for: (i) unique multi-data-point searching first through "AND" and then "OR", (ii) varied searches that use both user-created and system-generated tags; (iii) increased data variety and consistency, with full data manipulation; and (iv) an administration layer, which allows admins to approve and monitor users.
In this dynamic poster, we will demonstrate the central features of the database: general searching, easy access to data, and data management. We will perform sample searches in response to attendees' requests. By the time of the meeting, the database will contain ~500 GB of data on single neuron activity in the cat motor cortex and motor thalamus during overground locomotion with and without obstacles. Both raw and processed records will be available. Neuron identification, including data on axonal projections and conduction properties obtained in live subjects will be available. Approximate location of cell bodies within the structure determined by histology will be available. All data will be accompanied with behavioral data on task performance.
The cat brain database is started with data on locomotion collected in the laboratory of Dr. Beloozerova since 2000 as a part of NIH funded research. Later, data on cat brain activity during treadmill locomotion, balancing, and scratching will be added. Three-dimensional kinematic data on all behaviors will be added. The database is open to other laboratories for depositing their data on cat brain activity and body biomechanics. By making the data publicly available we seek to facilitate further research of the cat brain, which ultimately will lead to better understanding of human brain.

Title: A 'landscape view' of motor planning

Authors: *P. DEL GIUDICE[1], G. BAGLIETTO[2], S. FERRAINA[3]
[1]Italian Natl. Inst. of Hlth., Rome, Italy; [2]IFLYSIB, Inst. de Fisica de Liquidos y Sistemas Biologicos (UNLP-CONICET),, La Plata, Argentina; [3]Dept Physiol. and Pharmacol., Sapienza Univ. Rome, Rome, Italy

Abstract: We recently described (Baglietto et al, Plos One 2017) an approach to the analysis of multi-dimensional time series, like those obtained from multiple simultaneous electrophysiological recordings, based on a density-based clustering (DBC), and showed in a modeling study its potential for efficient representation, inference and complexity estimates. In this contribution we used DBC to analyze the spatio-temporal organization of cortical activity patterns during the execution of a 'countermanding' task, in which a monkey must perform a reaching movement to a target on a screen ('no-stop trials'), unless a stop signal prescribes to withhold the movement ('stop-trials'); no-stop and stop trials are randomly intermixed, and the stop signal occurs at random times within the monkey's reaction time. In a previous study using the same task (Mattia et al, J. Neurosci. 2013), a spectral analysis of multi-unit activity (MUA) from single electrode recordings of the dorsal premotor cortex (PMD) suggested that the development of the motor plan proceeds as a cascade of sudden UP-DOWN/DOWN-UP transitions in the local cortical neural population (module). The analysis suggested that transitions are autonomously generated in most excitable modules, and propagate to less excitable ones. In their relation with the completion of the motor plan, the time patterns of transitions were predictive of the movement time in no-stop trials, and of the correct or incorrect behavior in stop trials. Here we present preliminary result of the analysis of simultaneous MUA recordings from a 96-electrodes grid in PMD during the same countermanding task. We perform DBC on the 96-dimensional MUA time series, allowing to code it as a discrete sequence of clusters' centroid labels (so each label represents a 96-elements vector of MUA values in a given time bin, which is the centroid of the cluster currently visited by the neural dynamics). This coding offers a clean and compact view of the spatio-temporal dynamics, which confirms the picture suggested by the previous analysis and offers an explicit representation of the task-related activation sequences of cortical modules. Besides, to inquire into long memory effects in the dynamics, from the sequence of centroid labels we first estimated the matrix of transition probabilities between clusters, from which we constructed surrogate Markov centroid sequences. For both real and surrogate sequences we computed the Lempel-Ziv complexity, and defined an index measuring their relative complexities, thereby obtaining a quantitative measure of long-memory, non-Markov dynamic components.

Title: Inhibition of protein synthesis in M1 of monkeys disrupts performance of sequential movements guided by memory

Authors: *M. OHBAYASHI[1,2,3,4], P. L. STRICK[1,2,3,4]
[1]Univ. of Pittsburgh, Sch. of Medicine, Syst. Neurosci. Inst., Pittsburgh, PA; [2]CNBC, Pittsburgh, PA; [3]Dept. of Neurobio., Pittsburgh, PA; [4]Brain Inst., Pittsburgh, PA

Abstract: Motor skills may be improved with extensive practice to attain expert performance (e.g., playing the violin). Recent studies in monkeys indicate that extended practice on a motor skill alters patterns of neural activity and functional activation in M1 (Matsuzaka et al., '07; Picard et al., '13). We previously showed that inhibition of protein synthesis in M1 of monkeys disrupted performance of sequencial movements guided by memory, but not performance of visually-guided reaching (Ohbayashi et al., SFN Abstr., '15). These and other results suggest that M1 is a site of storage for highly practiced movements. Here we examine the effect of inhibiting protein synthesis in M1 on the development of expertise during a sequential motor task.We trained 2 monkeys (Cebus Apella) to make sequential reaching movements in two tasks (Ohbayashi et al., '16). In the Random task, movements were guided by vision. New targets were shown using a pseudorandom sequence 100 ms after contact of the prior target. In the Repeating task, movements were internally guided. New targets were shown according to a repeating 3 element sequence (e.g., 5-3-1-5-3-1 ...) 400 ms after contact of the prior target. The animal was allowed to contact the next target in the sequence before it was shown. The longer delay between target contact and the appearance of the next target promoted the occurrence of predictive responses. With practice, monkeys could perform the Repeating task without any visual cues. After the monkeys became proficient in the performance of the 1st trained sequence, a 2nd sequence (e.g., 1-2-4-1-2-4...) was introduced. The monkeys performed the two sequences and the Random task in alternate blocks.After training for more than 200 days on the 1st sequence and 50 days on the 2nd sequence, we injected the protein synthesis inhibitor anisomycin (5 µl of 100 mg/ml) at 2 sites in the arm area of M1 (monkey 1, n = 5; monkey 2, n = 1). After the anisomycin injections, Response Time (RT) and the number of errors increased significantly only during performance of the Repeating task. We compared the effects of anisomycin injections on performance of the 1st and 2nd sequences in each session. The RT increase induced

by the anisomycin injection was greater for the 2nd sequence than for the 1st one (n = 6). These results confirm the involvement of M1 is the development of expertise through practice. In addition, they suggest that the more recently learned 2nd sequence is more vulnerable to the inhibition of protein synthesis than the older 1st sequence.

Title: Intrinsic connections of motor cortex columns revealed with intracortical microstimulation and optical imaging in squirrel monkeys

Authors: N. S. CARD[1], A. SLOAN[1], *O. A. GHARBAWIE[2]
[2]Dept. of Neurobio. & Systems Neurosci. Inst., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In primary motor cortex (M1), a roughly concentric topography exists for the motor representations of the hand, elbow, and shoulder. Cortical columns within these representations send corticospinal projections that can influence activity in groups of arm and hand muscles. The muscle synergies needed for manual movements are therefore predicated on coordinated activity between M1 columns within the arm and hand representations. Multiple communication channels have the potential to coordinate activity in M1 columns. Intrinsic M1 connections represent the most direct channel of communication between M1 columns, but are perhaps the least understood among M1 connections. The objective of the present study is to investigate the spatial organization of the intrinsic connections of M1 in columns within the arm and hand representations. In three squirrel monkeys, we focused on mediolateral rows of cortical columns in M1, wherein motor output changes but other defining features are invariant. To study an individual column, we first determined the output targets of that column via intracortical microstimulation (ICMS) and electromyographic (EMG) recordings. Second, we identified zones in M1 that are connected to that column using ICMS (trains of 150 pulses, 0.2 ms/pulse, 300 Hz, 1000 μm below pia) and concurrent intrinsic signal optical imaging (630 nm illumination). For all M1 columns investigated in this study, the most prominent activation was a spatial cluster (~ 2.0 mm^2) of contiguous columns that surrounded the stimulating microelectrode. In addition, columns were preferentially connected with other clusters (~ 0.5 mm^2) of columns. The muscle

targets of the connected columns overlapped with the muscle targets of the microstimulation site. Our results build on tracer studies that showed that the *anatomical* connections of the thumb representation in monkeys (Huntly and Jones, 1991) and the wrist representation in cats (Keller, 1993), are widely distributed across the entire forelimb representation. Here, we show that the *functional* connections of M1 columns within the forelimb representation are spatially biased towards M1 columns that target the same muscle groups. Thus, our results to date suggest that *functional* connections within M1 may be primarily concerned with coordinating matched columns. In this framework, other communication channels (e.g. thalamic inputs, intra-areal connections) may be responsible for coordinating non-matched M1 columns. We are currently testing the effects of ICMS in one column on the activity of single units in connected columns to determine if interactions between connected columns are excitatory or inhibitory.

Title: Area-specific involvement of frontal areas and the basal ganglia in goal-directed behavior in monkeys

Authors: *Y. NAKAYAMA[1,2,3], T. YAMAGATA[2,3], N. ARIMURA[2,3], E. HOSHI[1,2,3]
[1]Neural Prosthesis Project, [2]Frontal Lobe Function Project, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [3]Tamagawa Univ. Brain Sci. Inst., Tokyo, Japan

Abstract: Regions in the frontal lobe form closed loop circuits with the basal ganglia. The areas composing these circuits are considered to play a role in achieving goal-directed motor behavior. However, the specific roles that each area composing these circuits plays still remain elusive. In the present study, we examined neuronal activity in multiple brain areas of monkeys (*Macaca fuscata*) while they performed a conditional visuo-goal task designed to include separate processes for determining a behavioral goal (reaching towards a right or left potential target) on the basis of visual object instructions, specifying actions (direction of reaching) to be performed on the basis of the goal, and preparing and executing the action (Nakayama et al., 2008, 2016). We compared neuronal activity in eight areas of the frontal cortex and basal ganglia: the ventrolateral and dorsolateral prefrontal cortex (vlPFC and dlPFC, respectively), pre-dorsal

premotor area (pre-PMd, or area F7), dorsal premotor area (PMd, or area F2), ventral premotor area (PMv), caudal cingulate motor area (CMAc), primary motor cortex (M1), and globus pallidus (GP). We found activity of neurons selective for (1) visual features of the instruction cues, (2) goal determination, (3) action specification, and (4) preparation and execution of the action. We next applied k-means clustering method to classify neurons into several groups based on patterns of their activity. We found clusters of neurons that were active when the monkeys determined a goal, specified an action, prepared the action, or executed the action. The proportions of neurons that belonged to each cluster were different between the eight areas. Based on these analyses, we found that (1) neurons in the vlPFC amply encoded visual features of objects, (2) neurons involved in the processes of determining goals and specifying and maintaining actions were found mainly in the vlPFC, dlPFC, pre-PMd, and PMd, (3) neurons involved in action preparation and execution were mainly found in the PMd, PMv, and M1, (4) neurons in the CMAc were involved in action execution regardless of directions of the action, and (5) neurons in the GP were involved in goal determination and action specification, but they did not maintain the information. These results suggest that each frontal area coordinates with the basal ganglia, and these areas contribute to goal-directed behavior in an area-specific manner.

Title: Premotor network exploration and reinforcement during practice of a stereotyped, learned motor action

Authors: *W. A. LIBERTI, III[1], J. SHEN[1], D. P. LEMAN[1], N. PERKINS[2], T. J. GARDNER[1]
[1]Biol., [2]Boston Univ., Boston, MA

Abstract: With practice, learned motor actions can be maintained for decades, but the biological basis of skill acquisition and persistence remains largely unknown. We do know that precise motor skills are learned and maintained through practice: a process of exploratory trial-and-error learning where actions are evaluated and ‘good’ performances are reinforced. For example, the adult male zebra finch sings a highly stereotyped courtship song that is stable for years. These finches will sing ‘undirected’ in isolation, and these songs are less stereotyped than when their

performance is ‘directed’ to another finch. In parallel, neurons impinging onto motor cortical area RA show increased variability in their firing patterns during undirected singing, and this variability is thought to provide a substrate for vocal exploration and trial and error learning. We deploy head mounted miniature microscopes and cell-type specific genetic tools in the pre-motor nucleus HVC, one synapse upstream of RA. We observe and compare the underlying neural activity during motor production of both ‘undirected’ and ‘directed’ song, to determine if this area also undergoes state-dependent changes in variability. On average, individual neurons have similar firing times in both conditions. However, preliminary data suggests that during undirected practice, individual neurons independently explore different firing modes. In contrast, when song is directed to a female, this exploration is largely diminished, and variance becomes more correlated across the network. This suggests that during undirected singing, neurons in HVC may also express variations that could form a substrate for trial and error learning to minimize vocal errors. In this poster we examine the correlation structure of neural variations in greater detail.

Abstract: Prepared movements are more efficient than those that are not prepared for. Although changes in cortical activity have been observed prior to a forthcoming action, the circuits involved in motor preparation remain unclear. Here, we use in vivo two-photon calcium imaging to uncover changes in the motor cortex during variable waiting periods prior to a forepaw reaching task in mice. Consistent with previous reports, we observed a subset of neurons with increased activity during the waiting period; however, these neurons did not account for the degree of preparation as defined by reaction time (RT). Instead, the suppression of activity of distinct neurons in the same cortical area better accounts for RT. This suppression of neural activity resulted in a distinct and reproducible pattern when mice were well prepared. Thus, the selective suppression of network activity in the motor cortex may be a key feature of prepared movements.

Title: Thalamo-cortico-thalamic circuits in a premotor-like frontal cortical area in the mouse

Authors: *K. GUO, N. YAMAWAKI, G. M. SHEPHERD
Physiol., Northwestern Univ., Chicago, IL

Abstract: What is the cellular basis for communication between thalamus and cortex? This question has been most extensively investigated in sensory systems, leading to concepts of thalamo-cortico-thalamic (T-C-T) loops, which particularly involve thalamocortical (TC) neurons in the thalamus and layer 6 corticothalamic (CT) neurons in the cortex. However, our recent studies indicate a distinct organization for T-C-T circuits in primary motor cortex (M1) of the mouse (Yamawaki & Shepherd, 2015, J Neurosci), including a paucity of monosynaptic connections between TC neurons in the ventrolateral nucleus and CT neurons in M1, in either direction. Instead, T-C-T loops of M1 appear to be polysynaptic, involving multiple nuclei in the

thalamus and multiple projection classes in the cortex, including pyramidal tract (PT) and intratelencephalic (IT) neurons in addition to CT neurons. Here, we extended our studies of motor-related T-C-T circuits to assess cellular connections between higher-order motor areas in the anterior frontal cortex and higher-order nuclei in motor thalamus. We applied optogenetic-electrophysiology tools to determine how IT, PT, CT, and TC neurons participate in the cell-type-specific connections that form T-C-T circuits. We focused on the anterior lateral motor (ALM) area, a frontal cortical region with premotor-like properties (Li et al., 2015, 2016, Nature), and its connections with the ventromedial (VM) nucleus, a basal-ganglia-recipient region of motor thalamus. The findings show several unusual properties of T-C-T circuits in this system, differing from both sensory and M1-related T-C-T circuits. In the T-->C direction, these included strong excitation from VM-TC axons onto layer 1 apical tuft dendrites of PT neurons that were identified by retrograde labeling as projecting back to VM. In the C-->T direction, PT axons strongly excited TC neurons in VM that were identified as projecting back to ALM. Thus, the results provide evidence for direct, recurrent loops in this higher-order motor-frontal T-C-T system in the mouse, mediated by PT neurons in ALM and TC neurons in VM. We speculate that such recurrence could be important for supporting reverberant activity associated with motor planning.

Title: Topography in the mouse motor cortex is a mosaic

Authors: *N. JAIN, S. R. JOHN, P. HALDER
Natl. Brain Res. Ctr., Manesar, India

Abstract: Mammalian motor cortex is considered to be globally topographic and locally non-topographic. Although the neurons that control movements of different body parts are topographically organized in the motor cortex, within the representation of a body part the organization is not precisely topographic. Such movement maps in the motor cortex have been described for a number of mammalian species including rodents and non-human primates. Topographic organization of the motor cortex is usually determined by intracortical microstimulation (ICMS). ICMS involves using microelectrodes to inject small amounts of current to stimulate layer 5 neurons. The stimulating current is reduced to the smallest threshold

value that elicits a visible movement of a body part. Here we used ICMS to determine organization of the motor cortex in mice.
We found that although there is an overall topographic organization in the mouse motor cortex, the locations of boundaries of representations of various body parts are variable. There is a medial whisker movement area, bordered on the lateral side by the forelimb area. Caudally there are small trunk and hindlimb movement regions, and a rather large tail area. Within these representations, there are scattered patches of neurons from where movements of other body parts, particularly the tail could be evoked.
Interestingly, stimulation at currents that were slightly higher than the threshold currents (i.e. suprathreshold currents) evoked movements of additional body parts at nearly all the sites. The increase in threshold currents required for additional movements was generally as low as 1 µA. For example, at suprathreshold currents whisker movements could be evoked from the forelimb area and *vice versa*. The number of tail movement sites increased throughout the motor cortex. The additional movements were unlikely to be due to the point-spread of the current, because these movements were observed not just at the boundaries of the representations, but throughout the motor cortex. Moreover, the movements evoked at suprathreshold currents could be of non-adjacent and distant body parts. In rats, in contrast, suprathreshold currents do not evoke movements of additional body parts, except that movements of the neck muscles are evoked from the whisker area (Tandon et al., Eur J Neurosci, 27:228, 2008).
We conclude that the mouse motor cortex has a mosaic representation of movements of different body parts.

Title: Corticocortical signaling drives activity in a downstream area efficiently, reliably, reversibly, and scalably

Authors: *X. LI[1], N. YAMAWAKI[1], K. P. KORDING[2], G. M. G. SHEPHERD[1]

Abstract: How effectively does activity in an upstream cortical area drive activity in a downstream area? Optogenetic photostimulation and multi-unit electrophysiology were used to characterize evoked upstream and downstream spiking activity in a parietofrontal pathway linking retrosplenial cortex (RSC) to posterior secondary motor cortex (M2) in mice, a pathway recently characterized at the level of cell-type-specific corticocortical connectivity (Yamawaki et al., 2016, J Neurosci). RSC neurons including their axons projecting to M2 were labeled with channelrhodopsin-2 (ChR2) by injection of AAV in RSC in wild-type mice. Optical fibers were placed over RSC, to activate the upstream RSC neurons directly, and also in M2, to activate the axons of the same RSC neurons and thereby activate them antidromically. Activity was simultaneously recorded in both RSC and M2 using linear arrays (silicon probes) with 32 channels each, to sample multi-unit activity across cortical layers in both areas. Photostimuli delivered to the upstream area (RSC) were robustly converted into local activity, which in turn drove activity in downstream M2 with nearly the same efficiency and reliability. Reverse (antidromic) driving, delivering photostimuli to M2, was similarly robust. In either direction, downstream activity scaled approximately linearly with stimulus intensity and sub-linearly with duration, and with an overall log-like relationship in this input-output system. Shorter-duration higher-intensity inputs were most effective, consistent with an adaptation-like process. The results show that corticocortical signaling in this pathway exhibits efficiency, reliability, reversibility, and scalability. The findings suggest that corticocortical signaling supports inter-areal communication across a wide dynamic range of activity levels and temporal patterns, but preferentially for briefer bursts of activity.

Title: Parvalbumin expressing GABA-ergic neurons in primary motor cortex signal reaching

Authors: *D. HOFFMANN[1,2], L. ESTEBANEZ[1,2,3], B. C. VOIGT[1,2], J. F. POULET[1,2]
[1]Max-Delbrück Ctr. For Mol. Med. (MDC), Berlin, Germany; [2]Neurosci. Res. Ctr., Cluster of Excellence NeuroCure/ Charité-Universitätsmedizin, Berlin, Germany; [3]Unité de Neurosciences, Information et Complexité, UNIC-FRE3693, Ctr. Natl. de la Recherche Scientifique, Gif-sur-Yvette, France

Abstract: The control of targeted reaching is thought to be shaped by distinct subtypes of local GABA-ergic inhibitory neurons in primary forelimb motor cortex (M1). However, little is known about their action potential firing dynamics during reaching. To address this, we recorded the activity of parvalbumin-expressing GABA-ergic neurons, fast spiking units and regular spiking, presumed excitatory, units in layer 5 of the mouse forelimb M1 during a sensory triggered reaching task. An acoustic cue signaled the onset of a trial, then mice reach and press a sensor following a brief vibrotactile trigger stimulus delivered to the same paw. M1 activity is required for the task, as injection of the GABA-A agonist muscimol disrupted reaching. Parvalbumin-expressing neurons showed short latency responses to the acoustic cue and vibrotactile trigger input as well as an increase in firing at reaching onset that was positively correlated with the amplitude of reaching. Unexpectedly, parvalbumin-expressing neurons fired before regular spiking units at reach onset and maintained high firing rates until the end of the reach. Thus, increasing M1 parvalbumin-expressing neuron firing rates may play a role in the initiation of voluntary reaching.

Title: Transcranial laser scanning photostimulation and video motion tracking for optogenetic cortical motor mapping of mouse corticospinal neurons

Authors: *L. LAMBOT, J. M. BARRETT, X. LI, G. M. SHEPHERD
Dept. of Physiology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: Motor mapping, based on stimulating different cortical locations and measuring the evoked movement, has long been used to define and study motor cortical areas. Traditional electrophysiological mapping methods have several limitations, including lack of cell type specificity and poor spatial resolution. Light-based mapping (LBM; Ayling et al., 2009) has

emerged as a method to overcome both these limitations, and several groups have recently developed various implementations of this technique for investigating limb and whisker movements in mice. We will present progress towards developing a variant of LBM based on combining transcranial laser scanning photostimulation (tcLSPS) with video motion tracking (VMT) using inexpensive cameras, with the aim of using tcLSPS-VMT to map the cortically evoked movements generated by selective photostimulation of channelrhodopsin-2 (ChR2) expressing corticospinal neurons. To selectively label corticospinal neurons with ChR2, we injected the cervical spinal cord with rAAV2-retro-Syn-ChR2-GFP (gift of Alla Karpova, Janelia), a recently developed retrogradely transported AAV (Tervo et al., 2016). Subsequently, ketamine-anesthetized mice were head-fixed and laser stimulus grids of varying size and resolution were oriented either over the labeled corticospinal neurons in motor cortex or to cover as much of cortex as accessible. Cortical sites in the grid were sequentially stimulated by tcLSPS by steering the beam of a blue laser with a pair of scanning galvanometers (Thorlabs), using a pair of acousto-optical modulators for power control. Videos of the evoked movements were simultaneously captured with a pair of USB3 CMOS video cameras (Chameleon3, FLIR) running at 100 or 250 fps. Laser parameters and video capture were controlled using LabView. A simple, offline, ROI-based, 2D cross-correlation-based motion tracking algorithm written in MATLAB was used to measure movements of each paw from the recorded videos. The results demonstrate the utility and efficacy of tcLSPS-VMT for detecting and characterizing cortically evoked limb movements, and furthermore demonstrate that such movements can be evoked by selectively activating corticospinal neurons.

Title: Oscillatory activity of supplementary motor areas reflects temporal integration of periodic events

Authors: *J. D. CADENA-VALENCIA, V. DE LAFUENTE
Inst. De Neurobiología, Querétaro, Mexico

Abstract: The perception of periodic events is essential to estimate incoming changes and to prepare and coordinate a timed motor command. To do so, the motor system must encode and compute temporal patterns and coordinate a motor plan according to the estimated periodicity of events. It is known that the supplementary motor area (SMA) is a structure that contains populations of cells that show tuning profiles ranging from specific motor actions to specific

time intervals in the millisecond scale. But it is not known the general population dynamics that is followed in order to give a coordinated output. The objective of the present project was to understand the general dynamics of SMA by studying its local field potentials (LFP) when monkeys have to perceive and anticipate visual periodic changes. We trained 2 rhesus monkeys in a task with 2 phases. First (Presentation phase) the monkeys have to attend a circular visual target that changes between two locations periodically over time. Then the target vanishes and the monkeys have to estimate the current position of the target as a function of the elapsed time (Estimation phase). A go cue presented at pseudorandom times instructed the monkeys to respond with the hand in which location the target would be at that time; the monkeys could not make any movements with the hand nor the eyes until the cue was presented. While monkeys performed the task, LFP was recorded in the SMA. To observe oscillatory patterns in the LFP we performed time frequency maps using multitaper techniques. In the estimation phase we found that even in the absence of a visual stimulus, the Gamma band´s amplitude (30-40 Hz.) changed accordingly to the previously presented stimuli. Studying Gamma power on single trial basis we observed Gamma bursting activity in the times when the target would change from one location to the next. Also we detected a linear relationship between the elapsed time and the average amplitude of the observed Gamma bursts. The observed patterns of LFP from SMA suggest that this structure is important to integrate temporal patterns even in the absence of a motor response. Also at population level, Gamma band activity may reflect the integration of different populations of cells in order to prepare a timed motor command.

Title: Motor cortical encoding of arm impedance during the coordinated control of both force and movement

Authors: *S. D. KENNEDY[1], A. B. SCHWARTZ[2]
[1]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept Neurobiol, Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: The coordinated control of both force and movement is fundamental to object manipulation. However, the relation between force and movement can be unstable or unpredictable, making these manipulations difficult to perform. An impedance control

framework can simplify this problem. In this study, we tested the idea that arm impedance may be encoded in the neural activity of the motor cortex, with the implication that it is explicitly controlled by the motor system. We trained a monkey to pull on a handle that was locked in place until a specific force threshold was crossed. The threshold crossing triggered the handle to be unlocked so that it could be moved along a linear track. The monkey was required to stop the handle in one of four different targets. We found that arm impedance increased for targets that required shorter movements. For comparison, we repeated this procedure for four different force thresholds and found that arm impedance also increased for higher thresholds. This pattern was consistent with the framework of impedance control and led to our specific hypothesis: if a neuron encodes information about arm impedance, then that information should be consistent across thresholds and targets. Indeed, we found that 20 of 101 neurons had firing rates that were correlated with both target and threshold. In addition, 18 of those neurons had correlations consistent with arm impedance encoding. Specifically, the firing rates of 8 neurons were negatively correlated with target and positively correlated with threshold, i.e. positively correlated with arm impedance. The remaining 10 neurons had the opposite correlation. These results demonstrate that the simultaneous encoding of both force and movement in the firing rates of motor cortical neurons correspond to the variation of arm impedance during object manipulation and suggests that impedance control could be implemented by the motor system. Consideration of arm impedance can provide a concrete description of the coordinated control of force and movement.

Title: Comparing M1 neural reorganization during contralateral and ipsilateral visuomotor rotation learning

Authors: *L. BAHUREKSA[1,2], W. JOINER[3], S. CHASE[1,2]
[1]Dept. of Biomed. Engin., [2]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [3]Dept. of Bioengineering, George Mason Univ., Fairfax, VA

Abstract: It is well known that neurons in primary motor cortex (M1) exhibit tuning to kinematics of the contralateral arm. Further, several studies have demonstrated changes in this neural tuning during adaptation of contralateral arm movements. It has also been shown that M1 neurons often exhibit tuning to kinematics of the ipsilateral arm, and it has been hypothesized that this ipsilateral representation may contribute to generalization of learning to the untrained limb (e.g., Kawashima et al, *Brain Res*, 1994; Anguera et al., *Brain Res,* 2007). However, it has yet to be demonstrated whether ipsilaterally-tuned neurons exhibit changes in neural tuning during adaptation of movements of the ipsilateral arm. Here we compared the changes in direction tuning of M1 neurons during learning with the contralateral and ipsilateral arm. We trained a rhesus macaque to perform five sets of 8-target center-out reaching movements in a virtual reality environment. The subject first performed center-out reaching movements using the contralateral and ipsilateral hands (separate sets, 160 trials per hand). The subject then performed a set of 160 trials to these 8 targets with either the ipsilateral or contralateral arm during application of a visuomotor rotation (VMR; +/-40°). Following this perturbation session, the subject again completed center-out reaches using the contralateral and ipsilateral arms. Cosine tuning curves were fit to the data from each session of the experiment, and tuning changes were quantified for baseline firing rate, modulation depth (amplitude of the tuning curve) and preferred direction (PD; direction of maximal firing of the M1 neuron). We found robust changes in PD during learning of the VMR, counter to the direction of perturbation (-29.49 +/- 13.6º) (SD), with smaller, less consistent changes in modulation depth (0.29 +/- 5.29) (SD). These learning-related changes in neural tuning were of comparable magnitude during learning with either the contralateral or ipsilateral arm. These data imply that reorganization of M1 neurons is not preferential to contralateral learning, which may provide a substrate for bimanual transfer of learning.

Title: Demarcation of subjective value from arousal during action observation in F5 neurons

Authors: *S. SPADACENTA[1], J. K. POMPER[1], F. BUNJES[1], M. A. GIESE[2], P. THIER[1]
[1]Hertie Inst. For Clin. Brain Res., Tuebingen, Germany; [2]Hertie Inst. For Clin. Brain Res. / CIN, Tuebingen, Germany

Abstract: It has been suggested that mirror neurons in premotor area F5 are involved in the valuation of grasping actions performed by others. It is, however, unclear if the observed modulation attributed to subjective value may not be better explained by differences in arousal. We therefore recorded a total of 190 mirror neurons from the ventral premotor cortex of two rhesus macaques tested in a paradigm that dissociates subjective value from arousal. This paradigm required the animals to observe a video of a human hand grasping an object followed by four possible endpoints. These endpoints were randomly chosen per trial. Knowledge of the expected endpoint was provided by a cue, presented at the beginning of the trial, before the onset of the video. The four endpoints were: delivery of a large reward (1.5 ml water), a small reward (0.5 ml), a small punishment (no reward but 0.5 sec of eccentric fixation) or a large punishment (no reward but 3-5 sec of eccentric fixation). We expected that the more salient cues (large reward, large punishment) would cause more arousal than the less salient ones, allowing the separation of arousal and value. Based on the monkeys´ choice behavior and heart rate changes, we could establish that this expectation was met. We found that only a few F5 mirror neurons were classifiable as either reflecting value or arousal and that this reflection was often unstable over time. In contrast, a clear signature of value, stable over time, became apparent when ignoring the diversity of responses of single neurons by subjecting the whole population to a dimensionality reduction analysis based on the multidimensional scaling approach. Interestingly, this reflection of value was also found in F5 neurons not classified as mirror neurons, characterized by a lack of responses to observed actions. This congruency suggests a role of F5 neurons in the valuation of environments in general, rather than a role confined to action observation.

Title: Head-restraint does not change the cortical dependence of a sensorimotor task in mice

Authors: T. BOLLU[1], N. PRASAD[2], *J. H. GOLDBERG[2]
[1]Neurobio. and Behavior, [2]Dept. of Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: Cortical control of behavior differs across species and behavioral paradigms [1]. In head-fixed animals, inactivation of motor cortex dramatically impairs reach and lick behaviors [2; 3; 4; 5], but freely-moving animals with permanent cortical lesions [6; 7] can execute seemingly comparable tasks spontaneously with little to no impairment. To our knowledge cortical function has not been tested in the same animals performing the same task across head-fixed and free experimental preparations. To test if restraint can affect experimental results, we trained head-fixed and head-free mice in an identical sensorimotor lick task and optogenetically silenced different motor cortical areas during behavior. Performance similarly depended on tongue but not forelimb motor cortex in both experimental conditions, demonstrating that restraint does not alter cortical control of a simple sensorimotor task.

Title: Representation of egocentric space in the frontal orienting field

Authors: *H. LI[1], H. H. YIN[2]
[1]Duke Univ., durham, NC; [2]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: The frontal orienting field(FOF) has been known to modulate orienting behavior in rodents. Lesion, stimulation and anatomical experiments suggested that the FOF is critical for orienting in navigation and decision making. Specifically, it was found that unilateral activations of FOF lead to orienting bias towards the contralateral side. How FOF output directly shapes the trajectories of orienting movements, however, is not well understood. Using optogenetics and 3D motion capture techniques, we were able to quantify the relationship between FOF neural activity and the trajectory of orienting behavior. We found that 1) stimulation to the FOF led to various head movements that resemble natural orienting movements in rodents; 2) stimulations of a specific location in the FOF caused orienting movements towards a specific location relative to the body, suggesting that the FOF contains a egocentric spatial map of destinations of orienting movements; 3) surprisingly, unilateral stimulation of FOF in either hemisphere was similar to bilateral stimulation, both resulting in orienting to a specific egocentric location. This result indicates that FOF in each hemisphere possibly contains symmetrical representations of bilateral spatial locations.

Title: Encoding properties of neurons in the orofacial sensorimotor cortex during bite force generation at varying gapes

Authors: *F. I. ARCE-MCSHANE[1], K. TAKAHASHI[1], B. J. SESSLE[2], N. HATSOPOULOS[1], C. ROSS[1]
[1]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Univ. Toronto, Toronto, ON, Canada

Abstract: Human mastication relies on the precise control of the generation of bite force at varying degrees of mouth opening, i.e. gapes. The role of orofacial sensorimotor cortex in the coordination of gape and bite force is unknown. Here we examined the spiking activity recorded with microelectrode arrays implanted chronically in the primary motor (MIo), primary

somatosensory (SIo), and cortical masticatory (CMA) areas of the orofacial sensorimotor cortex in monkeys (*Macaca mulatta*) trained to generate one of three bite force levels at one of three gapes per trial. We used generalized linear models to predict the time-varying spiking activity of each neuron as a function of bite force, gape, and spike histories of neurons recorded from the same cortical area. To assess model performance, we computed the area under the receiver operating characteristic curve (AUROC) obtained from cross-validated test trials and compared the values obtained from the full model that has bite force, gape, and spike histories of neurons as covariates against the performance of reduced models that have the bite force or gape excluded. We found that both bite force and gape were predictive of the spiking activity of the population of neurons in MIo, SIo, and CMA as AUROC values of full and reduced models were significantly above chance level (Wilcoxon Signed Rank Test, $p<0.00001$). In MIo, model performance was significantly degraded when the bite force was excluded from the predictors (Wilcoxon Signed Rank Test, $p<0.01$) and when both bite force and gape were excluded (Wilcoxon Signed Rank Test, $p<0.01$). In SIo and CMA, the AUROC values in the reduced models were not significantly lower than those in the full model (Wilcoxon Signed Rank Test, $p>0.05$). Overall, the results suggest that while single-unit and population responses in all three areas play a role in the coordination of bite force and gape, MIo may perform computations that are different from those performed by SIo and CMA.

Title: Presynaptic inhibition of muscle afferent input to spinal cord in awake, behaving monkeys

Authors: *S. TOMATSU[1], G. KIM[1], S. KUBOTA[1,2], K. SEKI[1,3]
[1]Natl. Inst. of Neuroscience, NCNP, Tokyo, Japan; [2]JSPS, Tokyo, Japan; [3]JST, PREST, Tokyo, Japan

Abstract: In the previous studies (Seki et. al. 2003 *Nat Neurosci* and 2009 *J Neurophysiol*), we have reported the modulation of the level of presynaptic inhibition on the input from cutaneous

afferent in monkey spinal cord during voluntary movement. In these report, we have developed the method to estimate the size of primary afferent depolarization by evoking antidromic volleys in the cutaneous nerve by applying the microstimulation to their intraspinal terminals (Wall's excitability testing). In the present study, we applied this technique to evaluate the modulation of presynaptic inhibition on a muscle afferent from wrist extensors in monkeys (n = 2) performing wrist flexion-extension task. After finishing the behavioral training, we implanted an oval chamber to the lower cervical vertebrae (C4-T1) for intraspinal microstimulation, a custom-made nerve cuff electrode to the deep radial nerve (DR) innervating wrist extensor muscles, and electromyographic electrodes to wrist and finger muscles. Using a tungsten microelectrode, we applied intraspinal microstimulation (10 Hz, 1-50 μA) to the ventral horn while monkeys are performing wrist movement to activate the terminal of DR afferents. In total, 49 volleys were recorded in the DR nerve of two monkeys (n = 38 and 11, respectively). Onset latency of each volley was distributed from 2.23 ms to 4.03 ms (mean 2.92 ± 0.47 ms and 3.23 ± 0.20 ms, respectively) suggesting a majority of volley were induced in the faster-conducting muscle afferents. In both monkeys, we found a significant reduction in the size of antidromic volleys in the DR nerve during wrist movements. In the first monkey, for example, task related reduction in their amplitude was found in ten among 28 putative antidromic volleys (35.7 %), and the reduction is found predominantly during isometric wrist extension ($p < 0.05$). In contrast, the facilitation in size (n = 6) of volley was not frequently observed in any specific epoch of the task. In the second monkey, the size of antidromic volleys was also suppressed when the monkey performed dynamic and isometric wrist extension ($p < 0.05$) in 11 putative antidromic volleys, so far. These results suggested that the level of presynaptic inhibition on a muscle nerve is suppressed during agonistic torque. Such disinhibition might allow the spinal cord to use the information from muscle afferent in an efficient way for the control of ongoing movement. Based on our previous finding on the facilitation of presynaptic inhibition on the cutaneous afferent during active movement (Seki et al. 2003, 2009), we can now conclude that task-relevant peripheral inputs are highlighted by the presynaptic inhibition in a highly selective way.

Title: Decoding neuronal firing patterns in the anterior lateral motor cortex into sensory cue information

Authors: *J.-W. SOHN[1], S. CHAE[2], S.-P. KIM[3]
[1]Daegu-Gyeongbuk Med. Innovation Fndn., Daegu, Korea, Republic of; [2]Design and Human Engin., Ulsan Natl. Inst. of Sci. and Technol., Ulsan / Ulsan Metropolitan City, Korea, Republic of; [3]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: Neurons in the anterior lateral region of the motor cortex (ALM) of rodents have been known to modulate their spiking activity according to conditioned sensory input from the whisker. However, the role of ALM in the flow of information from decision to action is not well known. The present study aims to address this by decoding neuronal firing patterns in the ALM to extract the information from sensory cues. For this, we analyzed single-unit activities recorded in the left ALM of rodents which were available from the CRCNS depository for public use. For the behavioral task, three mice performed the object discriminant task with a tactile sensory cue. In each task trial, a pole touched (1.3 s) a posterior whisker for indication of upcoming water reward from the right frontal side of the mice, and an anterior whisker from left frontal side (stimulus-on period). After the pole out, the mice were forced to wait for 1.3 s (delay period). Then, the mice licked to right or left based on memory (peri-movement period). The behavioral outcomes were divided into four types: hit right, hit left, error right and error left. The neuronal data were recorded from 32 channel micro electrode array while the mice performed the task. We decoded the sensory cue information (i.e. posterior vs. anterior) from the firing rates of the ensemble of 10 to 20 neurons using the linear discriminant analysis (LDA). We applied LDA for each of three periods with groups of neurons showing selectivity for sensory stimuli ($p<0.01$) based on mutual information. In addition, we tested the performance of decoder trained using either the hit trial data or error trial data and cross-validated to prevent overfitting. During the stimulus on period, the predicted accuracy of sensory cue of decoder trained with hit trials (error trials) was 49.60% (53.08%). In contrast, the performance of decoder was 78.72% (78.33 %) and 86.28% (82.05%) respectively during delay period and peri-movement period. The decoding analysis showed that we could decode neuronal firing patterns into sensory cue information significantly higher than the chance level (50%) during delay period and peri-movement period but not during stimulus on period. This tendency was preserved regardless of training data. This result implies that that the role of ALM may be related to retention of working memory and movement execution rather than decision making for sensory cue.

Title: Clustering of dendritic activity during decision making

Authors: A. M. KERLIN, *B. MOHAR, D. A. FLICKINGER, B. J. MACLENNAN, C. DAVIS, N. JI, N. SPRUSTON, K. SVOBODA
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Neighboring neurons in motor cortex exhibit diverse selectivity during sensation, movement preparation, and movement execution. Neuronal selectivity could emerge from diverse mechanisms, including selective connectivity and nonlinear interactions of synaptic inputs in dendrites. We studied dendritic integration in the anterior motor cortex of mice performing a tactile discrimination task with a delayed response (Guo and Li et al., 2014). We constructed a two-photon microscope that allows rapid (~15 Hz) imaging of up to 300 µm of contiguous dendrite while resolving calcium transients in individual dendritic spines. Two galvanometers and a remote focusing mirror (Botcherby et al., 2008) steer 16 kHz lines (24 µm extent) produced by a resonant mirror arbitrarily in three dimensions. Pyramidal neurons were labeled sparsely with GCaMP6f in transgenic mice. We imaged spine and dendritic calcium transients, as well as somatic calcium transients associated with action potentials. We developed methods to computationally remove the influence of backpropagating action potentials (bAPs), which allowed us to quantify the selectivity of spines and dendritic segments during sensation, movement preparation, and movement execution. Nearby spines and dendritic segments share similar selectivity (length constant of signal correlation, ~30 µm). This clustering was more often seen in distal than in proximal dendrites. Using a measure of local autocorrelation, we also found that this reflects distinct “hotspot” locations on the dendrite where nearby dendrite and spines are co-active in time. Hotspot selectivity was correlated with the behavioral selectivity of somatic spikes, suggesting that these locations may have privileged influence over the output of the cell.

Title: Predictive coding of temporal events through regulation of cortical dynamics

Authors: *S. W. EGGER[1,2], C.-J. CHANG[1,2], M. JAZAYERI[1,2]
[1]McGovern Inst. for Brain Res., [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Natural sensorimotor behavior relies on flexible and rapid integration of incoming sensory information with ongoing motor plans. To gain insight into the neural mechanisms of sensorimotor integration, we recorded from the dorsomedial frontal cortex (dMFC) of monkeys performing a novel timing task. Animals had to integrate information from the first three beats of a rhythm (S1, S2, and S3) in order to initiate a saccade at the expected time of the missing fourth beat (Go). Analysis of behavior indicated that animals integrated information from the S1-S2 and S2-S3 epochs to optimize their response, consistent with a Bayesian estimation model. We considered two algorithms the brain might use to perform this integration. The first was a sequential estimation algorithm in which the estimate is updated after each beat, and the second was batch estimation algorithm in which the estimate is derived in a single step after S3. Although dMFC responses were strongly modulated throughout the trial, computational principles of Bayesian estimation were not discernable at the level of single neurons. However, hallmarks of sequential updating algorithm emerged from an analysis of dynamics at the population level. Across task epochs, population trajectories resided in different regions of the state space, and within each epoch, they were systematically organized with respect to the inter-beat-interval. This organization exhibited two characteristics: 1) the speed with which the state evolved along the trajectory predicted the time of the upcoming beat, and 2) the neural state at the time of each beat encoded a prediction error signal. Importantly, error signals at the end of each epoch predicted the speed of population dynamics during the ensuing epoch. We captured these features in a cascade of two-neuron models, each capable of performing a canonical operation of converting an error signal to predictive dynamics by adjusting the speed. These results suggest that cortical circuits integrate sequentially presented information by implementing an error-based sequential updating mechanism, akin to predictive coding. More generally, our work highlights the importance of inferring algorithms of sensorimotor and cognitive computations at the level of population dynamics.

Title: Long-range inputs and H-current regulate different modes of operation in a multiscale model of mouse M1 microcircuits

Authors: *S. DURA-BERNAL[1], S. A. NEYMOTIN[2], B. A. SUTER[3], G. M. SHEPHERD[4], W. W. LYTTON[5]
[1]Physiol. and Pharmacol., State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [2]Dept. Neurosci., Brown Univ., Providence, RI; [3]Physiol., [4]Dept Physiol., Northwestern Univ., Chicago, IL; [5]SUNY Downstate, Brooklyn, NY

Abstract: We hypothesize the primary motor cortex (M1) may operate in different modes, or along a continuum of modes, characterized by the degree of activation of intratelencephalic (IT), corticothalamic (CT) and pyramidal tract (PT) neurons. The "IT/CT-predominant" mode would involve highly active IT and CT neurons but low PT activity; whereas the "PT-predominant" would exhibit the opposite pattern. In the "IT/CT" mode, a high level of H-current in PT neurons would modulate synaptic integration of inputs and reduce PT output activity. Downregulation of the H-current would lead to increased PT activity in the "PT" mode. The particular subset of M1 neurons targeted by different long-range inputs could also play a role in regulating the different modes: thalamic posterior nucleus (PO) and somatosensory cortical (S1 and S2) inputs would favor the "IT/CT" mode, whereas thalamic ventro-lateral (VL) and motor cortical (contralateral M1 and M2) would promote the "PT" mode.To study this hypothesis we developed a multiscale data-driven model of mouse M1 microcircuits, with over 10,000 cells distributed in a cylindrical volume of diameter 300 μm and cortical depth 1350 μm. L5 IT and PT neuron morphologies with 700+ compartments reproduced cell 3D reconstructions, and their ionic channel distributions were optimized within experimental constraints to reproduce in vitro recordings. The network includes over 30 million synaptic connections that depend on pre- and post-synaptic cell class and cortical depth. Data was based on optogenetic circuit mapping studies which determined that connection strengths vary within layer as a function of the neuron's cortical

depth. The synaptic input distribution across cell dendritic trees -- likely to subserve important neural coding functions -- was also mapped using optogenetic methods and incorporated into the model. The network was driven by the main long-range inputs to M1: thalamus PO and VL, S1, S2, contralateral M1, M2, and orbital cortex (OC). We studied the effect on M1 of increased activity in each of these regions, and of different levels of H-current in PT neurons. Microcircuit dynamics and information flow were quantified using firing rates, oscillations, and information transfer measures (Granger causality and normalized transfer entropy). Preliminary results support the different modes of operation hypothesis; further exploration will help characterize the underlying mechanisms and determine interactions between the factors involved.

Title: Primary motor cortex neurons which produce post-spike suppression provide an active descending command to turn off muscle activity

Authors: *D. M. GRIFFIN, D. S. HOFFMAN, P. L. STRICK
Systems Neurosci. Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Step-tracking movements are characterized by distinct spatiotemporal patterns of activity in agonist and antagonist muscles. Before the agonist burst of activity and the subsequent generation of movement occurs, there is a distinct phasic decrease in antagonist muscle activity. This premovement antagonist inhibition precedes the agonist burst by 50 milliseconds and has been termed the Hufschmidt phenomenon (Hufschmidt and Hufschmidt, 1954). It is generally accepted that the agonist and antagonist bursts of muscle activity are centrally generated. Here we provide evidence that the Hufschmidt phenomenon is also centrally generated. To investigate the origin of premovement antagonist inhibition, we examined primary motor cortex (M1) neurons that produced post-spike suppression effects in averages of electromyographic (EMG) activity. We trained a rhesus monkey to perform a center-out step tracking wrist task. Then, we collected neural activity from M1 and EMG activity from 12 task related wrist and digit muscles. We used spike-triggered averaging of EMG activity to identify 20 M1 neurons that produced

post-spike suppression in at least one recorded muscle. Eight of these neurons (40%) showed a phasic increase in activity when their target muscle functioned as an antagonist. These eight M1 neurons displayed phasic bursts of activity that occurred at the same time or slightly before the phasic decrease in the activity of their target muscle. Thus, the phasic activity of M1 neurons which produce disynaptic post-spike suppression of muscle activity clearly contribute to and may even generate the Hufschmidt phenomenon. Our results provide further evidence that M1 neurons are functionally tuned to sculpt distinct spatiotemporal patterns of muscle activity.

Title: Discrete attractor dynamics underlies selective ramping activity in frontal cortex

Authors: *H. INAGAKI, L. FONTOLAN, S. ROMANI, K. SVOBODA
JFRC, Ashburn, VA

Abstract: Short-term memory links past experience and future actions. Short-term memory is represented by changes in spike rates that are maintained internally. Neuronal time constants are typically on the order of milliseconds. Persistent and ramping activity related to short-term memory can last many seconds. The underlying mechanisms could be related to cellular bistability, chain-like sequential excitation in the circuit, or different types of circuits with positive feedback. We studied the mechanisms of short-term memory in a delayed response task. During the delay epoch, neurons in the mouse anterior lateral motor cortex (ALM) show monotonic and low-dimensional persistent activity that instructs future actions. To distinguish between different neural circuit mechanisms underlying selective persistent activity we performed whole-cell recordings and high-density silicon probe recordings in ALM. We found no evidence for cellular intrinsic bi-stability. Instead, both membrane potentials and population spiking dynamics funneled toward discrete endpoints during the delay epoch. The discrete endpoints were robust to shifts in population dynamics caused by optogenetic perturbation. Perturbation occasionally resulted in switching of the dynamics to the other endpoints, followed by incorrect actions. Our results support the idea that discrete attractors underlie short-term memory in frontal cortex.

Title: Models for short-term memory in a motor preparation task

Authors: ***L. FONTOLAN**, H. K. INAGAKI, K. SVOBODA, S. ROMANI
Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Short-term memory (STM) is the ability to temporarily hold stimulus-related information in order to carry out cognitive tasks. At the core of STM maintenance is the question of how to sustain a representation after the stimulus is removed. Persistent, stimulus-dependent neuronal activity has been observed in numerous brain areas during tasks requiring the temporary maintenance of information, either related to external stimuli or motor planning. Neural recordings performed during STM tasks typically reveal the presence of populations of neurons that display selective sustained activity during the delay epoch. Given that these persistent states can last seconds, i.e. orders of magnitude longer than the typical neuronal time constants, proposed mechanisms to explain the experimental evidence either rely on single-cell multistability or require circuit-level interactions. In this work, we tested the ability of these models to account for electrophysiological data in premotor cortex during a binary delayed-response task in rodents. Analysis of these data excluded single-cell multistability and neuronal chains, where information is passed along each node in a chain of connected neurons. Two major classes of STM models could still potentially account for the observed activity:
i) Positive or negative-derivative feedback transiently maintaining a memory trace by slowing down the decay towards a low-firing stable state.
ii) Strong positive feedback giving rise to a high-firing attractor state, where memory is maintained by balancing decay through reverberating excitatory loops.
Additionally, the firing patterns described above could generate trajectories of various dimensionality (e.g. point, line, etc) in the space of network population activity. To discriminate between these models, we generated predictions for network behavior during non-selective optogenetic manipulations, similar to those carried out experimentally. Models in (i) could be ruled out, since their dynamics would reflect the integration of the optogenetic manipulation, which was not observed in the data. Instead, models in (ii), implemented in our case as a bistable attractor network, could accurately reproduce the observed neuronal dynamics in both control and perturbed conditions. Our combined computational and experimental approach reveals the presence of a stable fixed point encoding the task-relevant information during the preparation of

motor actions. The formation of discrete attractors may be a general mechanism underlying STM in cortical circuits.

Title: Modulation of event-related potentials associated with orofacial skin stretch during speech production

Authors: *T. ITO[1,2], H. OHASHI[3], E. MONTAS[2], V. L. GRACCO[2,4]
[1]Gipsa Lab, CNRS, St Martin D Heres Cedex, France; [2]Haskins Labs., New Haven, CT; [3]Haskins Labs. Inc, New Haven, CT; [4]McGill Univ., Montreal, QC, Canada

Abstract: Modulation of sensory event-related potentials occurs before or during voluntary movement. For speech, the amplitude of auditory cortical potentials is reduced during speech production, the so-called speech induced suppression. However, it is unknown whether somatosensory processing is also suppressed during speech production. The current study addressed this question by examining whether somatosensory event-related potentials (ERPs) associated with facial skin deformation are changed during speech production tasks. We investigated changes in the magnitude of somatosensory ERPs during speech posture with and without voicing, and also with changes associated with different speech utterances. ERPs from 64 scalp sites in response to somatosensory stimulation associated with facial skin stretch were recorded. Participants engaged in: 1) a vowel production task, and, 2) a non-speech task in which participants maintain the same posture without voicing. Three vowels (/a/, /i/, and /u/) were used in these two production tasks. Somatosensory ERPs in the six task conditions (3 vowels x 2 production tasks) were compared with the ERPs from control (resting) condition. We applied global field power (GFP) measures to evaluate the amount of activity of each time point for the ERPs on the cortical surface. GFP showed two peaks consistently around 160 ms and 320 ms after somatosensory onset in all conditions. The first peak amplitude was significantly different for the three vowel tasks, but there were no significant changes in the second peak. The first peak in the vowel /u/ was reliably smaller than those in the other two vowels. This was found consistently in both vowel production and posture tasks. Cluster analysis of the temporal pattern of the GFP showed a significant reduction of somatosensory GFP in the /u/ condition relative to the control condition, while the other two vowel conditions were not reliably different.

Displacement of facial skin stretch was not different across the three vowel tasks, indicating that the changes of ERP responses were not attributed to a magnitude of the facial skin deformation. Taken together, the sensitivity of somatosensory ERP associated with facial skin deformation changes according to the specific vowel being produced. More importantly, there is evidence for a short latency (around 160 ms) suppression of somatosensory input during speech. It appears that sensory suppression mechanisms are reflected in both sensory modalities (auditory and somatosensory) associated with speech production and the somatosensory system may be modulated differently relative to phonetic identity.

Title: Lingual nerve transection induces neutrophil response in the anterior tongue of rats

Authors: *J. D. OMELIAN[1], S. I. SOLLARS[2]
[1]Psychology, Univ. of Nebraska at Omaha Dept. of Psychology, Omaha, NE; [2]Univ. of Nebraska At Omaha, Omaha, NE

Abstract: The anterior tongue is maintained by bilateral gustatory (chorda tympani) and somatosensory (lingual) nerves which innervate tissue in close physical proximity. These nerves appear to have a cooperative, multimodal relationship, in which loss of one nerve results in corresponding changes to the tissue (e.g., taste bud or fungiform papillae) associated with the other. Regardless of which nerve is transected, changes in morphology occur primarily on the denervated side of the tongue, with the contralateral intact side serving as control tissue. One possible mechanism for the observed multimodality of nerve transection effects may be in the inflammatory response following nerve injury. To investigate this possibility, we quantified the innate immune response in the anterior tongue following transection of the lingual nerve (LX), leaving the chorda tympani intact. Adult, female Sprague-Dawley rats underwent unilateral LX at 65 days of age and were allowed to recover for 12 or 24 hours. Following sacrifice, tongue tissue was collected, frozen, and sectioned. Immunohistochemistry was used to visualize myeloperoxidase positive neutrophils stained with DAB, and counts were taken from 10 μm sections within the first 1.5 mm of the anterior tongue. Neutrophil counts were compared between the intact and denervated sides of the tongue. Tissue from two age-matched nonsurgical animals was also processed, counted, and used for additional comparison. Preliminary results

suggest that average neutrophil counts do not differ between intact and cut sides of the tongue at 12 or 24 hours following unilateral LX in adult rats. Significantly more neutrophils were present on the denervated side of the tongue tissue than were present in non-surgical control tissue. Interestingly, the average number of neutrophils on the intact side of the tongue was also significantly higher than in non-surgical tongue tissue at 24 hours post-surgery, suggesting that LX may invoke an immune response which is not restricted to the denervated side of the tongue. This is in contrast with the changes in morphology reported following lingual or chorda tympani transection, which are typically restricted to the injured side of the tongue. Additional comparisons (e.g., animals that undergo sham surgery) will be needed to clarify the effect of LX surgery on neutrophil response in the anterior tongue.

Title: Motor control of the tongue during speech: Predictions of an optimization policy under sensorimotor noise

Authors: *P. BARADUC, P. PERRIER
Dpt Speech and Cogntion, Gipsa-Lab, CNRS / U. Grenoble-Alpes UMR 5216, Saint-Martin d'Hères, France

Abstract: Speech production necessitates a high dexterity. Some sounds like /i/, /s/ or /l/ require every precise positioning of the tongue, while tasks constraints can vary widely (inertial perturbations in walking/running, vocal tract perturbations during eating...). Moreover, tongue movements are very rapid, on the order of some tenth of millisecond, while proprioceptive and auditory feedback latencies are longer. Last, sensory and motor signals have limited precision (they are 'noisy'). For all these reasons, it has been proposed that the central nervous system (CNS) rely on an optimal estimation system ('internal model') in order to adjust the trajectories in real time. Moreover, the CNS also seems to optimize some perceived cost, as suggested by the motor stereotypies observed in eye or arm movements. In particular, the hypothesis of the minimization of an internal measure of effort, or the minimization of the impact of motor noise on endpoint variance account for a large body of experimental observations. Here we test whether an effort optimization controller coupled to an optimal state estimator can account for the trajectories of the tongue when a subject produces the three vowels /i/, /a/ and /u/ from a

neutral (schwa) initial posture. In a first step, we ran 20,000 simulations of a finite element model of the tongue in order to describe the effect of combinations of muscle activations ramps across six muscles of the tongue (3 intrinsic, 3 extrinsic). We then applied model identification techniques to obtain a computationally tractable dynamical model of the tongue in the sagittal plane. Assuming a fixed jaw position and a standard geometry for the rest of the vocal tract, we obtained a simplified model of the speech production system. We could then derive the first three formants of the voice from the instantaneous tongue position through a harmonic analysis. With the sensorimotor plant thus defined, we applied standard numerical techniques inside a time loop to simulate the function of an optimal estimator/controller subjected to sensory and motor uncertainty, and generated tongue trajectories from the initial posture to the final endpoints defined either in postural space or in acoustic (F1-F2) space. These simulations allow exploring how optimal control hypotheses can explain the average trajectories and the impact of sensorimotor noise on their variability.

Title: Entrainment of chewing rhythm by gait rhythm during treadmill walking in humans

Authors: H. MAEZAWA[1], S. KOGANEMARU[2], M. MATSUHASHI[3], M. FUNAHASHI[4], *T. MIMA[5]
[1]Hokkaido Univ., sapporo, Japan; [2]Hokkaido Univ., Sapporo, Japan; [3]Human Brain Res. Ctr., Kyoto Univ. Grad. Sch. of Med., Kyoto-Shi, Japan; [4]Hokkaido Univ, Grad Sch. Dent. Med., Sapporo, Japan; [5]Ritsumeikan Univ., Kyoto, Japan

Abstract: Autonomous rhythmic motor behaviors such as chewing and gait maintenance are critical for daily human life. These rhythmic motor behaviors are realized in different frequency bands for different body parts (i.e., those in the facial area for chewing and foot area for gait), suggesting that they are regulated by independent central mechanisms. However, it remains unclear whether the rhythmic processes of chewing and gait synchronize during concurrent execution in humans. To evaluate the entrainment of chewing rhythm by gait speed, we measured electromyography (EMG) signals from masticatory muscles and tibialis anterior (TA) muscles during chewing at a habitual rhythm while walking on a linear treadmill in 13 healthy volunteers. The up-and-down movement of the head was also measured using an accelerometer

on the back of neck. Each 6-min session included gait tasks performed at three speeds using treadmill (participant's self-selected gait speed: Gait-Auto, Gait-Auto × 1.3: Gait-High, Gait-Auto ÷ 1.3: Gait-Low). For control, we also measured EMG signals from masticatory muscles during chewing while stationary (Chew-Only) before the gait tasks. Chewing rhythm during walking was the same as that for head movement, occurring at twice the speed of the walking rhythm, in nine participants in the Gait-Auto condition, eight participants in the Gait-High condition, and eight participants in the Gait-Low condition. For these subjects, chewing rhythm in the Gait-Auto and Gait-High conditions differed significantly from that in the Chew-Only condition. However, no significant differences in chewing rhythm were observed between the Gait-Low and Chew-Only conditions. Significant differences of chewing rhythm were also observed between the Gait-Auto and Gait-High conditions, between the Gait-Auto and Gait-Low conditions, and between the Gait-High and Gait-Low conditions. Coherence between masticatory muscles and head movements was detected in all gait conditions (Gait-Auto, Gait-High, Gait-Low). Our findings therefore suggest that habitual chewing rhythm is entrained by gait rhythm, which may be mediated by the interaction between two central rhythm generators, or by head movement associated with walking via peripheral mechanisms.

Title: Somatosensory-based compensation to mechanical perturbations of the larynx during speech

Authors: *D. J. SMITH[1], A. F. SALAZAR-GOMEZ[2], C. E. STEPP[1], F. H. GUENTHER[1]
[2]Grad. Program for Neuroscience. Computat. Neurosci., [1]Boston Univ., Boston, MA

Abstract: When a brief, unexpected perturbation to a talker's auditory feedback gives the perception that voice fundamental frequency (f0) has decreased, he/she typically compensates by increasing f0 through auditory feedback control mechanisms. This compensatory response is only partial, typically less than 30% of the size of the perturbation. A brief, unexpected mechanical perturbation to the larynx (a somatosensory perturbation) causes a compensatory response in a manner similar to auditory perturbation. However the compensatory responses to somatosensory perturbations are greater than typically seen for auditory perturbations. Prior

studies of somatosensory perturbation of the larynx did not mask auditory feedback; thus it is unclear whether somatosensory feedback control mechanisms alone are responsible for this increased compensatory response. In the current study, we applied short (1-1.5 s) physical displacements of the larynx using a specially designed device while participants phonated the vowel /i/. To minimize the use of auditory feedback control mechanisms, participants received 90 dB speech-shaped masking noise over headphones. We found that displacing the larynx caused an initial decrease in f0 followed by a compensatory increase. When the larynx was released, f0 increased initially, then decreased toward the baseline value. These compensatory responses, mediated by somatosensory feedback control mechanisms in the absence of auditory feedback control, were much larger than typically seen in auditory perturbation studies, approaching 90% compensation within 1 second of the perturbation. There are at least two possible explanations for this discrepancy between compensatory responses to auditory versus somatosensory perturbations. First, the gain of the auditory feedback controller may be lower than the gain of the somatosensory feedback controller, possibly because longer delays in the auditory feedback system require a lower gain to maintain stability. Second, compensation to an auditory perturbation naturally leads to somatosensory feedback signals that do not match the speaker's somatosensory target, resulting in competition between the auditory and somatosensory feedback controllers. This competition is not present when somatosensory feedback is perturbed because the perturbation also perturbs auditory feedback in the same direction, allowing the speech motor control system to more completely compensate for the perturbation through somatosensory feedback control mechanisms.

Title: Speech movement parameters reflected in sensorimotor cortex activity

Authors: *E. SALARI, Z. V. FREUDENBURG, M. J. VANSTEENSEL, N. F. RAMSEY
Neurol. & Neurosurg., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Although the sensorimotor cortex is known to be an important area for controlling movements, neuronal activity in this area is not always linearly related to motor output. When repeating a finger movement, for example, neural activity declines over repetitions, despite equal

performance (Hermes et al. 2012). It is unknown whether other movements, such as those involved in speech, show a non-linear relationship with underlying neural activity. Insight in this matter will contribute to our understanding of speech production, but is also relevant for the development of speech-based brain-computer-interfaces.
Here, we investigated brain activity during repeated speech movements with electrocorticography (ECoG) over the sensorimotor mouth area. Four epileptic patients who were implanted with ECoG electrodes for diagnostic purposes participated in our study. Two subjects agreed to have an extra high-density electrode grid for research purposes. Subjects were asked to repeat the Dutch /i/ sound at 3 different rates (5,4 or 3 repetitions in 3 seconds). A trial started with an indication of the speech rate, followed by speech cues (at the same rate, visually presented). Conditions were repeated 13 times, in random order.
Brain data was preprocessed (noisy electrodes and line-noise removed, common average re-referenced) and the high frequency band (HFB; 65-135Hz) power was extracted and temporally smoothed for all electrodes that displayed significant correlation to the task. The audio signal was used to extract information about speech movement parameters (sound intensity, repetition rate, tongue position and lip rounding), which were included as independent variables in the analyses (compensation for variations across trials). Subsequently, for every /i/ sound repetition, the peak height of brain activity was determined and averaged over trials, before and after compensation for speech movement variations.
We found that, without considering movement parameter variations, brain activity decreased across movement repetitions for almost all subjects and movement rates. This decrease disappeared when movement parameters were included in the analysis. This indicates that the variability in neural activity across repetitions is associated with differences in speech movement parameters.
The results suggest that the activity in the sensorimotor mouth area is closely linked to motor output. As opposed to earlier findings for finger movements, repetitions of speech movements did not clearly affect the amplitude of the HFB response. The apparent difference between finger and mouth movement encoding warrants further research.

Title: Sensorimotor adaptation of speech with delays in the formant-shifted auditory feedback signal

Authors: T. MITSUYA[1], D. SHILLER[2], *L. MAX[1]
[1]Univ. Washington, Seattle, WA; [2]Ecole d'orthophonie et d'audiologie, Univ. of Montreal, Montreal, QC, Canada

Abstract: One potential problem for efficient motor learning arises when movement-related feedback is delayed. It is indeed well documented that perceiving the consequences of one's own actions with a delay results in the sensory information being processed similar to externally-generated, rather than self-generated, sensory input (e.g., Blakemore et al. 2000). Nevertheless, similar feedback delays have only limited effects on visuo-motor adaptation: despite changes in the rate of learning, the final extent of adaptation is only moderately affected with delays of 100-200 ms, and adaptation still occurs with delays as long as 5000 ms (Honda et al. 2012, Kitazawa et al. 1995, Tanaka et al. 2011). In other words, even in conditions where error assignment favors external factors, limb motor learning is relatively robust. For sensorimotor control of speech articulation, on the other hand, we have previously reported that auditory-motor adaptation to formant-shifted feedback is completely eliminated with delays of 100 ms or more (Max & Maffett 2015). Here, we test whether -- similar to visuomotor adaptation (e.g., Honda et al., 2012) -- the detrimental effects of delayed feedback signals can be minimized by first letting subjects habituate to the delay. Three groups of subjects completed an auditory-motor learning task in which a real-time vocal processor perturbed the subject's formant frequencies (i.e., speaker-specific resonance frequencies of the vocal tract) during the production of monosyllabic words (a manipulation known to induce an adaptive change in speech output). For the Control group, the formant-shifted feedback signal was delivered in real-time, but for the Habituation and Nonhabituation groups it was delayed by 75 ms. Prior to this adaptation task, each group completed 30 minutes of speaking tasks (word reading and picture naming): during these tasks, the Habituation group was already exposed to the 75 ms delay whereas the Nonhabituation group and Control group received only non-delayed feedback. All three groups showed adaptation in both the first and second formant. However, contrary to our hypotheses, the extent of adaptation was similar across all groups. Methodological differences between the present study and our previously published work may be key in understanding the effects of delayed feedback on sensorimotor adaptation in speech.

Title: Responses to brief mid-utterance formant perturbations in the auditory feedback of ongoing speech

Authors: *I. RAHARJO[1,2], H. KOTHARE[1], J. F. HOUDE[1], S. NAGARAJAN[1]
[1]UC San Francisco, San Francisco, CA; [2]UC Berkeley, Berkeley, CA

Abstract: We can hear and monitor different aspects of our speech to make sure it is produced with appropriate loudness, prosody, and clear vowels to convey the intended meaning. If our feedback does not match our expectations, i.e. different from the intended speech, we tend to compensate to 'fix' the speech we produce. In a lab setting, this compensation response has been investigated using two different perturbation scenarios. In one scenario, the perturbation is introduced unexpectedly and temporarily. This causes speakers to immediately respond (short term response). Often, these perturbations are initiated at utterance onset, which has been done for pitch and formant alterations. Perturbations can also be initiated at mid-utterance which has only been looked at for pitch and amplitude alterations, but not for formants. Furthermore, it has been shown that responses to onset and mid-utterance perturbations differ in the case of pitch alterations. However, whether similar differences would be seen in formant perturbations are unknown. In another scenario, if this 'unexpected' perturbation is repeated over and over again, the perturbation becomes expected and an adaptation will likely take place (long term response). Here we explored three questions. First, we examined compensation responses to transient mid-utterance formant perturbation. Second, we compare these responses with responses to formant perturbations initiated at utterance onset. Third, we examined whether this compensation response is crucial for driving for formant adaptation. To examine formant perturbation responses, we applied a real-time shift of the first formant frequency (F1) to participants' utterance. The shifts performed were -100 Hz, +100 Hz, -50 Hz, and +50 Hz all equally distributed along with no perturbation trials. The shift is applied either for the whole trial at utterance onset or for only 400 ms after a jittered delay, while participants phonated the word 'head' (vowel /ɛ/) for 1.5 seconds. For the formant adaptation paradigm, we applied a constant F1 shift for several trials (preceded and followed by no perturbation trials) while participants phonated the word 'head' normally. This is repeated for each shift values that were used in the transient formant perturbation study.
We found that participants do compensate for mid-utterance formant perturbation. Their F1 response starts about 200ms after onset of formant perturbation. The peak magnitude of the response in both 100Hz and 50Hz (both polarities) is about 5 Hz. These results will be compared with the responses found from perturbations at utterance onset and to the adaptation response to consistent formant perturbation.

Title: Speech auditory-motor learning: Are adaptation and de-adaptation similarly affected by practice schedule?

Authors: *K. S. KIM[1], *K. S. KIM[1], T. MITSUYA[1], L. MAX[1,2]
[1]Speech and Hearing Sci., Univ. of Washington, Seattle, WA; [2]Haskins Labs., New Haven, CT

Abstract: Sensorimotor adaptation plays a critical role in learning, maintaining, and refining voluntary movements. Surprisingly, few research efforts have been directed at uncovering the processes that occur when—after a period of sensorimotor adaptation—the feedback alteration or movement perturbation is removed (de-adaptation). The lack of research attention for de-adaptation may be related to the fact that subjects' behavioral responses gradually return to their pre-perturbation form, and that this change in behavior is often interpreted as an expected "forgetting" of newly learned internal models. This interpretation is typically based on the claim that de-adaptation is a faster process than adaptation. For some tasks, however, the rate of de-adaptation is not faster than the rate of initial adaptation even though the former involves re-adjusting movement parameters so that they once again account for sensorimotor transformations that previously had been experienced for many years. In addition, for limb movements, de-adaptation can take longer in children than in adults—if de-adaptation represents forgetting, this result would mean that children have better motor memory retention than adults. Instead, it may be more likely that de-adaptation itself represents new sensorimotor learning. Hence, de-adaptation may be better conceptualized as requiring an active re-learning of the appropriate sensorimotor maps rather than a process of forgetting. Addressing this question for auditory-motor learning in speech production, we investigated adaptation and de-adaptation as a function of the number of practice trials versus the amount of practice time during the corresponding phases of the experiment. For example, fewer trials performed per period of time in the post-exposure phase should lead to faster/increased de-adaptation if this phenomenon reflects mainly forgetting but to slower and decreased de-adaptation if the phenomenon reflects active sensorimotor re-learning of the non-perturbed environment. Forty adult subjects produced target words in pre-exposure (baseline), exposure (adaptation), and post-exposure (de-adaptation) phases of the experiment. During the exposure phase, all formants in the real-time auditory feedback signal were shifted 250 cents up. Participants were randomly assigned to four groups which differed in the rate at which trials were produced (either 18/min or 6/min) during the

adaptation and de-adaptation phases. Presentation of the findings will focus on the dissociation of effects due to the number of practice trials versus the amount of practice time and implications for speech motor learning and forgetting.

Title: High gamma neural responses dissociate between the acoustic and linguistic analysis of temporal speech structure

Authors: *G. B. COGAN[1], J. M. PEARSON[2], M. M. HAGLUND[1], S. R. SINHA[3], T. OVERATH[2]
[1]Dept. of Neurosurg., [2]Duke Inst. for Brain Sci., [3]Dept. of Neurol., Duke Univ., Durham, NC

Abstract: Speech perception entails the mapping of the acoustic waveform to its linguistic representation. For this mapping to succeed, the speech signal needs to be tracked across a large temporal range at high temporal precision in order to decode linguistic units (e.g. phonemes, syllables, words). Here we test how cortical processing of such temporal speech structure is modulated by higher-order linguistic analysis. To control the temporal scale of analysis, we used a novel sound-quilting algorithm that controls acoustic structure at different temporal scales; using fMRI, we recently showed that activity in human superior temporal sulcus (STS) increases as a function of temporal scale in an unfamiliar language (Overath et al., 2015). To control the linguistic content, we constructed speech quilts from both familiar and foreign languages. This ensures that any changes at the signal-acoustics level affect both languages identically, while manipulating the linguistic percept differently. Thus, neural responses that vary as a function of segment length but are shared or similar across the two languages suggest analysis at the signal-acoustics level, whereas neural responses that differ based on language familiarity imply the presence of linguistic processing. Here, we recorded electrocorticography (ECoG) from electrodes placed over left temporal or fronto-temporal lobes in three patients who were undergoing pre-surgical monitoring for pharmacologically resistant epilepsy. Patients listened to 6 s long English or Korean speech, quilted with 30 ms or 960 ms segment lengths. Electrodes with significant auditory responses were initially assessed via a permutation test between the 1 s time window following sound onset compared to the pre-stimulus baseline. Neural signals were filtered between 70 and 150 Hz (high gamma) and the results were Bonferroni corrected for multiple comparisons across electrodes. 20/124 electrodes demonstrated a significant auditory response. Within these electrodes, a follow-up analysis showed that sustained high gamma

responses throughout the 6 s sounds showed a main effect of segment length (30 vs. 960 ms) in 85% (17/20), a main effect of Language (English, Korean) in 60% (12/20), and an interaction in 50% of auditory electrodes (10/20). Specifically, electrodes that showed an interaction generally displayed a larger increase in high gamma power as a function of segment length in English than in Korean. These results suggest that high gamma neural responses are a potential neural mechanism for tracking speech-specific temporal structure. Title: Reciprocal connections between oral motor and agranular insular cortices mediate the control of consummatory behaviors

Authors: *L. M. AMARANTE[1], M. S. CAETANO[2], M. LAUBACH[1]
[1]American Univ., Washington, DC; [2]Univ. Federal Do ABC, Santo André, Brazil

Abstract: Traditional intracortical microstimulation (ICMS) studies in rodent have shown a role for the medial and lateral agranular frontal cortex (AGm - also known as M2 - and AGl, respectively) in oral facial motor responses. Additionally, studies have shown that these areas are connected with brainstem regions involved in the representation of jaw opening and closing and tongue protrusion. These studies did not assess cortico-cortical connections among these areas and did not report ICMS results in behaving animals. We performed ICMS in behaving and anesthetized rats and confirmed the motor output of the jaw/tongue region from stimulating in the AGm and AGl, as found in previous studies. A higher level of stimulation was necessary to evoke movements in AGm compared to AGl, suggesting that the AGl acts as a primary motor cortex and AGm acts as a secondary motor cortex for orofacial behaviors. ICMS in AGm of awake rats disrupted consummatory licking. Staining for the immediate early gene c-fos after microstimulation revealed anatomical connections between the AGm and the agranular insular / lateral orbitofrontal (AI/LO) cortex, an area traditionally implicated in gustatory responses.

These findings led us to investigate the anatomical and functional connections between these cortical regions. Retrograde tracing using Cholera Toxin Subunit B revealed direct anatomical connections from AI/LO to rostral AGm. Multi-electrode recordings in the two cortical areas during a consummatory licking task showed coherent rhythmic activity at the licking frequency. The recordings also found evidence for phase locking of LFPs to the lick cycle. These signals encoded relative reward value when rats licked for higher and lower concentrations of sucrose. Directed coherence analysis showed that lick-entrained activity across the two cortical areas was driven by activity in the rostral AGm. Multivariate analyses found evidence for correlation between the AI/LO and the rostral part of AGm, as well as anti-correlation between the rostral and caudal AGm. These findings, together with results from our ICMS and anatomical studies, suggest that reciprocal interactions between AI/LO and the rostral part of AGm may form a cortical circuit for the control of orofacial consummatory behaviors. We are currently investigating the interaction of these areas (AGm to AGl, and AGm to AI/LO) through using optogenetic perturbations with paired multi-electrode recordings in these areas.

Title: How primary is primary motor cortex for the control of vocalization?

Authors: *C. M. CERKEVICH[1,2,3,4], P. L. STRICK[1,2,3,4]
[1]Systems Neurosci. Inst., [2]Neurobio., [3]Univ. of Pittsburgh Brain Inst., [4]Ctr. for the Neural Basis of Cognition, Univ. Pittsburgh Sch. Med., Pittsburgh, PA

Abstract: Laryngeal muscles play a critical role in enabling vocalization in monkeys and humans. Yet, we know surprisingly little about the areas of the cerebral cortex that are involved in the descending control of these muscles. Here we used retrograde transneuronal transport of rabies virus to identify the cortical areas that are most directly connected to the motoneurons of laryngeal muscles in the macaque. This approach identified five cortical areas as the major origin

of output to laryngeal muscles. Two of these areas are on the lateral surface of the hemisphere and include the primary motor cortex (M1) and a region that overlaps portions of ventral area 6 (6V) and the motor proisocortex (ProM). Three of these areas are on the medial wall of the hemisphere and include the supplementary motor area (SMA), the rostral cingulate motor area (CMAr) and the ventral cingulate motor area (CMAv). We totaled the surface area of cerebral cortex that is the origin of descending control over laryngeal muscles. Then, we assessed the relative contribution of each motor area to laryngeal control. This analysis showed that M1 makes the single largest contribution to laryngeal control (~40%). The next largest output originates from two areas: 6V/ProM (~20%) and CMAr (~20%). In fact, taken together, the output from these two areas is equal to or greater than that from M1. Significantly smaller output originates from the SMA (~10%) and the CMAv (~6%). These results indicate that the descending control over laryngeal muscles originates from multiple cortical motor areas in the frontal lobe. M1 is the single largest source of cortical control over laryngeal muscles. Even so, the majority of the descending control originates from cortical areas outside of M1.

Abstract: Humans posses the ability to segregate one speaker from another, even when there is no spatial separation between them. Invasive human neurophysiology studies have revealed a spectro-temporal representation of an attended speaker in non-primary auditory cortex (superior temporal gyrus; STG) that rapidly changes depending on the attentional focus of the listener. However, how such a representation emerges in STG is unknown. In addition, the representation of speech in primary auditory areas (Heschl's gyri; HG) remains unexplored due to their inaccessibility from the surface. Here, we used invasive depth electrodes and surface recordings

to investigate the neural encoding of attended speech along the auditory cortical pathway. Subjects listened to a male and female speaker, both in isolation (single-speaker; S-S), and mixed together (multi-speaker; M-S), with no spatial separation between them. To characterize the tuning properties of each electrode site, we obtained their spectro-temporal receptive field (STRF). Electrodes in HG tended to respond at short latencies (~50 to 150ms) and were narrowly tuned, with some electrodes responsive to speaker-specific features (e.g., the fundamental frequency of the male speaker). These electrode sites retained this speaker-selectivity, even when that speaker was not being attended to. Electrodes in STG responded at longer latencies (~150 to 300ms), were more broadly tuned, showed relatively little speaker-selectivity, and responded preferentially for the attended speaker. Comparing the STRFs from the S-S condition with the M-S condition, the tuning properties of HG electrodes remained similar, whereas electrodes in STG changed their tuning to enhance the attended speaker and suppress the unattended speaker. These results provide a descriptive account of how the acoustic features of attended and unattended speech are progressively processed along the auditory cortical pathway.

Title: Decoding human speech articulation by multi-scale signals recorded from human sensory-motor cortex

Authors: *K. IBAYASHI[1], N. KUNII[1], T. MATSUO[2], Y. ISHISHIA[1], S. SHIMADA[1], K. KAWAI[3], N. SAITO[1]
[1]Dept. of Neurosurg., Univ. of Tokyo, Grad. Sch. of Med., Tokyo, Japan; [2]Tokyo Metropolitan Neurolog. Hosp., Tokyo, Japan; [3]Jichi Med. Univ., Shimotsuke, Japan

Abstract: Recent studies on Brain Computer Interface (BCI) has been proving its applicability in the clinical scene to restore human ability. Among the neural signals obtained from intracranial recordings, Single/Multi unit activity (SUA/MUA), Local field potential (LFP) and ECoG (Electrocorticography) are usually used as the input for the decoders used in BCI. Each of

these signals represent different scales of neuronal populations, and has been proven to be a good candidate as an input signal for BCIs especially for the control of prosthetic limbs. Our objective in this study was to evaluate the combined use of these multi-scale neural signals which were simultaneously recorded from the human ventral sensory-motor cortex (vSMC) while articulating Japanese phoneme. We recorded neural activities from subjects with refractory epilepsy, who underwent intracranial electrode placement for the purpose of evaluating the epileptic foci. 6 subjects whose vSMC was included in the potential peri-epileptogenic zone, had an electrode consisting of 6 microneedle combined with 3 macroelectrodes ("hybrid electrode") placed over the vSMC. The task was to pronounce a single Japanese phoneme displayed on a monitor. Articulation related neuronal activity was simultaneously recorded from the macroelectrodes and the microneedles. A standard expectation maximization clustering was performed to obtain SUAs by Offline Sorter® (Plexon Inc., Dallas, Texas, U.S.A.). LFPs and ECoG signals underwent time-frequency analysis to obtain spectral power for various frequency bands (Delta, Theta, Alpha, Beta, Low Gamma, High Gamma, Ultra-High Gamma). Spike firing frequency derived from SUAs and multi-frequency spectral power derived from LFP/ECoG were input as the feature vector. We constructed multiclass classifier using SLR (Sparse Logistic Regression) to decode spoken phonemes. Decoding accuracy for 5 spoken vowels were highest when feature from multiple signals were combined, which was 59% when averaged across subjects. The electrode location that performed best was compatible with tongue/lip area of human vSMC.
Although there are rooms for improvement, our results suggest that the hybrid electrode has the potential in providing consistent significant decoding accuracy by simultaneously recording multi scale neural activities. The less invasiveness in its implantation procedure and a possible longevity could be an advantage in future application for constructing speech-assisting BCI.

Title: Oscillatory modulation during swallowing revealed by human electrocorticograms

Authors: *H. HASHIMOTO[1], M. HIRATA[2], S. KAMEDA[2], T. YANAGISAWA[2], S. OSHINO[1], H. KISHIMA[1], T. YOSHIMINE[2]

[1]Neurosurg., Osaka Univ., Suita-Shi, Japan; [2]Endowed Res. Dept. of Clin. Neuroengineering, Osaka University, Global Ctr. for Med. Engin. and Informatic, Suita-Shi, Japan

Abstract: Swallowing-related neural activity has been examined by non-invasive methods in human and there are several studies investigated by PET, TMS, NIRS, fMRI and MEG. We applied human electrocorticograms (ECoGs) to the analysis of swallowing-related neural activities. Four patients with intractable epilepsy participated in this study (4 females). In all cases, subdural electrodes were temporalily placed over the frontotemporal area. We injected 2 ml water bolus into their mouth by a syringe and asked them to swallow it at their own pace. Electroglottography (Laryngograph®) and a throat microphone were used to detect swallowing movement and timing. ECoG signals were measured using a 128-channel digital EEG system (EEG 2000; Nihon Koden, Japan) and digitized at a sampling rate of 1000 Hz. A 20 channel ECoG grid (5 × 4 contacts) which was placed over the caudolateral primary somatosensorymotor cortex was chosen for analysis. Fourier transformation and wavelet transformation were applied to ECoG signal. Power increase in the high frequency band (HFB, 76 - 100 Hz) appeared in the caudolateral pericentral gyrus, the frontal operculum and BA 43 during both swallowing preparation and execution. The power increase of BA 43 was strongest. Time-frequency plots of BA 43 demonstrated that high gamma band activity appeared from -1.0 s before swallowing corresponding to the preparation period and suddenly disappeared at 0.5 s after swallowing. At that time, there was no change in the low frequency band (LFB, 8-32 Hz), but LFB power increase was observed from 0.5 s after swallowing. High gamma band activities are more spatiotemporally focal than lower frequency activity and well reflect neural function. Therefore, high gamma band activity in BA 43 correlates with swallowing-related neural activities. High gamma band activity in BA 43 was observed within -1 to 0.5 s time interval which corresponded to swallowing preparation (-1 to 0 s) and oral phase (0 to 0.5 s). These phases are controlled voluntarily. High gamma band activity disappeared suddenly at 0.5 s and the activity transition from HFB to LFB was observed from 0.5s after swallowing. The involuntary swallowing starts from 0.5 s after swallowing execution and these periods are called pharyngeal and esophageal phase. This is the first reports that swallowing related high gamma activities were revealed. The switching of oscillatory modulation from HFB to LFB may reflect cerebral activity that converts voluntary swallowing into involuntary swallowing.

Title: Positive and negative BOLD contributions to speech production: An ICA approach

Authors: *V. L. GRACCO[1,2], H. OHASHI[1], N. BOURGUIGNON[3]
[1]Haskins Labs., New Haven, CT; [2]McGill Univ., Montreal, QC, Canada; [3]Ghent Univ., Ghent, Belgium

Abstract: Behavior reflects the engagement of distributed functional brain networks (FBN) that interact and overlap in reconfigurable ways. Here we focus on identifying the FBN engaged in the cognitive and sensorimotor processes underlying speech production. Our approach includes a detailed examination of the negative blood-oxygenation level dependent (BOLD) response (NBR) - a ubiquitous feature of all neural activity often associated with the default mode network. In contrast to the positive BOLD response (PBR) which has been associated with excitatory neural activity, the NBR appears to reflect suppressive operations. To understand the contribution of the PBR and NBR found in these networks during speech production, we used independent components analysis of fMRI data (ICA) to extract spatially distributed networks from global changes in the BOLD signal and examine their contribution to task manipulations and performance. We collected fMRI data from two speech production experiments in which speech was elicited under repetition conditions as well as word reading, picture naming and verb generation. We used these tasks to sample a range of control conditions from sensorimotor to cognitive. Speech production tasks engaged both task positive and task positive networks. General linear modeling and functional connectivity analyses were then applied to the ICA results to assess the functional contribution and interaction of the FBN supporting speech production. Several FBNs were identified in relation to specific tasks, together with several areas in which positive and negative BOLD signals overlap. Changes in functional connectivity within networks reflected flexible task positive and task negative interactions with task demands. Our results are consistent with a diverse and complex contribution of the PBR and NBR to speech production and to functional networks. These distributional characteristics of the positive and negative BOLD signals may reflect the consequence of excitatory and inhibitory interactions within and across these functional networks.

Title: Articulatory gesture encoding in human sensorimotor cortex during continuous speech production

Authors: *J. CHARTIER[1], G. K. ANUMANCHIPALLI[2], E. F. CHANG[2]
[1]Bioengineering, [2]Neurosurg., Univ. of California, San Francisco, San Francisco, CA

Abstract: To speak, we must coordinate over 100 muscles to precisely actuate our lips, jaw, tongue, larynx, and other vocal tract articulators. It is an extraordinary motor control feat, yet nearly all of us produce fluent speech. Our previous work focused on short consonant-vowel syllable production, and demonstrated that the human ventral sensorimotor cortex (vSMC) is functionally activated along somatotopic representations of articulators. However, natural continuous speech is far more complex and dynamic than single syllables because of co-articulation between adjacent segments and execution of motor plans over longer duration. To address this, we studied the encoding of kinematic properties in the human vSMC during natural sentence production. We recorded high-density intracranial electrocorticography signals, while speakers produced a set of sentences designed to cover all phonetic contexts in American English (MOCHA-TIMIT). We first developed a method to estimate vocal tract kinematic parameters from phonetic transcriptions and produced acoustics (acoustic-to-articulatory inversion). We then fit linear kinematic-trajectory models to each electrode using kinematic parameters to predict neural activity. We found single electrode encoding of dynamical representations of highly specific, coordinated out-and-back trajectories of articulators (e.g. tongue protrusion, lip closure, etc). Kinematic trajectories of electrodes clustered into four main categories differentiated by place of vocal tract constriction. Furthermore, electrodes in each trajectory category showed activations during the production of phonemes with similar places of articulation. Each trajectory category appeared to be spatially localized in the sensorimotor cortex. Lastly, the kinematic-trajectory model better explained electrode activity when compared against phoneme and single articulator representations. We have used natural continuous speech to demonstrate the neural representation of articulatory gestures in speech production.

Title: Cortical representation of articulatory gestures

Authors: *E. M. MUGLER[1], K. LIVESCU[4], M. C. TATE[2], J. W. TEMPLER[1], M. GOLDRICK[3], M. W. SLUTZKY[1]
[1]Neurol., [2]Neurolog. Surgery, [3]Linguistics, Northwestern Univ., Chicago, IL; [4]Toyota Technological Inst. at Chicago, Chicago, IL

Abstract: Speech is an important method of human communication. Despite decades of research, we do not completely understand the fundamental neural control of speech production. Current theories model speech production as a hierarchy, starting from sentences and phrases to words, syllables, speech sounds (phonemes) and - at the lowest level - the movements of speech articulator muscles to produce these sounds (articulatory gestures). We investigated the cortical representation of articulatory gestures and phonemes in speech motor, premotor, and inferior frontal cortices. We simultaneously recorded ECoG from M1v, PMv, and IFG (pars opercularis) and speech audio during single word utterances by human participants undergoing either functional mapping during awake craniotomies for resection of brain tumors or extra-operative monitoring for seizure localization. We manually labeled the onset of each phoneme and articulatory gesture. We analyzed the how cortical high gamma activity (70-300 Hz) varies with the context of phonemic and gestural events (i.e., co-articulation) in 9 subjects producing consonant-vowel-consonant words. The high gamma activity patterns across M1v and PMv did not change with position of the gesture within a word. In contrast, when aligned to phoneme onset, high gamma activity in M1v and PMv did vary with position within the word. We also used cortical activity to decode gestures and phonemes in each region. Combined M1v/PMv activity classified among all gestures with 65.6±5.5% accuracy (mean over subjects) and among all phonemes with 33.2±9.84% accuracy. Gestures were decoded significantly better than phonemes even after subtracting chance accuracy levels for each (paired t-test, $p = 5.2 \times 10^{-4}$). Our results indicate that primary motor and premotor areas more accurately represent gestures than phonemes. These findings suggest that the cortical control of speech production shares a common representation with that of other types of movement, such as arm and hand movements.

Title: Adaptive representation of noise and speech in human auditory cortex

Authors: *B. KHALIGHINEJAD[1,2], J. L. HERRERO[3,4], A. D. MEHTA[3,4], N. MESGARANI[2,1]
[1]Dept. Electrical Engineering, Columbia Univ., New York, NY; [2]Mortimer B. Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY; [3]Hofstra Northwell Sch. of Med., New York City, NY; [4]The Feinstein Inst. for Med. Res., New York City, NY

Abstract: Humans are experts at perceiving speech, even in the presence of interfering sound sources. Recent studies suggest that this perceptual ability may arise from a noise-invariant representation of speech in the auditory brain, resulting in several computational models to explain the robust encoding of stimulus. However, little is known about the dynamic properties of neural networks as the auditory system adapts to new noisy conditions.To understand the adaptation of auditory system during varying additive distortions, we recorded intracranial signals from four human subject who were implanted with high-density electrodes as a part of their clinical procedure. Subjects listened to continuous speech corrupted by additive background noise which changed randomly every three seconds to one of the four conditions of clean, bar, jet, and city noise.Analysis of the neural responses to the speech signal revealed an adaptation phase which lasted between 100 to 800 ms after the onset of noise change. This was also true for transitions from noisy to clean conditions. We investigated the encoding and representation of noise at each time point with respect to the transition time, and found that the representation of noise gradually degraded as subjects adapt to the new condition. Moreover, we examined the differences in spatial and correlation patterns between the adopted and non-adapted conditions, and found that correlation between activities of different brain regions increased during the adaptation phase.In addition, we show that current models of stimulus-response mapping fail to replicate the dynamic adaptation property of neural responses. To explore possible computations that could predict this dynamic response property, we implemented a cascade of Linear-Nonlinear models using a feed forward neural network. Incorporated a top-down adaptive mechanism that used the statistical structure of neural activation patterns allowed the model to replicate the temporal dynamic properties observed in the neural response at noise transitions. The proposed model thus offers insight into the biologically plausible computational mechanisms that can explain the robust speech perception observed in real-world hearing conditions.

Title: Real-time functional mapping assists electrical cortical stimulation to identify the eloquent cortex

Authors: *J. R. SWIFT[1,2], R. PRUECKL[3], C. KAPELLER[3], C. GUGER[3]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., Albany, NY; [2]g.tec neurotechnologies USA inc, Rensselaer, NY; [3]Guger Technologies OG, Schiedlberg, Austria

Abstract: In several clinical scenarios, there is a need for associating cortical regions with their respective body functions. This is particularly relevant in the course of surgical treatment of patients who suffer from brain tumor or drug-resistant epilepsy. To minimize post-surgical functional deficiencies, it is essential to establish a functional map of involved cortical areas prior to the surgical intervention. Cortical areas covering important body functions such as movement, sensation, receptive and expressive language are commonly subsumed as “eloquent cortex.”
Electrical cortical stimulation (ECS) is considered the gold standard for identifying the eloquent cortex. During an ECS mapping session, electrical pulses are injected into the patient’s brain, leading to reversible excitation or inhibition of body functions. Relating the symptoms to the stimulation site allows establishing a functional brain map. This is however a tedious process for the patient, including the risk of pain or seizures.
An alternative to ECS is passive real-time functional mapping (RTFM), which is based on the analysis of brain signals invasively recorded via electrocorticography (ECoG). During an RTFM session, the patient performs certain tasks (movement, listening, speaking) while cortical activation in the High-Gamma Band (above 50 Hz) is extracted simultaneously for all ECoG electrodes. A functional map is then available within minutes without any risk for the patient.
In this study, we test whether a prevenient RTFM can assist ECS mapping to reduce stimulation time and risk. Four epilepsy patients underwent clinical ECS mapping and volunteered for an RTFM session. During the latter, all patients performed hand movement, tongue movement, and listened to words. We evaluated whether the RTFM-guided ECS outperforms random guidance. Additionally, the potential reduction of required stimulations was calculated.
On average, 52 electrode pairs were stimulated, where on average 18.8 electrodes related to motor, sensory, or language-related functions. The number of stimulations potentially obsolete due to RTFM guidance was 20.7 electrodes on average (reduction by 39.8%). Even with the reduced number of stimulations, all electrodes that had originally been revealed, were still identified. The RTFM significantly improved the ECS protocol for all four subjects ($p < 0.05$).
Compared to plain ECS, the proposed combined approach considerably reduces the overall mapping time and effort as RTFM indicates potential stimulation targets and therefore provides effective guidance. We are confident that the presented system improves functional mapping in clinical practice.

Title: Reconstructing Mel-scaled spectrograms of speech from electrocorticography

Authors: *C. HERFF[1], G. D. JOHNSON[3], J. J. SHIH[5], D. J. KRUSIENSKI[4], T. SCHULTZ[2]
[1]Computer Sci., [2]Univ. of Bremen, Bremen, Germany; [4]Electrical & Computer Engin., [3]Old Dominion Univ., Norfolk, VA; [5]UC San Diego, San Diego, CA

Abstract: Remarkable progress in the decoding of speech aspects from neural recordings has been made in the last decade. The ultimate goal of restoring speech to severely disabled persons, however, is still far off. We use Electrocorticography (ECoG) to reconstruct the spectrogram of speech instead of classifying the speech process into discreet classes. In this study, ECoG activity was recorded during prompted speech from patients requiring surgical mapping for epilepsy treatment. While participant's spoke, ECoG and acoustic data were recorded simultaneously. Data was dissected into overlapping 50 ms long windows. The audio data was transferred into the frequency domain using Fast Fourier Transform. As human perception of frequencies is non-uniform, we scaled the spectrogram using the Mel-scale. To make the distribution of spectral power more Gaussian, we computed the logarithm of spectral coefficients. For the ECoG data, we extracted gamma power (70-170 Hz) for each channel and window. Brain process associated with speech production span a long duration prior to and after sound production. To capture this dynamic, neighboring feature vectors were stacked. Using regularized regression models, we show how the ECoG gamma activity can be directly mapped to the log mel-spectrograms. Our results show that the even simple regression approaches yield better than chance reconstruction of the speech spectrogram. This is an important step towards direct speech synthesis from brain activity.

Title: The neural correlates of lip movements during continuous speech for the development of speech neuroprosthetics

Authors: S. LESAJA[1], C. HERFF[3], G. JOHNSON[1], J. SHIH[4], T. SCHULTZ[3], *D. J. KRUSIENSKI[2]
[1]Biomed. Engin., [2]Electrical & Computer Engin., Old Dominion Univ., Norfolk, VA; [3]Computer Sci., Univ. of Bremen, Bremen, Germany; [4]UC San Diego, San Diego, CA

Abstract: Recent work has shown that it is possible to decode aspects of continuously-spoken speech from electrocorticographic (ECoG) signals recorded on the cortical surface. The ultimate objective is to develop a speech neuroprosthetic that can provide seamless, real-time synthesis of continuous speech directly from brain activity. The aim of this work is to investigate the neural correlates of speech-related lip movements from video recordings and to utilize this information in the development of improved decoding models. ECoG data have been collected from subjects undergoing clinical monitoring for epilepsy. The subjects performed a battery of speech tasks including modal and imagined continuous speech, as well as spontaneous modal and imagined speech via standard picture description and directed conversation tasks. The high gamma-band power (70-170 Hz) of ECoG was extracted and analyzed in conjunction with the recorded speech signals. From simultaneous video recordings, lip movement features (e.g., mouth opening height) were extracted using computer vision algorithms and correlated to the gamma-band activity at multiple time-lags. Preliminary analysis of the resulting spatio-temporal relationships between brain activity and lip movements will be presented.

Title: Decoding individual phonemes from ECoG neural responses using convolutional neural networks

Authors: *J. BEREZUTSKAYA, Z. V. FREUDENBURG, N. F. RAMSEY
Brain Ctr. Rudolf Magnus, Univ. of Utrecht, Utrecht, Netherlands

Abstract: Despite the large body of work on language decoding from the brain activity, it remains challenging to identify individual phonemes based on the neural responses. In the present study we used convolutional neural networks to decode classes of phonemes from the electrocorticography (ECoG) recordings. Four patients participated in an ECoG experiment. Each patient pronounced phonemes presented on the screen one by one. Four phonemes (/p/, /k/, /a/ and /u/) and a baseline rest condition were used. Microphone recordings of the patients pronouncing the phonemes were obtained simultaneously with the ECoG recordings. Each patient was implanted with a high density grid covering a mouth motor cortex. Gabor wavelet decomposition was used to extract high frequency band power signal from the raw ECoG data. Per patient the ECoG data were partitioned into trials. Each trial was defined as a [-0.5 - 1] s window around the voice onset (VO) of the phoneme. For the baseline condition the window was defined based on the cue onset. For decoding we constructed a 1D convolutional neural network (CNN) with one convolutional layer (32 filters) and a linear layer on top. The convolution was performed over time. Per patient the CNN was trained to predict the probability distribution over 5 classes (4 phonemes + rest) for each trial. In addition, for a number of patients we tested the CNN's capacity to identify these phonemes during a set of spoken words by applying the CNN using a sliding window over time. The CNN model showed significant decoding accuracy for the phoneme trials in all four patients: $a_1 = .8$, $a_2 = .54$, $a_3 = .81$ and $a_4 = .74$ (chance level = .2). The CNN decoding accuracy was comparable or better than the decoding accuracy obtained with a template match linear classifier ($\hat{a}_1 = .61$, $\hat{a}_2 = .36$, $\hat{a}_3 = .83$, $\hat{a}_4 = .61$). Per patient the decoding accuracy varied depending on the size and number of filters in the convolutional layer of the CNN. When tested on a continuous word pronunciation data, the CNN model reliably identified word periods vs rest. The exact phoneme decoding accuracy was moderate, due to presence of other phoneme classes the CNN had not been exposed to during the training. The CNN confused new phonemes with acoustically similar known classes: /b/ with /p/, /u:/ with /u/ and so on. In

the present study we trained a CNN to decode individual phonemes from the ECoG neural responses. In all patients the CNN model performed quite well on the neural data partitioned into phoneme trials. In addition, preliminary but promising results were obtained with identifying phonemes during a stream of spoken words. The results suggest that CNN analysis may facilitate decoding of spoken words from sensorimotor cortex.

Title: Topography of human motor speech area using externally recorded 12-20Hz beta peaks during articulatory movements and phoneme expression

Authors: *P. R. KENNEDY[1], T. LIMTOM[2], C. GAMBRELL[2], A. KIRILLOV[3]
[1]Neural Prosthetics, Neural Signals Inc, Duluth, GA; [2]Human Recording lab, Neural Signals Inc., Duluth, GA; [3]Neuroexplorer Inc, Houston, TX

Abstract: During our ongoing efforts to produce a near conversational rate speech prosthetic, we noticed that our locked-in subject produced 12-20 Hz beta peaks prior to the onset of covert speech (Sarmah and Kennedy 2013). Further studies in speaking adults demonstrated beta peaks at onset, offset and during inflection points in words or phrases (SFN Abstr. 2016). To investigate this further, we continue to record from the scalp over the motor speech area. This area was delineated by Bouchard and Chang using ECOG (2014), confirmed by functional MRI in PK, and further confirmed by cortical recording of single units related to articulatory movements, sensory responses and phonemes in PK. To determine if this topological map could be detected externally, we simultaneously record using four electrodes placed anterior and superior to the left ear. Recordings are made using CWE amplifiers at 200x gain and filtered between 1 Hz and 10 KHz. Data is archived on a Cygnus data recorder (at 10 KZ) and immediately digitized on a Neuralynx Cheetah software package using six continuous channel, four for the electrodes, one for speech and one for an event marker. Data is being analyzed using NEX (5.1 Neuroexplorer Inc. Texas, USA) with the assistance of Alex Kirillov, who wrote a script to assist in speeding up the analysis. To date, we have analyzed the six articulatory movements (jaw up and down, tongue protruded and retracted, cheeks pout out and retracted (grin). As these data show, these articulatory movements are differentially represented. With respect to the phonemes, the five vowel sounds and nine consonants are differentially displayed over this area, whether from the point of view of numbers of beta peaks or average amplitude of the beta peaks. We chose the vowels and consonants for analysis based on their articulatory

features such as fricatives, stops, nasals and so on. The aim of this project is to develop a simple speech prosthetic with a vocabulary restricted to 10 or 20 useful words distinguished on the basis of the timing of beta peak onsets, offsets and inflections points. In future studies, auditory feedback will be provided to the user so as to improve the consistency of the speech output and hence the beta peak patterns. These data suggest that a distributed pattern of beta peak production as well as the pattern found with a single electrode (SFN 2016) could be used to detect speech. This technique will be applied to locked-in subjects. The output from the recordings will be fed into a mobile phone loaded with an app that applies the beta detection and decoding software that drives words and phrases from the phone.

Education, Tokyo Gakugei Univ., Tokyo, Japan; [5]Dept. of Hlth. and Sports Sciences, Fac. of Education, Chiba Univ., Chiba City, Japan

Abstract: Fatigue is among the key factors determining practical motor performance in exercises of various durations, such as short and long distance categories in running, cycling, and skating. Recent studies showed that transcranial direct current stimulation (tDCS) to the leg area of the motor cortex could reduce fatigue and prolong time to exhaustion in submaximal cycling for ~6-

8 min, but it is unknown whether tDCS can improve motor performance for a wide range of exercise durations. Central fatigue, which is attributable to suboptimal central drive, is widely known to restrict motor output and gradually increase during both maximal and submaximal isometric force output. Therefore if central fatigue is involved with degradation of cycling performance, the effects of tDCS could differ depending on exercise duration. We therefore investigated how tDCS affects the power output in different durations of exhaustive cycling.We recruited 12 well-trained athletes. tDCS was applied with a stimulation electrode on the vertex and a reference electrode on the right forehead. tDCS was applied while the participants rested in a reclining chair. Three different stimulus polarities in stimulus electrode (i.e., anodal, cathodal, and sham) were tested. The stimulus intensity was 2 mA with 15-s ramp-up and -down periods. After 15 min of tDCS, the participants performed maximal effort sprint cycling for 8 s with a constant load (0.02 kp / kg body weight). The participants then performed an endurance cycling task involving submaximal, constant speed cycling until exhaustion. The load in this task started at 0.06 kp/ kg body weight and, after 5 min, increased in 0.5 kp steps every 3 min. In the endurance cycling task, anodal tDCS prolonged the time to exhaustion significantly more than cathodal or sham tDCS did. Anodal tDCS also resulted in significantly greater accumulative total power output than sham or cathodal tDCS did. In the sprint cycling task, neither anodal nor cathodal tDCS improved the peak or accumulative power relative to sham tDCS. Our findings showed that the effect of tDCS on cycling performance strongly depends on cycling duration and cycling type, with central fatigue progressing in different ways.

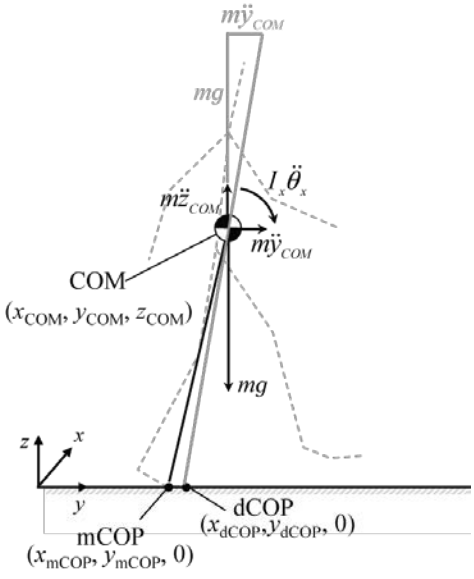
Title: Novel measure of dynamic balance during walking

Authors: J. YOO[1], T. YAMAGUCHI[2], M. SHINYA[3], M. MILOSEVIC[4], *K. MASANI[5,1]
[1]Inst. of Biomaterials and Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada; [2]Grad. Sch. of Engin., Tohoku Univ., Sendai, Japan; [3]Hiroshima Univ., Higashi-Hiroshima, Hiroshima, Japan; [4]Grad. Sch. of Arts and Sci., Univ. of Tokyo, Tokyo, Japan; [5]Toronto Rehab Inst., Toronto, ON, Canada

Abstract: In the control system of humanoid robots, the key for maintaining postural stability during walking is to control the center of pressure under the entire body (COP). One successful strategy is to control the feet placement by aiming to place the measured COP (mCOP) on top of

the desired COP (dCOP). dCOP is defined as a virtual point on the ground, where the moment around the body center of mass (COM) becomes zero when dCOP and the measured COP (mCOP) coincide (i.e., a modification of the Zero-Moment Point concept used in the Honda humanoid robot)(Figure). Here we investigated whether this concept can be used to assess dynamic balance of human gait. We measured the mCOP and COM behavior (i.e., displacement, velocity and acceleration) of fourteen healthy male subjects during walking on an instrumented treadmill, under four conditions with different dynamic stabilities: (1) natural walking, (2) walking with rhythmic auditory stimulation, (3) walking while performing a cognitive task, and (4) walking with arms restrained. Then the dCOP was calculated using COM behavior according to Eq. 1. In all conditions, the trajectories of dCOP and mCOP were highly correlated during each step. Also, the distance between dCOP and mCOP (dCOP-mCOP) was relatively small on average. These results suggest that dCOP approximately follows mCOP. The small distance between dCOP and mCOP (dCOP-mCOP), which is proportional to the rotational acceleration of COM, was statistically different among the four conditions. The stride interval variability, which is an established measure of dynamic balance, also differed among the four conditions. Further, we found that the dCOP-mCOP was also highly correlated with the stride variability. These results supported that the dCOP-mCOP may cause gait instability, which results in larger stride variability. In conclusion, we suggest that a control strategy successfully used in humanoid robotics using dCOP may represent the dynamic balance of human gait, and may be used to assess people with deteriorated gait such as neurological patients and the elderly.



For y direction

Eq. 1 $$y_{dCOP} = y_{COM} - \frac{\ddot{y}_{COM}}{\ddot{z}_{COM} + g} z_{COM}$$

Eq. 2 $$y_{dCOP} - y_{mCOP} = -\frac{I_x \ddot{\theta}_x}{m(\ddot{z}_{COM} + g)}$$

Title: Implicit manipulation of gait parameters by a visuomotor adaptation paradigm

Authors: ***K. YAMAMOTO**[1], T. IKEGAMI[2], M. HIRASHIMA[2]
[1]Grad. Sch. of Physical Educ., Natl. Inst. of Fitness and Sports In Kanoya, Kagoshima, Japan; [2]Natl. Inst. of Information and Communications Technol., Suita City, Osaka, Japan

Abstract: A central issue in human gait analysis is to manipulate gait parameters like gait speed, step width, or foot angle, and assess its effects on joint and muscle loads during gait. Most previous studies have investigated this issue by asking participants to explicitly modify these gait parameters. However, such explicit intervention often leads to some exaggerated or unnatural behavior at unspecified parts of the body. More critically, how much to modify the gait parameters is not properly controlled but depends on participants. Thus, explicit modification may not be appropriate to systematically manipulate gait parameters in human gait analysis. Here we propose a new methodology to use a visuomotor adaptation paradigm, which allows participants to implicitly modify gait parameters during gait. We constructed an elaborate experimental setup in which participants walk on a treadmill while viewing real-time visual feedback of their own movements through an avatar skeleton, which is scaled to each participant's body size and displayed on the front screen. The visual feedback was presented as a computer-generated motion of the avatar so that visuomotor discrepancy between actual and virtual body can be artificially added. In this study, we specifically examined whether participants can implicitly modify the "step width" (i.e., mediolateral distance between the heels in double support phase). Two parallel rails were displayed as a virtual walking road on the screen. The distance between the rails was fixed as a natural step width for each participant, which was recorded in advance without visual feedback. Five healthy males (22.2±1.48 yr) were asked to walk while viewing the avatar's motion so that each step of the avatar contacted on the corresponding rail (i.e., left step on left rail). During outward (inward) adaptation trials, in the first 5 minutes, we gradually added a visuomotor discrepancy whereby the avatar's step width was displayed to be smaller (larger) than the actual one by the participant. Then the visuomotor discrepancy was gradually returned to the original level, zero in the next 5 minutes. Our participants significantly increased or decreased their actual step width according to the

magnitude of discrepancy in outward ($F(4,2) = 19.7$, $p < 0.001$) or inward ($F(4,2) = 34.0$, $p < 0.001$) adaptation trials, respectively. Importantly, all participants were unaware of the visuomotor discrepancy applied on the step width. The result suggests that gradual visuomotor adaptation technique can implicitly guide human behavior, and thus is useful to systematically manipulate participants' gait kinematics without any deliberate motions.

Title: Biomechanical effects of differential limb-loading demands in the fore-aft direction on relative interlimb propulsion symmetry during walking

Authors: *A. NAIDU[1], C. P. HURT[2], D. A. BROWN[3]
[1]Rehabil. Sci., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Dept. of Physical therapy, [3]Physical Therapy, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: **PURPOSE:** Hemiparesis following stroke impairs paretic (P) limb-loading dynamics and propulsive-force generation during walking. By integrating a split-belt treadmill with a robot-assistive device, we have developed a novel method to differentially load one limb relative, specifically in the for-aft direction during walking. Our long-term goal is to develop a treadmill-based training paradigm to improve P limb propulsive-force generation and participation during walking. Hence, the purpose of this study is to measure the relative interlimb propulsion symmetry in nonimpaired individuals, engaged in walking in our novel robotic, split-belt, environment under differential limb-loading demands in the fore-aft direction. Results from these studies will be compared with a similar paradigm in individuals poststroke.
HYPOTHESIS: In nonimpaired individuals, a single limb working against greater fore-aft, limb-loading demands will comparatively increase its propulsive-force during walking due to greater proprioceptive load-feedback integration, causing interlimb-propulsion (IP) asymmetry.
METHODS: Nonimpaired individuals walked at tied-belt (TB) speeds (1m/s) within the robotic interface at different trunk inclination angles (IA) correlated with low, mid and high force effort, against the interface's pelvic mechanism. To induce differential limb-loading participants walked at the same IA's with belts split in a 2:1 split-belt (SB) speed ratio. Steady state kinetic

(propulsion) and kinematic data (stride length) for all trials was compared.
RESULTS/CONCLUSION: Data of 7 participants (Male:2, Mean age 28 ± 5 years) was analyzed at 2 TB and 4 SB differential conditions at low and high force effort, respectively. No difference in interlimb-propulsion impulse (i.e. time integral of propulsion) during TB conditions was seen. However, an 11% symmetrical increase was noted from low to high effort TB trials, respectively. During the SB-1 conditions (left=1 Right=0.5m/s), IP asymmetry increased from 2% at low effort to 17% at high force effort respectively, with greater propulsion by the right (slower moving) leg. IP asymmetry was also noted during the SB-2 conditions (left=1 Right=1.5m/s), with greater propulsion by the left (slower moving) leg from 0.3% at low effort to 11% at high force effort, respectively.
IMPLICATIONS: Results from this work will enhance mechanistic understanding of how differential fore-aft loading demands can influence individual-limb neuromuscular force responses during walking, in nonimpaired individuals. Potentially, these results can also be used to test new split-belt training paradigms for people poststroke.

Title: Balance and muscle activation patterns during sit-to-stand across four initial foot positions

Authors: *W. JEON[1], D. GUPTA[1], J. FENNELL[2], J. L. JENSEN[1], L. GRIFFIN[1]
[1]Kinesiology and Hlth. Educ., The Univ. of Texas At Austin, Austin, TX; [2]Univ. of Melbourne, Melbourne, Australia

Abstract: *Introduction:* A posterior foot position before the onset of sit-to-stand (STS) has been reported to have several kinetic advantages. Previous studies, however, have not assessed the ideal initial foot position (IFP) and its relationship to balance during STS. The purpose of this study was to investigate leg muscle activation patterns in 4 different symmetric IFP's (neutral; both knees at 90° flexion, and one-third, two-thirds and three-thirds of each participant's foot length posterior to neutral) and to examine the effects of IFP on maintaining balance after standing. *Methods:* EMG activity of 4 leg muscles (rectus femoris (RF), gastrocnemius (GAST), biceps femoris (BF), and gluteus maximus (GM)) during STS was measured in 10 healthy individuals and normalized to the EMG recorded during maximum voluntary contraction of each muscle. The standard deviation (SD) of the ground reaction force (GRF) (antero-posterior and

lateral) for 1 second after completing fully upright posture in 4 different IFP's was used to measure balance during the stabilization phase. *Results:* On average, EMG activity of RF and GAST increased as IFP moved posteriorly from neutral to three-thirds of the individual's foot length (21% to 35% and 11 to 21% EMGmax respectively), while BF and GM decreased (19 to 11% and 21 to 10% EMGmax respectively). The antero-posterior SD of GRF was the lowest at the posterior two-thirds IFP and was highest at the neutral IFP ($p < 0.05$). There was no difference in the lateral SD of GRF across the 4 IFP's. *Conclusion:* While there is a trade-off of leg extensor and thigh extensor muscles with changes in IFP, the posterior two-thirds foot length IFP is the most stable for maintaining balance during the stabilization phase before quiet standing.

Title: Movement dynamics associated with response strategies in running

Authors: *J. L. MCDONNELL[1], J. C. MIZELLE[2], T. R. DERRICK[4], S. MEARDON[3]
[2]Kinesiology, [3]Physical Therapy, [1]East Carolina Univ., Greenville, NC; [4]Kinesiology, Iowa State Univ., Ames, IA

Abstract: Introduction: Single subject analysis of movement strategies adopted throughout the acquisition of a motor tasks is imperative in understanding dynamic task performance. Specific footwear features, such as midsole hardness, elicit adaptive movement dynamics, allowing examination of response strategies. Degree of adaptation falls on a continuum between a mechanical response (MR) in which landing forces increase with harder midsoles and a neuromuscular response (NMR) in which forces are neutralized. Kinematics, kinetics, and individual characteristics associated with response strategies have not been evaluated in the context of internal model stability. The purpose of this study was to examine responses to footwear changes and potential explanatory factors.
Methods: 40 participants were categorized as either a mechanical (MR) or neuromuscular (NMR) responder based on the change in the rate of ankle joint contact force loading (ROL) across 3 midsole hardness conditions during running. MRs exhibited consistent reduction of the both the peak ankle joint contact force and ROL, with a softer midsole. Inversely, NMR did not display a change in force or ROL across footwear conditions. Group differences in variables thought to influence response strategy included: age, height, mass, sex, running pace, volume

and experience, injury history, foot mobility, joint and leg stiffness and somatosensation.
Results: 29 MR demonstrated an increased ROL with increased midsole hardness and 11 NMR exhibited no significant change in ROL across midsole hardness conditions. Of the demographic variables examined, only years of running experience differed between groups (MR: 8±3.5, NMR: 4.8 ±2.8). Further, both MR and NMR exhibited increased ankle stiffness as midsole hardness increased while only the NMR displayed decreased knee stiffness with increasing midsole hardness.
Discussion: Adopted motor strategies for different shoe material may be related to internal model stability. Repetitive execution of behavior generates persistent changes in kinematic and neurologic measures. The adherence to a movement pattern regardless of varying conditions suggests a stable internal model in which feedback and feedforward mechanisms maintain intended strategy of execution. Response strategies observed here may reflect the dynamical process of motor skill learning, where sensory-motor coupling can update an existing internal model to increase stability.
Conclusions: MR possessing significantly more years of experience, may reflect the influence of time on adaptive responses. Further analysis of jerk, a well-established indicator of motor adaptation is warranted.

Title: Contribution of lower limb joint movement to symmetrization of step length in split-belt locomotion

Authors: *K. HIRATA[1], T. KOKUBUN[2], H. YOKOYAMA[3], T. MIYAZAWA[4], K. KUBOTA[1], M. SONOO[1], H. HANAWA[1], N. KANEMURA[2]

Abstract: [Introduction] Most studies on the split-belt walking paradigm, in which two belts are driven independently of each other, were utilized as models to demonstrate the adaptability of human bipedal locomotion. Predictive feedforward mechanism was proved by the interlimb parameters, such as step length and double support time, changed slowly during adaptation

process, eventually acquiring symmetry. However, kinetic contribution to the symmetrization of step length has not yet been clarified. Step length is defined by the cosine theorem using the length of leading leg and its limb angle, and the length of trailing leg and its limb angle at heel strike. This study aims to investigate the contribution to step length about limb angle and lower limb joint angles (hip and knee joints). [Methods] Ten young adults walked on split-belt treadmill in symmetric and asymmetric conditions. In these conditions, we investigated the changes in limb angle, hip angle, knee angle, and step length at heel strike using Vicon motion capture system. All parameters were corrected three periods, which in symmetric conditions (baseline period), asymmetric conditions before adaptation (early adaptation period), and after adaptation (late adaptation period). The ratio from three periods were analyzed using ANOVA with repeated measures. Post-hoc analyses were performed using Tukey's honest significant difference test when the ANOVA yielded significant results. The statistical significance level for all measures was set as $p < .05$. [Results] Hip angle at heel strike on one side was not significantly different between the baseline and the late adaptation periods similar to the step length. In contrast, hip angle at heel strike on the other side, limb angles and knee joints showed significant differences between the baseline and the others periods ($p < .05$). [Discussion] In the present study, the symmetrization of the step length occurred as results of the limb angle of the fast leg increased and that of the slow leg decreased at heel strike on the fast side. Similarly, these of the limb angles on the slow leg decreased and those on the fast leg increased at heel strike on the slow side. However the limb angle was asymmetry at heel strike, the hip flexion angle was symmetry. Namely, the hip flexion movement could be predictively controlled similar to step length and double support time. Then, it is possible that the lower limb length could be extended to minimize the vertical movement of the center of gravity at the time of grounding by reducing the knee flexion movement derived from the hamstrings. In conclusion, the dynamic strategy of predictive feedforward control during locomotion was suggested.

Title: Retention of locomotor learning: Effects of practice duration and washout periods

Authors: *J. E. GALGIANI, S. M. MORTON
Physical Therapy, Univ. of Delaware, Newark, DE

Abstract: Locomotor adaptation has been studied extensively using the split-belt treadmill paradigm (i.e. where the two feet are driven at different speeds). The cerebellum has been shown to be an essential brain region responsible for the initial learning of the new split-belt walking pattern, but it is less clear what areas are responsible for its long-term retention. Likewise, although it has been postulated that shorter practice durations and use of a 'washout' period should lead to relatively reduced retention, evidence for this is not sufficient. Here, we exposed two groups of young, healthy adults to split-belt treadmill walking with the belt speeds at a 3:1 ratio. The SHORT group adapted for 5 minutes on Day 1 followed immediately by a 5 minute washout period in which they walked with the belts tied. The LONG group adapted for 15 minutes on Day 1 and had no washout period. We examined retention of the learned split-belt walking pattern (changes in step length symmetry) 24 hours later, when both groups returned to the lab and performed a 15 minute bout of split-belt walking. We hypothesized that on Day 2, the SHORT group would demonstrate reduced recall, relearning and overall retention of the walking pattern learned the previous day. Though the performance of the LONG group was better than the SHORT group at the end of adaptation on Day 1, surprisingly, we found that neither the shorter period of walking nor the completion of a washout immediately after learning reduced how well subjects in the SHORT group remembered the next day. That is, neither immediate recall, nor relearning, nor overall retention was different between the SHORT and LONG groups. This suggests that split-belt learning in healthy individuals is quite robust, and that it is possible to see retention with very little practice. Additionally, these data may warrant re-examination of the previous idea that retention is dependent on practice duration.

Title: Is it "pain, no gain" rather than "no pain, no gain" for motor learning?

Authors: *P. W. HODGES[1], S. E. SALOMONI[2], L. J. BOUYER[3]
[1]Univ. Queensland, Brisbane, Australia; [2]The Univ. of Queensland, Brisbane, Australia; [3]Rehabil. Dept- CIRRIS, Univ. Laval Fac Med., Quebec, QC, Canada

Abstract: Here we questioned the commonly accepted assumption that ***pain*** should be endured to make ***gains*** *in motor performance* - that is, “no pain, no gain”. The contrasting view is that pain may affect the ability to learn new motor skills and this is critical to resolve as it has implications for training sport skills in the presence of pain or developing movement strategies to overcome pain in rehabilitation. Limited evidence in humans shows contrasting results from major to no interference of pain on learning. Some also report compromised learning on subsequent training of the same task after pain resolution. We aimed to resolve this debate by studying the impact of task-related pain on learning during treadmill walking perturbed by a force field that pulls the leg up and forward. This requires compensation by early activation of knee flexor muscles to successfully overcome the perturbation and prevent falling. The task was performed on 2 consecutive days. On Day 1, electrical stimuli over the posterior thigh elicited pain with an intensity that was induced in a manner that was proportional to the degree of knee flexor muscle activity (Pain group N = 13; Control N = 14). The task was practiced again on Day 2 in the absence of pain. Kinematics of the lower limb were recorded with a three-dimensional motion analysis system (Vicon, USA) using a standard marker set. The novel force perturbation applied to the leg on Day 1 led to increased foot velocity compared to baseline walking and required several strides before an adaptation was learned to overcome the perturbation. Compared to pain-free walking, task-related pain reduced the overall performance (greater foot velocity) and led to a different adaptation of gait, with less optimal features such as a longer swing phase duration. This solution results in suboptimal performance, with greater active torque and potential for higher metabolic costs. This less ideal gait pattern was repeated when the task was practiced again 24 hours after pain exposure, despite the absence of pain. Our results show that pain does not prevent learning, but can modify the solution used to learn a new task. This modified solution is likely suboptimal and is retained during re-exposure to the same task, despite absence of pain. Our results indicate that the presence of pain limits gains in motor performance, contradicting the old adage of “no pain, no gain”. As far as learning a new motor skill and recovery of function are concerned, training through pain may not be ideal after all.

Title: Proximal-to-distal segmental sequence of toppling observed during human quiet standing

Authors: *S. SASAGAWA[1], A. IMURA[2]
[1]Dept. of Human Sciences, Kanagawa Univ., Yokohama, Kanagawa, Japan; [2]Dept. of Hlth. Promotion Sci., Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: Recent studies have shown that all major leg joints (i.e., ankle, knee, and hip) have significant contributions to the control of human standing balance (e.g., Yamamoto et al. 2015). However, what kinematic patterns exist among these joints is still unclear. In the present study, by focusing on "micro falls," which are characterized by destabilizing rise in velocity of the body's center of mass (CoM) and occur frequently during quiet standing (Loram et al. 2005), and by using time-locked averaging technique, we examined the kinematic patterns among the three leg joints. Ten healthy young participants were required to stand quietly on a force platform for 60-s with eyes open. The anterior-posterior (AP) position of the center of foot-pressure (CoP) was measured by a force platform. At the same time, the ankle, knee, and hip joint angles in the sagittal plane were calculated from the three-dimensional Cartesian coordinates of reflective markers attached to the characteristic points of the participants' body. By low-pass filtering the CoP data, the time-series of the AP position of the CoM was estimated (Caron et al. 1997). The CoM velocity and the CoM acceleration were obtained by single and double numerical differentiation of the position data, respectively. In the following analysis, we identified CoM velocity maxima (negative-going zero-crossing of CoM acceleration) for the averaging points at the center of the micro falls and averaged the kinematic data 1.0 s either side of these points to highlight the signal features. As a result, we found a proximal-to-distal sequence of forward toppling of the body segments during the micro falls; i.e., at first the hip starts flexing, then the knee extending, and finally the ankle dorsiflexing. With respect to the angular velocity maximum, the knee and ankle lags the hip by approximately 400 ms and 700 ms, respectively. To understand neural mechanisms behind such sequential toppling, further investigations focusing on muscle activities and/or joint torques are needed.

Title: Effects of motor fatigue on walking stability during concurrent cognitive challenges

Authors: *P.-C. KAO, M. A. PIERRO, K. BOORAS
Physical Therapy, Univ. of Massachusetts Lowell, Lowell, MA

Abstract: Cognitive-motor interference, a negative influence on the performance of one or both tasks, is manifested when simultaneously performing a cognitive task and a motor task. It has been shown that motor fatigue reduces neuromuscular performance such as a temporary decline in the ability of generating required force level. However, little is known about the effects of motor fatigue on the cognitive performance and more importantly, on the cognitive-motor dual-tasking performance, an important capability during our daily lives. The purpose of this study is to investigate how motor fatigue affects people's cognitive performance (e.g., information processing, working memory), motor performance (i.e., walking), and the performance in cognitive-motor dual tasking. We recorded kinematic data as subjects walked on a treadmill at 2.8 mph under three different conditions: walking only, while receiving the Paced Auditory Serial Addition Test (PASAT), and a modified color-word Stroop test before and after a submaximal muscle fatigue exercise session that includes leg presses, calf and toe raises. We quantified walking stability by computing dynamic margins of stability (MOS), gait variability, and short-term local divergence exponent (LDE) of the trunk motion. For dynamic MOS, we calculated the distances between the "velocity-adjusted" center of mass position and boundaries of base of support at heel strikes. The preliminary data of seven healthy young subjects show that subjects demonstrated significantly greater local instability ($p<0.05$) in the mediolateral trunk motion after the muscle fatigue session compared to the baseline. Subjects had significantly greater mean MOS_{AP} and mean MOS_{ML} after the muscle fatigue session by walking with greater step length and width compared to the baseline. In addition, subjects had significantly greater variability in the trunk motion, MOS, lower-extremity joint angels and spatiotemporal gait measures after muscle fatigue. During the dual-task conditions, subjects walked with similar local stability level but significantly less variability of knee and hip joint angles as well as less MOS variability compared to walking only, suggesting that subjects may try to control their foot placement and joint kinematics during walking. For the cognitive performance, there are no significant differences in the number of errors during the PASAT or the modified Stroop test before and after muscle fatigue. These preliminary data suggest that motor fatigue does not affect cognitive performance but motor performance under the cognitive-motor dual-task conditions in healthy young individuals.

Title: Locomotor learning "in the wild": Motorized shoes can induce split-belt-like adaptation over ground

Authors: *Y. AUCIE[1], X. ZHANG[2], R. SARGENT[2], G. TORRES OVIEDO[1]
[1]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]The Robotics Institute, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: There is a clinical interest to correct step length asymmetry post-stroke (i.e., limp) because it impairs patients' mobility. Promising studies have shown that stroke survivors recover gait symmetry after walking on a split-belt treadmill that augments their step asymmetry by moving the legs at different speeds. However, the transfer of gait improvements to over ground walking is limited. We hypothesize that gait improvements would be more general if we could induce locomotor learning by augmenting step asymmetry like split-belt treadmills while walking over ground. Thus, we developed motorized shoes, called Nimbus, that can move the legs at different speeds while walking over ground. In this study, we determined if the Nimbus shoes could induce similar gait adaptation effects to those observed on the split-belt treadmill. Thus, we compared walking kinematics between subjects wearing the Nimbus shoes on a regular treadmill (n=8) vs. subjects wearing regular shoes on a split-belt treadmill (n=9). Both groups experienced an adaptation period when the legs move at different speeds (3:1 speed ratio). Positions from the ankle and the hip were collected bilaterally and used to compute step length, step position, and step time asymmetry, which are known to adapt during split-belt walking. These parameters were used to contrast between groups 1) the extent of adaptation (i.e., changes in gait from early to late adaptation) and 2) the magnitude of after-effects (i.e., changes in gait before and after the adaptation period). We found that subjects in both groups adapted their gait as shown by the changes in behavior from early to late adaptation. However, the extent of adaptation was smaller in the Nimbus than split-belt group in step position (step asymmetry $p=0.104$; step position: 0.036; step time $p=0.863$) likely due to the smaller velocity differences in the Nimbus than split- belt group (Step velocity: $p<0.001$). Importantly, subjects from both groups had after-effects in all parameters except for step time in the split-belt group, as shown by the significant differences in behavior before and after the adaptation phase (step asymmetry: Nimbus $p<0.001$, split-belt $p<0.001$; step position: Nimbus $p<0.001$, split-belt $p<0.001$; and step time: Nimbus $p=0.003$; split-belt $p=0.172$). This indicates longer lasting after-effects in gait timing in the nimbus group than the split-belt group. In sum, our results demonstrate that the Nimbus shoes are portable devices that can induce error-based locomotor learning comparable to split-belt walking but outside the laboratory, which holds the great promise of improving patients' gait during real- life situations beyond the clinic.

Abstract: Gait adaptation on split-belt treadmills provides insights on the underlying control structure for walking. For example, observations on infants and adults walking on split-belt treadmills with various speed configurations have led to a consensus that the locomotion controller consists of separate functional networks for each leg and for different locomotion modes (e.g., forward vs. backward walking). However, most of the interpretations of these experiments are based on an assumption that the spinal motor circuits are governed by central pattern generators (CPGs). Here, we investigate the possibility that humans adapt their gait without CPGs. In other words, we evaluated the extent to which human gait adaptation on split-belt treadmills moving the legs at different speeds can be reproduced in simulation by a spinal-reflex-based neuromechanical model, which consists of a network of spinal reflexes mediated by supraspinal control without CPGs. Our results show that the reflex-based neuromechanical model can successfully generate stable split-belt walking with one leg moving at 1.5 m/s and the other one at 0.5 m/s. Moreover, our preliminary results show that, when the reflex control parameters are optimized for minimum metabolic consumption, the model reproduces most of the stepping features observed in human split-belt treadmill walking. Specifically, we performed a one-sample t-test to find significant differences between the gait features of nine healthy subjects and those produced by our model and found that both the subjects and the model converged to the same step-position ($p=0.25$), step-time ($p=0.010$) and step-velocity ($p=0.056$). Interestingly, we found differences in the step length asymmetry reached by the simulation and the experimental results ($p<0.001$), suggesting that metabolic consumption may not be the only factor optimized in humans. We are currently investigating the effect of optimizing for different costs, including metabolic energy, muscle fatigue, and gait asymmetry, to explore the physiological basis of human gait adaptations upon sustained changes in the walking environment imposed by the split-belt treadmill. Once we identify the cost function driving locomotor learning, we will further investigate the contributions of individual reflex pathways in

the gait adaptation of the model. The findings will allow us to augment gait rehabilitation with devices such as the split-belt treadmill.

Title: Interference in locomotor adaptation

Authors: *A. SALATIELLO[1], G. TORRES-OVIEDO[2]
[1]Bioengineering, [2]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Split-belt treadmill walking, in which legs move at different speeds, can be used to improve patients' mobility by correcting their gait asymmetry (e.g. Reisman et al 2013). For this strategy to be effective it is necessary to maximize the *retention* of motor memories acquired during the training. In order to do so, it is important to know how motor memories learned within the same environment influence each other. In this study we specifically tested whether learning two locomotor patterns counteracting equal and opposite perturbations is possible or instead the memories *interfere* with one another. To this end we studied unimpaired subjects' ability to counteract the same perturbation twice after either experiencing an opposite perturbation in-between (interference group, n=8) or walking without any perturbation (savings group, n=8). Critically, unlike prior work (Malone et al 2011), we removed the opposing perturbation gradually to reduce the experienced errors known to reinforce the motor memory initially learned (Herzfeld et al. 2014). As a measure of error, we used step length asymmetry. We compared across groups 1) the change in initial error that subjects experienced when the perturbation was introduced, 2) the change in steady state value reached and 3) the percent change in adaptation rate. We found that while both groups had similar initial change in errors (and thus where similarly perturbed, p=0.69), and similar change in steady state values (indicating a comparable ability in facing the perturbation at steady state, p=0.11), the dynamics of adaptation were significantly different. In fact, the interference group re-adapted 38.27% slower (p=0.035, 95% bootstrap CI [3.52%, 80.99%]), whereas the savings group re-adapted as fast as during the first exposure. In sum, our results indicate that the memory of adapted walking patterns is subject to *interference* and that this memory can be reinforced by the errors experienced during de-adaptation. These findings can inform the design of more effective rehabilitation techniques to counteract step length asymmetry in stroke survivors.

Title: Treadmill versus overground body weight support training in stroke patients: Effects on coordination variability during walking

Authors: *M. L. CELESTINO[1,2], A. M. F. BARELA[1], G. L. GAMA[1], J. A. BARELA[1,3], R. E. A. VAN EMMERIK[2]

Abstract: Gait training with body weight support (BWS) system is commonly performed while walking on a treadmill during gait rehabilitation of patients with stroke. It is currently unknown how BWS training on differently surfaces (treadmill versus overground) affects coordination during walking. The aim of this study was to assess the effects of two different training protocols with BWS on gait intra-limb coordination variability of patients with stroke. Twenty-eight patients were recruited and were randomly assigned to two training groups: overground group (OG) and treadmill group (TM). They performed two evaluations of free overground walking: T0 (pre-training) and T1 (post-training). During the evaluations, a video system of movement capture (VICON) was used to obtain the kinematic data and reconstruct hip and knee joint angles for both paretic and non-paretic limbs. After the T0 evaluation, both groups participated in six weeks of training with BWS, three sessions per week (18 sessions). Vector coding was used to quantify intra-limb coordination between hip and knee joints of paretic and non-paretic sides. The key dependent variable was the coordination variability between stride cycles, derived from the mean phase angle between hip and knee joint angular changes. For both the paretic and non-paretic sides, there existed significant interactions between training group and evaluation, with the OG group increasing coordination variability after training (T0 to T1) and the TM group decreasing variability after training (p's $< .0001$). A similar interaction was found for the non-paretic limb during the swing phase, with higher variability on T1 for the OG and lower

variability on T1 for the TM group. No differences were observed for the swing phase on the paretic side. We conclude that the training with BWS on different surfaces impacts gait coordination differently; training overground with BWS improves gait adaptability in both paretic and non-paretic limbs, especially during the stance phase, as shown by increased coordinative variability. In contrast, training on a treadmill with BWS reduces coordinative variability and possibly gait adaptability during free overground walking.

Title: Learning and generalization of locomotor skills acquired during a virtual obstacle negotiation task

Authors: *A. KIM, J. M. FINLEY
USC, Los Angeles, CA

Abstract: Obstacle negotiation is an essential skill for everyday locomotor performance. Recent studies have demonstrated that obstacle negotiation can be trained in a goal-oriented manner by providing people with auditory feedback of errors between actual and desired levels of foot clearance. Although the performance of this skill can be improved within a single day of training, it remains to be seen how this type of locomotor skill is retained and generalized to over-ground walking. We developed a novel virtual obstacle negotiation task to assess how locomotor skills are learned in fully-immersive virtual environments and how this learning generalizes to obstacle negotiation in the real world. This study involved two visits on consecutive days. Day 1 began with an over-ground baseline where participants negotiated a single physical obstacle ten times (PRE). They then completed a treadmill-based, skill acquisition phase which involved stepping over 120 virtual obstacles viewed through a head-mounted display (Oculus Rift DK2). Participants were instructed to minimize the clearance between the foot and the obstacles during the crossing step. During acquisition, participants were provided with three types of auditory performance feedback: a pleasant sound when foot clearance was within a target range of 0-2 cm, an error sound whose frequency scaled with foot height when clearance was greater than 2 cm, and a failure sound following collisions with the obstacle. Generalization was assessed by repeating the over-ground baseline procedure (POST).

On Day 2, participants revisited the lab and completed one retention block of 40 virtual obstacles with no auditory feedback. We then assessed over-ground retention in the same manner as the generalization trials on the previous day. There was a significant improvement in performance during the acquisition period as participants reduced foot clearance from 6.0 ± 2.6 cm in Block 1 to 3.2±1.4 cm at the end of Block 3 on Day 1. We observed some forgetting on Day 2 as initial foot clearance increased 1.3±1.0 cm in the retention trial compared to the end of Day 1. However, compared to the initial foot clearance on Block 1, the initial foot clearance on Day 2 (4.5±1.7 cm) was lower. The improvements observed in the virtual environment also transferred to the real world. Clearance was reduced from 13.8 ± 2.9 cm during PRE to 9.6 ±1.2 cm during POST and some of this improvement was retained on Day 2 (10.7 ± 1.3 cm). Overall, these results extend previous work by demonstrating that obstacle negotiation skills can be learned and retained in VR, and also demonstrating that locomotor skills acquired in VR can be transferred to the real world.

Title: Regulation of whole-body angular momentum during adaptive locomotor learning

Authors: *S. PARK[1], J. M. FINLEY[2]
[1]Biokinesiology and Physical Therapy, [2]USC, Los Angeles, CA

Abstract: One of the primary challenges of bipedal locomotion is to transport our bodies through the environment without falling. Although we typically achieve this goal through the use of symmetric walking patterns, it is unclear if we actively vary asymmetry to maintain stability when adjusting to novel demands during walking. Here, we explore this possibility in the context of adaptation to walking on a split-belt treadmill. As people adjust to walking with the belts moving at different speeds, they gradually change their foot placement and timing to take steps of equal length. Although the acquisition of symmetry has been described as an error-based learning process, it is also possible that adaptation stems a desire to control whole-body dynamics to maintain balance. Therefore, we determined how whole-body dynamics are

regulated during split-belt adaptation, and how this regulation is affected when stability is augmented by allowing participants to hold on to a handrail.
Participants adapted to walking on a split-belt treadmill at a 3:1 belt speed ratio and we measured whole body dynamics using a full-body marker set. To characterize changes in whole-body balance during adaptation, we computed the angular momentum about the center of mass (CoM) and quantified how peak-to-peak angular momentum and integrated angular momentum were modified over the course of adaptation. We hypothesized that both measures of angular momentum would be reduced over the course of adaptation in parallel with changes in step length asymmetry. We further hypothesized that providing an external source of stability by holding on to handrails would reduce the range of whole-body angular momentum during both early and late adaptation.
We found that the peak-to-peak range of the whole-body angular momentum for each stride was increased during early adaptation compared to baseline and then decreased as people reduced step length asymmetry over the course of adaptation. Counter to our initial hypothesis, changes in the peak-to-peak range of angular momentum were consistent across stability conditions. These results indicate that regulation of the whole-body angular momentum was indeed perturbed by the imposed asymmetry during early adaptation and improved during adaptation. However, since there were no significant differences in adaptation or momentum control across stability conditions, control of whole body rotational dynamics does not appear to be a sensitive measure of the change in fall risk across stability conditions.

Title: The influence of objects in the peri-personal space on standing sway

Authors: M. A. BRYANTON[1], *K. K. FENRICH[2], J. E. MISIASZEK[2]
[1]Occup. Therapy, [2]Fac. of Rehabil. Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Background: The proximity of an object within an individual's peri-personal space has been previously documented to impact postural sway in healthy young adults. While some researchers suggest that improved postural stability occurs due increased optic flow, which provides greater online visual feedback of body sway, others suggest that a restriction of sway and shifting of center of pressure (COP) away from the object occurs to prevent contact with the

object regardless of the availability of vision. Aim: The purpose of this investigation was to evaluate both the effect of object proximity and positioning on COP sway characteristics with and without visual feedback. Methods: Participants were asked to stand quietly on a foam pad placed on a force platform, with feet shoulder width apart, for 90s. A cardboard wall (i.e. spatial restriction device (SRD)) adjusted to neck height was placed either directly in front, or to the side (left and right) of the participant, at two distances (10 and 20 cm relative to the 1st distal phalange for front placement or lateral edge of the foot for left/right placement). These 6 locations of the SRD were tested with eyes open (EO) and eyes closed (EC) for a total of 12 experimental conditions. Two additional trials without the SRD were also performed to characterize baseline sway characteristics with EO or EC. Conditions were presented randomly across participants. Results: When vision was provided, the mean COP position tended to shift away from the SRD location. In addition, when the SRD was placed directly in front, preliminary results showed a marked reduction in COP sway area (EOF10: 56.8±22.5%; EOF20: 52.1±13.0%) and velocity (EOF10: 22.9±17.0%; EOF20: 19.4±15.2%). These pronounced effects on sway area and velocity were not apparent when the SRD was placed to either side of the participant. The placement of the SRD had no effect on sway parameters during EC trials, despite the participants being aware of the location of the SRD prior to closing their eyes. Discussion: These results indicate that objects in the peri-personal space reduce postural sway only when vision is provided. This suggests that either 1) the threat of contact with the object is not a critical influence in the control of standing sway, or 2) visual feedback is required to accurately estimate the location of objects in space. Regardless, these findings indicate that sway is influenced by the presence of objects in the peri-personal space, which may represent a simple means of introducing a progressive, adaptive training paradigm for standing balance control.

Title: Improvement of dynamic balance control by an exercise program

Authors: *D. SHIBATA
Univ. of New Mexico, Albuquerque, NM

Abstract: Central processing of multi-sensory feedback and motor commands responsible for force production are critical for balance control. An exercise program designed to realign spinal curvature was recently developed, but its effect on balance control is unknown. This study examined changes in center of gravity (CoG) sway on stable and unstable surfaces after completing the exercise program. Subjects (n = 27) were randomly assigned into one of three groups: exercise on a cylinder-shaped tube (StretchPole, LPN Corporation, Nagoya, Japan, Ex-SP group, n = 9), exercise on a flat surface (Ex-FS group, n = 9), and a control group that rested on a flat surface (n = 9). The exercise program consisted of three preparatory positions and seven small motions, and the session lasted approximately 15 mins. Subjects in the Ex-SP group performed the exercise program while lying on the cylinder-shaped tube, while those in the Ex-FS group performed the same exercise program lying on a flat surface. Subjects in the control group lay supine on a flat surface for 15 mins. Each subject's pre- and post-test CoG sway was measured while standing on a balance system platform (Biodex Medical Systems, Shirley, NY, USA) under a static and dynamic condition. Subjects were instructed to stand still and the platform was held stationary (e.g., no tilt) during the static condition. During the dynamic condition the platform was allowed to tilt in response to changes of CoG and subjects were instructed to maintain the platform in a horizontal position to the best of their ability. Subjects performed 5 trials of each test condition, for 20 s each. Two 2 □3 mixed-model ANOVAs were used to examine changes in average CoG sway and group differences. The hypotheses of this study were: a) the decrease in Ex-SP group CoG sway would be significantly greater than in the other two groups, and b) the decrease in CoG sway during the static platform test condition would be significantly larger than during the dynamic platform test condition.
There were no significant differences during the stable platform test condition. A significant interaction was observed during the dynamic platform test condition, and *post-hoc* analyses revealed that CoG sway significantly decreased in the Ex-SP group ($p < 0.05$), but there were no differences in the other two groups. These findings indicate that CoG sway significantly improved when completing the exercise program on a cylinder-shaped tube, but only when the standing surface was unstable. It is speculated that performing the exercise program on a cylinder-shaped tube might enhance central processing of sensory feedback, as well as the motor commands responsible for force production in balance control.

Title: Quantifying the non-linear properties of center of pressure patterns during different running styles

Authors: *C. D. BOWERSOCK, S. MORRISON, D. RUSSELL
Old Dominion Univ., Norfolk, VA

Abstract: Running is a popular mode of exercise used to meet recommended physical activity levels and sustain a healthy lifestyle. In order to better understand the benefits and disadvantages of different running styles, the majority of studies have focused on lower limb kinematics and/or kinetics. A less common approach has been to assess changes in center of pressure (COP) progression over successive steps during running. Given the current trend to utilize different running styles to decrease injury risk, consideration of how the COP structure may change during different running styles should be made. The aim of this study was to quantify the dynamic structure of three different running styles and identify the unique signatures of each. Specifically, we examined differences in basic spatiotemporal measures and COP measures using linear and non-linear analysis. Nineteen young active individuals without prior lower extremity injuries participated in the study. Each individual ran at a standardized speed under three different running conditions, namely; 1) preferred running style, 2) forefoot strike pattern and, 3) rearfoot strike pattern. All persons performed the task on a Zebris instrumented treadmill with an inbuilt pressure plate. A single 5-minute trial was performed for each condition with the COP and spatiotemporal measures recorded continuously for the trial duration. Standard linear analyses were used to quantify COP displacements, step length, stride time and cadence. Non-linear analyses included detrended fluctuation analysis (DFA) and approximate entropy (ApEn) to quantify the COP structure. The results revealed several differences between the three running styles. The forefoot condition was characterized by shorter COP path length, decreased stance times and increased cadence compared to the other two running patterns. The ApEn analysis revealed inherent differences between the three running patterns with regards to their pattern of regularity while no differences were observed for the DFA analysis. The DFA results produced values between 0.5 and 1 across the 3 running conditions, suggesting persistence in the COP structure irrespective of the point of initial contact. Several differences in the COP dynamics were observed between running styles using ApEn measures. In particular, the ApEn results revealed differences in the structure of the COP patterns, implying each running style possess its own unique COP signature. Together, the findings of this study highlight that assessing COP patterns during running provide insight to the dynamics underlying different running styles.

Title: Saccadic eye movements influence postural sway after fatiguing and stretching

Authors: *J. M. HONDZINSKI, M. A. YEOMANS, A. G. NELSON, M. J. MACLELLAN
Kinesiology, Sch. of Kinesiology; Louisiana State Univ., Baton Rouge, LA

Abstract: The purpose of this study was to better understand postural control declines that stem from muscular fatigue and provide insight into a possible mechanism to improve these declines. Fatigue can decrease muscle force and increase sway during quiet stance to diminish postural control compared to a non-fatigued state. In contrast, by performing saccadic eye movements during quiet stance, people can attenuate postural sway thus possibly improve postural control. We reasoned that saccades may also attenuate sway accompanying fatigued states and chose to test this in the present study. Barefooted young adults were asked to stand still on a force plate and either stare at a fixation point (FIX) or to perform saccadic eye movements (SAC) by viewing targets appearing alternately at 1 Hz on left and right sides of a computer screen at a 20 degree visual angle. Subjects performed 6 trials (3 FIX and 3 SAC) under non-fatigued (NF), plantar- and dorsi-flexed stretched (S), and plantar- and dorsi-flexed fatigued (F) conditions with either a wide or narrow base of support (BOS). We included S as a secondary condition, as it can decrease muscle force without fatigue. Performance of NF trials preceded S trials which preceded F trials. S involved rounds of passive unweighted dorsiflexion and plantarflexion immediately before performance of every two trials. F involved toe rises on a step until range of motion decreased below 75% or subjects could do no more prior to each trial. Analyses performed on several sway measures for the center of pressure revealed the following. When using a narrow BOS during FIX, S frequently attenuated sway and F often intensified or equaled sway compared to NF conditions, while use of saccades often attenuated sway. Outcomes varied by measures so that changes occurring with different conditions influenced sway in different directions. Moreover, the condition influences were not as evident with a wide BOS. Results of the present study match previous work which showed fatigue can deteriorate standing sway, yet contrast others which indicated that stretching also deteriorates standing sway. Differences for the latter can be explained by unilateral verses bilateral stance and/or the muscles stretched, as opposing muscles were stretched in the current study. However, changes in somatosensory feedback remain a candidate for altered postural control after fatiguing and stretching. These data also support the use of saccades to increase the external focus of attention to improve postural control. We conclude that saccades may improve postural control thus standing balance in populations susceptible to muscle fatigue.

Title: Analysis of kinematic synergy in arm swing during gai

Authors: *T. FUJINO, N. KANEMURA, T. KOKUBUN, K. KUBOTA, K. HIRATA, H. HANAWA, A. KOBAYASHI, K. TAKAYANAGI
Saitama Prefectural Univ., Koshigaya-Shi, Japan

Abstract: Kinematic synergy allows the movement of redundant joint systems in a coordinated manner. It is known that foot placement is stabilized by kinematic synergy of the lower limb joints during gait. Moreover, arm swing contributes to gait stability and energy efficiency. However, kinematic synergy of the upper limb joints is little understood. The purpose of this study is to investigate kinematic synergy in the arm swing during gait and to clarify on the basis of what synergy, is the arm swing during gait controlled. Eight healthy young male volunteers participated in this study. Arm swing movement was measured during self-selected gait velocity on a treadmill. Joint motions were measured using motion capture system and trunk segment angle on frontal and horizontal plane and elevation angles of body segments (upper arm, lower arm) on sagittal plane were calculated from measured motion. Each angular velocity was calculated by the first derivative of segment angles. In order to extract kinematic synergy, uncontrolled manifold (UCM) analysis was performed on important performance variables. Hand placements and velocities in anterior-posterior (AP) and superior-inferior (SI) directions were used as performance variables in the UCM analysis. The angle and angular velocities were set to elemental variables, and "good variance" (VUCM), which does not affect performance variables, and "bad variance" (VORT), which affects task performance variables, were calculated. ΔV, which is an index of synergy, was obtained from VUCM and VORT. The more positive ΔV, the stronger the synergy. Negative values suggest the absence of a stabilizing synergy. In the case where hand placement was taken as a performance variable, ΔV was negative value(AP:-0.39±0.05,SI:-0.47±0.15). There was no kinematic synergy that stabilizes step-by-step variations in both AP and SI directions. In contrast, ΔV was positive value(AP:0.08±0.02,SI:0.43±0.11), when using hand velocity as a performance variable, in both directions, the existence of kinematic synergy was observed. In arm swing during gait, it was suggested that there is a cooperative structure to stabilize variations in hand velocity. Hand velocity strongly reflect angular velocity of the upper extremity. Since the angular velocity of the upper limb is affected by the angular momentum of other segments, such as the trunk and lower limbs, the kinematic synergy restrains variance of the angular momentum, which may contribute to gait stability. These preliminary findings show that hand velocities during gait is controlled

more coordinative than hand placements and suggested possibility to more reflect control by central nervous system.

Title: Automatic unsupervised analysis of motor function by deep learning

Authors: *B. OMMER[1], B. BRATTOLI[1], U. BÜCHLER[1], A.-S. WAHL[2], M. E. SCHWAB[3]
[1]Heidelberg Univ., Heidelberg, Germany; [2]Brain Res. Institute, Univ. and ETH Zurich, Zuerich, Switzerland; [3]Univ. Zurich, Zurich, Switzerland

Abstract: Motor behavior analysis provides a crucial non-invasive and easily accessible diagnostic tool for biomedical research. A detailed analysis of posture changes during skilled motor tasks can reveal distinct functional deficits and their restoration during recovery. Our specific scenario is based on a neuroscientific study of rodents recovering from a large sensorimotor cortex stroke and skilled forelimb grasping is being recorded. Given large amounts of unlabeled videos that are recorded during such long-term studies, we seek an approach that captures fine-grained details of posture and its change during rehabilitation without costly manual supervision.
Therefore, we have developed a deep learning approach that utilizes self-supervision to train a convolutional neural network to analyze motor function. The underlying posture and behavior representations are automatically learned by having the convolutional neural network watch a large number of unlabeled grasping videos. Achieving this goal depends on the following fundamental contributions: (i) automatic limb detection based on a fully convolutional network that is initialized solely using motion information, (ii) a novel self-supervised training of long short term memory networks using only temporal permutation yields a detailed representation of behavior, and (iii) back-propagation of this sequence representation also improves the description of individual postures.
We have established a novel test dataset with expert annotations for evaluation of fine-grained behavior analysis. Moreover, we demonstrate the generality of our approach by successfully applying it to self-supervised learning of human posture on standard benchmark datasets.

Title: Contributions of pelvic roll to weight-supported locomotion in the neonatally spinalized rat

Authors: *J. VANLOOZEN, S. F. GISZTER
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Rats spinalized at T9/10 as neonates (P5/6) show recovery of hindlimb alternation as adults (NTX).Around 20% of animals show autonomous weight-supporting locomotion without therapeutic intervention. Utilizing robot-assisted treadmill-based rehabilitation based at the pelvis, some NTX animals increase the amount of weight-supported stepping across a 30-day training period. Previous work has demonstrated that expansion of trunk motor cortex is critical for NTX animals who learn to weight-support using the pelvic rehabilitation paradigm (Oza, 2015). Lesioning of trunk motor cortex in weight-supporting NTX animals reduces their ability to take weight-supported steps (Giszter, 2008).
Trunk motor cortex is likely of particular importance in spinal animals undergoing locomotor rehabilitation because it serves as a mechanical link between cortically-controlled upper trunk muscles and spinally-controlled areas under the lesion site. Further investigating the effects of locomotor training on pelvic roll can reveal mechanisms and effects of trunk motor cortex expansion in weight-supporting spinal animals. Kinematics were recorded from animals throughout robot-assisted treadmill training at the hip and ankle using OPTOTRAK 3020. Pelvic roll, pitch, yaw and translation and foot position across the step-cycle were used to correlate changes in biomechanics to changes in weight-supported stepping. Roll control seems especially important.
In animals that transition from low levels of weight-supported stepping (<50% WSS) to higher levels of weight-support (>50% WSS) (TWS NTX) we reduced pelvic roll precedes expansion of the hind-limb task-space; together these changes enable development of weight-supported stepping in NTX animals. In NTX animals beginning training at a high-level of weight-support pelvic roll remains stable with training, with minor limb representation expansion. Animals beginning training at a low level of weight-support that fail to increase weight-supported stepping with training do not stabilize pelvic roll either early or late in training. In some the hindlimb task-space was expanded, albeit non-functionally, without a reduction in pelvic roll so

that animals were unable to take weight-supported steps.
These data suggest that control of pelvic roll via trunk musculature is a critical component of successful locomotor rehabilitation in the NTX rat. Reduction in pelvic roll occured prior to expansion of the hindlimb limb task space in the TWS NTX, and suggests that rehabilitation of trunk control balance motor action components may be an important first step in locomotor rehabilitation of spinal animals.

Title: Adaptations of neural control to mediolateral perturbations of the patella

Authors: *F. BARROSO, C. ALESSANDRO, T. SANDERCOCK, M. TRESCH
Northwestern Univ., Chicago, IL

Abstract: Research on motor control is usually done considering task level variables, for example, by assessing how the central nervous system (CNS) produce joint torques that successfully accomplish desired behavioral goals such as stable locomotion. In this context, the activation of the quadriceps muscles vastus lateralis (VL) and vastus medialis (VM) produce similar knee joint torques. However, VL and VM produce opposite mediolateral patellar forces (internal joint variables), which may result in patellofemoral pain if muscle activations are not properly coordinated. Therefore, in addition to task variables, internal joint variables may be also controlled by the CNS to maintain the integrity of muscles and internal joint structures. In this poster, we will present preliminary results of a study that assessed the hypothesis that the balance of quadriceps muscles activation is altered when mediolateral patellar forces are unbalanced.
In order to apply a controlled mediolateral force on the patella, we implanted bone screws on the patella and the lateral aspect of the femur, and we secured a rubber band (spring) between them. The spring was detached two weeks after the initial implant. Kinematic (joint angles) and spatiotemporal parameters, as well as electromyography (EMG) patterns of VL and VM were analyzed during locomotion of three rats from baseline (before spring attachment) until one week after spring detachment.
In two of the rats, there was a decrease of VL activation after spring attachment, while VM activation maintained similar values. After detachment of the spring in these two rats, VL activation went back to baseline values, with little alteration in VM activation. In the third rat,

VM activation increased in response to spring attachment and went back to baseline values after detachment, while VL activation was similar all the time. These results are consistent with the hypothesis that the CNS regulates internal joint variables, countering the lateral patellar force by altering the balance between VM and VL activation. In addition to these alterations in muscle activations, spatiotemporal and kinematic parameters changed after spring attachment in the three rats. Most of the values went back to baseline values after spring detachment.
We are currently assessing two more rats. If the biomechanical and muscle activation analysis show similar results to those obtained for these three rats, that would strengthen our hypothesis that CNS alters the balance of quadriceps muscles activation when mediolateral patellar forces are unbalanced.

Title: Adaptation to quadriceps paralysis as a window into neural control of internal joint variables

Authors: *C. ALESSANDRO[1], B. RELLINGER[1], F. BARROSO[1], T. G. SANDERCOCK[1], M. C. TRESCH[2]
[1]Physiol. department, [2]Biomed. Eng, Physical Med. and Rehab, Physiol., Northwestern Univ., Chicago, IL

Abstract: Scientists have typically considered the question of how the central nervous system (CNS) determines motor commands in terms on task performance. In this context, muscle activations should generate joint torques that successfully accomplish the desired behavioral goal.
In our work we recognize that, in addition to task variables, muscle contractions also influence internal joint structures, leading to ligament strains and contact stresses. Poor regulation of these internal joint variables may cause pain and injuries. We therefore hypothesize that the CNS determines motor commands not only based on behavioral constraints, but also based on the need of maintaining joint integrity.
To test this hypothesis, we examine the neural control of quadriceps muscles acting at the rat knee. We show that activation of any quadriceps muscle lead to similar extension torques (task

variables). On the other hand, vastus medialis (VM) and vastus lateralis (VL), produce opposite mediolateral forces on the patella (internal joint variables). This renders the rat knee an ideal model to disambiguate a pure task-variable control, from a strategy that balances the actions of VM and VL to reduce contact stresses within the knee capsule.
In particular, such a conceptual simplicity allows us to formulate clear predictions on how the CNS may adapt to VL paralysis. One possibility may be to only increase the activity of VM. This strategy would be able to restore the lost knee extension torque, but it would produce unbalanced mediolateral forces on the patella. On the other hand, a control strategy that regulates both task and internal joint variables would increase both VM and RF, with a preference on RF, in order to minimize mediolateral patellar movements. Finally, since RF is a multi-articular muscle, a sole increase of RF activity would lead to extra hip flextion torque that would require additional compensation.
We paralyzed VL in a group of rats (n=6) by transecting the corresponding branch of the femoral nerve, and we observed the subsequent adaptation pattern. More than a week after VL paralysis, subjects showed partial recovery of baseline locomotor kinematics (before nerve cut). Their EMG activity patterns exhibited a large increase of RF, and a minimal increase of VM in all animals. These results support our hypothesis that the CNS regulates both task and internal joint variables. Additional experiments will be performed to validate these results, and to investigate the afferent signals that drive this mechanism. Establishing whether the CNS regulates internal joint variables would have impact on our interpretation of neural control of movements both in healthy and pathological subjects.

Title: Correlations between quadriceps muscles during locomotion in the rat

Authors: *M. C. TRESCH[1,3], C. ALESSANDRO[1], F. BARROSO[2]
[1]Biomed. Eng, Physical Med. and Rehab, Physiol., [2]Northwestern Univ., Chicago, IL; [3]Shirley Ryan AbilityLabs, Chicago, IL

Abstract: We have previously shown that in rats the quadriceps muscles vastus medialis (VM) and vastus lateralis (VL) produce very similar forces across the skeleton; when each muscle is

stimulated, the forces measured at the distal tibia are nearly identical. On the other hand, stimulation of VM and VL produces opposing mediolateral forces on the patella. As a consequence, unbalanced activation of these muscles would lead to a net mediolateral force on the patella, causing abnormal contact stresses against the patellar groove on the femur and potentially leading to patellofemoral pain or osteoarthritis. Thus, while VM and VL are synergists in terms of their contributions to task performance variables, they are antagonists in terms of their contributions to internal joint stresses.
We are evaluating whether the nervous system considers these contributions to joint variables when choosing muscle coordination patterns during behavior. In this study we consider the step to step correlations between quadriceps muscle activations during locomotion in rats. We hypothesized that if the nervous system regulated the net mediolateral forces on the patella, there should be a strong positive correlation between VM and VL; i.e. on steps where the activation of VM was high, the activation of VL should also be high in order to minimize any potential net mediolateral patellar force. The correlations between VM and VL to rectus femoris (RF) or to vastus intermedius (VI) might be weaker since those muscles should not produce substantial mediolateral patellar forces.
We therefore recorded quadriceps EMG activity during treadmill locomotion in rats. We examined only stance related EMG activity when all muscles were active, calculating the integrated EMG during each step. In 7 animals, we found that VM and VL were in fact strongly correlated while the correlation between these muscles and RF was considerably lower, consistent with the hypothesis that the nervous system balances mediolateral forces on the patella. We have also performed preliminary experiments in 2 animals recording activity from VI, finding a consistent strong correlation to VM, a less consistent correlation to VL, and a consistent weak correlation to RF. Taken together, these results support the hypothesis that the nervous system regulates quadriceps muscle activations in order to minimize mediolateral stresses on the patella. By coordinating VM and VL activations, the nervous system avoids development of abnormal mediolateral patellar forces. The preliminary observation here, that VI appears to be correlated with VM and, to a lesser extent VL, is harder to explain in terms of neural control of mediolateral forces.

Title: In pursuit of a generalized model of legged locomotion

Authors: *G. ANTONIAK[1], V. BHANDAWAT[1], T. BISWAS[2]
[1]Duke Univ., Durham, NC; [2]Loyola Univ., New Orleans, LA

Abstract: Legged locomotion is complex. However, center of mass (COM) movement is simpler and can be fit with simple mechanical models. The inverted pendulum (IP) and the spring-loaded inverted pendulum (SLIP) are two such models. While the IP and SLIP models have been successful in explaining the COM trajectory during walking and running, respectively, they have inherent limitations. IP and SLIP can only model the radial forces, which act along the length of the leg. They are not able to model the tangential forces, which act perpendicular to the leg. Thus, IP and SLIP cannot model cases in which the ground reaction force (GRF) does not directly act on the COM. Because of their inability to model the tangential forces, IP and SLIP do not possess a mechanism for modulating stance duration - the time that the leg is in contact with the ground. Their limitations are especially evident when applied to the locomotion of Drosophila melanogaster, which walks at slow size-specific speeds. The gravitational forces left unopposed by IP and SLIP would necessitate that the fly walk faster than is experimentally observed. The angular spring-loaded inverted pendulum (aSLIP) is a model that successfully describes the fly's locomotion. In aSLIP, an angular spring is added to the IP model. This spring resists motion away from the vertical position of the leg, which occurs at midstance. The angular spring serves as a mechanism of modelling tangential forces, which help to overcome the effects of gravity. By changing the stiffness of the spring, the stance duration of the organism can be tuned. The combination of aSLIP and SLIP successfully predicted the COM trajectory of the fly based on experimental data. This generalized SLIP (GSLIP) model is a likely candidate for a general model of locomotion over all speeds, since aSLIP is optimal for slower locomotion, and SLIP for faster locomotion. The generalizability of the model was evaluated by applying it to the locomotion of several animals including humans, where it predicted the characteristic vertical GRF during walking with a minimum occurring at midstance. Neither IP nor SLIP can predict this characteristic vertical GRF without the addition of transmission dynamics.

Title: The role of ankle extensors when adjusting to treadmill speed in chronic spinal cats

Authors: *J. HARNIE, C. CÔTÉ-SARRAZIN, M.-F. HURTEAU, Y. THIBAUDIER, C. DAMBREVILLE, E. DESROCHERS, A. DOELMAN, T. ROSS, A. TELONIO, A. FRIGON
Physiologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Modulating locomotor speed is critical for goal-oriented behaviors, requiring temporal and spatial kinematic adjustments in the gait pattern, as well as in the neural drive to muscles. Studies in spinal-transected cats have shown that adjustments to speed can be mediated by spinal locomotor circuits interacting with somatosensory feedback from the hindlimbs. However, how this is accomplished is poorly understood. To investigate the role of ankle extensors in controlling speed, we performed a unilateral denervation of the lateral gastrocnemius and soleus (LGS) muscles in spinal cats. Seven cats were implanted with electrodes to chronically record electromyography (EMG). The spinal cord was then transected at low thoracic levels and cats were trained to recover hindlimb locomotion. After stable hindlimb locomotion recovered, data (EMGs and kinematics) were collected at speeds ranging from 0.1 to 1.0 m/s in 0.1 m/s increments. The LGS nerve was then sectioned unilaterally. Data collection resumed 1-2 days later, up to 8 weeks post-denervation. All cats could step 1-2 days after denervation, albeit with some alterations in the pattern, particularly at slow and fast speeds. In some cats, paw placement was impaired at contact, with the digits curled into flexion. At the slowest speed of 0.1 m/s, the limb ipsilateral to the denervation consistently took two steps for every step of the contralateral limb in 5 cats. This 1:2 coupling between the contralateral and ipsilateral limbs was due to a more rostral position of the paw relative to the hip at the stance-to-swing transition. At the fastest speeds (0.9 m/s and 1.0 m/s), some cats had difficulty maintaining an alternating gait, transitioning to gallop. These alterations in the pattern gradually disappeared over time. The mean EMG amplitude of extensors generally increases linearly with speed. To investigate this modulation, we measured the regression coefficient (R^2) of the ipsilateral medial gastrocnemius (iMG) at 3 time points in 3 cats. The mean amplitude of iMG increased linearly with speed before denervation ($R^2 = 0.94$), whereas this modulation was lost 1-2 days after denervation ($R^2 = 0.01$) before returning 1-8 weeks later ($R^2 = 0.64$). The loss of modulation early after denervation was because of the relatively larger increase in iMG amplitude at slower speeds. The present results demonstrate that ankle extensor muscles play a major role in the control of hindlimb locomotion, particularly at slow and fast speeds, and that spinal circuits interacting with somatosensory feedback are capable of remarkable compensation when modulating locomotor speed.

Title: The modulation of forelimb and hindlimb muscle activity with increasing treadmill speed before and after an incomplete spinal cord injury in adult cats

Authors: *A. W. DOELMAN, T. ROSS, M.-F. HURTEAU, E. DESROCHERS, Y. THIBAUDIER, C. DAMBREVILLE, A. TELONIO, A. FRIGON
Physiologie-Pharmacologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: A change in speed is required for goal-oriented behaviors. The CNS modulates speed by controlling spinal motoneuronal outputs, which can be estimated during real movements by recording the electrical activity of muscles (EMG, electromyography). After an incomplete spinal cord injury (SCI), people often walk slower and have difficulty modulating their speed. Despite its importance, the modulation of motor outputs with increasing speed after incomplete SCI is poorly understood. The purpose of the present study was to investigate the modulation of EMG activity as a function of speed before and after an incomplete SCI in adult cats. Eight cats were chronically implanted with EMG electrodes in several fore- and hindlimb muscles. Data (EMGs and kinematics) were recorded during treadmill locomotion at speeds ranging from 0.4 to 1.0 m/s in 0.1 m/s increments. After obtaining data in the intact state, a lateral spinal hemisection was made at mid-thoracic levels on the right side. Recordings resumed 1 week later and up to 8 weeks after hemisection. After hemisection, cats were trained 5 times a week for 15-20 min to recover or maintain an adequate quadrupedal locomotion. Mean EMG amplitude generally increases linearly with speed during locomotion. To determine if this linear modulation was maintained or altered after SCI, we measured the regression coefficients (R^2) of selected muscles in all four limbs before, 1 week and 8 weeks post-hemisection. In hindlimb extensors (vastus lateralis or lateral gastrocnemius) contralateral to the hemisection (left hindlimb), the modulation of mean EMG amplitude was linear in the intact state ($R^2 = 0.92$). This linear modulation was lost 1 week after hemisection ($R^2 = 0.27$) but recovered 8 weeks later ($R^2 = 0.96$). In hindlimb extensors ipsilateral to the hemisection (right hindlimb), the linear modulation in the intact state ($R^2 = 0.96$) was also reduced 1 wk after hemisection ($R^2 = 0.42$) before returning at 8 wks ($R^2 = 0.85$). In forelimb extensors (triceps brachii), the linear modulation with speed was largely maintained with R^2 values ranging between 0.89 to 0.93 and 0.76 to 0.93 for the ipsilateral and contralateral forelimb, respectively. Therefore, these preliminary results suggest that the linear modulation of EMG amplitude in hindlimb extensor muscles is altered after a lateral spinal

hemisection and that it recovers over time, whereas the modulation in forelimb extensors is generally unaffected. Changes in the modulation of EMG amplitude in hindlimb extensors with speed could explain some of the deficits observed after hemisection, as well as provide clues regarding the impairment in modulating walking speed in people with incomplete SCI.

Title: The spinal control of hindlimb muscle synergies during locomotion

Authors: E. DESROCHERS, M.-F. HURTEAU, J. HARNIE, A. DOELMAN, A. TELONIO, *A. FRIGON
Dept. of Pharmacology-Physiology, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: The mammalian body is a highly complex system composed of a large number of elements (bones, joints, muscles) with multiple degrees of freedom. It has been proposed that the CNS simplifies the control of movement by co-activating groups of muscles with similar actions, termed muscle synergies. However, where in the CNS muscle synergies are controlled is poorly understood. The basic pattern of locomotion is produced by a network of neurons within the spinal cord called the central pattern generator (CPG). To determine if the spinal locomotor CPG coordinates muscle synergies, we obtained the electromyography (EMG) of several hindlimb muscles during locomotion in cats before and after a complete spinal transection. Two cats were trained to step on a treadmill at different speeds and implanted with electrodes for chronic EMG recordings. After obtaining data (EMG, kinematics) in the intact state at speeds ranging from 0.4 to 1.0 m/s, a spinal transection was made at low thoracic levels and cats were trained to recover hindlimb locomotion. Data collection resumed once the cats achieved stable hindlimb locomotion. To characterize muscle muscles synergies, EMG burst onsets and offsets were determined by visual inspection from the raw EMG waveforms using a custom-made program. A cluster analysis was then applied to group muscles based on their activation time (Krouchev et al. 2006 J Neurophysiol, 96: 1991-2010). In the intact state, we identified 5 muscle synergies that included two flexor and three extensor synergies. Flexor synergy 1 included the semitendinosus and semimembranosus, and was related to knee flexion. Flexor synergy 2 included the tensor fasciae latae, anterior sartorius, medial sartorius, tibialis anterior and extensor digitorum longus,

and was related to hip and ankle flexion. Extensor synergy 1 included peroneus longus, soleus and flexor digitorum longus, and was related to ankle extension. Extensor synergy 2 included flexor hallucis longus, medial gastrocnemius and plantaris, and was related to ankle extension. Extensor synergy 3 included vastus lateralis, vastus medialis, anterior biceps femoris and posterior biceps femoris, and was related to knee and hip extension. The same five synergies were present during hindlimb locomotion after spinal transection. Therefore, these preliminary results indicate that hindlimb muscle synergies during locomotion are primarily controlled by the spinal locomotor CPG interacting with somatosensory feedback from the periphery.

Title: Selective genetic ablation of adrenergic cells leads to dramatic and progressive motor control and metabolic deficits in adult mice

Authors: S. MANJA[1], A. OWJI[1], L. LINDO[1], J. ALTIER[2], K. ROBY[1], R. RASOOL[1], S. NANDINI[1], J. AYALA[4], S. KING[1], *S. N. EBERT[3]
[1]Biomed. Sci., [2]Med., [3]Burnett Sch. of Biomed. Sciences/College of Med., Univ. of Central Florida, Orlando, FL; [4]Sanford Burnham Prebys Med. Discovery Inst., Orlando, FL

Abstract: Phenylethanolamine N-methyltransferase (Pnmt) converts norepinephrine to epinephrine, and thus serves as a marker for adrenergic cells. To determine the roles of adrenergic cells *in vivo*, we created a novel mouse model by crossing *Pnmt-Cre* knock-in mice with *ROSA26-eGFP-DTA* mice resulting in expression of the *Diptheria Toxin A (DTA)* gene exclusively in Pnmt+ cells, leading to selective ablation of these cells due to DTA-induced apoptosis. *Pnmt-Cre/DTA* mice appeared relatively normal and healthy until they reached adult stages, but soon thereafter (2-3 months of age), began to exhibit labored and discoordinated gait movements, diminished grip strength, decreased nocturnal ambulatory activity, and inability to maintain balance on Rotorod and balance beam tests. Further testing revealed that hindlimb reflexes were significantly impaired relative to control mice as early as 1 month after birth. Remarkably, the *Pnmt-Cre/DTA* mice also failed to gain weight beyond 2-3 months of age despite no significant differences in food or water intake relative to age-matched sibling controls. Evaluation of body composition revealed that the lack of weight gain was likely due, in part, to lack of accumulation of fat and, to a lesser extent, lean body mass. None of these phenotypes were observed in control (*Pnmt-Cre* without *DTA*, or *ROSA26-eGFP-DTA* without *Cre*) mice,

nor were they observed in *Pnmt*$^{-/-}$ (knockout) mice lacking the ability to produce epinephrine. These results indicate that the observed motor and metabolic phenotypes are due to selective loss of adrenergic cells. To determine the cellular anatomical correlates of the motor and metabolic phenotypes observed, we are evaluating adrenergic-derived neurons in the cerebellum and hypothalamus, respectively, through immunofluorescent histochemistry and cellular fate-mapping experiments focused in these regions of the brain known to be important motor and metabolic control centers, respectively, where Pnmt expression has previously been observed. These studies offer exciting new and unexpected insights into the roles of adrenergic neurons in the CNS that could potentially lead to novel therapeutic strategies/targets for treating motor control and/or metabolic disorders.

Title: Injured corticospinal tracts prevented learning of split wheel walking in mice

Authors: *J. SONSINI[1], A. CHUGHTAI[2], Z. AHMED[1]
[1]Biol., Grad. Ctr. City Univ. of New York, New York, NY; [2]Biol., CUNY Col. of Staten Island, New York, NY

Abstract: Corticospinal tract (CST) damage is a cause of motor impairment in prevalent acquired neurologic conditions such as spinal cord injury and stroke. The CSTs are responsible for distal fine motor control used in precision gait (Lemon, 2008). Functional ambulation includes the ability to step in different directions. When quadrupeds or humans walk on a treadmill (TM) their limbs step in the opposite direction to the belt (Musienko, et al. 2012). In a hybrid condition, in which one belt moves forward and the other backward healthy adults can easily walk with their legs moving in opposite directions (Choi & Bastian, 2007). We sought to determine whether: 1.) mice could learn hybrid walking, 2.) connectivity patterns between motor cortices and sciatic nerves changed over learning 3.) CSTs are necessary for hybrid walking. We analyzed stepping strategies during hybrid walking coded from video using frame by frame analysis. Strategies were categorized into 6 types. Types 0-3 involved turning repeatedly or dragging limbs for 3 seconds or more, types 4-6 involved increasing levels of left/right and fore/hind limb coordination. Control and mice with histologically confirmed bilateral pyridomoty (Bpx) were examined in free and head restrained conditions before, during, and 4 weeks after an intensive training. Training consisted of walking on a custom made motorized

wheel in which one side of the wheel moved forward and the other backward at the same speed for 2 hrs/day for 10 days**.** We also analyzed gait during TM walking before and after hybrid training. To measure connectivity, 4 different structures were reciprocally tested: sensorimotor cortices and sciatic nerves. Control mice were able to learn and retain strategies 5-6 and never used strategies 0-3. Unrestrained control mice learned in 4 days of training; restrained who were prevented from turning or rearing learned within 2 hours. In contrast, all Bpx mice were never able to learn hybrid walking. Bpx animals never demonstrated stepping strategies types 4-6 and were unable to move their limbs opposite to the direction of the wheel. Before and after training, bPX mice performed TM walking with similar limb coordination as control mice but at slower speeds. Electrophysiological results showed changes in reciprocal connectivity between the involved sites. We concluded that intensive training is not sufficient for mice with Bpx to learn a complex locomotion skill such as hybrid walking. These results indicate that the CSTs are important for learning complex locomotion.

Title: Uncovering the structure of the mouse gait controller with mechanical and neural perturbations

Authors: *A. VAHEDIPOUR[1], P. SHAMBLE[2], O. MAGHSOUDI[1], M. SHORT[1], B. ROBERTSON[1], A. SPENCE[1]
[1]Bioengineering, Temple Univ., Philadelphia, PA; [2]FAS Ctr. for Systems Biol., Harvard Univ., Cambridge, MA

Abstract: Locomotion is essential to survival in most animals. Studies have shown that animals, including humans, choose a gait that minimizes the risk of injury and maximizes energetic efficiency. Individuals often encounter obstacles and perturbations during normal locomotion, from which they have to recover. Despite the importance of understanding the mechanisms that enable recovery from perturbations, ethical and experimental challenges have prevented full exploration of these in legged systems.
A powerful paradigm with which to tackle this difficulty would be the application of external and internal manipulation of the nervous system. These perturbations could target how gait is regulated and how the neural systems process sensory information to control locomotion during

an unexpected perturbation.
The study here presents data on the behavioral and gait response of mice to rapid, precisely timed, and spatially confined mechanical perturbation applied by a treadmill system. Our data elucidate that after the mechanical perturbation, the mouse gait control structure pushes away from the ideal trot to potentially less stable gaits, and mostly towards bounding. We quantified this shift by projecting the observed gait during each stride onto the line between trot and bound, in the space of quadrupedal gaits. We refer to the value of this projection as λ. For $\lambda = 0$, the gait is the ideal trot; for $\lambda = \pi$, it is the ideal bound. We found that the substrate perturbation caused a significant shift in λ towards bound during the stride in which the perturbation occurred (linear mixed effects model: $\Delta\lambda = 0.14 \pm 0.07$; random effect for animal, $p = 0.041$, $n = 8$ mice). We hypothesize that this is because the bounding gait is better suited to rapid acceleration or deceleration; absorbing or injecting kinetic energy. To determine if the gait shift from trot towards bound is a result of a fear response rather than a response to the mechanical stimulus of the substrate perturbation, we will carry out control experiments using a predator odor as a fearful stimulus.
To evaluate whether the same structure of gait controller exists when undergoing an entirely different class of manipulation, we will apply an internal, neuromuscular perturbation. We will directly stimulate the hamstring muscle using implanted electrodes and a custom magnetic headstage. If the same control structure generalizes across external and internal perturbations, then we expect a similar gait structure that prefers bound during recovery.

Title: Simulated cockroach walks in different directions at cockroach-like speeds and stepping frequencies

Authors: ***N. S. SZCZECINSKI**[1], S. E. RUBEO[1], R. E. RITZMANN[2], R. D. QUINN[3]
[2]Biol., [3]Mechanical and Aerospace Engin., [1]Case Western Reserve Univ., Cleveland, OH

Abstract: In this work, we refine a previously developed neuromechanical model of cockroach locomotion (Szczecinski et al. 2014, doi: 10.1007/s00422-013-0573-3). Our neural model contains about 1800 dynamical neurons and about 3300 synapses. The mechanical body has 30

actuated degrees of freedom, each with passive and active components. Each degree of freedom is actuated by an antagonistic pair of Hill muscles. Each pair of muscles has stretch and force feedback reflexes, a CPG that produces oscillation, leg position and force feedback pathways for coordinating inter-joint motion, and position and force feedback pathways for coordinated inter-leg stepping (gait). The model walks at cockroach-like speeds (20 cm/s) in a continuum of directions. This continuum is produced by sparse, abstract descending commands that alter motion only by altering leg-local reflexes (Martin et al. 2015, doi: 10.1016/j.cub.2015.09.044). A major challenge in building a useful model is picking parameter values that produce the intended dynamics. This poster presents a rapid method for selecting parameter values for the neurons, synapses and muscles of the model, totaling about 20,000 parameters. Rather than optimizing or evolving the parameter set that produces locomotion, we tune small, functional subnetworks, which when assembled produce the intended walking. Exploiting the structure of the nervous system to tune parameters eliminates dependence on black-box approaches that may capture animal behavior, but provide no insight into how the system functions.

Title: Hypoxia Ischemia mice show behavior deficiency on DigiGait and Intelicage behavior test

Authors: *C. XIE
CBR, Univ. of Goteborg, Stockholm, Sweden

Abstract: Background: Different tests were used to measure the behavior alternation after Hypoixa Ischemia (HI) on mice, but most of them are not suitable or sensitive enough. We aim to test two new HI behavior tests (DigiGait, Intelicage) and four other widely used behavior tests to find the most suitable tests for HI studies. **Method:** Male and female mice were subjected HI on postnatal 9 days**.** Injury was valued by infarction volume from MAP-2 staining**.** Six different behavior tests were used including DigiGait, Intelicage, Open field, Object recognition, Rotarod, and Elevate plus maze. **Result:** Intellicage showed HI mice performed less total visits and nose pokes and less incorrect visits ration and nose pokes ratio in both male and female mice. DigiGait show left and right fore paw perform differently in male mice. There is No difference between 2 groups in other behavior tests expect Rotarod test show HI mice have significant

lower riding time 31.08s compare with control group 54.92s (p=0.0029). **Conclusion:** Intelicage, DigiGait and Rotarod tests can clearly show difference between HI and control groups, while other tests have no difference. So Intelicage and DigiGait could be used as two new efficient behavior tests together with Rotarod when conducting HI mice studies.

Title: Specificity of excitatory spinal neurons involved in generation of rhythmic activity for locomotion

Authors: *A. E. TALPALAR[1], V. RIBEIRO CALDEIRA[1], T. I. TALPALAR[1], S. M. DYMECKI[2], O. KIEHN[1]
[1]Dept. Neuroscience, Karolinska Institutet, Stockholm, Sweden; [2]Harvard Med. Sch., Boston, MA

Abstract: Locomotion is characterized by repetitive activity of muscles that displace the body in space. The neurons, network structure, and mechanisms that give rise to rhythmic activity in the mammalian motor system are not fully understood. Glutamatergic Shox2- and Hb9-interneurons play an important role in rhythm-generation in mammals (Dougherty et al. 2013; Caldeira et al. 2017). However, experiments in vitro have shown that a minimal inhibitory network can also generate rhythmic activity in presence of drugs and absence of glutamatergic neurotransmission (Talpalar et al 2011). To resolve this apparent discrepancy, we studied the generation of rhythmic activity both in vitro and in vivo using mouse genetics, electrophysiology and behavioral methods. Inactivation of all spinal glutamatergic neurons allowed the production of drug-induced rhythmic-activity in vitro (n=12) but was associated with limb paralysis and lack of postural activity in vivo (n=14), indicating that excitatory neurons are necessary for locomotor function in intact animals. Inactivation of dorsal spinal glutamatergic interneurons produced ataxia and slow locomotion, but did not essentially change other locomotor features (n=7). Inactivation of subpopulations of neurons in particular the Shox2-derived glutamatergic neurons preserved locomotor pattern in vitro and in vivo but reduced its frequency (n= 7). Inactivation of

glutamatergic Hb9-interneurons preserved the production of in vitro rhythmic activity but lead to decline of hindlimb locomotor activity in vivo (n=5). We conclude that while the normal production of locomotor activity in vitro can be replaced by inhibitory networks that are appropriately activated by high concentrations of drugs this is not the case in vivo where spinal glutamatergic neurons are essential for locomotion. Shox2-interneurons are necessary for eliciting high but not low frequency locomotor activity in vivo. While glutamatergic Hb9-interneurons are essential for execution of rhythmic motor activity at all frequencies in in the hindlimbs but not the forelimbs. Together our results confirm that glutamatergic neurons are essential for rhythm generation in the mammalian spinal cord. Supported by NIH, VR and ERC.

Title: Computational modeling of interactions between cervical and lumbar CPG circuits in the rodent spinal cord *In vitro*

Authors: *N. A. SHEVTSOVA, S. M. DANNER, I. A. RYBAK
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The mammalian spinal cord contains central pattern generators (CPGs) that can produce locomotor-like activity in the absence of rhythmic inputs. In quadrupedal animals, each limb is controlled by a separate CPG. The CPGs controlling forelimbs are located in the cervical cord whereas the CPG controlling hindlimbs are located in the lumbar cord. Fictive locomotor activity evoked in the isolated spinal cord of rats by application of neuroactive drugs is characterized by left-right and flexor-extensor alternation in both cervical and lumbar compartments as well as by homolateral alternating and diagonal synchronized activity between the two compartments. Coordination between the left and right circuits in the spinal cord is mediated by excitatory and inhibitory commissural interneurons (CINs). Cervico-lumbar interactions are mediated by ascending and descending ipsi- and contralateral long propriospinal neuron (LPN) connections. If isolated from each other *in vitro* by sucrose blockade, the cervical and lumbar CPGs can independently generate locomotor activity at regular and similar

frequencies (Juvin et al. 2005). Selective activation of the lumbar cord induces coordinated rhythmic activity at the cervical level. In contrast, chemically activating the cervical cord cannot elicit lumbar locomotor activity (Juvin et al. 2005). Midsagittal lesions of the isolated cord at different levels showed that LPN connections contribute to the left-right coordination in fictive locomotion (Juvin et al. 2012; Cowley and Schmidt, 1997). To investigate the role of different LPNs in maintaining the left-right and cervical-lumbar coordination in fictive locomotion we extended our previous models of the spinal locomotor CPGs (Shevtsova et al. 2014; Danner et al. 2016) by incorporating LPNs in accordance with the recent experimental findings (Ruder et al. 2016). The model includes four RGs (left and right cervical and left and right lumbar). Each RG consists of the flexor and extensor half-centers mutually inhibiting each other. Coordination between the left and right RGs is provided by excitatory and inhibitory CINs, including excitatory $V0_V$ and V3 and inhibitory $V0_D$ CINs. Cervical-to-lumbar interactions involve excitatory ascending and excitatory and inhibitory descending LPNs. Our model reproduces the above experimental data and provides explanations for a series of experimental results, including the consequences of selective activation of cervical or lumbar CPGs and midsagittal lesions at different levels. The model provides important insights into the organization of spinal CPG and neural control of locomotion.

Title: Computational modeling study of the role of long propriospinal neurons in speed-dependent gait expression

Authors: S. M. DANNER, N. A. SHEVTSOVA, *I. A. RYBAK
Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: To effectively move in a complex and dynamic environment, limbed animals should vary locomotor speed and adapt gaits to the desired speed. With increasing speed, most quadrupedal animals, including mice, switch from walk to trot and then to gallop and bound. Centrally, the locomotor gaits are controlled by interactions between four central pattern generators (CPGs) located on the left and right sides of the lumbar and cervical enlargements of

the cord, and each producing rhythmic activity controlling one limb. The activity of CPGs are coordinated by commissural interneurons (CINs), projecting across the midline to the contralateral side of the cord, and by long propriospinal neurons (LPNs) that connect the cervical and lumbar CPG circuits in both directions. We use computational modeling to investigate how the LPN connections between the cervical and lumbar CPGs can be organized and what roles different LPN pathways can play in the control and speed-dependent expression of different gaits. Our model contains four rhythm generators (RGs) with left-right cervical and lumbar CIN interactions and homolateral and diagonal ascending and descending LPN interactions. These interactions are organized via several interneuronal pathways mediated by genetically identified neuron types and are based on their suggested functions and connectivity. Supra-spinal (brainstem) drives excite all RGs, thereby controlling oscillation frequency, and inhibit some CINs and LPNs, which allows the model to reproduce the speed-dependent gait transitions observed in the intact mice (Bellardita and Kiehn, 2015). The model reproduces the experimentally observed loss of particular gaits after selective removal of genetically identified neurons (V2a, $V0_V$, or all V0) and the speed-dependent disruption of hind limb coordination after deletion of ascending (cervical-to-lumbar) LPNs (Ruder et al. 2016). The model suggests that (1) $V0_D$ and $V0_V$ CINs together secure left-right alternation, whereas V3 CINs promote left-right synchronization, and that (2) $V0_D$ LPNs support diagonal alternation, whereas $V0_V$ LPNs promote diagonal synchronization. Thus, $V0_D$ CINs and LPNs together stabilize walk and $V0_V$ CINs and LPNs stabilize trot. The transition from trot to gallop and bound occurs when the activity of V3 CINs overcomes the activity of (brainstem-drive inhibited) $V0_V$ CINs and diagonal LPNs. The model proposes a series of testable predictions, including the anticipated effects of the deletion of ascending LPNs, and can be used for simulating various spinal cord perturbations and injuries including hemisections and contusions.

Title: Genetic dissection of the spinal locomotor circuit in DSCAM mutant mice

Authors: *L. THIRY[1], F. BRETZNER[2]
[1]CRCHUQ, Quebec, QC, Canada; [2]Psychiatrie et Neurosciences, CRCHUQ - Univ. Laval, Quebec, QC, Canada

Abstract: Recently, we have shown that a systemic mutation of DSCAM (Down Syndrome Associated Cell Adherence Molecule) induces anatomical and neurophysiological changes in spinal interneuronal and sensorimotor circuits, contributing to functional locomotor deficits. In order to genetically identify and characterize the neuronal populations underlying these functional changes, DSCAM expression was conditionally impaired in either excitatory or inhibitory neurons by back-crossing VGluT2-cre or vGAT-cre mice with DSCAMf/f mice. During fictive locomotion, neonatal VGluT2-cre;DSCAMf/f mutant spinal cords displayed a left-right synchronization of the ventral root activities, while the flexor-extensor alternation was preserved. Combining retrograde tracing and immunohistochemistry, we found that the number of excitatory spinal commissural interneurons was significantly increased in these neonatal mutant spinal cords. In contrast, the conditional mutation of DSCAM in inhibitory neurons, using VGAT-cre;DSCAMf/f spinal cords, was characterized by an increase in the number of inhibitory spinal commissural interneurons, associated to a normal left-right alternation but a significant reduction in the flexor-extensor coordination during neonatal fictive locomotion. In summary, our studies argue that conditional mutations of DSCAM in either excitatory or inhibitory spinal interneurons can impair different spinal locomotor circuits.

Title: V2a interneuron sub-circuits controlling the speed of locomotion

Authors: I. PALLUCCHI[1], J. SONG[1], K. AMPATZIS[1], J. AUSBORN[2], *A. EL MANIRA[1]
[1]Karolinska Inst., Stockholm, Sweden; [2]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Animals constantly adjust the speed and coordination of their movements to adapt to changes in the internal or external environment. Yet the circuit mechanisms underlying the change in speed of locomotion remain poorly understood. We have previously shown, in the adult zebrafish, that the spinal locomotor network is not uniform, but consists of three distinct microcircuit modules. These microcircuits comprise three subclasses of the premotor V2a excitatory interneurons which respectively drive the slow, intermediate and fast motor neurons. The speed of locomotion is thus increased through sequential activation of the three modules. However, the logic of V2a interneuron connectivity and how it mediates the precise control of locomotor speed has remained elusive. Here we reveal, using dual patch-clamp recordings in the adult zebrafish, the properties and connectivity pattern of the three V2a interneurons sub-circuits. Each sub-circuit comprises a functionally distinct V2a interneuron subtype forming a reciprocally interconnected excitatory network. Furthermore, V2a interneurons of adjacent sub-circuits display asymmetrical connectivity with higher connectivity probability and synaptic strength from faster to slower sub-circuits (e.g. intermediate to slow and fast to intermediate). A proportion of V2a interneurons within each sub-circuit display intrinsic bursting properties and their minimum bursting frequency directly correlates with their minimum recruitment frequency during locomotion. These intrinsically bursting V2a interneurons are unevenly distributed among the three sub-circuits with a greater number in the slow circuit. The intrinsic bursting properties combined with the connectivity pattern between V2a interneurons within and across sub-circuits may enable the transformation of tonic commands from the brain into rhythmic locomotor activity and increase in speed. Thus, our results reveal an excitatory circuit motif for generation of the locomotor rhythm and smooth change of speed.

Title: Connectivity analysis of multielectrode neural recordings using a stochastic framework

Authors: *M. ABOLFATH-BEYGI[1], T. D. SANGER[1], S. F. GISZTER[2]
[1]Dept. of Biomed. Engin., USC, Los Angeles, CA; [2]Dept Neurobiol & Anat, Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: We are developing a new methodology for connectivity analysis using a stochastic model along with neural perturbation. The mothod is based on stochastic dynamic operators (SDO) in order to quantify the inter-relations of neural dynamics. Current stimulation techniques for connectivity is based on pairwise neural perturbations. Our goal is to develop a methodology for discovering the connectivity map with the stimulation of much fewer neurons. Since the SDOs quantify uncertainty in the dynamics, we also aim to use this framework for discovering connectivity in the presence of uncertainty in high-level network behavior. The main purposes of developing this framework are detecting neural connectivity and developing predictive models suitable for neuroprostheses. The advantages of SDOs over current neural analysis and predictive models include: 1) its ability to describe state-based dynamic effects of neurons, 2) its methodolgy to embed nonlinear dynamics in a linear frameork, and 3) its capacity to extend pair-wise neural analysis to multi-neural analysis through linear superpositions. SDO is an operator triggered by neuron spikes that maps the probability of current state of movement to the probability of next state. An SDO thus represents both sensory and motor effects in the neuron. We use real neural data collected in spinal frogs, and artificial data from a simulated spinal network as a 'ground truth' network of known connectivity and hierarchy, driven by Hodgkin-Huxley dynamics. This network has been developed by Rybak, Shevtsova, and Markin for spinal cord simulation of populations of pattern generation neurons. The 'fictive' simulated network generates rhythms and motor pool spiking which can be integrated to simulate electromyographic (EMG) recordings. Previous tests on the simulated network validated the use of SDO-based predictive models of EMG as well as interneuron firing activities. Recently, our SDO-based technique for discovering connectivity have been tested on the simulated network. By periodic pulse perturbation of a single population, we are able to find the effective SDO of the perturbed population towards a target population for example a motorneuron pool. With the same data, we quantify the change in the firing patterns of all the other populations caused by perturbation as well as their SDOs towards the target population. Evaluation of these SDOs and the firing activity patterns showed that we are able to discover most of the neural pathways that connect the stimulated population to the target population. Therefore we conclude that the SDOs provide a promising mathematical model for understanding neural connectivity.

Title: Interconnectivity within a spinal locomotor rhythm generating interneurons in mouse

Authors: *N. HA[1], L. YAO[2], K. DOUGHERTY[1]
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ. Col. of Med., philadelphia, PA

Abstract: The central pattern generator (CPG) controlling hindlimb locomotion is located in the thoracolumbar spinal cord. Within the CPG, rhythm generating (RG) interneurons (INs) are responsible for the timing of the movements, providing the rhythmic drive to other downstream neurons in order to generate coordinated locomotor behavior. Recently, a class of INs that express the transcription factor Shox2 has been demonstrated to make up part of the rhythm generating kernel, along with other yet to be identified INs. Given the important function of RG Shox2 INs, detailed analysis of cellular and network properties can provide information about rhythmogenic mechanisms. Here, in order to investigate the interconnectivity between Shox2 INs, we performed whole cell paired recordings from identified Shox2 INs in dorsal horn removed preparations or spinal slices from Shox2::Cre ; Ai9 neonatal (P0-P5) mice. We found that both unidirectional and bidirectional synaptic coupling were present within subsets of the Shox2 IN population. The synaptic delay and shape of the excitatory postsynaptic potentials in unidirectional pairs of Shox2 INs suggested chemical synaptic transmission. Bidirectional coupling, however, was detected at a significantly higher rate. In bidirectional pairs of Shox2 INs, a gap junction blocker, but not glutamatergic receptor antagonists, efficiently abolished the connections, demonstrating exclusively electrical synapses. Similar to electrical synapses demonstrated in other systems, those between Shox2 INs acted as low-pass filters. Further, we examined the interconnectivity within the Shox2 IN population in more mature spinal networks, as electrical coupling may only be present at early postnatal stages. In juvenile mice (P13-P17), we found that electrical coupling persisted between Shox2 INs. Measured coupling coefficients, amplitudes of post-junctional current, and latency of post-junctional current delays were similar between neonate and juvenile age groups, indicating that the strength of electrical transmission did not decline. Experiments in the lab probing interconnectivity between Shox2 INs in slices from adolescent (P23-P29) and adult (>P60) mice are ongoing. Overall, our data demonstrate the presence of chemical transmission and electrical transmission within a subset of Shox2 INs with the latter detected at a higher incidence. We propose that electrical transmission is implicated as one of the mechanisms to promote synchronization of RG Shox2 INs.

Title: Distinct neural mechanisms underlie half center oscillators for homologous swimming behaviors of two sea slug species

Authors: *A. SAKURAI[1], P. S. KATZ[1,2]
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Dept. of Biol., Univ. of Massachusetts, Amherst, MA

Abstract: Rhythmic motor pattern generation often involves neurons with reciprocal inhibition forming a half-center oscillator (HCO). The central pattern generators (CPGs) for swimming in the nudibranch molluscs, *Dendronotus iris* and *Melibe leonina* are both organized as HCOs. Although a phylogenetic analysis indicates that the swimming behaviors are homologous, the synaptic organization of the CPGs are very different. In *Dendronotus*, the swim CPG consists of two pairs of reciprocally inhibitory neurons, Si2 and Si3. Si3 drives the contralateral Si2 through an excitatory synapse and electrical connection, causing them to burst nearly synchronously and in alternation with their contralateral counterparts. Here, we found that Si3 exhibited a hyperpolarization-activated slow inward current. We also found that Si2 had a recurrent inhibitory synapse to the contralateral Si3, which caused the Si3 spike rate to decrease during each burst of the swim motor pattern. Concurrently, the contralateral Si3 gradually depolarized because of the slow inward current activation. The transition of excitation occurred when Si3 escaped from the inhibition of the contralateral side.
In contrast, the *Melibe* swim CPG consists of four bilaterally symmetric swim interneurons (Si1-4), each forming reciprocal inhibition with its contralateral counterpart. The ipsilateral Si1, Si2, and contralateral Si4 are electrically coupled and together form the primary kernel of the HCO. We found no active membrane properties in these neurons that could provide the dynamics needed for rhythmic transition of excitation from one side to the other in the HCO. Instead, the transition was mediated by complex synaptic interactions between the primary kernel and Si3. During the swim motor pattern, a burst in neurons on one side of the primary kernel induced a burst in the contralateral Si3, which in return terminated the burst in the primary kernel. Cessation of bursting on one side of the kernel released the other half to fire a burst, which in turn terminated the ongoing Si3 burst. Thus, the two halves of the primary kernel and each Si3 generated rhythmic activity through a mechanism of recurrent cyclic inhibition. These results demonstrate that although the swimming behaviors are homologous and resemble each other, the neural mechanisms underlying the generation of bursting differ substantially.

Title: Multi-compartmental cardiac ganglion large cell model to study single cell and network outputs

Authors: *S. S. NAIR[1], D. C. WOOD[2], J. WANG[2], D. KICK[3], D. SCHULZ[3]
[1]Electrical & Computer Engin., Univ. of Missouri Columbia, Columbia, MO; [2]Biol. Engin., [3]Div. of Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: The crustacean cardiac ganglion (CG) network in *Cancer borealis* consists coordinates the rhythmic bursting of the heart muscle contractions to control the circulation of blood. Although the network consists only 9 cells, 5 ‘large cell’ motor neurons (LCs) and 4 small endogenous pacemaker cells (SCs), the role of the large cells with variable sets of conductances, in coordinating the features of the network rhythm remain unclear. We developed an improved multi-compartmental biophysical model for the LCs that better represents the morphology including locations of SC-LC synapses. The nominal model used reported conductance data including from our own current measurements. Earlier, we reported single cell model predictions about correlations among conductances that preserved LC response characteristics. The revised LC model is used to first investigate potential distributions of conductances in multiple compartments to preserve the same passive and current injections properties. The set of single LC models from such a study will then enable an investigation of correlations between maximal current conductances, both within a single compartment and across compartments that preserve response characteristics at the single LC level. These LC models with variable underlying conductances are then used in network models to study the effect of variations in the underlying conductances, and of the LC-SC feedback, on the features of the network rhythm.

Title: Balancing inhibitory and excitatory coupling in a multifunctional central pattern generator with slow and fast rhythms

Authors: J. R. P. GREEN[1], R. KHWAJA[2], A. N. KLISHKO[3], B. I. PRILUTSKY[4], *G. S. CYMBALYUK[2]
[1]Neurosci., [2]The Neurosci. Inst., Georgia State Univ., Atlanta, GA; [3]Sch. of Applied Physiology, Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA; [4]Georgia Inst. Technol., Atlanta, GA

Abstract: We have investigated whether mammalian central pattern generators (CPGs) could be multifunctional, controlling more than one functional rhythmic behavior. We constructed a model of a single CPG that controls both locomotor-like rhythm (1 Hz) and paw shake-like rhythm (10 Hz) in cats to propose general biophysical mechanisms, supporting vastly different rhythms of a multifunctional CPG. This model consists of four neurons: two inhibitory neurons carry reciprocal inhibition between two excitatory neurons. Each of these neurons represents a neuronal population in the cat CPG. The excitatory neurotransmission is conducted by NMDA and AMPA glutamatergic synaptic currents and the inhibitory neurotransmission is GABAergic and glycinergic. This model exhibits coexistence of the locomotor-like rhythm and the paw shake-like rhythm. The paw shake-like response can be elicited by applying an excitatory pulse of current in either the multistable model or a monostable model. The described mechanism of multistability provides various testable predictions about bursting dynamics throughout a paw shake-like response. These predictions were also tested in a corresponding population model, consisting of two inhibitory populations of 10 neurons each that carry reciprocal inhibition between two excitatory populations of 10 neurons each. The population model also exhibits coexistence of locomotor-like and paw shake-like rhythms and provides predictions consistent with the four neuron model. Our models predict that the flexor burst duration and the extensor interburst interval increase throughout a single paw shake-like response. Adult cats where trained to walk on a walkway using food reward. Hindlimb kinematics and muscle activity were recorded during walking and during paw shake responses; the latter were elicited in cats by attaching an adhesive tape on the hindpaw and letting the cat walk on a walkway. The cats performed paw-shake responses intermittently while walking, and each paw-shake response consisted of 4 to 10 cycles. We found that experimental results were consistent with model predictions. There was a progressive increase in EMG burst duration in consecutive paw-shake cycles for flexors and a progressive increase in EMG interburst interval for extensors. We concluded that a paw-shake response might be a transient response to sensory input to the locomotor CPG.

Title: Factors influencing beta-band motor unit coherence with changining force level

Authors: *L. M. MCMANUS, M. LOWERY
Univ. Col. Dublin, Dublin, Ireland

Abstract: Communication within the neural network may be reflected in the synchronization observed between spatially distinct neural oscillators. The synchronous discharge of motor units, particularly in the beta-band (15-30 Hz) frequency range, has been linked to oscillatory cortical and sub-cortical processes. A reduction in corticomuscular coherence and in synchronization between pairs of motor unit (MU) has been shown with increasing force [1,2]. We examined whether a systematic change occurred in the beta-band coherence among populations of MUs with changing muscle force in the first dorsal interosseous (FDI), and used a model of the motoneuron pool to explore the factors that could alter MU coherence [3].
Beta-band MU coherence was investigated in the FDI (N=6) where subjects increased their force from 20% to 35% MVC, or decreased it from 35% to 20% MVC, midway through a contraction (45s). Each subject performed both the increasing and decreasing force trial. Coherence in the was also investigated in the FDI muscle during separate contractions at 10% and 20%. Discriminable MUs were extracted from the surface EMG using decomposition algorithms (Delsys, Inc.).
In the trials with two force levels (20% and 35%MVC), pooled MU coherence in the beta-band decreased at the higher force level (-75±18%) and increased at the lower force level in all subjects (278±225%). Beta-band coherence was higher in contractions at 10%MVC (19±4) when compared to those at 20%MVC (13±7, $p<.05$). Model simulations suggest changes in both the proportion and strength of common inputs and in motoneuron firing rates could alter the resulting expression of synchronization and coherence among MU firing times.
In this study, beta-band intra-muscular coherence decreased at higher force levels. Several factors may be contributing to the observed reduction. Reduced synchronization of pre-synaptic inputs to the motoneuron pool, slight changes in the frequency of these inputs or in motoneuron firing rates could all alter the resulting expression of synchronization and coherence among MU firing times. In addition, it is possible that the relative strength of common synaptic inputs is weakened in the presence of higher excitatory drive to the motoneuron pool. A parallel increase in synaptic noise could also potentially decrease the synchronization between MU firings without

any change in the proportion of common input to the motor neuron pool.

Title: Common drive of motor units during dynamic activities of the upper-limb

Authors: *J. C. KLINE, P. CONTESSA, S. H. ROY, G. DE LUCA
Delsys, Inc, Natick, MA

Abstract: Studies of motor unit firing behavior have reported varying degrees of “common drive”, or correlated firing rates, depending on whether muscles are activated in synergist or antagonist contractions [1]. Although such studies of isometric muscle activity inform the control mechanisms that govern stationary contractions, there remains a need to determine how the central nervous systems regulates functional tasks of normal voluntary movement. Therefore, we employed recently developed surface electromyographic (sEMG) decomposition technology to investigate the activation of motor units during cyclic movements of the upper-limb. Non-invasive sensors recorded sEMG signals from extrinsic muscles of the hand and forearm during voluntary dynamic activities of opening and closing the hand or grasping different objects. The recorded sEMG signals were processed by algorithms to extract the action potentials and corresponding firing times of the active motor units [2]. The measured motor unit data were validated for accuracy and compared with the force, position and angular velocity of the fingers, hand and arm using the Trigno™ sensor system (Delsys, Inc. Natick, MA). Based on these data we observed that motor unit firing rates within each muscle: 1) were ordered in an inverse hierarchical relationship relative to the motor unit action potential amplitude as previously described by the “onion-skin” phenomenon; and 2) were correlated with respect one-another and with the output movement in accordance with the common drive [2]. When comparing these data across muscles we found that the firing rates of motor units from different muscles maintained a

relatively high degree of correlation across all activities. However, the latency of the firing rate correlation shifted depending on the activity being performed. When two muscles were coactivated as synergists, such as when grasping an object, the correlation of the motor unit firing rates manifested approximately zero latency. Yet when the same muscles were activated as antagonists the degree of correlation remained relatively high but the latency of the correlation increased. These data indicate that the central nervous system coordinates the synergist and antagonist activation of groups of muscles by regulating the latency of the common drive between the motor unit firing rates during different voluntary movements. This gives evidence to the importance of the common drive control scheme for regulating functional voluntary movement. References 1. **De Luca CJ, et al**. *J. Title: Influence of synergist muscle activation on motor unit firing behavior during fatigue

Authors: J. LETIZI, J. C. KLINE, *P. CONTESSA
Delsys Inc, Natick, MA

Abstract: Previous investigations have indicated that the neuromuscular system adapts by concurrently increasing motor unit firing rates and recruitment to sustain force production during fatigue [1]. This control scheme has been verified in the vastus lateralis muscle of the leg [1-2], but it has never been observed in the first dorsal interosseous (FDI) muscle of the hand, which is typically associated with decreasing motor unit firing rates with fatigue [3-4]. These contrasting reports raise questions as to whether the control scheme governing motor unit behavior during fatigue is altered across muscles, or whether other factors such as force compensation from synergist muscles may account for such differences. Therefore, we set out to investigate motor unit firing behavior during a fatigue protocol in the FDI muscle. Seven healthy (22-34 years old) subjects performed voluntary isometric contractions of the FDI sustained for 10 s at 50% maximal voluntary contraction force and repeated to the endurance limit. Motor unit action

potentials and firing times were extracted using surface electromyographic (sEMG) decomposition technology [5]. To monitor the contribution of synergist muscles to index finger abduction force we recorded sEMG signals from the Flexor Carpi Radialis, Extensor Carpi Radialis, Pronator Teres, and Flexor Carpi Ulnaris muscles. As the FDI contractions were repeated to the endurance limit, we found that motor unit firing rate increased while motor unit recruitment threshold decreased. The increasing trend in firing rate stopped or reversed in four subjects. When the increasing trend stopped or reversed, the sEMG root-mean-square (RMS) from the FDI muscle decreased while that of synergist muscles concurrently increased. These data indicate that increased activation of synergist muscles compensates for decreased activation of the FDI muscle. Our findings provide evidence that fatigue-induced adaptations in motor unit firing behavior in the FDI result from increased excitation to the motoneuron pool that is suggested to compensate for decreases in muscle force-twitch that are reported to occur during fatigue [6]. This control scheme is consistent with our previous observations [1]. Contrasting reports of decreasing or stagnant motor unit firing rates during fatigue may not indicate alterations in the control scheme, but may result from changes in the relative contribution of synergist muscles to the output force.

Title: Motometrics: A guided analysis toolbox for annotating and analyzing motor evoked potentials

Authors: *S. RATNADURAI GIRIDHARAN[1], D. GUPTA[1,2], J. N. HILL[1,2,3], A. PAL[1], A. M. MISHRA[1], J. B. CARMEL[1,2,3]

[1]Burke Med. Res. Inst., White Plains, NY; [2]Weill Cornell Med., New York, NY; [3]Blythedale Children's Hosp., Valhalla, NY

Abstract: To assay the physiology of the motor system, often the brain is stimulated and the muscle response, or motor evoked potential (MEP), is recorded. To understand the relationship between stimulation intensity and MEP, a recruitment curve is often produced (Fig. 1A). This S-shape curve details the complex input-output relationship between brain stimulation and MEP. Often, one would like to compare multiple recruitment curves that may correspond to different subjects, experimental conditions, and/or different points in time. Generating these curves from data and subsequently analyzing them can be arduous. For this purpose, we provide a software solution called Motometrics. The software uses an intuitive graphical user interface first to annotate and load acquired MEP data independent of the electrophysiological recording system. The user then chooses a signal metric such as the area under the curve to quantify MEPs. The data are fitted to an S-shaped recruitment curve, which in turn can be quantified using several metrics; users can choose a percentage of either the stimulus intensities or MEPs. The metric is applied to all recruitment curves to compare them as shown in Fig 1B. Motometrics is generalizable across humans and animals. It allows the experimenter to perform near real-time analysis of recruitment curves. As an open-source tool (https://bitbucket.org/burkemedicalresearch/motometrics), Motometrics is intended to grow with the needs of the motor physiology community.

Title: Motor unit rate coding and recruitment of elbow flexion agonists does not always reflect muscle length-tension curve relationships

Authors: *Z. ADAMS[1], R. E. AKINS, Jr[3], T. S. BUCHANAN[2,1]
[2]Delaware Rehabil. Inst., [1]Univ. of Delaware, Newark, DE; [3]Nemours - Alfred I. Dupont Hosp For Children, Wilmington, DE

Abstract: Muscles produce force via a length-tension relationship, where the force a muscle produces is a function of the number of overlapping fibers during contraction. While relationships between resultant joint kinetics and muscle length-tension curves are well established, little is known about motor unit (MU) activation and muscle length-tension. We hypothesized that MU recruitment and rate coding between elbow flexion agonists would follow normal length-tension relationships. Six subjects (21-29 years) completed a force matching isometric elbow flexion task. Surface electromyography (sEMG) was collected from the right biceps (BB) and brachioradialis (BRA). This task was repeated at various joint angles: 60, 90 and 120 degrees. The task was a ramp to target torque and maintaining for ten seconds. Each task was performed at 30% of the subject's maximal torque. The sEMG was decomposed into individual MU action potential trains. MU train characteristics were obtained from these trains and used for analysis.
BB and BRA MUs surprisingly activated differently with respect to joint angles. A decrease in MU activation was expected as a muscle moves to a more optimal length while maintaining a constant force. BB MU peak firing rates decreased as the muscle length increased ($p<0.05$). Unexpectedly no relationship was found between BRA MU any firing behavior and joint angle. Several factors may play a role in why this occurs. According to normal length-tension curves in the measured range both muscles have an increasing fiber length with an increase in joint angle. This indicates more force production at larger joint angles due to greater fiber overlap. This is demonstrated in the BB data with a decrease in firing rates while maintaining the same resultant torque (30%) without substantial changes to the mechanical advantage of the muscle action. Unlike in the BB the BRA in the ranges measured is closer to optimal fiber length, thus it may not require MU firing changes to maintain a similar load. In addition to muscle length properties BB and BRA also recruited their MUs at different times during force production. BB MUs recruited earlier during the contraction, with BRA recruiting on average 1 second later ($p<0.05$). This is significant when the recruitment ramp was three seconds long. It may be that by recruiting motor units later in the contraction the BRA contributes less to the total joint torque

than the BB, requiring less adjustment along the length-tension curve. These results demonstrate that while BB MUs follow normal muscle length-tension trends the BRA recruits and produces force differently during isometric elbow flexion.

Title: Is increased activation of PFC with cognitive demands associated with the motor unit variability?

Authors: *B. NOH[1], K. C. PHILLIPS[2], H. MAAT[2], T. YOON[3]
[1]KIP, Michgan Tech., Hancock, MI; [2]Kinesiology and Integrative Physiol., Michigan Technological Univ., Houghton, MI; [3]Michigan Tech. Univ., Houghton, MI

Abstract: Exposure to a cognitive challenge impairs motor control by increasing motor unit discharge rate variability and increases activation in the prefrontal cortex (PFC) during low-force contractions. The purpose of this pilot study is to examine whether the increase activation in the PFC is associated with the motor unit variability. Two healthy young men (31.0 ± 5.7 years) participated in this pilot study. A submaximal isometric contraction of the elbow flexor muscles was repeated at 10, 30, 40 and 50% of maximum voluntary contraction (MVC) with and without a mental math task (serial subtractions by 13 from 4-digit numbers). The order of the control (motor task only) and combined task (motor + mental math) were randomized, and the order of the contractions was randomized for each participant but the same throughout each task. Motor control was quantified as force fluctuations (coefficient of variation, CV=100 × Standard deviation of force/mean force). Brain activation was assessed as the change in average oxygenation level (HbO2-HbR) using near infrared spectroscopy (NIRS) over the PFC. Motor unit variability was quantified as discharge rate variability (CV of interspike interval, ISI) of motor units decomposed from surface electromyography signal. Force fluctuations were greater during the combined task compared to the control task at all intensities (2.80 ± 0.39 vs. 4.49 ± 1.43%, $P < 0.05$; averaged value of each intensity). Oxygenation level was increased from baseline ($P < 0.05$) and the increase was greater during the combined task compared to the control task at all intensity (-0.24 ± 0.13 vs. 2.01 ± 0.20 μM, $P < 0.05$). 18-58 motor units decomposed at each contraction were compared, and ISIs were similar between both tasks (0.34 ± 0.01 vs. 0.35 ± 0.00%, $P > 0.05$). No significant correlation was found between oxygenation level with ISI ($r = -0.16$, $P > 0.05$). Increased activation of the PFC was not associated with the

changes in motor unit variability when the cognitive demand was imposed. This result may be due to the small sample size of this pilot study. Further study with large sample size is warranted.

Title: Optimal force production by an idealized motor pool necessitates a flexible interplay between size and speed principles

Authors: *N. J. MARSHALL, L. ABBOTT, M. M. CHURCHLAND
Neurosci., Columbia Univ., New York, NY

Abstract: A motor pool consists of ~10^2-10^3 motor units (MUs), providing innumerable ways to generate a desired force. During slow-ramp and steady-state isometric force production, MUs are recruited in ascending rank order by size. At apparent odds with this size principle, there exists evidence for the selective recruitment of large MUs when force must be generated quickly, including during rapid dorsiflexion in humans and running in rats. As larger MUs generally contain faster-contracting muscle fibers, these findings suggest that speed, as well as size, may influence MU recruitment. It seems intuitively appropriate to recruit faster fibers for faster movements, but does this in fact confer advantages?
We explored this question at the theoretical level by computing the optimal firing rates of a pool of five idealized MUs whose twitch responses displayed inversely related peak tensions and contraction times (i.e., larger units were faster twitch). The force contributed by each MU was modeled as the convolution of its twitch response with its spikes, produced via an

inhomogeneous Poisson process. The model's goal was to match the total force to a variety of time-varying target forces: ramps, steps, and sinusoids. Error could arise from two sources: trial-to-trial variability in output force and systematic discrepancies between the average output and target forces. We incorporated both sources of error into a cost functional over the set of firing rates. With the added requirement of non-negative solutions, we formulated the cost functional as a bound-constrained quadratic programming problem and numerically derived the optimal set of MU responses.
For steady-state and linearly increasing forces, optimization yielded the usual size principle: MUs were recruited in ascending order by their peak tension (i.e., slower/smaller units were recruited first). Similarly, units were de-recruited from largest to smallest for slowly decreasing ramp forces. More complex force profiles yielded more intricate optimal strategies. For example, when force had to be quickly decreased, optimal force production required de-recruiting smaller/slower motor units early and compensating with larger/faster motor units. This strategy is optimal because just prior to force offset, most force is generated by faster units whose force output can be rapidly terminated. Similarly complex optimal strategies were seen for sinusoidal forces. These results indicate that optimal force production requires flexible recruitment strategies; the size principle is optimal under only some circumstances. Whether the nervous system displays such flexibility remains an open question.

Title: Evidence of increased synchrony within and between muscles during isometric leg extension in Parkinson's disease

Authors: *M. W. FLOOD[1,3], B. R. JENSEN[4,5], A. MALLING[4,5], M. M. LOWERY[2,3]
[2]Sch. of Electrical & Electronic Engin., [1]Univ. Col. Dublin, Dublin, Ireland; [3]Insight Ctr. for Data Analytics, UCD, Dublin, Ireland; [4]Dept. of Neurology, Odense Univ. Hosp., Univ. of Southern Denmark, Odense, Denmark; [5]Integrated Physiology, Dept. of Nutrition, Exercise & Sports, Univ. of Copenhagen, Copenhagen, Denmark

Abstract: The result of a depletion of dopaminergic neurons of the substantia nigra, Parkinson's disease (PD) is characterised by the triad of motor symptoms - tremor, rigidity and bradykinesia. While Parkinsonian tremor has long been associated with oscillations at frequencies <10 Hz,

enhanced beta band oscillatory activity (12-30 Hz) within the cortico-basal ganglia network has more recently been linked to bradykinesia and rigidity in individuals with PD. To examine whether evidence of increased neural synchrony is present in the motor neuron pool in PD, coherence and nonlinear signal processing methods were used to investigate differences in EMG signal structure in simultaneously active muscles during isometric leg extension. These methods were also applied to simulated EMG data to assess the influence of enhanced synchronous oscillations to the motor neuron pool on the structure of the surface EMG signal.Surface EMG was recorded from extensor and flexor muscles of the upper leg in 13 controls (65 ± 6yrs.) and 13 PD patients (63 ± 6yrs.) during isometric leg extension at 15% of maximum voluntary contraction. Intermuscular coherence was estimated using 60s rectified EMG signals concatenated from 15s sections from each trial. Determinism (%DET) and sample entropy (SampEn) were estimated from 9 overlapping windows (1.5s) in each trial. Surface EMG was simulated *a posteriori* using a model of EMG from two agonist leg muscles with an additional common modulation current (17.5-22.5 Hz) to the motoneuron pool.Average intermuscular coherence between agonist muscle pairs was significantly higher in PD than controls in the alpha (pre: $p = 0.014$, post: $p = 0.029$) and beta (pre: $p = 0.013$, post: $p = 0.011$) bands. %DET was higher and SampEn was significantly lower in the PD group. Intermuscular coherence of simulated EMG increased in the presence of a common beta modulation to the motoneuron pool. SampEn was lower and %DET higher in the simulated EMG in the presence of common input. Values were similar to those obtained from experimentally recorded EMG, when the common modulation accounted for 5% of the total current input to each motoneuron.
This study identified differences in intermuscular coherence between individuals with PD and age-matched controls during an isometric leg extension. The higher levels of intermuscular coherence and reduced complexity observed in EMG of individuals with PD, and in simulated EMG with enhanced synchronous input, suggests higher levels of MU synchrony within and between muscles in PD.The simulation results additionally suggest that this could be caused by an increase in synchronous inputs to the motoneuron pool in the beta frequency range.

Title: The role of common synaptic input to populations of motor neurons in the generation of force

Authors: *F. NEGRO[1], K. G. KEENAN[2], C. ORIZIO[1]
[1]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy; [2]Human Movement Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Spinal motor neuron activity is modulated by a combination of shared and independent synaptic input from spinal and supraspinal regions of the central nervous system. For this reason, correlation analysis between populations of motor neuron spike trains recorded *in vivo* shows a significant amount of synchronization between action potential discharge timings, both in low and high frequency bands. It has been hypothesized that low frequency components (< 5 Hz) are the effective neural drive to muscle and the main determinants of force control. On the other hand, high frequency components (6-32 Hz) may have a role in the generation of fast movements, tremogenic oscillations, and non-linear force control. Even at very low forces, the averaging process performed by the activation of hundreds of motor neurons act as a linear filter that attenuates uncorrelated synaptic activity and transmits the shared components almost unchanged to the force output. For these reasons, it is important to understand which characteristics of the shared synaptic input may influence the force signal and the functional significance of correlated motor neuron activity in human motor control. In this study, we begin to address these questions using a computational model comprising 445 motor units, similar to the tibialis anterior muscle, that received a broad frequency Gaussian synaptic input (0-50 Hz) with different levels of synaptic activations and shared input (0-100%). The first set of simulations showed that the amount of common synaptic input has a moderate influence on the rate-of-force-development at relatively low force levels and almost no impact at higher forces. On the other hand, changes in the amount of common synaptic input to the motor neuron pool had a significant effect on the linearity of the relation between variability and mean simulated force. Specifically, the inclusion of the shared synaptic input was necessary to increase the slope of the relation between standard deviation (SD) and mean force level after full motor unit recruitment (0-75% MVC) to better approximate experimental findings. Similar behavior was observed in the simulation of a smaller muscle (120 motor units, as in the first dorsal

interosseous of the hand) with a narrower recruitment range (0-50% MVC). In conclusion, the likely functional role of common synaptic input to populations of motor neurons innervating a single muscle is to shape the variability of the force output, but not to increase the rate of force development in fast contractions.

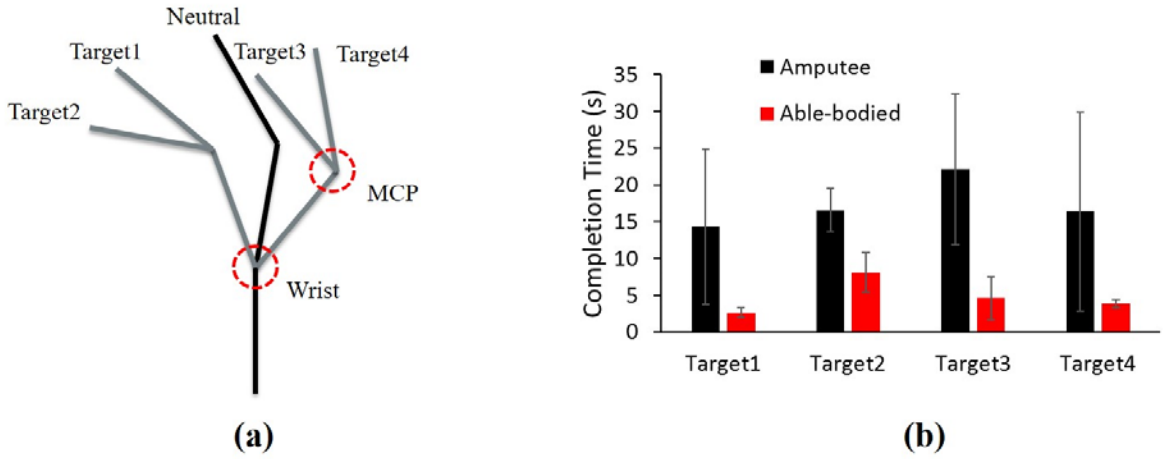
Title: Can one EMG-based neural-machine interface fit all

Authors: *L. PAN, D. CROUCH, H. HUANG
NCSU/UNC Joint Dept. of Biomed. Engin., NC State Univ. and UNC-Chapel Hill, Raleigh, NC

Abstract: Introduction: Electromyography (EMG)-based movement intent decoding for neural-machine interfaces (NMI) has been used for prosthesis control for several decades. No matter which algorithm is used for EMG decoding, customizing the NMIs for individual users is always needed. Recently, we developed an EMG decoder based on a musculoskeletal model for predicting simultaneous flexion/extension motions at the metacarpophalangeal (MCP) and wrist joints. Since the model directly incorporates biological movement processes, and humans' own neural control is adaptive, customizing the model for each user might not be necessary. Therefore, the objective of this study was to investigate how well previously uninvolved subjects could control a generic EMG-based NMI in real-time to perform a task.
Materials and Methods: Based on previous data recorded from 6 able-bodied subjects, we developed a generic musculoskeletal model by averaging the model parameter values across all subjects and all trials. The model was used to control the position of a virtual hand on a computer screen. One other male able-bodied subject and one female transradial amputee were instructed to move a planar virtual hand from a Neutral posture to four Target postures (Fig. 1.a). The four

targets were presented in a random order in each of 4 trials. EMG were recorded from the able-bodied subject from surface EMG electrodes placed over four muscles: ECRL, ED, FCR, and FD. For the amputee subject, four fine-wire EMG electrodes were inserted in the same four muscles under ultrasound guidance.



Results: Impressively both the able-bodied and the amputee subjects completed all trials for all target postures, although the completion time of the able-bodied subject was lower than that of the amputee subject for all Target postures (Fig. 1.b).
Discussion and Conclusions: The results suggest that a generic EMG-based NMI could potentially enable effective real-time NMI control for both able-bodied subjects and arm amputees. More training might be needed to further improve amputee performance in using EMG-based NMI for prosthesis control.

Title: Influence of muscle architecture on the sEMG signal of the first dorsal interosseous muscle: A subject-specific model based on diffusion tensor imaging

Authors: *D. PEREIRA BOTELHO[1], N. COLGAN[2], A. FAGAN[3], K. CURRAN[1], M. LOWERY[1]

[1]Univ. Col. Dublin, Dublin, Ireland; [2]Natl. Univ. of Ireland, Galway, Ireland; [3]Trinity Col. Dublin, Dublin, Ireland

Abstract: The aim of this work is to examine the influence of the muscle architecture on the surface electromyography (sEMG) signal recorded during the activation of the first dorsal interosseous (FDI), a multifunctional muscle of the hand responsible for both index finger flexion and abduction. Diffusion tensor imaging (DTI) was used to assess fiber track information, which was incorporated into a subject-specific finite element model of the electric potential detected at the skin surface. General anatomical features of the hand were assessed through conventional magnetic resonance imaging (MRI). Subjects were positioned lying prone in a Philips 3T Achieva MRI scanner with their dominant hand prone (palm down) and supported on a purpose-built rig in a 16-element transmit/receive radiofrequency knee coil. The MRI compatible rig was conceived to minimize involuntary hand motion and provide loads for index flexion and abduction. DTI data were acquired using the same experimental arrangement with the hand at rest and while the subjects performed index finger abduction and flexion. A deterministic fiber tracking approach was used, after motion and eddy current correction, to estimate FDI muscle fiber direction. The acquired MRI data for the hand at rest were segmented into distinct tissues (bone, muscle, fat, skin) and a three-dimensional model of the hand was constructed. The finite element model was then created with different dielectric properties associated with each tissue. The estimated muscle fiber direction and curvature were used to determine material anisotropy and the trajectory of action potential propagation. Single fiber action potentials at an array of electrodes located on the skin surface above the FDI were then estimated as the convolution of a weighting function representing the response at the electrode due to propagation of a unit point current source and the intracellular action potential current, incorporating fiber start- and end-effects at the neuromuscular junction and tendon. Motor unit action potentials comprised of single fiber action potentials from all fibers within the motor unit were then simulated during index finger flexion and abduction. The proposed approach constitutes a basis for simulation of subject-specific muscle models which can be used to investigate muscle activation under a range of conditions. Insights obtained through a better understanding of the contribution of structural and architectural properties of the muscle and surrounding tissues enable the extraction of precise/specific information regarding the state of the muscle and nervous control mechanisms using advanced sEMG recording and analysis techniques.

Title: High-density electromyogram decomposition using different blind source separation algorithms

Authors: *C. DAI, X. HU
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Electromyogram (EMG) decomposition is a technique that can separate the composite EMG signals into constituent motor unit spike trains. Blind source separation algorithms are efficient approaches that can decompose high-density EMG signals recorded from a densely-spaced electrode grid. Our study compared three independent component analysis (ICA) based blind source separation algorithms (i.e., InfomaxICA, FastICA and RobustICA) in combination with the convolution kernel compensation method. We also examined the overall decomposition performance of these different approaches in both offline and online configurations. These algorithms were evaluated using 64-channel simulated EMG signals with different numbers (10, 20 and 50) of motor units and signal-to-noise ratios (5, 10 and 20 dB). The performance of each algorithm was evaluated based on the yield of the detected motor units and the spike timing accuracy of individual motor units. Our offline decomposition results showed that all algorithms had comparable performance with mean accuracy > 98% for the simulated EMG signals with 10 or 20 motor units. However, the RobustICA outperformed (in both the yield and timing accuracy) the FastICA and the InfomaxICA for more complex signals with 50 motor units. In addition, the computation time of the RobustICA was approximately 25% shorter than the FastICA, and both algorithms were substantially faster than the InfomaxICA. The real-time decomposition of RobustICA and FastICA was also performed on the simulated EMG with 50 motor units. The accuracy was approximately 90% and approximately 7 motor units were detected by using RobustICA or FastICA. Our findings indicate that the RobustICA-based decomposition technique can provide accurate decomposition results in both offline and real-time settings. Our approach shows great promise as a research tool that can help us understand the control of motoneuron pool. The online decomposition outcome can also be used as a real-time control input of rehabilitation/assistive devices, which can help improve system performance.

Title: Development of a simple device for assessment of spasticity

Authors: *K. TAKEDA[1], H. MAEDA[2], S. SONODA[2]
[1]Sch. of Hlth. Sci., Fujita Hlth. Univ., Toyoake, Aichi, Japan; [2]Dept. of Rehabil. Med. II, Sch. of Med., Fujita Hlth. Univ., Tsu, Mie, Japan

Abstract: Stroke, spinal cord injuries, multiple sclerosis, cerebral palsy, and traumatic brain injury can cause spasticity, which is an involuntary and abnormal muscle tone. Spasticity causes difficulty in motion, abnormal posture, and contractures leading to limited joint mobility. Clinical evaluation of spasticity has been usually performed by modified Ashworth scale (MAS) which is an ordinal scale that assesses the resistance during passive joint movement by an examiner's subjectivity. In the present study, for an objective assessment, we developed a simple device for an ankle joint spasticity, which measures resistance torque (plantar flexion torque) during manual passive dorsiflexion. The device consists of an ankle-foot orthosis (AFO) that can move the ankle joint from 25 degrees of plantar flexion to 15 degrees of dorsiflexion. The resistance torque is measured by strain gauges which were attached to the vicinity of the toe of the AFO. Simultaneously, the joint angle can be measured by a potentiometer which is installed on the ankle joint axis. This proposed system is also be able to record surface electromyography (sEMG) of the gastrocnemius (GC) and tibialis anterior (TA) muscles simultaneously at 1 kHz sampling. The time course of the torque, angle, angular velocity, and rectified sEMG signals is drawn with a slight time delay on a PC display. Because a generally accepted definition of spasticity is ‘a velocity dependent increase in tonic stretch reflex with exaggerated tendon jerks, resulting from the hyperexcitability of the stretch reflex’, it is important to dorsiflex the ankle joint passively in the same angular velocity. Therefore, the proposed device also provides two guides so that the examiner can perform dorsiflex at a constant angular velocity. For one of the guides, the time course of the angle that the examiner should trace is indicated visually on the display in advance. Another one is sound guide which is an up-chirp signal with starting frequency 440 Hz and ending frequency 880 Hz of a duration of the dorsiflexion time. For the dorsiflexion of the ankle joint at a low angular velocity, e.g. under 2 deg/s to assess an elasticity of the joint, high reproducibility could be seen by relying on the visual guide. On the other hand, high reproducibility at a high angular velocity over 200 deg/s could also be performed by using the auditory guide. The proposed system may be useful for assessing spasticity objectively.

Title: Sources of muscle weakness in stroke survivors based on a motor unit simulation

Authors: *X. HU[1], H. SHIN[1], W. Z. RYMER[2], N. L. SURESH[3]
[1]BME, UNC Chapel Hill, Chapel Hill, NC; [2]Rehabil. Inst. of Chicago, Chicago, IL; [3]Sensory Motor Perf Prgm, Rehabil. of Chicago, Chicago, IL

Abstract: Muscular weakness is a major motor impairment in stroke survivors. Concurrent impairment in the control of motor unit pool can contribute to the observed weakness. However, the relative contribution of different aspects of impaired motor unit control is not clear. To address this issue, we used a physiologically based motor unit pool model to simulate different altered motor unit properties observed experimentally in stroke survivors. Our results showed that a reduction in the discharge rate and the motor unit size (i.e., twitch amplitude) led to substantial muscle weakness. Additionally, a reduced recruitment range (i.e., a clustered recruitment at a low excitation drive) also contributed to muscle weakness substantially. In contrast, a disturbance in the discharge rate organization across units had moderate influence on the force output, and a disturbance in the orderly recruitment (i.e., size principle) had a minimal impact on muscle weakness. Our findings indicate that several factors can contribute to muscle weakness, including an inefficient activation of the motor units at low discharge rate, a reduced motor unit size possibly due to atrophy, and a compressed recruitment threshold of motor units triggering early muscle fatigue. Overall, using a previously developed motor unit pool model, we were able to distinguish the different altered motor unit properties in contribution to muscle weakness in stroke survivors.

Title: Muscle synergies underlying sit-to-stand tasks in acute stroke patients

Authors: *H. HANAWA[1], K. KUBOTA[1], T. KOKUBUN[2], K. HIRATA[1], T. MIYAZAWA[3], M. SONOO[1], T. FUJINO[1], N. KANEMURA[2]

Abstract: *[INTRODUCTION]* Neurophysiological evidence suggests that the nervous system controls motion by using a low-dimensional synergy organization for muscle activation.

Recently, abnormal muscle synergies in stroke patients have also been clarified. However, it is not clear if such abnormal muscle synergies occur during sit-to-stand tasks.
[METHODS] Three stroke patients with left hemiparesis (time since stroke = 6.3 ± 2.3 days), and two healthy adults participated in this study. A surface electromyogram (EMG) device was used to collect muscle activity data from seven muscles (tibialis anterior, soleus, gastrocnemius, vastus lateralis, rectus femoris, long head of biceps femoris [BFL], and gluteus maximus [GM]) in the left leg. Subjects performed a six-direction isometric contraction task in the supine position to verify fundamental muscle synergies. Then, they performed a sit-to-stand task. A non-negative matrix factorization algorithm was applied to the EMG data for each task to extract muscle synergies. Subsequently, hierarchical cluster analysis was used to classify these synergies.
[RESULTS] Four subjects accomplished all isometric contraction tasks with four muscle synergies. Each muscle synergy was included in the same cluster (correlation coefficient = 0.84 ± 0.06). One patient with severe hemiparesis could perform only one-sixth of the contraction directions. The number of muscle synergies of this patient decreased to two. All subjects completed the sit-to-stand task. Healthy adults had four muscle synergies. In two of the stroke patients, the number of muscle synergies decreased to three as GM activity disappeared. To compensate, these patients prolonged the BFL activity; therefore, this muscle synergy formed a different cluster from healthy adults. The patient with severe hemiparesis had four muscle synergies. Because most muscles are co-active in the extension phase, this muscle synergy formed a different cluster from healthy adults. Other muscle synergies were included in the same cluster in all subjects (correlation coefficient = 0.93 ± 0.01).
[DISCUSSION] The presence of fewer muscle synergies in stroke patients corresponds to an overall reduction in motion control complexity (Bowden MG, 2010). This finding was applicable to the sit-to-stand task. However, muscle synergies in stroke patients were different in the two tasks. Patients likely changed fundamental muscle synergies to achieve the sit-to-stand task, even in the acute phase. This study contributes to the findings regarding how a nervous system injury may alter the organization of muscle synergies.

Title: Relationship between muscle synergy in knee osteoarthritis patients and the functional evaluation of knee joints

Authors: *K. KUBOTA[1], H. HANAWA[1], T. KOKUBUN[2], M. SONOO[1], K. HIRATA[1], T. FUJINO[1], G. OONO[1], N. KANEMURA[2]

Abstract: *[Introduction]*Muscle synergy is believed to reflect alterations in motion control caused by a dysfunction in the redundant musculoskeletal system. While muscle synergy has been applied to central nervous system diseases, there are still few applications for orthopedic diseases. Knee osteoarthritis (KOA) is a degenerative disease that features osteophyte formation, cartilage destruction, and joint space narrowing. KOA is thought to have sensory and motor impairments that affect force generation and motor unit recruitment of the knee extensors and flexors. While several previous studies have shown changes in individual muscle activity, there have been no studies to show changes in muscle synergy. The purpose of this study was to clarify the relationship between changes in muscle synergy and knee function evaluation in KOA.
*[Methods]*Six healthy adults and three KOA patients participated in this study. Subjects performed gait on the treadmill at different speeds (1km/h or 2 km/h). EMG activity was recorded from 14 left leg and lower-back muscles. The gait cycle was defined using ground reaction force data obtained from each belt of the treadmill. Data were time-interpolated over individual gait cycles to fit a normalized 200-point time base. EMG signals were factored to apply non-negative matrix factorization to determine the muscle synergy. To determine the minimum number of synergy, we calculated the variability accounted for. Furthermore, to compare knee function evaluation, the following outcomes were evaluated: knee pain of WOMAC and range of motion (ROM) of both knees.
*[Results]*Healthy subjects had extracted muscle synergy values of three or four, while KOA patients had extracted muscle synergy value of two. Synergy during the stance phase was confirmed using simultaneous activity of the lower leg and multiple thigh muscles in KOA patients. The extension ROM was -5° for KOA1, -10° for KOA2, and -10° for KOA3. The WOMAC scores of the three KOAs were, on average, 37/96.
*[Discussion]*The main finding of this study was that muscle synergy was reduced in KOA patients. A reduction in muscle synergy indicates the co-activation of muscles. As many previous studies have indicated, co-activation of muscles results in increased joint stiffness. In this way, muscle synergy can be manipulated to address the pain and instability of KOA patient. Our results support these findings. The abnormal structuring of muscle synergy may reflect both abnormal musculo-skeletal dynamics and other biomechanical properties of the limb. This study contributes to the finding that musculo-skeletal system injury may alter the organization of muscle synergies.

Title: Anterior interosseous nerve syndrome variant confirmed by MRI and electromyography

Authors: *I. JUNG[1], S. JEE[1], I. KIM[2]
[1]Dept. of Rehabil. Med., Chungnam Natl. Univ. Hosp., Daejeon, Korea, Republic of; [2]Dept. of Rehabil. Med., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Introduction: Anterior interosseous nerve (AIN) syndrome is a rare disorder with complex clinical presentations. Anatomical variation of the proximal median nerve has been reported and should be confirmed before identifying the lesion of AIN.
Methods: We report two similar cases of an AIN variant. Patients presented with pain sensations and subsequent hand weakness. To confirm muscle denervation and identify the causes of proximal median nerve injury at the forearm, electromyography and magnetic resonance imaging (MRI) were performed.
Results: The electrodiagnostic study suggested proximal median nerve injury and AIN. However, no abnormal nerve conduction in the median sensory nerve and abductor pollicis brevis was found. Denervation of muscles innervated by the proximal median nerve was observed in MRI.
Conclusion: We observed an AIN variant innervating muscles dominated by the proximal median nerve. We recommend that this be considered in future examinations to confirm lesions of whole median nerve fascicles through electromyography or MRI.

Title: Modulation of jaw reflex responses during peripherally and centrally evoked swallowing

Authors: *T. SUZUKI, M. YOSHIHARA, K. TSUJI, J. MAGARA, T. TSUJIMURA, M. INOUE
Div. of Dysphagia Rehabil., Niigata Univ. Grad. Sch. of Med. and, Niigata-Shi, Japan

Abstract: [Purpose] We previously demonstrated that the jaw-opening reflex (JOR) responses were inhibited during swallowing evoked by superior laryngeal nerve (SLN) stimulation. The aim of this study was to investigate whether the JOR responses were modulated during not only peripherally but also centrally evoked swallowing. We also examined the effect of peripherally and centrally evoked swallows on the jaw-closing reflex (JCR) responses. [Materials and Methods] Experiments were carried out on rabbits anesthetized with urethane. Electromyographic activity was recorded from the digastric, masseter and thyrohyoid muscles for monitoring the JOR, JCR and swallowing, respectively. To evoke the JOR and JCR, the inferior alveolar nerve and the trigeminal mesencephalic nucleus were electrically stimulated. The intensity of the stimulus pulse was 2.0 times (T) the threshold for eliciting the JOR and JCR. Either the SLN or cortical swallowing area (Cx) was stimulated at 30 Hz to evoke swallows. Stimulus intensity of SLN and Cx was set at 0.8-4 T and 0.8-1.4 T the threshold for evoking the swallowing at least once for 10 sec, respectively. In a recording session, either the JOR or JCR was evoked continuously at 1 Hz for 30 sec. In the middle 10 sec, SLN or Cx was simultaneously stimulated. The mean amplitudes and latencies of the JORs and JCRs were compared among the conditions; before, during and after SLN or Cx stimulation. [Results & Discussion] The amplitudes of the JORs were significantly decreased during and after SLN/Cx stimulation compared with before stimulation, whereas the latencies were not changed among the conditions. Inhibitory effect increased as the stimulus intensity of the SLN and Cx increased. On the other hand, there was no significant difference in the amplitudes and the latencies of the JCRs among the conditions. These results suggest that the JOR was inhibited, whereas the JCR was not modulated during peripherally and centrally-evoked swallowing, probably to prevent unnecessary jaw opening evoked by the oral sensory inputs during swallowing.

Title: The influence of the difference in the volume of keying on trunk movement during piano performance

Authors: *A. KOBAYASHI[1], T. KOKUBUN[2], D. NOHARA[3], H. SHONO[3], M. MATSUNO[3], H. HANAWA[4], N. KANEMURA[2]
[1]Grad. Course of Hlth. and Social Services, Grad. Sch. of Saitama Prefectural Univ., Koshigaya, Japan

Abstract: INTRODUCTION: Pianists acquire sophisticated performance skills through years of practice. As with other sportsmen, they often have somatic complaints. Recently, incorrect usage of the body was referred to as one of the causes of this disorder. Compared to the old piano, the modern piano requires approximately five times the keying force; therefore, the pianists are required to play rationally with the whole body. The aim of this study is to clarify the role of the trunk during the playing of the piano, and it is shown that the role of the trunk can be effectively used for the prevention and treatment of a pianist's disorder. METHOD: Five pianists who have received piano instruction for 20 ± 12.7 years and five non-pianists participated in the study. By using the 3D motion-analysis device VICON, the motion of the trunk, upper limbs, and fingers during a key stroke was recorded. The conditions of sound intensity were 64 and 96 MIDI velocity. For the musical performance, the accuracy of the key depression tempo and the keying volume and its coefficient of variation were calculated. In addition, the keying contribution degree and keying contribution rate were calculated from the measured trunk inclination angle and the joint angles of the shoulder, elbow, wrist and finger. The Friedman test was carried out and the Wilcoxon signed-rank sum test was conducted for multiple comparisons. All experimental protocols were reviewed and approved by the Research Ethics Review Committee of Saitama Prefectural University. RESULTS: Both sets of pianists and non-pianists could key at the prescribed tempo and volume; the coefficient of variation of the keying volume was smaller when the volume was higher. When the volume was small, the pianists showed a higher positive contribution. Further, as the volume increased, the positive contribution of both the pianists and non-pianists decreased. The pianists showed higher keying efficiency at any given volume and displayed an increase in the keying efficiency as the volume increased, but the non-pianists portrayed a decrease in the keying efficiency as the volume increased.DISCUSSION: The pianist was using the trunk to hit the key at a small volume. It was more difficult to hit a key with a small volume. Pianists took a strategy to shorten the distance between the trunk and the piano against a challenging task. It is suggested that pianists play not only with arms and hands, but also trunks. The results obtained by measuring the movement of the entire body during a piano performance suggest the necessity of such an evaluation, with special emphasis on the trunk.

Title: Knee flexors and extensors are defined by the task and not anatomy

Authors: *P. SRIYA, T. RICHARDS, S. ASTILL, S. CHAKRABARTY
Sch. of Biomed. science, Fac. of Biol. Sci., Leeds, United Kingdom

Abstract: The knee is a modified hinge joint used for both flexion and extension thus allowing one to walk, stabilize posture and do sit to stand. Control of the knee is typically assigned to the flexors (semitendinosus (ST) and bicep femoris (BF)) and extensors (rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM) and vastus intermedius(VI)). It is assumed that the activity at the knee is defined by that of these muscles, which maintain their respective role across all knee positions and range of motion. In this study, we examined this premise by recording surface EMGs from the flexors (ST and BF) and extensors (RF, VL and VM) simultaneously during an isometric knee extension task in 2 distinct positions across the range of motion. We hypothesized that the isometric conditions of the task will allow interactions between the muscles to be unaffected, thus remaining the same across conditions and range of motion (**0°, 20°, 60°** and **90°)**. In position 1, the participant was supine lying with both legs stretched forward, and in position 2, their left knee is bent towards the gluteal on the bed.We examined the activation patterns (onset, offset and duration) along with RMS amplitude changes in these muscles. Using hierarchical clustering and Pearson's correlations across 17 healthy participants (18-30), we found that in at **0°** and **20°** in position 1 RF and VL acted as putative agonists. At **60°** in position 1 and at **90°** in position 2 the activity patterns were similar with RF, VL, ST and BF in the same agonist cluster, but not VM. As if VM in this scenario is more a flexor than its traditional role of an extensor. It is likely, as has been previously suggested that the muscles do undergo stretching thus providing proprioceptive feedback. We suggest that the muscle interactions are controlled dynamically and not anatomically regulated, possibly by the proprioceptive feedback from muscles and joints. This has significant implications for clinicians, as these tests are routinely used to assess functional state of the knee, but the variations observed suggest the 'normal' needs to be redefined.

Title: Concurrent recordings of motor unit and spinal interneuron discharge patterns during reflex activation

Authors: *C. K. THOMPSON[1], F. MARCHIONNE[2], A. J. KRUPKA[2], F. NEGRO[3], D. FARINA[4], M. A. LEMAY[2]
[1]Spinal Neuromotor Lab., [2]Dept. of Bioengineering, Temple Univ., Philadelphia, PA; [3]Dept. of Clin. and Exptl. Sci., Univ. degli Studi di Brescia, Brescia, Italy; [4]Dept. of Bioengineering, Univ. Col., London, United Kingdom

Abstract: Spinal alpha motoneurons receive most of their synaptic input through spinal interneurons, yet there are few investigations linking the population activity of spinal interneurons to the discharge of spinal motoneurons. Here we present an approach to record the discharge times of several tens of spinal interneuron in combination with motor units in order to better quantify how interneurons influence the firing of spinal motoneurons. The experiment was performed using the spinal decerebrate cat. A laminectomy was performed from L3 through L6, dura and pia over the recording sites were removed. The right hind limb was secured to a rigid frame and the posterior leg muscles were exposed. Two separate 64-channel intraspinal linear microelectrode arrays were inserted at L3 and L6 just medial to the ipsilateral dorsal root entry zone to record throughout the intermediate zone of the spinal gray. Additionally, a single 64-channel electrode array was placed onto the muscle belly of the right medial gastrocnemius muscle. Reflexive motor activity was evoked through an eccentrically weighted rotary motor rotating at ~100Hz that was held manually against the distal tendon of the right medial gastrocnemius for 30 seconds. Neural and EMG data were decomposed offline into their corresponding discharge times. Discharge times from 50-70 interneurons and 10-15 motor units were decomposed from each trial. Motor units from the medial gastrocnemius were quiescent at rest, but showed a robust increased discharge rate in response to vibratory stimulus, each motor unit spike train demonstrates an ISI histogram that was highly punctuated at subharmonics of the vibration frequency. In contrast, a large majority of interneurons were active at rest. During vibration, interneurons demonstrated a significant increases in average discharge rate (from 11 to 19 imp/s), though less than 10% of the recorded interneurons demonstrated punctuated ISI histograms. These data are consistent with the direct monosynaptic projections from the muscle spindle onto the homonymous motor pool; highly punctuated ISI histograms are exclusively

observed at the level of the motoneurons, but observed relatively infrequently across spinal interneurons. This approach may be helpful in identifying the synaptic input of specific spinal interneurons. Moreover, the ability to collect these spike train data will allow us to better quantify the synaptic input from spinal interneurons to spinal alpha motoneurons under a variety of reflexive, pharmacological, and surgical conditions, further elucidating the role of spinal interneurons on motor output.

Title: Sex differences in neuromuscular control of quadriceps muscles during various levels of knee extension force

Authors: *Y.-L. PENG, D. GUPTA, J. JENSEN, L. GRIFFIN
Dept. of Kinesiology and Hlth. Educ., The Univ. of Texas At Austin, Austin, TX

Abstract: Patellofemoral pain syndrome is twice as prevalent in women than in men. The main cause of increased rates in women is believed to be due to imbalance of control of muscles tracking the patella. Clinicians commonly recommend vastus medialis oblique (VMO) training to counteract the excessive force of the vastus lateralis (VL) on the patella. However, it is unclear whether the activation patterns of the vastus muscles differ between sexes and force levels. The purpose of the study is to investigate the onset time and EMG amplitude of the quadriceps muscles in healthy individuals during isometric knee extension at three force levels. Thirteen men and 13 women performed isometric knee extension at 25%, 50%, and 75% of maximal voluntary contraction (MVC). All participants performed a ramp contraction by tracing a line on the screen with a rate of rise of 7.5% MVC/sec up to the target force. Levels were maintained for 10 sec at 25% and 50% MVC and for 5 sec at 75% MVC. Surface electromyography (EMG) was recorded from the VL, VMO, vastus medialis (VM), and rectus femoris (RF) muscles. EMG onset time and average holding EMG amplitude (normalized to maximum) were determined. A two-way repeated measure ANOVA with Tukey post hoc tests were used to compare onset time between Sex (male/female) and Muscle (VM/VMO/VL/RF). EMG amplitude was evaluated across Force (25/50/75%MVC), Sex, and Muscle by a three-way repeated measure ANOVA with Tukey post hoc tests. There was a significant Muscle effect on the onset time (p=0.00). The VL (0.21±0.04 sec) was activated significantly earlier than the VM (0.47±0.04 sec) and RF (0.56±0.07 sec), but not the VMO (0.37±0.06 sec). There was a significant 3-way interaction of

Muscle*Sex*Force for the EMG amplitude (p=0.04). The activation amplitude of the VL (21±5% EMGmax) was significantly lower than the VM (46.6±5% EMGmax) and RF (55.5±8% EMGmax), but was not different than the VMO (36.9±9% EMGmax). Women showed 36.7±8% EMGmax higher percentage of muscle activation for all the vastus muscle compared to men to complete the task in all force levels (p=0.00). A marginal significant difference in the EMG amplitude was found between the 25% and 75% force level (p=0.06). Different force levels had less effect on the activation pattern of the quadriceps muscles. However, the VL and VMO were recruited earliest muscles, possibly to counterbalance the lateral and medial force on patella during the knee extension task. With the same relatively force exertion, women exhibited much higher muscle relative muscle activation of all vastus muscles compared to men.

Title: Stress-induced pro- and anti-inflammatory cytokine expression in casual drug and alcohol users

Authors: *M. ARCHEY[1], K. N. SHEFFIELD[1], C. NEUTZLER[1], H. R. RHODES[1], J. A. BOYETTE-DAVIS[2]
[2]Psychology, [1]St. Edward's Univ., Austin, TX

Abstract: Research shows that various recreationally used substances have distinctive effects on neuromodulation, and those effects can produce observable health outcomes. For example, while alcohol is associated with increased inflammation in the body, marijuana has been shown to possess anti-inflammatory properties. The present study aimed to investigate how recreational use of these substances and their corresponding modulation of cytokines, in conjunction with daily, non-illness related stress, can influence overall health and well-being. Seventy-nine participants completed sessions in which they provided detailed information about their health, frequency of symptoms associated with inflammation, self-reported stress, personality, and drug and alcohol use. Based on self-reports, participants were categorized as abstainers (no reported drug/alcohol use), daily users of marijuana, marijuana plus alcohol users, moderate alcohol users, or heavy/binge alcohol users. During the session, participants provided saliva samples before and after exposure to mild, acute stress, induced by the completion of both mental arithmetic and Stroop tests. Inflammation scores were significantly correlated with perceived stress ($r = .48$, $p = .003$). Cytokine levels - interleukin-6 (IL-6) and interleukin-10 (IL-10) - were analyzed via saliva by enzyme immunoassays. No significance was found for IL-10 levels. However, results

revealed significant increases in IL-6 according to differential substance use patterns. Specifically, those who were daily consumers of marijuana or moderate users of alcohol experienced increases in this pro-inflammatory cytokine. This study highlights the importance of investigating immune function in recreational drug users and the overall effect of controlled substances on health and stress.

Title: COMTval158met polymorphism effects on inflammation and enduring stress response: A novel mechanism of PTSD risk

Authors: *J. DESLAURIERS[1,2], X. ZHOU[1,2], V. B. RISBROUGH[1,2]
[1]Psychiatry, Univ. of California San Diego, LA Jolla, CA; [2]Ctr. of Excellence for Stress and Mental Health, VA, La Jolla, CA

Abstract: Background and hypothesis: The catechol-*O*-methyltransferase (COMT) enzyme is implicated in the catabolism of catecholamines and plays a key role in cortical signaling. The val158met single nucleotide polymorphism (SNP) in the COMT gene has been associated with a greater risk for posttraumatic stress disorder (PTSD). Recent evidence has implicated immune function as a potential mechanism of PTSD risk and symptom maintenance. Because catecholamines play a key role in immune signaling we hypothesized that the COMTval158met SNP association with PTSD risk may be via alteration of the inflammatory state. We have previously shown, in a mouse line "humanized" for the COMTval158met SNP, that Val/Val carriers, compared to Met/Met carriers, exhibited altered inflammatory responses and greater enduring anxiety-like responses up to 14 days after predator stress exposure. To determine if greater inflammation plays a causal role in the enduring effects of stress in COMT mice, here we examined the long-term effects of inflammation on anxiety-like behaviors.
Methods and results: We investigated the effect of lipopolysaccharide (LPS), a toll-like receptor 4 (TLR4) agonist, in the "humanized" COMTval158met mouse line. LPS (1 mg/kg, IP) or saline was administered in male Met/Met and Val/Val carriers. Avoidance behaviors were assessed in the open field (exploratory behavior) and light-dark box (anxiety behavior) one week after injection. A composite avoidance score (Z score) was calculated for each animal across both

tests. We found that LPS increased avoidance behaviors in both genotypes, with the highest response in Val/Val mice. Val/Val mice also exhibited greater baseline inflammation compared to Met/Met mice.
Conclusions: These results (1) show that the COMTval158met SNP modulates the response to LPS; and (2) confirm that the COMTval158met-modulated inflammation plays a role in stress-induced behaviors. These findings suggest that targeting the immune signaling pathways might be a novel therapeutic alternative for PTSD patients, and that the COMTval158met SNP might modulate the response to anti-inflammatory treatments. The long-term effects of LPS on inflammatory markers in the "humanized" COMTval158met mouse line will also be presented.

Title: Adaptive immunity in depressive mood states

Authors: *S. L. KIGAR[1], M. UDAWATTA[1], M. L. LEHMANN[1], S. J. LISTWAK[1], A. G. ELKAHLOUN[2], D. MARIC[3], M. HERKENHAM[1]
[1]Section on Functional Neuroanatomy, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Microarray Core, Natl. Human Genome Res. Inst., Bethesda, MD; [3]Flow and Imaging Cytometry Core, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Despite its striking prevalence in the general population, treatment options for most mood disorders including depression are quite limited; for example, available pharmacological agents fail to yield therapeutic value in up to 70% of patients diagnosed with major depressive disorder. Thus, novel treatment strategies and drug targets are urgently needed. Clinical and genome-wide association studies show a strong correlation between aberrant peripheral immunity and major depression in a subset of patients. Additionally, introducing cytokines (i.e., immune cell signaling products) into the body as a treatment for cancer in otherwise non-depressed patients was shown to induce depressive symptoms, suggesting that the immune system may play a role in the etiology of depression. These data and mounting evidence that normal immunity is critical for species-typical cognition and behavior have therefore engendered

increasing interest in elucidating how the immune system exerts influence on the brain. The relative impenetrability of the blood brain barrier (BBB) to immune cells and cytokines has led researchers to examine the immunogenic properties of the meninges, where lymphocytes of the adaptive branch of the immune system reside in abundance. Our laboratory recently showed that adoptive transfer of lymphocytes from chronically stressed donor mice conferred an anti-depressant effect in recipients (Brachman et al., 2015). This led us to hypothesize that (1) chronic stress alters the transcriptional profiles and signaling potential of T lymphocytes, and (2) that T cells within the meningeal compartment secrete a BBB-soluble factor that modifies a depressive-like behavioral phenotype. To investigate these hypotheses, we conducted microarray, flow cytometric, and immunohistological analyses to characterize T cells from a variety of immunological compartments, including the spleen, lymph nodes, and meninges. Moreover, using *in vitro* and *in vivo* assays, we explored the possibility that meningeal T cells release BBB-permeable, microRNA (miRNA)-containing extracellular vesicles, i.e., exosomes. Our preliminary data suggest that trafficking, activation status, and miRNA content of T cells is altered considerably by chronic social defeat stress, and these transcriptional changes impinge on the brain to affect mood.

Title: Inflammatory pathways in the medial prefrontal cortex modulate the anxiogenic effect induced by an acute stress

Authors: *S. F. LISBOA[1], C. VILA-VERDE[2], D. L. ULIANA[3], L. A. BRAGA[2], L. B. M. RESSTEL[4], F. S. GUIMARAES[2]
[1]Pharmacol., [3]Pharmacol. Departament, [4]Pharamacoloy, [2]Univ. of Sao Paulo - FMRP/USP, Ribeirao Preto, Brazil

Abstract: Background: Nitric oxide (NO) is involved in stress-related disorders and can be synthesized by three enzymes, including the inducible NO synthase (iNOS), which is involved in

the production of inflammatory mediators. Psychological stressors induce iNOS expression in cortical neurons and activate inflammatory mechanisms in the medial prefrontal cortex (MPFC), which is implicated in several psychiatric conditions. Nuclear factor kβ (NF-kβ) is the main regulator of iNOS expression and is also implicated in stress-related responses. However, it is unknown if MPFC inflammatory pathways, particularly iNOS and NF-kβ, exert key role in the development of behavioral consequences induced by stress. Therefore, the aim of this study was to determine if acute inhibition of iNOS or NF-kβ in the MPFC attenuated the anxiogenic-like effect induced by acute restraint stress (RS). Methods: Male Wistar rats (260-280 g) had guide cannulae implanted bilaterally in the MPFC for the administration of vehicle (0.2 µl), the selective iNOS inhibitor, N-[[3-(Aminomethyl)phenyl]methyl]-ethanimidamide dihydrochloride (1400W dihydrochloride; 10^{-4}, 10^{-3}, 10^{-2} nmol/0.2µL), or the NF-kβ inhibitor, 1-Pyrrolidinecarbodithioic acid ammonium salt (PDTC; 10^{-3}, 10^{-2}, 10^{-1} e 1nmmol/0.2 µl). Naïve or guide cannulae-implanted rats were submitted to an acute restraint stress (RS; 2h) and were maintained single-housed for additional 24h until behavioral analysis. Non-stressed and stressed rats received drugs intra-MPFC and 10 min later were tested in the elevated plus-maze (EPM) for 5 min. Results: RS induced anxiogenic-like effect and pre-treatment with 1400W (10^{-3} and 10^{-2} nmol) or PDTC (10^{-3} and 10^{-2} nmol) prevented this effect (stress and treatment effect $p<0.05$). Most importantly, the drugs did not change behavior in non-stressed rats ($p>0.05$), indicating that its effect depends on alterations induced by the stress. Conclusions: Our results showing that RS-induced anxiogenic behavior involves iNOS and NF-kβ in the MPFC suggest that targeting inflammatory mechanisms in the MPFC could treat stress-related disorders.

Title: Neonatal administration of prolactin decreases glial population and attenuates stress-induced cytokine expression in the hippocampus of male rat pups

Authors: *L. TORNER[1], G. ZINZUN-IXTA[1], A. OCHOA-ZARZOSA[2]
[1]Inst. Mexicano Del Seguro Social, Morelia, Mexico; [2]Ctr. Multidisciplinario de Estudios en Biotecnología, Univ. Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Abstract: Abnormal activation of hormones and neurotransmitter systems early in life leads to a high vulnerability to develop physiologic alterations and produce psychiatric illness. Neonatal administration of prolactin (PRL) to rat pups was shown to reduce hippocampal neurogenesis by postnatal day (PN) 15. Since PRL is a cytokine, it probably exerts its actions through the modulation of the neuroendocrine system. Here we analyzed the effects of neonatal PRL on the morphology of hipocampal glial cells and on its cytokine expression (under basal and stress-stimulated conditions) in the hippocampus and in the periphery at PN15.
Sprague Dawley male rat pups were used. PRL (13 mg/kg bw) or vehicle were daily injected to pups through PN1-14, and other pups were left undisturbed (control). Pups were sacrificed on PN15, either under basal (no-stress) conditions or were subjected to a stressor (3h maternal separation) before sacrifice. Brains (basal) or hippocampi (basal/stress) were isolated and trunk blood was collected. Immunocytochemistry for GFAP and Iba1 was performed to analyze glial cells; qPCR was used to assess TNF-α, IL-1$_\beta$, e IL-6 expression in the hippocampus and ELISA techniques to evaluate plasma cytokine concentrations.
We show that neonatal PRL administration has no effect on microglial cell density in the hippocampus, and no change in the amount of the activated cells was found. In contrast, PRL induces a significant decrease in the astrocyte population in the hipocampal hilus. Hippocampal expression of TNF-α, IL-1$_\beta$, e IL-6 was not altered by PRL under basal conditions, but it became attenuated in response to stress. Peripheral concentrations of TNF-α increased in PRL-treated pups under basal and stressed conditions, IL-1$_\beta$ concentration decreased in PRL-treated pups after stress, and IL-6 concentration was not affected. We conclude that a chronic neonatal administration of PRL induces an attenuated response of cytokine expression in response to stress, perhaps due to a decreased population of astrocytes. Title: Effects of chronic low-grade inflammation on basolateral amygdala function in rats

Authors: *S. MUNSHI, J. A. ROSENKRANZ
Rosalind Franklin Univ. of Med. & Sci., North Chicago, IL

Abstract: Systemic inflammation and infection can cause changes in mood or affect accompanied by a group of physical manifestations including lethargy, malaise, anhedonia, listlessness, decreased appetite and fever. These changes in the neurophysiologic and behavioral aspects seen with peripheral inflammation are mediated at the molecular level by proinflammatory cytokines such as interleukin (IL)-1β, IL-6, and TNF-α. The basolateral amygdala (BLA) is a key brain region involved in emotion. Recent evidence suggests that acute peripheral immune challenge by the proinflammatory cytokine IL-1β in a dose that causes sickness-like behavior alters *in vivo* BLA neuronal firing in rats. Although acute infection and inflammation are associated with the pathogenesis of sickness behavior, very little is known about how chronic, low ("subthreshold") dose of inflammation affects mood and behavior, especially at the level of the BLA neuronal involvement. In the present study, adult male Sprague Dawley rats were treated with different doses of the inflammagen IL-1β (0, 0.25, 0.50 and 1 μg, intraperitoneal (i.p.), single dose) to determine their time-dependent effects (30 min, 2h, 4h and 24h) on locomotion in the open field test. Low dose of IL-1β (0.25 μg) did not cause any significant decrease in the distance traveled and the speed of movement. Hence this dose was used to induce a chronic low-grade inflammation without causing overt sickness. We hypothesized that chronic low-grade inflammation affects BLA-dependent behaviors and increases the BLA neuronal activity. To test this hypothesis, low-dose IL-1β (0.25 μg, i.p.) was administered twice/day for five consecutive days. On the sixth day, anxiety-like behavior was evaluated by open field test, and spontaneous BLA neuronal firing rate was determined using single-unit *in vivo* extracellular electrophysiological recordings. Our preliminary behavioral data show that the chronic low-dose of IL-1β (CLD $_{(IL\text{-}1\beta)}$) causes a trend of decrease in the time spent and the distance traveled in the central area of the open field, without affecting the total distance traveled and the speed of movement, indicating that the CLD $_{(IL\text{-}1\beta)}$ causes anxiety-like behavior. Additionally, our electrophysiological data show that the spontaneous neuronal firing rate is significantly increased in the CLD $_{(IL\text{-}1\beta)}$ group compared to the control. These results indicate that chronic subthreshold inflammation can induce anxiety behavior and amygdala hyperactivity even in the absence of overt sickness. This may contribute to effects of inflammation in mood disorders.

Title: Stress impairs memory and activates caspase-1 via a mechanism involving adrenergic signaling and adenosine

Authors: *A. E. TOWERS[1], M. L. OELSCHLAGER[2], M. R. LORENZ[3], G. G. FREUND[4]
[1]Div. of Nutritional Sci., [2]Animal Sci., [3]Program in integrative immunology and behavior, [4]Dept. of Pathology, Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Inflammation is a central component to the etiology of many cognitive and mood disorders (Dantzer et al., 2008). In the brain, one of the main pro-inflammatory messengers is the cytokine IL-1β. Recent evidence suggests that stress induced by a variety of common events, such as handling, environmental changes, and metabolic disruptions can activate the IL-1 arm of the neuroimmune system leading to cognitive impairment and anxiety-like behaviors (Goshen and Yirmiya, 2009). However, the precise mechanisms by which stress activates IL-1β in the brain remain poorly understood. Here we subjected 10-week old male C57BL/6 mice to handling stress utilizing common experimental procedures (ie. weighing, scruffing, and needle prick) over a period of 6 hrs. 6 hrs of stress increased the IL-1β activating enzyme caspase-1 by 120% in the prefrontal cortex, amygdala, and hippocampus. Stress also impairs recognition memory in the novel object recognition (NOR) task by 12%. These effects of stress on NOR are mechanistically linked to IL-1β activation, as genetic deletion of both caspase-1 and IL-1 receptor 1 (IL1R1) increased NOR by 13% and 21%, respectively, as well as pharmacological inhibition of IL1R1 by 12%. To determine how the stress response hormones affect stress-induced memory impairment we administered mice propranolol and mifepristone prior to initiating stress. Propranolol increased NOR by 13%, while mifepristone had no effect on NOR suggesting that the adrenergic stress hormones mediates memory impairment due to stress. As adrenergic signaling can increase extracellular adenosine levels (Crosson and Petrovich, 1999), and we have previously shown exogenous adenosine is capable of inducing anxiety-like behaviors (Chui et al., 2014), we wanted to determine if adenosine plays a role in stress-induced memory impairment. We found that blocking adenosine signaling by administration of caffeine improved novel object performance following stress by 16%. Furthermore, the effects of adenosine during stress appear to be specific to the A2A receptor, as A2A specific antagonists, but not A1A antagonists, improved memory by 18% following stress. Inhibition of the A2A receptor also decreased caspase-1 activation by 80% in the amygdala following stress. Taken together, these data show that it is the adrenergic arm of the stress response, through its effects on adenosine signaling, that leads to IL-1β activation in the brain and cognitive impairment. These results further our understanding of how stress interacts with the neuroimmune system, as well as identify new potential targets for therapeutic intervention.

Title: Estradiol mediates chronic stress effects on microglial morphology in medial prefrontal cortex in female rats

Authors: *J. L. BOLLINGER, C. L. WELLMAN
Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Recent studies indicate a role for neuroimmune pathways and microglia in psychological health and disease. Microglia can regulate synaptic plasticity by releasing neuroactive factors, directly pruning dendritic spines, and modulating neuronal architecture. We have shown that stress differentially affects microglial cell activation and immune factor expression in males and females in a number of brain regions critical for emotion regulation and cognitive function, including medial prefrontal cortex (mPFC). Contrary to findings in male rats, chronic stress reduces microglial morphological activation state in the prelimbic region (PL) of mPFC in females. To investigate the potential role of 17β-estradiol (E) in stress-induced microglial remodeling in female rats, animals underwent sham surgeries (SHAM), ovariectomies (OVX), or ovariectomies with E replacement (OVX+E). After a recovery period, rats received daily restraint stress (3 h/day, 10 days) or were left unhandled except for weighing. Following the final day of restraint, brains were processed for visualization of microglia via Iba-1 immunohistochemistry. In 4 sections evenly spaced through the rostral-caudal extent of PL, the total area of Iba-1-positive (Iba-1+) material was assessed within layers 1, 2/3, 5, and 6 (for a total of 32 separate 67,500 μm^2 sampling areas per rat) using a semi-automated thresholding technique. The total area of Iba-1+ material was similar across unstressed groups regardless of hormonal manipulation. Congruent with previous findings, chronic stress reduced the total area of Iba-1+ material in mPFC in SHAM females, suggesting a reduction in morphological activation state. Chronic stress had no effect on the total area of Iba-1+ material in OVX females. However, the chronic stress-induced reduction in Iba-1+ material was restored in OVX+E animals. Thus, estradiol mediates the effects of chronic stress on microglial morphology in mPFC in female rats. This suggests that gonadal hormones may contribute to the differential effects of stress on microglial biology in mPFC and, in turn, neural structure, function, and behavior in males versus females.

Title: Exposure to an acute stressor disinhibits microglia via down-regulation of CD200R: A mechanism of neuroinflammatory and microglial priming

Authors: *M. G. FRANK, *M. G. FRANK, L. K. FONKEN, J. ANNIS, L. R. WATKINS, S. F. MAIER
Univ. of Colorado, Boulder, CO

Abstract: Prior exposure to acute and chronic stressors has been found to potentiate the neuroinflammatory and microglial response to subsequent immune challenges, suggesting that stress shifts the activation state of microglia from surveillant to primed. Interestingly, a primed immunophenotype has also been observed in animals lacking CD200, a neuronal and endothelial membrane glycoprotein that inhibits microglia through its cognate receptor CD200R. Thus, we explored the possibility that disruption of CD200:CD200R signaling may be involved in stress-induced neuroinflammatory priming. Male Sprague-Dawley rats were exposed to inescapable tailshock (IS) or served as home cage controls (HCC), and 3 separate experiments were conducted to measure mRNA expression of CD200R 24 hr after stress in 1) whole hippocampus, 2) micropunches of hippocampal sub-regions (CA1, CA3 and dentate gyrus) and 3) hippocampal microglia. We found that IS induced a consistent and robust down-regulation of CD200R in each experiment. Additional immunophenotypic markers (MHCII, TLR4, RAGE, CX3CR1 and CD200) as well as pro-inflammatory mediators (IL-1 beta, IL-6, TNFa, NF-kBIA and NLRP3) were measured in these experiments, but only CD200R was significantly altered by stress at the 24 hr timepoint. This down-regulation of CD200R suggested that CD200:CD200R inhibitory signaling of microglia may similarly be down-regulated, thereby inducing a primed immunophenotype in microglia. To test this notion, male Sprague-Dawley rats were injected intra-cisterna magna with a soluble fragment of CD200 (CD200 Fc; 5 ug) or a control protein (human IgG1 Fc) in sterile PBS. Immediately after injection, animals were exposed to IS or served as HCC. 24 hr after IS treatment, hippocampal microglia were isolated, suspended in media (DMEM + 10% FBS) and treated with the TLR4 agonist lipopolysaccharide (LPS; 0, 1, 10 and 100 ng/ml) for 2hr. mRNA of pro-inflammatory mediators was then measured using real time RT-PCR. Consistent with prior findings, exposure to IS potentiated the pro-inflammatory response (IL-1 beta, TNFa, NF-kBIA, and NLRP3) to LPS compared to the cytokine response in HCC. Treatment with CD200 Fc blocked this stress-induced potentiation of the pro-inflammatory response to levels observed in HCC animals, suggesting that CD200 Fc had abrogated stress-induced priming of microglia by increasing inhibitory drive via CD200R. Taken together, the present findings suggest that stress-induced down-regulation of CD200R on microglia may serve to disinhibit microglia, thereby priming the microglial pro-inflammatory response to subsequent immune challenges.

Title: Neuromolecular mediators of resilience to chronic stress in the bed nucleus of the stria terminalis of the mouse

Authors: *A. GURURAJAN[1], J. M. LYTE[2], A. VENTURA DA SILVA[2], G. M. MOLONEY[1], T. M. BECKER[2], R. O. CONNOR[2], M. BOEHME[2], M. V. WOUW[2], *B. MERCX[1], T. G. DINAN[2], J. F. CRYAN[1]
[1]Anat. & Neurosci., [2]APC Microbiome Inst., Univ. Col. Cork, Cork, Ireland

Abstract: Chronic stress is a major risk factor for the onset of various psychopathologies. However, not all who are exposed go on to develop the symptomatology that is associated with these disorders, a phenomenon termed stress resilience. Several key limbic structures have been implicated as regulators of the stress response, namely the prefrontal cortex, amygdala and the hippocampus. Their effects on the HPA axis are via subthalamic relay structures such as the bed nucleus stria terminalis (BNST). Thus, the BNST is centrally placed to gate the response to stress and may play an unexplored, critical role in determining whether an individual is stress resilient or stress susceptible. The aim of our study was to identify correlates of stress resilience and stress susceptibility. Additionally, we wanted to characterise the neuromolecular phenotypes of the BNST in both groups of mice. Male C57Bl/6 mice were subjected to the chronic psychosocial defeat stress paradigm after which they were tested for social avoidance behaviour and labelled as either stress-resilient or stress-susceptible based on test performance. Prior to the start of the paradigm and the day after the last defeat session, tail blood was collected for analysis of plasma corticosterone levels. The day after behavioural testing mice were culled. Trunk blood was collected and used to characterise the immunophenotype by flow cytometry. Brains were dissected out into several brain regions which were processed to analyse expression of genes implicated in the stress-response; for some mice, the hippocampus was used for microelectrode array experiments. Peripheral corticosterone levels were higher in stress susceptible than stress resilient mice before and after the social defeat stress paradigm. PCR analyses revealed regionally specific effects on the expression of corticotrophic release factor and its receptors, gluco- and mineralocorticoid receptors and FKBP5. RNA-Seq of the BNST is ongoing to identify differential expression of coding and non-coding genes. Flow cytometry and electrophysiology analyses are also underway to detect differences between stress resilient and stress susceptible mice. **Conclusion:** Consistent with recent literature, we have shown that stress

resilience is defined by a complex molecular and physiological profile which spans central and peripheral compartments. Stress resilience could be predicted based on baseline peripheral corticosterone levels. Importantly, our research will potentially reveal a role for the BNST not just as a relay station for limbic input but also a structure involved in neuroadaptative processes that facilitate the development of stress resilience.

Title: Acute-stress induced gastrointestinal serotonergic responses are region-dependent and host strain specific

Authors: *J. M. LYTE[1], M. S. GOODSON[3], N. KELLEY-LOUGHNANE[3], T. G. DINAN[2], J. F. CRYAN[2], G. CLARKE[2]
[2]APC Microbiome Inst., [1]Univ. Col. Cork, Cork, Ireland; [3]711th Human Performance Wing, Air Force Res. Lab. Wright-Patterson Air Force Base, Dayton, OH

Abstract: Objective: Host genetics influence the acute stress response, the impact of which is frequently manifested in altered gastrointestinal function and exacerbated in brain-gut axis disorders such as irritable bowel syndrome.Gut-derived serotonin (5-HT) produced following a stressor can exert physiologically and clinically important local and systemic effects. We sought to define the gastrointestinal serotonergic system response to and recovery from an acute stressor in genetically-distinct mice strains. **Methods:** Adult male NIH Swiss Webster, BALB/c, and C57/BL6 mice were randomly allocated to the unstressed control or stress group. Stressed animals were subjected to 15min of restraint stress (n=4-8 mice/timepoint/strain) and sacrificed

post-stressor +0, 5, 15, 30, 45, 60, or 240min. Plasma corticosterone was assayed using an ELISA. Ileal and colonic 5-HT and 5-HIAA concentrations were determined using HPLC. Results were analyzed by student's t-test or ANOVA, where applicable, and statistical significance was set at a $p<0.05$. **Results:** Plasma corticosterone was significantly ($p<0.05$) elevated immediately after restraint stress compared to control group in each strain. C57/BL6 exhibited a greater ($p<0.05$) plasma corticosterone concentration post-stressor compared to BALB/c or NIH Swiss Webster mice. Colonic 5-HT levels were higher than ileal 5-HT in all mouse strains. Strain differences in distal ileal 5-HT and 5-HIAA concentrations at baseline were maintained post-stressor. Ileal 5-HT and 5-HIAA concentrations were frequently highest in C57/BL6 compared to other strains at baseline and post-stress. Proximal colonic 5-HT and 5-HIAA were different ($p<0.05$) at several post-stressor timepoints in C57/BL6 compared to other strains. Analyses are ongoing for neural correlates following an acute stressor. **Conclusions:** Host genetics heavily influences the stress response. The C57/BL6 strain displayed the largest post-stress HPA axis activity and had higher levels of 5-HT in the colon and ileum at multiple timepoints post-stressor. Further studies are required to understand the implications of these findings for the control of stress-induced 5-HT-mediated gastrointestinal symptoms and to assess the role of the gastrointestinal microbiota and microbial metabolites in regulating the local gastrointestinal serotonergic system response to acute stressors.

Title: The effects of stress-inflammation interaction on behavior and gene expression in mice models of mood and anxiety disorders

Authors: *S. FLAISHER-GRINBERG[1], L. OLEK[2], J. KUEHN[2]
[1]Dept. of Psychology, [2]St. Francis Univ., Loretto, PA

Abstract: Chronic exposure to stress affects a variety of physiological systems and has been linked to the activation or amplification of pathological conditions such as depression, Post-Traumatic Stress Disorder and Alzheimer's. While neuroinflammation has been implicated in the deleterious outcomes of chronic stress, the effects of the timing, and regimen of immune activation on brain area-specific gene expression and behavioral functioning is yet to be determined. The current project evaluated the effects of acute and repeated Lipopolysaccharide (LPS, a pro-inflammatory agent) administration, before or during the exposure of C57BL6/J mice to the unpredictable chronic mild stress paradigm. Behavioral effects were assessed using the Open Field, Black-White box, Elevated-Plus Maze, Tail-Suspension Test and Forced Swim Test, and the expression of NPY1R, NPYR2, BDNF and HTR2C genes was evaluated in the hippocampus, hypothalamus, amygdala and medial-prefrontal cortex of C57BL6/J mice using qPCR. Results demonstrate that the combination of chronic stress exposure and pro-inflammatory challenge yield differential effects on mood and anxiety-related behaviors, as well as region-specific gene expression. The findings provide insight into the mechanisms regulating the behavioral response to stress and inflammation, and highlight particular targets for brain area-specific intervention.

Abstract: Background: Early childhood adversity has been previously implicated with lifelong altered stress reactivity. Maladaptive stress reactivity may result in compromised neurocognitive and emotional regulation aptitudes and may lead to acute and chronic post traumatic stress disorder and depression. The current study explores the predictive value of blood based expression changes for identifying individual stress related vulnerability. **Methods:** Several hundred adolescent trainees undergoing combat military training were screened for exposure to early childhood trauma. An extremes case control sample compared those with high and low childhood trauma for prospective anxiety depressive and post traumatic symptoms, neuropsychological measures, and blood sampling, at rest and during exposure to extreme stress under simulated combat training conditions. Premorbid characteristics and neuropsychological and biological measures were employed to predict mal/adaptive outcomes following simulated combat. **Results:** Distinct blood expression profiles and psychological measures mark stress vulnerability and may help predict longer term outcomes before and immediately following exposure to trauma. **Conclusion:** Distinct signatures in blood may help focus preventive and interceptive efforts on vulnerable subjects during stress exposure and at its immediate aftermath, before chronic PTSD or depression develop. Results may further shed light on the role of inflammatory and neuro endocrine reactivity in mediating the transduction of stress into long term maladaptive neuropsychiatric outcomes.

Abstract: Background: Altered immune cell reactivity during the development of depression after delivery, may point to biomarkers and potentially implicate underlying immune mechanisms. Methods: Genome scale mononuclear expression patterns after delivery were compared between mothers prospectively diagnosed with depression and resilient mothers. Results: Differential immune cell gene expression patterns associate significantly enriched pathways revealing altered immune function that accompany the triggering of postpartum depression. Pathway involvement implicate relevant immune candidates. Discussion: Differential mononuclear cell transcripts sampled postpartum point to unique immune activation among depressed mothers. Beyond serving as potential biomarkers, findings may point to pathogenetically relevant molecular targets involved in the development of depression.

Title: Effects of repeated stress on the ying-yang of catecholamines and glucocorticoids in the regulation of brain cytokines

Authors: *D. F. BARNARD[1], K. GABELLA[1], A. KULP[2], A. PARKER[1], J. D. JOHNSON[3]
[2]Biomed. Sci., [3]Biol Sci. Dept, [1]Kent State Univ., Kent, OH

Abstract: The elevation in pro-inflammatory cytokines in the brain, particularly IL-1β, following stress exposure have potent behavioral and physiological altering effects. Stress-induced cytokine responses are tightly regulated by catecholamines and glucocorticoids, which have opposing regulatory control over pro-inflammatory cytokine production. Specifically, catecholamines enhance cytokine production via beta-adrenergic receptors (β-ARs) while glucocorticoids (largely corticosterone in rodents) suppress cytokine production. The aim of this current study was to examine how repeated stress exposure effects the regulation of brain pro-

inflammatory cytokines. Fischer rats were exposed to four days of repeated mild stress and 24h following the last stressors animals were administered vehicle, propranolol (β-AR antagonist), metyrapone (corticosterone synthesis inhibitor) or combination of propranolol and metyrapone. Two hours after drug injections, limbic areas (Amygdala, Hippocampus, and Hypothalamus) were collected and processed for measurement of IL-1β mRNA. Stress had no effect on basal IL-1β mRNA levels in vehicle treated animals. Administration of propranolol had no effect in non-stressed controls; however, it did significantly decrease IL-1β mRNA in stress animals in the amygdala and hippocampus. Metyrapone significantly increased IL-1β mRNA in both control and stressed animals in the amygdala and hypothalamus, but the increase was blocked by prior administration of propranolol. These data indicate that β-AR stimulation is critical for maintaining basal IL-1β production in the amygdala and hippocampus of animals exposed to repeated stress. Furthermore, the increase in levels of IL-1β mRNA following blockade of corticosterone synthesis is dependent on β-AR stimulation, suggesting glucocorticoids may regulate brain cytokines via modulating norepinephrine release. Currently, similar studies using female animals will uncover potential sex differences in the effect repeated stress has on the regulation of brain IL-1β production.

Title: Sex-differences in prenatal stress model of microglial activation in stress-regulating structures

Authors: *S. N. CASSELLA, E. J. JONES, D. WILSON, A. GRANT, E. RHINEHART
Susquehanna Univ., Selinsgrove, PA

Abstract: Prenatal stress has shown to have adverse effects on various aspects of the developing brain, such as alterations in neuroendocrine functioning and neuroinflammatory processes. These changes may directly contribute to the development of psychiatric disorders such as addiction, anxiety, and schizophrenia. Psychiatric disease research has found an association between these disorders and altered immune function. The innate immune cells of the central nervous system are microglia, and they range in morphology from ramified with a surveying function, to amoeboid with a pro-inflammatory function. Neuroinflammation occurs when microglia

accumulate and become active. We sought to determine if our prenatal stress model would induce neuroinflammation that would correlate with previously reported changes in neuroendocrine and behavioral outcomes, and further, if these alterations differed between the sexes. To model prenatal stress, we used a food deprivation paradigm (FD50) in which food was restricted by 50% during the second half of pregnancy. We examined microglia in the stress response-regulating regions of the hippocampus, prefrontal cortex (PFC), amygdala, and hypothalamus. Offspring brains were collected at postnatal day (P) 30 and P60 and microglial morphology was analyzed via soma area and branching complexity to determine differences in relative activation between groups. Ongoing analysis shows a significant increase in soma size between the control and restricted groups in only the infralimbic PFC of females, suggesting that these cells are functioning in a relatively activated state. Understanding the relationship between prenatal stress, inflammation and behavioral alterations could lead to enhanced prenatal care and therapies in the future.

Title: Microglia during early life contribute to myelination, HPA axis development, and the behavioral effects of neonatal stress

Authors: *L. H. NELSON[1], S. WARDEN[2], K. M. LENZ[3]
[1]Ohio State Univ., Columbus, OH; [2]Dept. of Neurosci., The Ohio State Univ., Columbus, OH; [3]Psychology, Ohio State Univ. Dept. of Psychology, Columbus, OH

Abstract: Microglia, the brain's resident immune cells, regulate many processes of normal brain development, including cell genesis, cell death, myelination, axon guidance, and synaptic patterning (Pierre et al., Brain Behav Immun 2016). Early life perturbations, such as stress, perturb microglial function, and increase anxiety-like behavior (Delpech et al., Brain Behav Immun, 2016). We have previously shown that neonatal microglial depletion during the early postnatal period decreases anxiety, behavioral despair and the acute stress response in adulthood (Nelson et al., 2016, Bev Brain Res). Yet the mechanisms through which microglia impact the early life programming of mood related behavior at baseline or in response to early life perturbations remains unknown. To probe the mechanisms through which microglia contribute to

such early life programming of behavior, we centrally infused liposomal clodronate (2μL icv; Encapsula Nanoscience) on postnatal days (P) 1 and 4, which temporarily depletes 90% of forebrain microglia. To determine the brain regions responsible for the dampened HPA axis response we previously observed in microglia depleted animals, we assessed cFos expression in the medial prefrontal cortex (mPFC) after acute restraint stress in adults. We found decreased cFos expression in the mPFC in clodronate treated animals relative to controls. We are currently assessing the cFos expression in the amgydala to determine if there is region-specific sensitivity to early life programming effects of microglia. Several studies have found changes in synaptic- and myelination-related gene expression due to early life stress (Wei et al., 2015 Dev Neuro; Bath et al., 2016 Horm Bev) thus microglia may be programming mood-related behavior via underlying changes in these endpoints. We assayed the gene expression of several synaptic genes (NR2A, NR2B, PSD95, vGlut1) and the developmental time-course of myelin basic protein (MBP) in the mPFC and amygdala following microglial depletion. We found no changes in synaptic genes at P12 in the amygdala. However, we found that MBP was decreased at P12 in the mPFC and amygdala, and still decreased at P22 in the amygdala but increased at P22 in the mPFC. Currently, we are combining early life microglial depletion with maternal separation stress to determine whether microglia are necessary for stress-induced programming of mood-related behavior and underlying perturbations in brain development. These studies are important for elucidating the functional role that microglia play in normal and abnormal development of the brain and behavior.

Abstract: β-adrenergic signaling has been found to affect important intracellular processes that contribute to cancer development and progression. In the tumor microenvironment, β-adrenergic receptors on tumor cells are activated by norepinephrine released from peripheral sympathetic nerve fibers. Clinical and pre-clinical investigations have associated the use of propranolol (a non-specific β-antagonist) to reduced rates of progression for solid tumors. Although norepinephrine-activated β-adrenergic signaling has been increasingly linked to cancer progression, this neuroendocrine mechanism in the carcinogenesis context is still poorly understood. In this pre-clinical study, we have used a new methodology based on oral carcinogenesis model in rats to test the hypothesis that norepinephrine levels in the normal tissue microenvironment pre-carcinogenic induction would have a significant predictive value for cancer occurrence and progression. Male Wistar rats were underwent to a normal tongue tissue biopsy for measuring norepinephrine levels before carcinogenic induction with 4-nitroquinoline-1-oxide (4NQO) carcinogen. Then, animals were euthanized for evaluation of oral squamous cell carcinoma (OSCC) or oral leukoplakia (non-cancerous lesion) occurrence into tongue. Increased norepinephrine concentrations in the tissue microenvironment before 4NQO treatment were predictive for OSCC occurrence. Higher pre-carcinogen hormone levels were also correlated to CDKN2a-p16 mRNA lower expression in OSCCs. Furthermore, increased norepinephrine concentrations in OSCC were associated to a higher tumor volume and thickness, and with a lesser intensity of the lymphoplasmocytic infiltrate underlying to tumor. In another experimental set, to assess the effects of adrenergic signaling on OSCC incidence, animals were treated with propranolol or only saline solution (sham group) during carcinogenic induction. Propranolol treatment inhibited OSCC incidence and reduced cancer-related cachexia. This study demonstrates that increased pre-carcinogen norepinephrine levels in the normal tissue microenvironment can be predictive for chemically induced carcinogenesis in rats. Moreover, the suppression of adrenergic signaling protected these animals from the cancer development.

Title: Preimmunization with heat-killed Mycobacterium vaccae enhances fear extinction in the rat fear-potentiated startle paradigm

Authors: *J. E. HASSELL, JR[1], J. H. FOX[1], P. H. SIEBLER[1], M. R. ARNOLD[1], A. K. LAMB[1], D. G. SMITH[2], H. E. W. DAY[3], T. SMITH[1], E. M. SIMMERMAN[1], A. A. OUTZEN[1], K. S. HOLMES[1], C. J. BRAZELL[1], C. A. LOWRY[1]
[1]Integrative Physiol., [2]Chem. and Biochem., [3]Psychology and Neurosci., Univ. of Colorado, Boulder, CO

Abstract: The hygiene hypothesis or "Old Friends" hypotheses proposes that inflammatory diseases are increasing in modern urban societies, due in part to reduced exposure to microorganisms that drive immunoregulatory circuits, and a failure to terminate inappropriate inflammatory responses. Inappropriate inflammation is also emerging as a risk factor for trauma-related, anxiety, and affective disorders, including posttraumatic stress disorder (PTSD), which is characterized as persistent reexperiencing of the trauma after a traumatic experience. Traumatic experiences can lead to long lasting fear memories and fear potentation of the acoustic startle reflex. The acoustic startle reflex is an ethologically relevant reflex and can be potentiated in both humans and rats through Pavlovian conditioning. *Mycobacterium vacca*e is a soil-derived, bacterium with immunoregulatory and anti-inflammatory properties that has been demonstrated to confer stress resilience in mice. Here we immunized adult male Sprague Dawley rats 3x, once per week, with a heat-killed preparation of *M. vaccae* NCTC 11659 (0.1 mg, s.c., in 100 ul borate-buffered saline) or vehicle, and, then, 3 weeks following the final immunization, tested them in the fear-potentiated startle paradigm; controls were maintained under home cage control conditions throughout the experiment (n = 11-12 per group). Rats were tested on days 1 and 2 for baseline acoustic startle, received fear conditioning on days 3 and 4, and underwent fear extinction training on days 5-10. Rats were euthanized on day 11 and brain tissue was sectioned for analysis of *tph2, htr1a, slc6a4*, and *slc22a3* mRNA expression throughout the brainstem dorsal and median raphe nuclei. Immunization with *M. vaccae* had no effect on baseline acoustic startle or fear expression on day 5. However, *M. vaccae*-immunized rats showed enhanced between-session and with-session extinction on day 6, relative to vehicle-immunized controls. Immunization with *M. vaccae* and fear-potentiated startle altered serotonergic gene expression in a gene- and subregion-specific manner. These data are consistent with the hypothesis that immunoregulatory strategies, such as preimmunization with *M. vaccae*, have potential for prevention of stress- and trauma-related psychiatric disorders.

Title: Influence of depressive-like behavior on tumor onset and progression in a chemically induced cancer model

Authors: *D. G. BERNABE, L. KOBAYASHI, F. VERZA, V. VALENTE, J. FIGUEIRA, B. SARAFIM-SILVA, M. CRIVELINI, M. SUNDEFELD, É. BIASOLI, G. MIYAHARA, S. OLIVEIRA
São Paulo State Univ., Araçatuba, Brazil

Abstract: Cancer is often accompanied by psychological disorders. Some studies have suggested that psychological or behavior traits like depression are associated with cancer incidence and progression. Head and neck cancer (HNC) patients can show higher levels of psychological disorders like depression, but the association between depression-related behavioral phenotype and susceptibility to tumor is poorly known. In this study we have used a oral carcinogenesis model to test the hypothesis that high-depressive phenotype would result in an increased tumor incidence and progression of HNC chemically induced cancer. Wistar rats were phenotyped as high- or low-depressive at baseline prior to tumor induction using forced swim test. The rats were treated with carcinogen 4-nitroquinoline 1-oxide (4NQO) during 5 months for inducing oral squamous cell carcinomas (OSCCs). Tongue sections were analyzed by microscopy for OSCC occurrence and aggressiveness diagnosis. OSCC incidence was 30% higher in the high-depressive group compared to low-depressive animals. Rats with high-depressive phenotype showed increased tumor volume than those with lower levels of depression-like behavior. Moreover, tumors from high-depressive rats had a greater degree of nuclear pleomorphism. There were no differences between the two groups regarding other clinicopathological features as weight loss, tumor thickness, pattern of tumor invasion and microscopy lymphoplasmacytic infiltrate. The depression-like behavior was also examined after chemically induced carcinogenesis and depression levels were positively correlated with tumor size. These results

suggest that high trait depression may influence susceptibility to tumor initiation and/or growth in chemically induced cancers.

Title: Microglial responses in the dentate gyrus after 72 hours sleep deprivation in mice

Authors: *C. TSAO[1], L.-H. TUAN[1], L.-J. LEE[1,2,3]
[1]Grad. Inst. of Anat. and Cell Biol., [2]Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Sleep insufficiency is a serious health issue that has been linked with various physiological and psychological problems. In the present study, we adopted the multiple platform paradigm to deprive ERM sleep in adult mice. After 72 hours sleep deprivation, adult neurogenesis in the dentate gyrus was dramatically reduced. Since microglia play important roles in this process, we examined the morphometric features of microglia in the dentate gyrus. The density and morphology of Iba1-positive microglia were measured in the molecular layer, granular cell layer, subgranular zone and hilus subregions of the dentate gyrus, respectively. Compared with normal sleep and large platform controls, the density of microglia in sleep-deprived mice was increased in the hilus, while in other regions, the numbers were not altered. The morphology of microglia was also checked in a subregion-specific manner. In the molecular layer, the shape of microglia was not changed; whereas in all other subregions, the number and length of ramified microglial segments were reduced in 72-hour sleep-deprived mice. These results indicated a subregion-specific microglial responses in the dentate gyrus after sleep deprivation which could be correlated with the reduction of neurogenesis and impaired memory function in subjects of insufficient sleep.

Title: Yawning as a thermoregulatory response to manipulations of brain temperature

Authors: *M. L. SHOUP-KNOX, Z. FALK, M. D. KEITER
Psychology, James Madison Univ. Dept. of Psychology, Harrisonburg, VA

Abstract: The current study aims to measure brain temperature and the potentially thermoregulatory behavior of yawning in rats. Previous literature has shown that increases in brain temperature are followed by the onset of yawning, suggesting a thermoregulatory function which restores the brain to cooler temperatures (Shoup-Knox et al., 2011). Additionally, increasing environmental temperature results in increased yawning frequency as well as other thermoregulatory behaviors in parakeets (Gallup, Miller & Clark, 2009, 2010), white-faced capuchins (Campos & Fedigan, 2009, also see Gallup, 2010), and rats (Gallup, Miller & Clark, 2012). To elucidate the relationship of brain temperature and yawning frequency, independent of ambient temperature effects, it is necessary to directly manipulate brain temperature above and below the normative set point and observe the changes in yawn frequency. We propose that as we increase brain temperature we will observe an increase in yawning behavior, while decreasing the brain temperature, or holding it constant, will decrease or eliminate yawning behavior. Brain temperature was manipulated via close-ended stainless steel cannulas that were surgically implanted into the pre-optic anterior hypothalamus (POA), the area of the brain responsible for thermoregulatory behaviors. During each of four trials brain temperatures were collected and averaged over an initial 5-minute period to determine baseline. Then the POA was perfused with to water either 3° above baseline (hot condition), 1° above baseline (warm condition), or 3° below baseline (cool condition) brain temperature. Trials were each 30 minutes in duration (15 minutes water perfusion followed by 15 minutes no perfusion/recovery) and the temperature condition order was counterbalanced across animals. A control condition, also experienced by each animal, preserved baseline brain temperature. Yawning behavior was observed and recorded across the duration of each 30 minute trial. Preliminary analyses indicate that yawning occurs less frequently when baseline POA temperature is maintained and that yawning behaviors across all conditions are more likely to occur during the second 15-minute interval (recovery) of the trial. This suggests that yawning functions to restore homeostatic brain temperatures in response to warming and cooling. These data provide support for the hypothesis that yawning has evolved has as a thermoregulatory function.

Title: Increased core temperature following ablation of neurokinin 3 receptor-expressing neurons in the mouse median preoptic nucleus and adjacent preoptic area (MnPO/POA)

Authors: S. J. KRAJEWSKI-HALL, 85724[1], E. M. BLACKMORE[1], J. R. MCMINN[1], N. T. MCMULLEN[2], *N. E. RANCE[1,2,3]

Abstract: We have previously proposed that KNDy neurons play a role in the generation of hot flushes via neurokinin 3 receptor (NK_3R) signaling in the preoptic hypothalamus. This hypothesis is strongly supported by recent clinical studies showing that the number and severity of hot flushes is reduced by treatment with NK_3R antagonists. To determine if preoptic NK_3R neurons modulate thermoregulation in the mouse, we selectively ablated them using injections of saporin conjugated to a NK_3R agonist (NK_3-SAP). NK_3-SAP was stereotaxically injected into Tacr3-EGFP mice to target the MnPO/POA. Controls received injections of BLANK-SAP. The mice were ovariectomized (OVX) and a telemetry probe was implanted i.p. to measure core temperature (T_{CORE}) and activity. Skin temperature (T_{SKIN}) was monitored using a temperature data-logger attached to the surface of the tail. In experiment 1, circadian temperature rhythms were monitored over a 3 day period in mice housed in their home cages (12 light:12 dark). In experiment 2, mice were exposed to three temperatures, 18, 28 and 35ºC, in an environmental chamber. Mice were then implanted s.c. with estradiol (E_2) capsules and the experiments repeated. We verified by immunohistochemistry and quantitative microscopy that approximately 80% of the EGFP-NK_3R neurons in the MnPO were ablated using NK_3-SAP. Ablation of NK_3R neurons significantly elevated T_{CORE} during the light phase in both OVX and OVX + E_2 mice (OVX: BLANK-SAP, 36.7 $\pm$ 0.1 vs NK_3-SAP 37.4 $\pm$ 0.1; OVX+E_2: Blank-SAP 36.1 $\pm$ 0.1 vs NK_3-SAP 36.8 $\pm$ 0.1). NK_3-SAP injections had no significant effect on T_{CORE} during the dark phase. Ablation of NK_3R neurons also increased T_{CORE} during the light phase in mice exposed to 18ºC and 28ºC. All mice exhibited hyperthermia at 35ºC. In contrast, ablation of NK_3R neurons in the MnPO/POA had no effect on T_{SKIN} or activity regardless of experimental treatment. These data suggest that NK_3R neurons in the MnPO/POA participate in the thermoregulatory axis by

promoting heat loss during the day and provide further insight into the CNS thermoregulatory pathways that may be activated during the generation of hot flushes.

Title: The TRPV1 channel modulates body temperature and cardiovascular responses during physical exercise in rats

Authors: A. C. KUNSTETTER[1], *A. A. ROMANOVSKY[2], W. C. DAMASCENO[1], D. D. SOARES[1], W. PIRES[1], S. P. WANNER[1]
[1]Physical Educ., Federal Univ. of Minas Gerais, Belo Horizonte, Brazil; [2]St Joseph's Hosp. and Med. Ctr., Phoenix, AZ

Abstract: Introduction: The transient receptor potential channel - vanilloid subtype 1 (TRPV1) is a polymodal channel activated by noxious heat, capsaicin and protons. The TRPV1 channel is involved in body temperature regulation in resting rats and in rats exposed to heat. Moreover, this channel mediates metaboreflex and baroreflex responses in rats under general anesthesia. Therefore, in this study, we investigated whether the TRPV1 channel modulates thermoregulatory and cardiovascular responses and performance in rats subjected to a physical exercise.
Methods: The study was approved by a local ethics committee (protocol 31/2014). Male Wistar rats aged between 16-19 weeks were implanted with an abdominal temperature sensor and with a catheter into the ascending aorta artery to measure their core body temperature and blood pressure, respectively. The rats received an intra-arterial injection of a TRPV1 antagonist, N-(4-[6-(4-trifluoromethyl-phenyl)-pyrimidin-4-yloxy]-benzothiazol-2-yl)-acetamide I (AMG 517), at a dose of 60 μg/kg or vehicle (20% ethanol and 80% saline) and then were subjected to a fatiguing, incremental-speed treadmill running at 24°C. During exercise, the rats had their pulsatile arterial pressure, abdominal and tail skin temperatures measured. Mean, systolic and diastolic arterial pressure and heart rate were obtained from the pulsatile arterial pressure

recordings. In addition, the maximal speed attained by the running rats was determined. Results: The injection of AMG 517 increased the abdominal (core) temperature threshold for cutaneous heat loss (38.79 ± 0.30°C vs. 37.66 ± 0.20°C; $p < 0.05$), thus exaggerating the exercise-induced increase in abdominal temperature (39.26 ± 0.43°C vs.38.37 ± 0.38°C; at fatigue; $p < 0.001$) relative to the injection of vehicle. Moreover, the blockade of TRPV1 channels induced a greater increase in mean (130 ± 4 mmHg vs. 120 ± 3 mmHg; at the 30th min; $p < 0.05$) systolic and diastolic arterial pressures. The heart rate increased in both trials, with exaggerated increases being observed during exercise performed after treatment with AMG517. The TRPV1 antagonist did not change the maximal speed attained by the rats (24.2 ± 1.0m/min AMG 517 vs. 22.9 ± 0.7 m/min vehicle; $p = 0.863$).
Conclusions: These data indicate that physiological TRPV1 activation increases cutaneous heat loss, thereby avoiding exaggerated increases in core temperature during exercise. Moreover, TRPV1 activation modulates the exercise-induced increase in arterial blood pressure and heart rate.

Title: A novel neuronal circuit for thermoregulatory inversion

Authors: *D. TUPONE[1,2], G. CANO[3], S. F. MORRISON[4]
[1]Neurosurg., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Dibinem, UNIBO, Bologna, Italy; [3]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA; [4]Neurolog. Surgery, Oregon Hlth. and Sci. Univ. Dept. of Neurolog. Surgery, Portland, OR

Abstract: We recently described Thermoregulatory Inversion (TI) (DOI: 10.1152/ajpregu.00022.2017), a novel thermoregulatory paradigm, which may be relevant for the induction of hibernation/torpor hypothermia and therapeutic hypothermia to improve outcomes in ischemic pathologies. In contrast to normal thermoregulation, during TI, skin cooling leads to the inhibition of brown adipose tissue (BAT) thermogenesis, whereas skin warming activates

thermogenesis. Here we demonstrate the existence of previously unrecognized, direct neuronal pathways between the dorsal lateral (dl) and the external lateral (el) subdivisions of the parabrachial nucleus (PBN) and the dorsomedial hypothalamus (DMH) that mediate, respectively, the skin cooling-evoked inhibition and the skin warming-evoked activation of BAT thermogenesis during TI. A pre-DMH brain transection induced TI in anesthetized rats that had also received an injection of the retrograde tracer CTb in the DMH. Warm exposure (90 min) of pre-DMH transected rats increased BAT thermogenesis and increased c-fos in DMH and in elPBN neurons projecting to DMH. In anesthetized rats after a pre-DMH transection, inhibition of neurons in either the DMH or the PBN blocked the warm-evoked activation of BAT thermogenesis characteristic of TI. These results are consistent with elPBN neurons relaying warm thermal information to the DMH, resulting in activation of DMH neurons and BAT sympathetic premotor neurons in the rostral raphe pallidus (rRPa) and eliciting a warm-evoked activation of BAT during TI. A population of dynorphinergic neurons in dlPBN projects to DMH, and injection of the k-receptor antagonist (NOR-BNI) in the DMH of pre-DMH transected rats prevents the cold-evoked BAT inhibition during TI. Also, a dynorphin injection in the DMH of intact rats blocks the cold-evoked activation of BAT. This demonstrates the existence of a novel dynorphinergic projection from dlPBN to DMH that may be involved in the inhibition of BAT thermogenesis during TI. We conclude that a novel, short- loop thermoregulatory pathway: skin thermoreceptors → PBN → DMH → rRPa mediates the inverted control of BAT thermogenesis during TI, and that a dynorphinergic input to DMH plays a role in the cold-evoked inhibition of BAT thermogenesis during TI.

Title: Protection of adiposity during dieting: A role for (lack of)leptin in the dorsomedial hypothalamus

Authors: *R. A. ADAN[1], R. PANDIT[1], A. OMRANI[1], S. E. LA FLEUR[2]
[1]UMCU, Utrecht, Netherlands; [2]Endocrinol. and Metabolism, Academic Med. Center, Univ. of Amsterdam, Amsterdam Zuidoost, Netherlands

Abstract: Weight loss in obesity is hampered by counter regulatory mechanisms such as reduced thermogenesis that can be reversed by injecting leptin peripherally. We discovered that restoring leptin signaling in the dorsomedial hypothalamic nucleus (DMH) is sufficient to normalize the reduced thermogenesis caused by withdrawal from an obesogenic diet. In support of this,

inhibition of leptin signaling in the DMH reduces thermogenesis and promotes adiposity independent of food intake. Leptin's effect on thermogenesis involves DMH neuronal projections to the lateral/dorsolateral periaqueductal grey area. When these neurons are depolarized by leptin or chemogenetically activated by CNO core body temperature and brown adipose tissue thermogenesis increases. These studies collectively demonstrate that a state of relative leptin deficiency during dieting reduces leptin signaling in the DMH resulting in reduced thermogenesis and provides a mechanistic explanation for preservation of adiposity despite lowered caloric intake during dieting.

Title: Bombesin-like receptor 3 neurons regulate body temperature, heart rate and food intake

Authors: *R. A. PINOL[1], S. H. ZAHLER[2,1], C. LI[3], B. TAN[3], A. SAHA[3], C. XIAO[3], O. GAVRILOVA[3], A. V. KRAVITZ[4], M. J. KRASHES[5], M. REITMAN[6]
[1]NIH, Natl. Inst. of Diabetes and Digestive, Bethesda, MD; [2]UCSF, San Francisco, CA; [3]NIH, Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD; [4]NIDDK, Natl. Inst. of Hlth., Bethesda, MD; [5]NIH, Bethesda, MD; [6]Diabetes, Endocrinology, and Obesity Br., NIDDK, NIH, Bethesda, MD

Abstract: Bombesin-like receptor 3 (Brs3) is an orphan G protein-coupled receptor expressed in several brain regions, including the dorsomedial hypothalamus (DMH) and paraventricular nucleus of the hypothalamus (PVH). Deletion of Brs3 in mice causes obesity, with reduced energy expenditure and increased food intake, as well as reduced resting body temperature and heart rate in the light phase. Brs3 agonists activate brown adipose tissue (BAT), suppress food intake and cause weight loss. The aim of this project is to identify populations of and circuitry employed by Brs3 neurons that contribute to the regulation of energy expenditure, body temperature, heart rate and food intake. The DMH and PVH have established roles in the regulation of energy expenditure, body temperature, hear rate and in food intake. Nucleus-targeted MK-5046 injections in the DMH, but not in the PVH, raised BAT temperature. Fos activation in DMH^{Brs3} neurons was increased in acutely cold-exposed mice, compared to acutely warm-exposed, but did not change in PVH^{Brs3} neurons. To assess the effect of acute activation of Brs3 populations in freely moving mice we developed Brs3-2A-Cre mice and expressed the

excitatory DREADD hM3D(q). Chemogenetic activation of DMH^{Brs3} neurons increased energy expenditure and body temperature, without influencing physical activity or food intake. In contrast, chemogenetic activation of PVH^{Brs3} neurons had no effect on energy expenditure or body temperature, but suppressed food intake. Optogenetic stimulation of DMH^{Brs3} neurons increased heart rate and blood pressure in addition to body temperature. Accordingly, chemogenetic inhibition of DMH^{Brs3} neurons in reduced the body temperature. DMH^{Brs3} neurons project to the preoptic area, paraventricular nucleus of the hypothalamus, periaqueductal grey and brain stem raphe pallidus (RPa), among other regions. Only optogenetic stimulation of axonal projections from DMH^{Brs3} to the RPa contribute to DMH^{Brs3} neuron mediated thermogenesis. Taken together, the results suggest that the food intake suppression and thermogenic effects of Brs3 activation are mediated by different subsets of Brs3-expressing neurons. Specifically, DMH^{Brs3} neurons can increase energy expenditure, body temperature and heart rate, and PVH^{Brs3} neurons can suppress food intake

Title: Erythropoietin in the brain reduces high fat-diet-induced microglial activation and regulates glucose metabolism

Authors: *S. DEY[1], J. CABAN[1], Z. CUI[2], M. GASSMANN[3], C. T. NOGUCHI[4]
[1]Mol. Med. Br., [2]Mouse Metabolism Core, NIDDK, Bethesda, MD; [3]Inst. of Veterinary(Physiology Vetsuisse Fac., Univ. of Zurich, Zurich, Switzerland; [4]Mol. Med. Branch, NIDDK, Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD

Abstract: High fat-diet (HFD) feeding adversely affects hypothalamic regulation of energy homeostasis. Saturated fatty acids present in HFD can enhance local inflammatory cytokine production and lead to disruption of glucose homeostasis. We hypothesized that Erythropoietin (Epo) signaling in brain could regulate HFD-induced inflammation and thereby maintain glucose and metabolic homeostasis. To study the effect of Epo in the brain, we examined a mouse model of chronic over-expression of human *EPO* transgene in brain (*Tg21*). On normal diet, weights for *Tg21* and wild-type (WT) mice were similar, but Tg21 mice showed significantly improved

glucose tolerance. Insulin levels were not markedly different during Glucose Tolerance Test (GTT) at 0 and 30 minutes for Tg21 and WT mice, but insulin level was significantly lower in Tg21 mice at 120 minutes after glucose injection. When placed on HFD-feeding for 3 weeks, *Tg21* mice gained less fat mass and body weight, and had lower fasting blood glucose compared to WT mice. Moreover, *Tg21* mice on HFD showed improved glucose tolerance compared to WT mice in GTT assay. Insulin levels at baseline were similar in *Tg21* and WT mice, increased transiently at 30 min after glucose injection with *Tg21* mice reaching a level twice that of WT mice, and returning to baseline at 120 minutes. Immunofluorescent staining of the arcuate nucleus region of hypothalamic sections showed lower inflammatory cytokine TNFα and activated microglia marker Iba1 in *Tg21* compared to WT mice. To determine the direct response in brain to elevated EPO, WT mice underwent acute intracerebroventricular administration of Epo (Epo ICV). EPO ICV prevented HFD-induced fat mass and weight gain relative to saline-controls (saline ICV), although no difference in food intake was observed. Epo ICV mice also showed lower fasting blood glucose. Hematocrits were unchanged compared with saline ICV, suggesting no peripheral effects of Epo ICV. Epo ICV mice showed lower hypothalamic gene expression for inflammatory markers *TNFα, IL6, IL1α, SOCS3* and higher expression of anti-inflammatory *IL10*. In summary, our studies suggest an important regulatory role of Epo in the brain in preventing HFD fat gain, glucose homeostasis, not mediated by a primary alteration in insulin production, and in protecting against HFD associated brain inflammation and microglial cell activation in the hypothalamus.

Title: Perinatal high fat diet leads to DNMT activity deficits in the offspring prefrontal cortex

Authors: *K. R. LLOYD[1], S. E. MCKEE[3], N. M. GRISSOM[4], B. L. SMITH[2], T. M. REYES[2]
[2]Psychiatry and Behavioral Neurosci., [1]Univ. of Cincinnati, Cincinnati, OH; [3]Univ. of Pennsylvania, Philadelphia, PA; [4]Dept. of Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Excessive gestational weight gain and maternal obesity increase the risk of neurological disorders, including schizophrenia, autism, and attention deficit/hyperactivity disorder (ADHD) in offspring. These disorders of cognition and attention implicate the prefrontal cortex (PFC), a region important for action selection, executive function, and inhibitory control. Previously, we have shown that offspring of a maternal high-fat diet (HFD) have whole-genome DNA hypomethylation, promoter-specific hypomethylation and dysregulated gene expression in the PFC, suggesting that DNA methylation deficits may contribute to the neurodevelopmental programming deficits induced by gestational exposure to a HFD. We were interested in understanding whether HFD offspring had specific deficits in DNA methyltransferase expression, localization or function which may contribute to the risk for neurodevelopmental programming deficits. Using a mouse model of maternal overnutrition, we identified decreases in overall DNMT activity due to maternal HFD in offspring, without changes in RNA gene expression or protein levels. We provide evidence for cytoplasmic sequestration of DNMT1 proteins, as cytoplasmic sequestration of DNMT1 has been observed in the PFC in schizophrenia and dementia. However, immunoprecipitation experiments revealed no difference in the binding of DNMT1 to kinases which regulate DNMT1 nuclear import and catalytic function. Overall, these findings demonstrate that early life nutrition can permanently alter the function of DNMT1 into adulthood, possibly predisposing to neurological disorders.

Title: Embryonic exposure to ethanol in zebrafish: Effects on development and migration of hypothalamic orexin neurons

Authors: *A. EVANS, E. RAMIREZ, V. HALKINA, V. KEWALDAR, G.-Q. CHANG, O. KARATAYEV, S. F. LEIBOWITZ
Rockefeller Univ., New York, NY

Abstract: Embryonic ethanol is known to increase alcohol drinking in humans and animals and have long-term effects on neurochemical systems in rodent brain. In our recent paper, we demonstrated a similar phenomenon in adult zebrafish (ZF), where voluntary consumption of an ethanol-gelatin meal significantly stimulates the orexigenic neuropeptide, orexin/hypocretin

(ox/hcrt), in the anterior hypothalamus (AH) and also behaviors induced by this peptide. Additionally, embryonic exposure to ethanol in water compared to control stimulates neurogenesis in the AH, the proliferation and expression of neurons expressing ox/hcrt, and voluntary consumption of 10% ethanol-gelatin in adult ZF. In this study, we further characterized this model of 10% ethanol-gelatin feeding and found that the daily number of bites taken by the ZF of an ethanol-gelatin meal in 5 minutes was the most reliable, day-to-day measure and strongly positively correlated with blood alcohol levels ($r=+0.73$, $p<0.05$). Daily consumption of an ethanol-gelatin meal for 4 weeks compared to plain gelatin significantly increased novelty-induced locomotor behavior and aggression in the adolescent offspring and neurogenesis and density of neurons expressing ox/hcrt in the AH, as revealed by immunofluorescence histochemistry and *in situ* hybridization. To further understand how early ethanol exposure affects the development of ox/hcrt neurons that promote ethanol intake and related behaviors, we utilized live imaging techniques to characterize the proliferation and migration of these neurons in the hcrt:EGFP transgenic fish. Using Imaris software, examination of larvae exposed to 0.5% ethanol in water from 22-24hpf and imaged from 24 to 28hpf revealed a novel finding, that ethanol compared to water control strongly hinders the movement of ox/hcrt cells within the developing hypothalamus. In response to ethanol, the ox/hcrt cells traveled a shorter net distance within the 4 hour imaging period, as indicated by a decrease in displacement length ($p<0.03$). They also migrated in a disorganized manner, as indicated by the reduced straightness of their individual migratory paths ($p<0.01$). Further, preliminary data suggest that the horizontal movement of ethanol-exposed cells differs from controls, with the latter moving away from the midline while the former migrate towards it. This demonstrates that embryonic exposure to ethanol in ZF markedly affects the brain and behavior of larval and adult offspring, providing new evidence for ethanol-induced changes in the migratory path of ox/hcrt cells in developing hypothalamus that may affect their ultimate location and contribute to the behavioral disturbances.

Title: Effects of maternal over-nutrition on offspring´s cognitive processes and behavioral patterns

Authors: *Y. BARB[1], E. NAVARRETE[1], R. MONTÚFAR-CHAVEZNAVA[2], A. SALAZAR[1], P. OSTROSKY-SHEJET[1], I. CALDELAS[1]
[1]Inst. De Investigaciones Biomédicas, UNAM, Ciudad de México, Mexico; [2]Facultad de Ingeniería, Univ. Nacional Autónoma de México, Ciudad de México, Mexico

Abstract: Chronic malnutrition during pregnancy has been associated to structural, physiological and metabolic changes, as well as behavioral impairments in the offspring. It is critical to elucidate whether chronic over-nutrition induced by the intake of a high lipids and carbohydrates diet during pregnancy, affect the cognitive processes and behavioral patterns of the offspring. In order to address this issue, a Food Preference Test (FPT) and a Novel Object Recognition Test (NOR), were performed on six months old European rabbits obtained from females fed with a standard diet (CON) or with a high lipids and carbohydrates diet during gestation (HLCD). In order to asses if the HLCD rabbits had a predisposition for unbalanced food, FPT was performed with a total of 47 rabbits. In order to evaluate the effect of the nutritional status during embryonic development on short-term declarative memory of offspring, the NOR test was performed with a total of 40 rabbits.
In the FPT, animals from the HLCD group ingested significantly more food than the rabbits from the CON group. HLCD males required more time to choose one of the diets. However, the sequence of behaviors associated with food consumption was similar between both groups, with the exception of grooming, that exhibited a significant increase in the frequency in the HLCD animals. The grooming and urination frequency was greater in males than in female rabbits. In the NOR test, the HLCD rabbits exhibited a significant increase on the latency of exploration of the novel object.
Preliminary results from the FPT indicate that the subjects obtained from over-nourished females exhibit hyperphagia, however, they did not show a preference for high fat/carbohydrates diets, as suggested in studies in other species. The significant increase in the grooming behavior presented by the rabbits of the HLCD group, in the FPT test, may be considered as an indicator of the presence of stereotyped and/or compulsive behaviors. In addition, the HLCD rabbits require more time to exhibit a proper response to novel objects. Further studies are needed to determine with more accuracy the effects of maternal nutrition on cognitive processes.

Title: Female adolescent opioid exposure confers vulnerability to metabolic dyshomeostasis in F1 offspring in a diet-specific context

Authors: *A. TOORIE[1], F. M. VASSOLER[2], A. KUBEREK[3], C. WYSE[3], E. M. BYRNES[4]
[1]Biomed. sciences, Tufts Univ., North Grafton, MA; [2]Dept. of Biomed. Sci., Tufts Univ. Cummings Sch. of Vet. Med., North Grafton, MA; [4]Biomed. Sci., [3]Tufts Univ. Cummings school of Vet. Med., North Grafton, MA

Abstract: In the US, opioid abuse is a current major public health issue. Opioids regulate reward- and motivation- related behaviors and chronic opioid use results in dysfunctions in the brain's reward system. Opioid misuse/abuse amongst adolescents has increased significantly; yet, the long-term consequences of this experience has yet to be realized. Data from animal models, however, reveal that adolescently opioid-exposed females transmit to F1 offspring transgenerational neurobehavioral and endocrine changes at both baseline and in the context of various stimuli. For example, the offspring of females that were exposed to morphine during adolescence (Mor-F1) display significant differences in hypothalamus-pituitary-adrenal axis function, and increased hypothalamic ARC proopiomelanocortin (*POMC*) gene expression in a sex-specific manner. In the brain, POMC is the precursor to several neuropeptides involved in homeostatic and adaptive processes. Two bioactive derivatives of POMC, β-EP and α-MSH, are central regulators of energy homeostasis and metabolism. In the present study, Mor-F1 and Sal-F1 (maternal history of adolescent saline exposure; control) animals were maintained under different dietary conditions (control, high fat diet, or high sucrose diet) to assess neuroendocrine and metabolic changes. Specifically, we tested the hypothesis that Mor-F1 offspring are vulnerable to the development of metabolic dyshomeostasis when challenged with excessive fat or sugar. In the current study, Mor-F1 offspring displayed increased ARC POMC levels alongside alterations in β-EP and α-MSH levels within the ventral tegmental area, in a diet-specific manner. F1 animals also displayed differences in fasting glucose levels, alongside changes in the glucoregulatory hormones, insulin and corticosterone. In addition, Mor-F1 animals sex-specifically displayed changes in sexual maturity. Collectively, results demonstrate sex-dependent alterations to neuroendocrine systems that facilitate development and metabolism as a function of maternal opioid use during adolescence. Moreover, results suggest that female adolescent opioid exposure increases the risk of diet-induced metabolic derangement (i.e., weight gain, fasting hyperglycemia) in F1 progeny. Current studies are examining the underlying mechanisms responsible for bodyweight gain and glucose dyshomeostasis in F1 offspring.

Title: Neonatal nutritional programming and hypothalamic glial cell morphology: the role of leptin in the modulation of TCPTP and conexins

Authors: *L. K. DEBARBA[1], P. B. MARANGON[2], F. M. V. VECHIATO[2], H. V. P. SILVA[2], J. C. VENÂNCIO[2], B. C. BORGES[2], G. ALMEIDA-PEREIRA[2], M. C. JAMUR[3], J. ANTUNES-RODRIGUES[2], L. L. K. ELIAS[2]
[2]Physiol., [3]Cell and Mol. Biol. and Pathogenic Bioagents, [1]Ribeirão Preto Med. Sch. / USP, Ribeirao Preto, Brazil

Abstract: Nutritional changes in the neonatal period induce energy balance impairment in the juvenile and adult life. Astrocytes provide energy substrate to the neurons through conexin 43 (CX43). CX30 exerts a role in the maintenance of astrocyte morphology. The T-cell protein tyrosine phosphatase (TCPTP) is a counter-regulatory molecule of leptin signaling which also modulates CX43 expression. We used the neonatal nutritional programming model by altering the litter size during lactation in rats: 3 puppies - Small Litter (SL); 10 puppies - Normal Litter (NL) and 16 puppies per dam - Large Litter (LL). The SL animals showed higher body weight at weaning and thereafter until the 60th post-natal day (PN). LL animals reduced body weight gain at weaning, however they reached the same body weight gain of NL animals at PN35, and this effect was associated with hyperphagic behavior and increased *Il1b* mRNA expression in the arcuate nucleus (ARC). In the SL (PN21) and in the SL and LL (PN60) there were an increase in: a) leptin and insulin plasma concentrations; b) ARC *Ptpn2* (TCPTP encoding gene) mRNA expression; c) hypothalamic TCPTP protein content; d) ARC GFAP and IBA1 immunoexpression and e) TCPTP overlap with GFAP in the ARC. In the SL at PN21 an increase in ARC CX43 immunoexpression was observed while at PN60 there was a reduction of CX30 immunoexpression and an increase of *Tnf* mRNA expression in the ARC in both groups, SL and LL. At PN21 SL showed an increase in the soma and, also, in the process extension of the microglia and astrocytes in the ARC. Similar result was observed in ARC astrocytes of both SL and LL groups at PN60. Using primary culture of rat hypothalamic astrocytes, we observed that the leptin [5000ng / mL] increased the *Ptpn2* mRNA expression in the, as well as, an increase of

TCPTP and CX43 immunoexpression and a reduction of CX30 immunoexpression. These effects of leptin were associated with a marked increase of astrocyte soma. Moreover, the silencing of *Ptpn2* (siRNA *Ptpn2*) was able to reverse all these results promoted by leptin. The data demonstrate that neonatal nutritional changes induce long-lasting alterations in the energy balance in the juvenile and adult life. These changes are associated with morphological changes of glial cells and an increase of proinflammatory cytokines in the ARC. Leptin appears to play a role in the alterations of astrocyte morphology regulating the expression of TCPTP, which in turn modulates the expression of gap junction protein CX30.

Title: Effects of perinatal programming by caloric restriction on the cocaine and amphetamine regulated transcript (CART) neurons in the lateral hypothalamic area of weaned rats

Authors: *C. D. MACHADO[1], M. G. MARTINS[1], I. Z. GUIATI[1], J. C. BITTENCOURT[2], J. A. C. HORTA, Jr[1]
[1]Anat., Inst. of Biosci. of Botucatu, Botucatu, Brazil; [2]Anat., Inst. of Biomed. Sci., Sao Paulo, Brazil

Abstract: Perinatal programming is related to adaptations performed in response to insults during key points of development, leading to effects in organs' structure and function. Maternal nutritional status during pregnancy and lactation is considered an important programming inductor, since nutrient deficiency causes significant changes in body weight, energy balance, food intake and neuropeptides expression. The cocaine and amphetamine regulated transcript (CART) is a neuropeptide widely expressed in the hypothalamus. In the lateral hypothalamic area (LHA), it is involved in the energy balance, playing an anorexigenic role. Our aim was to analyze the impact of maternal perinatal undernutrition on the number, distribution and ultrastructure of CART-neurons in the LHA of weaned rats. Two groups of pregnant *Wistar* rats (Ethical Committee Approval nº722) were studied: control group (CG), *ad libitum* standard diet,

and caloric restricted group (RG), 50% restriction in diet compared to the control group during pregnancy and lactation. Male pups in postnatal day 21 (N=8/group) were analyzed. All animals were transcardially perfused with fixative and their brains processed for CART-neurons analysis in the LHA, according to immunohistochemistry protocols (N=5) and transmission electron microscopy (N=3). Body weight, body length, brain and adipose tissue (visceral and retroperitoneal) weights and glycemia were also evaluated. The mapping and estimation of CART-neurons number in the LHA were performed using 3D reconstruction and stereology. Quantitative data were compared and statistically analyzed ($p < 0.05$). RG animals showed a decrease in body weight and length. Glycemia, brain, visceral and retroperitoneal adipose tissue also reduced in RG animals. There were fewer CART-neurons in LHA in RG, however there were no differences in LHA total area and volume between groups. CART-neurons distribution in LHA was similar both in CG and RG animals. Positive-labeled neurons were identified mainly in mamilar and tuberal LHA regions, and in dorsolateral, perifornicial and ventrolateral LHA sub-regions. No relevant differences between groups were found in CART-neurons ultrastructure. Nuclear membrane invagination and labeled Golgi apparatus with dense granules, typically found in peptidergic neurons, were observed. Granular endoplasmic reticulum cisternae and multivesicular bodies were also labeled. Our results indicated that maternal perinatal undernutrition induced body structural changes and decreased CART-neurons in the LHA of weaned rats. Nevertheless, LHA total area and volume, CART-neurons ultrastructure and distribution were not modified.

Title: Effect of prenatal stress on adrenal and thyroid axes of adult male rats subjected to light-phase feeding during prepuberty

Authors: *C. GARCIA-LUNA, P. SOBERANES-CHAVEZ, P. DE GORTARI
Inst. Nacional De Psiquiatria, Mexico city, Mexico

Abstract: Obesity development involves interaction between factors including feeding patterns and stress. Neuronal circuits responsible for energy homeostasis regulation and stress response mature during gestation and early postnatal stage, thus fluctuations in serum hormones levels

implicated in those functions such as leptin, insulin, thyroid hormones and corticosterone (GC) could alter the programmed regulation of neuroendocrine axes and limbic neural nets leading to hyperphagia and overweight that might last up to adulthood. Prenatal stress (PS) induces high GC serum content that affects development of the hypothalamic-pituitary-adrenal (HPA) and hypothalamic-pituitary-thyroid (HPT) axes that could lead to an aberrant HPA axis response to stress and to an impaired regulation of basal energy expenditure by HPT axis later in life. Prepuberal un-stressed animals subjected to time-restricted feeding schedules (tRF) during rest phase present hyperphagia and overweight up to adulthood due to a changed energy homeostasis regulation that was associated to hyperactivity of HPA axis and inhibition of HPT axis function. PS induces neuroendocrinology impairments by altering neural development, thus we analyze if PS is able to exacerbate prepuberal tRF-induced changes in HPT and HPA axis function of adult rats. Pregnant Wistar rats were subjected (PS-C) or not (C) to chronic mild stress on the last week of gestation, their male offspring divided and subjected to light-phase feeding (PS-LPF) or dark-phase feeding (PS-DPF) from 21-35 postnatal (PN) days; after that, they had *ad libitum* access to food until day 70PN. Body weight and food intake were measured weekly. Rats were sacrificed at week 10, trunk blood collected to evaluate GC, thyroid hormones (TH), leptin and insulin content; brain excised and kept at -70°C to analyze PVN TRH and CRF RNAm expression by ISH. Body weight and food intake did not differ between PS groups although they were higher than C animals. TH content did not show differences between PS groups or vs C suggesting an inhibition of HPT axis that could favor overweight; GC levels were higher than C but did not differ among PS rats showing HPA axis hyperactivation by PS, leptin and insulin content was higher vs C relating them to the overweight and suggesting leptin and insulin resistance since PS rats showed hyperphagia and those hormones are anorexigenic agents. PVN TRH and CRF mRNA expression did not differ between PS groups or vs C. In conclusion, PS did not exacerbate changes caused by tRF; both conditions caused hyperphagia, overweight, HPA axis hyperactivity, non-responsive HPT axis to positive energy balance, and a possible insulin and leptin resistance.

Abstract: Obesity is basically induced by an imbalance between energy intake and energy expenditure. Overweight has becoming increasingly prevalent in children's and teenagers. According to WHO, obesity is an epidemic disease and the subsequent morbidity and mortality are the major health challenge worldwide. Early postnatal overnutrition in rats induce a rapid grow, weight gain, fat deposition, hyperphagia during lactation and hypertriglyceridemia in adulthood. Several antidepressants such as selective serotonin reuptake inhibitors (i.e fluoxetine also known as Prozac) are now prescribed not only for depression, but also to obesity treatment. With this our aim was to evaluate the effect of fluoxetine treatment during 21 days (from 39 to 59 days of age) in the control of energy balance. To induce neonatal overnutrition, the primary litter size was then reduced on the third day of life to only three pups per litter (SL; n =8). In normal litters, the size was adjusted to 9 neonates per mother (NL; n =9). The fluoxetine treatment started with 39 days of age, using 10mg/Kg B.W. (i.p injection) in male Wistar rats. At 60 days of age was evaluated blood parameters, 24 hours food intake, 12 hours in dark cycle food intake, 12 hours in light cycle food intake, food intake after 3 hours of food-deprived, body weight, white and brown adipose tissue weight, POMC and NPY mRNA. Our result showed that neonatal overnutrition induces body weight increase, white adipose tissue weight, increases triglycerides, but no differences were observed in food intake in basal situation, but after 3 hours of food-deprivation, SL group eat 40% more than NL. Additionally, neonatal overnutrition has higher NPY expression than NL. After fluoxetine treatment, we observed decreases in body weight, white adipose tissue weight, triglycerides, food intake after food-deprivation and NPY expression combined with increase in POMC expression. Our results suggest that fluoxetine treatment modulates energy balance in obese rats, mainly by control food intake after restriction and fat deposition.

Title: Estradiol protects proopiomelanocortin neurons against insulin resistance

Authors: *J. QIU[1], M. A. BOSCH[1], U.-V. NAVARRO[1], C. C. NESTOR[1], O. K. RØNNEKLEIV[1,2], M. J. KELLY[1,2]

Abstract: The incidence of metabolic syndrome sharply increases in women after menopause. Neurons, similar to fat and muscle cells, can develop hyperinsulinemia-induced IR, which results in severe injury to the nervous system as seen in diabetic neuropathies and stroke. At the center of the regulation of energy homeostasis, and hence the central feedback of insulin, are the anorexigenic proopiomelanocortin (POMC) and orexigenic neuropeptide Y/agouti-related peptide (NPY/AgRP) neurons in the hypothalamic arcuate nucleus. Since 17β-estradiol (E_2) augments the excitability of the anorexigenic POMC neurons, we investigated the electrophysiological effects of insulin in diet-induced obese (DIO) male and female mice, and the neuroprotective effects of E_2 in females. We found that the ability of insulin to activate canonical transient receptor potential 5 (TRPC5) channels and depolarize POMC neurons was significantly reduced in DIO male (by 70%) but not in DIO female mice. However, the insulin response in POMC neurons was attenuated in ovariectomized, DIO females but restored with E_2 replacement. E_2 increased T-type calcium channel *Cav3.1* mRNA expression and currents but downregulated stromal-interaction molecule1 (*Stim1*) mRNA, which rendered POMC neurons more excitable and responsive to insulin-mediated TRPC5 channel activation. Also, in females E_2 prevented the increase in *Socs3* mRNA expression with DIO that was seen in males. Therefore, E_2 protects female POMC neurons from insulin resistance with DIO by enhancing POMC neuronal excitability and the coupling of insulin receptor to TRPC5 channel activation.

Abstract: Leptin is a hormone released from adipose tissue that works exclusively in the brain to regulate energy balance and glucose homeostasis. Dysfunctions in leptin or leptin signaling induce severe obesity and diabetes. Since the discovery of leptin in 1994, various efforts have been made to identify the first-order leptin-responsive neurons that mediate its anti-obese and anti-diabetic effects. Recent studies have shown that leptin completely rescues streptozotocin-induced type 1 diabetes (T1D) in an insulin- independent manner. Using this model, we postulated that STZ-induced T1D induces altered neuronal activity in the CNS, which can be reversed upon leptin treatment. Surprisingly, we found over 50 sites with increased neuronal activity, and identified a small group of hypothalamic neurons that acutely reversed its neuronal firing upon leptin treatment. Furthermore, we inhibited these hypothalamic neurons using DREADDs in STZ-treated mice and found that acute neuronal inhibition completely attenuated the diabetic hyperphagia and dramatically reduced hyperglycemia. To assess whether the increased neuronal activity was due to a lack of leptin in an STZ mouse model, we utilized the CRISPR/Cas9 system to efficiently knockout leptin receptors in these hypothalamic neurons of adult mice. Leptin receptor deletion induced 81% of the severe obesity phenotype observed in *db/db* mice, suggesting that these hypothalamic neurons are a primary target of leptin to regulate energy balance and glucose homeostasis. These findings provide an innovative framework of brain-based mechanisms controlling energy balance and glucose homeostasis, provide novel information towards the understanding and treatment of obesity and diabetes, and bring about potential brain- related therapeutic strategies to treat severe metabolic disorders.

Title: Behavioral, anatomical and molecular investigation of PACAP and leptin interactions in the rat ventromedial hypothalamus

Authors: *M. M. HURLEY, E. M. HESS, B. MAUNZE, C. LAMBERTON, M. FRENKEL, G. CALLAN, N. S. PATEL, D. A. BAKER, S. CHOI
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Obesity is rising at an alarming rate in the United States of America and it is critical that we address this growing crisis as this disease puts great socioeconomic strain on our society. Leptin, a hormone that is produced peripherally by adipose cells, has been shown to play an important role in regulating mammalian energy states. As obese individuals demonstrate impairments in leptin mediated signaling, it remains critical to continue to interrogate the mechanisms by which leptin regulates normal and pathological feeding states. Leptin has been shown to act centrally in the ventromedial hypothalamic nuclei (VMN). Previous work has demonstrated that leptin microinjected into the rat VMN, strongly suppresses feeding and increases phosphorylation of signaling transducers and activators of transcription 3 (P-STAT3) as well as brain derived neurotrophic factor (BDNF) and suppressor of cytokine signaling 3 (SOCS3) mRNA expression. Our current data demonstrate that the secretin family neuropeptide pituitary adenylate cyclase-activating polypeptide (PACAP), much like leptin, also decreases feeding behavior, body weight gain and increases phosphorylation of STAT3 and BDNF/SOCS3 mRNA expression when injected into the VMN. To assess if both leptin and PACAP are signaling through co-dependent molecular mechanisms in the VMN, we antagonized VMN PACAP receptors with PACAP6-38 followed immediately by a leptin microinjection. We observed that animals pretreated with PACAP6-38 did not display leptin induced hypophagia. This interesting behavioral effect suggests that endogenous PACAP receptor-dependent activity is necessary for leptin-induced suppression of feeding behavior in the VMN. To further validate the relationship between PACAP and leptin signaling in the VMN, we conducted double fluorescent *in situ* hybridization which showed that PAC1 and leptin receptor mRNA transcripts are co-expressed in the same cells within the VMN. Taken together, these data suggest a functional link between PACAP and leptin signaling, and possibly BDNF, in the VMN in the regulation of feeding behavior and metabolism. Future studies will further explore the functional interactions between leptin, PACAP, and BDNF in the regulation of energy homeostasis and feeding behavior.

Title: Cellular actions of adropin on paraventricular nucleus neurons

Authors: *S. P. LOEWEN, A. V. FERGUSON
Dept. of Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Adropin is a peptide hormone that has been observed to have metabolic roles in the periphery and a central role to inhibit water intake. We have recently shown that adropin directly influences the excitability neurons in the hypothalamic paraventricular nucleus (PVN). The current study uses electrophysiological techniques to examine the responsiveness of PVN neurons to adropin at different extracellular glucose concentrations and determine the ionic mechanisms involved. In our original experiments at 10 mM glucose (central hyperglycemia), adropin (10 nM) elicited responses in 68% of cells tested (n=57/84). The majority of cells (58%) depolarized (5.2 ± 0.3 mV; n=49) in response to adropin, while the remaining responsive cells (10%) hyperpolarized (−3.4 ± 0.5 mV; n=8). Here, we show that reductions in the extracellular glucose concentration eliminates hyperpolarizing responses. In 3 mM glucose (central normoglycemia), adropin (10 nM) elicited responses in 47% of cells tested (n=7/15), all of which were depolarizations (4.8 ± 0.5 mV). In 1 mM extracellular glucose (central hypoglycemia), 10 nM adropin elicited depolarizations in 67% of cells tested (6.0 ± 0.8 mV; n=8/12), while the remaining 33% of neurons (n=4) did not respond to adropin application. The magnitudes of adropin-mediated depolarizations did not differ at each glucose concentration (one-way ANOVA, p=0.50). Additionally, analysis of action potential shape in neurons that depolarized revealed a broadening of spikes after adropin application, suggesting adropin may affect a potassium conductance during these responses. These findings demonstrate that the glucose environment affects adropin-mediated responses in PVN neurons and reveal the importance of considering glycemic state when studying molecules or pathways pertaining to the central regulation of energy homeostasis.

Title: In search of the cocaine- and amphetamine-regulated transcript (CART) receptor: Identification of CART binding sites in the rodent brain

Authors: *L. A. TAN, M. H. PERRIN, J. M. VAUGHAN, C. M. ARIAS, K. A. LEWIS, J. E. RIVIER, P. E. SAWCHENKO
LNSF-S, Salk Inst. For Biol. Studies, La Jolla, CA

Abstract: Cocaine- and amphetamine-regulated transcript (CART) is an endogenous peptide that has been implicated in the regulation of food intake and reward. CART exists in two forms, CART(55-102) and CART(61-102), with a highly conserved structure governed by three disulfide bridges. CART is abundantly expressed in many areas of the brain associated with the reward circuit and the control of feeding and stress responses, as well as peripherally, in the adrenal and pituitary glands and GI tract. CART satisfies many of the requirements of a neurotransmitter, and injections of CART into the brain reduce food intake and inhibit the effects of psychostimulants. Despite a wealth of literature on the physiological roles of CART peptides, no putative CART receptor has been identified, although binding sites have been reported on PC-12 and AtT-20 cell lines and nucleus accumbens primary neurons. To facilitate identification of CART receptors in rodent brain, we developed a new CART analog, [^{125}I-Tyr^{58},Thr^{62},Nle^{67}]CART(55-102), and demonstrated its high affinity (low nanomolar), specific binding to membranes from porcine anterior pituitary, rodent brain and pancreatic-, neuronal- and adrenal-derived cell lines. Because CART is present at high levels in rat plasma (333-675 pg/ml), we used this tracer to gain clues regarding receptor disposition by identifying potential source(s) and target(s) of circulating peptide. Neither adrenalectomy nor hypophysectomy affected plasma peptide levels, while sleeve gastrectomy did, implicating the GI tract as the major source of circulating CART. Following i.v. injection, however, we failed to resolve time-dependent sequestration of the tracer in the brain or any peripheral tissue, as measured by gamma counting or SPECT imaging. Taking advantage of the resolution afforded by *ex vivo* autoradiography, we were able to demonstrate robust, specific binding in rat and mouse brain that was competable in a dose-related manner by unlabeled CART. Such binding was restricted to secretory structures including the paraventricular and supraoptic nuclei of the hypothalamus, choroid plexus, and anterior pituitary, and did not parallel the widespread central distribution of CART projections, or include such demonstrated sites of peptide action as the nucleus accumbens. These findings provide the first autoradiographic localization of CART binding sites in brain and pituitary. This information, and the novel radioligand that fostered it, should provide leverage in further efforts to identify the CART receptor(s).

Title: Intracellular signaling involved in neurokinin NK1 receptor-mediated emesis in the least shrew

Authors: W. ZHONG[1], S. CHEBOLU[2], *N. A. DARMANI[2]
[1]Basic Med. Sci., [2]Coll Osteo. Med. Pacific, Western Univ. Hlth. Sci., Pomona, CA

Abstract: Previously we have found a major CNS emetic component for the neurokinin 1 receptor (NK1R)-mediated vomiting evoked by the selective NK1R agonist GR73632 (5 mg/kg, i.p.) in the least shrew. The evoked vomiting was suppressed in a dose-dependent manner either by the NK1R antagonist (netupitant, i.p.); or the L-type Ca^{2+} channel (LTCC) blocker (nifedipine, s.c.). Here we examined the downstream intracellular signaling effectors in the shrew brainstem. Using immunohistochemistry performed on brainstem slices, substance P immunoreactivity was increased in the brainstem emetic nucleus, dorsal motor nucleus of the vagus, 15 min following GR73632 administration (5 mg/kg, i.p.), but not by its 1 mg/kg non-emetic dose. Moreover, we performed Western blot on brainstems collected respectively at 0, 5, 10, 15, 20, 25, 30 min after GR73632 challenge (5 mg/kg, i.p.). GR73632 caused time-dependent increases in effector phosphorylation, such as Ca^{2+}/calmodulin kinase IIα (CaMKIIα) and extracellular signal-regulated protein kinase1/2 (ERK1/2). Netupitant or nifedipine pretreatment completely abrogated the evoked phosphorylations. Additionally, we analyzed the contribution of intracellular Ca^{2+} release channels, inositol trisphosphate receptor (IP3R) and ryanodine receptor (RyR) on the basis of intracellular Ca^{2+} elevation in response to NK1R activation by substance P and GR73632 in vitro cultured neurons as reported previously. As a result, the IP3R inhibitor 2-APB pretreatment achieved a significant reduction of NK1R-mediated emesis, however the RyR inhibitor dantrolene did not. Our present studies demonstrate GR73632-evoked emesis occurs in a Ca^{2+}-dependent manner following NK1R activation involving IP3R which is in agreement with Miyano et al. (2010)'s observation that NK1R stimulation by GR73632 in spinal astrocytes induces Ca^{2+} release through IP3R. These results extend what we have previously observed for 5-HT3Rs, suggesting an important role for the brainstem Ca^{2+}-CaMKII/ERK interplay in the mediation of NK1R-mediated emesis in least shrews. Future effort will focus on studies to evaluate whether such mediators are acting individually or in a sequential manner.

Title: Elucidating the central anorexigenic mechanism of corticotropin releasing factor in chickens (Gallus gallus domesticus)

Authors: *J. WANG, E. R. GILBERT, M. A. CLINE
Dept. of Animal and Poultry Sci., Virginia Tech., Blacksburg, VA

Abstract: Central administration of corticotropin-releasing factor (CRF), a 41-amino acid peptide, is associated with anorexigenic effects across various species, such as rodents and chickens. The hypothalamus is a primary site for regulation of energy intake and expenditure and contains several important appetite-associated nuclei. To date, the central mechanism of the potent anorexigenic effect of CRF is still unclear. Hence, the primary objective of the current study was to identify hypothalamic regions and neurotransmitters that mediate CRF-induced anorexic effects in chickens. At 1 h post-intracerebroventricular (ICV) injection, there were more c-Fos immunoreactive cells in the arcuate nucleus (ARC), dorsomedial hypothalamic nucleus (DMN), ventromedial nucleus of the hypothalamus (VMH), and the paraventricular nucleus (PVN) of 0.02 nmol CRF-injected than vehicle-injected chicks. Neuropeptide Y receptor sub-type 1 (NPYR1) mRNA was greater in the hypothalamus of chicks injected with CRF than those injected with vehicle. In the ARC, mRNA expression of orexigenic factors including neuropeptide Y (NPY), neuropeptide Y receptor sub-types 1 (NPYR1) and agouti-related peptide (AgRP) and the anorexigenic factors such as CRF, CRF receptor sub-types 1 (CRFR1) were decreased and increased, respectively. In the DMN, NPYR1 mRNA decreased in CRF-treated chicks. The exogenous administration of CRF increased CRF receptor sub-type 2 (CRFR2) and mesotocin (MT) mRNA in the PVN and VMH, respectively. In conclusion, our results suggest that the anorexigenic effects of CRF in the chicken are primarily influenced by overriding anorectic tone originated from the competitive interaction between CRF and NPY in the ARC and that the neural pathways connected the ARC with other appetite-associated nuclei are essential for mediating such anorectic tone within the hypothalamus.

Title: Central neuropeptide FF injection is associated with anorexigenic effects in Japanese quail

Authors: *A. L. LOGAN, E. R. GILBERT, M. A. CLINE
Animal and Poultry Sci., Virginia Polytechnic Inst. and State Universit, Blacksburg, VA

Abstract: Central neuropeptide FF (NPFF) administration was associated with anorexigenic effects in domesticated broiler chickens (*Gallus gallus*). The purpose of the present experiment was the evaluate the effects of NPFF on feeding behavior in a less artificially-selected avian species, the Japanese quail (*Coturnix japonica*). In Experiment 1, 7 day-old Japanese quail were intracerebroventricularly injected with 0 (vehicle), 8, 16, or 32 nmol NPFF and food and water intake were quantified over a three-hour period. During the first thirty min post-injection, food intake was decreased in the 32 nmol NPFF-injected compared to the vehicle-injected group, while water intake was not affected. In Experiment 2, we conducted a comprehensive behavior analysis following central injection of 0 or 32 nmol NPFF. In NPFF-treated quail, the number of water pecks, distance moved, and steps taken significantly decreased, while the time spent in deep rest significantly increased, compared to vehicle-injected quail. In Experiment 3, we collected the hypothalamus at 1 h post-injection of 0 or 32 nmol NPFF and measured mRNA abundance of appetite-associated factors via real time PCR. NPFF injection was associated with increased expression of melanocortin receptor sub-type 3 (MC3R) mRNA and decreased abundance of neuropeptide Y receptor 1 (NPYR1) and prodynorphin (PDYN) mRNA, compared to vehicle injection. In sum, there are threshold differences in food intake and behavior between quail and chicken in response to central injection of NPFF. Additionally, the hypothalamic mechanism mediating NPFF-induced satiety in quail may involve MC3R, NPYR1 and PDYN.

Title: Neuropeptigeric control of feeding in Trichoplax, an animal lacking synapses

Authors: C. L. SMITH[1], *T. S. REESE[2], A. SENATORE[3]
[1]NINDS, [2]NINDS - Lab. of Neurobio., NIH, Bethesda, MD; [3]Neurosci. Inst., Univ. of Toronto, Mississauga, ON, Canada

Abstract: *Trichoplax adhaerens* is a flat, millimeter-sized marine animal that adheres to surfaces and grazes on algae, displaying a repertoire of different feeding behaviors despite the apparent

absence of a true nervous system with electrical or chemical synapses. It glides along surfaces to find food, propelled by beating cilia on cells at its ventral surface, and pauses during feeding by arresting ciliary beating. We find that when endomorphin-like peptides are applied to an animal, ciliary beating is arrested, mimicking natural feeding-pauses. Antibodies against these neuropeptides label cells that express the neurosecretory proteins and voltage gated calcium channels implicated in regulated secretion. These cells are embedded in the ventral epithelium, where they comprise only four percent of total cells, and are concentrated around the edge of the animal. Each bears a cilium likely to be chemosensory and used to detect algae. *Trichoplax* pausing during feeding or spontaneously in the absence of food often induce their neighbors to pause as well, even neighbors not in direct contact. Pausing-behavior propagates from animal to animal across distances much greater than the signal that diffuses from just one animal, so we presume that the peptides secreted from one animal elicit additional secretion from nearby animals. Signal amplification by peptide-induced peptide secretion explains how a small number of sensory secretory cells lacking processes and synapses can evoke a wave of peptide secretion across the entire animal to globally arrest ciliary beating and allow pausing during feeding.

Title: Alpha-melanocyte stimulating hormone-induced anorexia in Japanese quail(Corturnix japonica) likely involves the ventromedial hypothalamus and paraventricular nucleus of the hypothalamus

Authors: *M. O'DONNELL[1], E. GILBERT[1], M. A. CLINE[2]
[2]Animal and Poultry Sci., [1]Virginia Tech., Blacksburg, VA

Abstract: Alpha-melanocyte stimulating hormone (α-MSH) reduces food intake in birds and mammals. The objective of this experiment was to determine effects of α-MSH on food and water intake, and hypothalamic c-Fos immunoreactivity and appetite-associated factor mRNA in Japanese quail (*Coturnix japonica*), a gallinaceous species that has not undergone the same artificial selection for growth-related traits as the chicken. At 7 days post-hatch, 3-hour-fasted quail were intracerebroventricularly (ICV) injected with 0 (vehicle), 0.5, 5, or 50 pmol of α-MSH and food and water intake were recorded at 30 minute intervals for 180 minutes. In the second and third experiment, quail were injected with 50 pmol α-MSH and hypothalami were collected at 1 hour to determine c-Fos immunoreactivity and mRNA abundance, respectively. At 30 minutes, chicks injected with 5 or 50 pmol of α-MSH ate and drank less than vehicle-injected

chicks. Chicks injected with 50 pmol ate less for the entire duration of the experiment and drank less than vehicle-injected chicks for 120 minutes post-injection. Corticotropin-releasing factor mRNA was greater in male than female α-MSH-injected chicks. Expression of agouti-related peptide and DOPA decarboxylase were greater in vehicle- than α-MSH-injected quail, whereas melanocortin receptor 4 (MC4R) mRNA was greater in α-MSH- than vehicle-injected birds. Alpha-MSH injection was associated with more c-Fos immunoreactive cells in the ventromedial hypothalamus (VMH) and paraventricular nucleus (PVN) of the hypothalamus. Results suggest that the anorexigenic effect of α-MSH is conserved among avians and that effects are mediated via the VMH and PVN and involve MC4R.

Title: The role of ventral tegmental area melanocortin 3 receptor-expressing neurons in the regulation of feeding and body weight

Authors: *A. I. DUNIGAN, A. G. ROSEBERRY
Biol., Georgia State Univ., Atlanta, GA

Abstract: The melanocortin and the mesolimbic dopamine (DA) systems are both intricately involved in the regulation of feeding and body weight. The melanocortin system, which is comprised of proopiomelanocortin and agouti-related protein neurons, the neurotransmitters they release, and their receptors, including the MC3R and MC4R melanocortin receptors, is well known for its role in controlling normal, baseline, need-based feeding, whereas the mesolimbic DA system, which is comprised of the DA neurons of the ventral tegmental area (VTA) and their afferent and efferent projections, is the primary neural circuit controlling reward and motivated behavior, including the rewarding and motivational qualities of food. Increasing evidence indicates that the melanocortin system can act on dopamine circuits to control feeding. For example, intra-VTA injection of MC3R/MC4R agonists increases DA release and decreases both need-based and reward-based feeding. The mechanisms underlying these behavioral effects, including the identity of the melanocortin receptor subtypes mediating these effects, and how alterations in VTA neuron activity lead to the observed changes in feeding are unknown, however. In these studies we used transgenic mice expressing cre recombinase in MC3R-expressing neurons (MC3R-cre mice) to examine the role of VTA MC3R neurons in the control

of feeding and body weight. Viral tracing was used to map the efferent projections of the VTA MC3R neurons and optogenetics coupled with brain slice electrophysiology were used to determine the identity of the neurotransmitters released by VTA MC3R axons at these targets. We have also used Designer Receptors Exclusively Activated by Designer Drugs to test the effects of activation and inhibition of VTA MC3R neurons on feeding and body weight. Our data indicate that VTA MC3R neurons project to a restricted set of efferent target regions and release multiple neurotransmitters in the different efferent targets. Furthermore, activation of VTA MC3R neurons appears to acutely decrease feeding and body weight. These studies advance our understanding of how the melanocortin and mesolimbic dopamine systems interact to control feeding and body weight through the regulation of the activity of VTA MC3R neurons.

Title: Peripheral neuropeptide Y differentially influences adipogenesis and lipolysis in chicks from lines selected for low or high body weight

Authors: *Y. XIAO, L. LIU, G. WANG, S. L. SHIPP, P. B. SIEGEL, M. A. CLINE, E. R. GILBERT
Dept. of Animal and Poultry Sci., Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: Neuropeptide Y (NPY) stimulates appetite and promotes lipid deposition in the adipose tissue. We previously demonstrated a differential sensitivity in the food intake response to central NPY in chicks from lines selected for low (LWS) or high (HWS) body weight. The LWS are relatively lean and hypophagic whereas HWS are all compulsive eaters that become obese. The purpose of this study was to determine whether such differences exist between the lines in adipose tissue metabolism after peripheral NPY administration. At 5 days post-hatch, LWS and HWS chicks were intraperitoneally injected with 0 (vehicle), 60, or 120 μg/kg BW NPY. Subcutaneous adipose tissue and plasma were collected at 1, 3, 6, 12, and 24 h post-treatment (n=12 per treatment per time point). Peripheral NPY injection increased food intake in both lines. In response to NPY injection, glycerol-3-phosphate dehydrogenase (G3PDH) activity at 1 and 3 h was increased and was greater in HWS than LWS, whereas plasma non-esterified fatty acids (NEFAs) were reduced at 1 and 12 h and were lower in HWS than LWS. At 1 h, peroxisome proliferator-activated receptor gamma (PPARγ), CCAAT/enhancer binding protein α

(C/EBPα), and microsomal triglyceride transfer protein (MTTP) mRNAs were reduced in NPY-injected chicks whereas NPY receptor 1 (NPYR1) mRNA was increased, relative to vehicle-injected chicks. Expression of stearoyl-CoA desaturase (SCD1) was increased by NPY at 1 h in HWS but not LWS. PPARγ (3 and 6 h), C/EBPβ (3 h), C/EBPα (6 h) and NPYR1 and NPYR2 (24 h) mRNAs were greater in NPY- than vehicle-injected chicks. At several times, genes encoding factors associated with lipolysis (adipose triglyceride lipase, perilipin 1, NPYR1), and adipogenesis (MTTP and NPYR2) were more highly expressed in LWS than HWS, while expression of SCD1, glycerol-3-phosphate acyltransferase 3 and lipoprotein lipase, which encode enzymes that are associated with lipid synthesis and deposition, were greater in HWS than LWS. In conclusion, NPY promotes adipogenesis and inhibits lipolysis in chicks, with line differences indicative of greater rates of lipolysis in the lean LWS and adipogenesis in obese HWS chicks.

Title: Morphological and neurochemical characterization of the melanin-concentrating hormone [MCH] peptidergic system in the CNS of the mouse

Authors: *G. B. DINIZ[1], P. M. CHERUBINI[1], J. C. G. DUARTE[1], J. G. P. FERREIRA[1], D. S. BATAGELLO[1], L. V. SITA[1], J. C. BITTENCOURT[1,2]
[1]Dept. of Anat., Inst. of Biomed. Sci., Univ. of São Paulo, Sao Paulo, Brazil; [2]Ctr. for Neurosci. and Behavior, Inst. of Psychology, Univ. of São Paulo, São Paulo, Brazil

Abstract: The *Pmch* is a highly-conserved gene in vertebrate species. It encodes three peptides, the melanin-concentrating hormone [MCH], Neuropeptide E-I [NEI] and Neuropeptide G-E [NGE]. MCH has been implicated in several biological processes, including the coordination of

motivated behaviors, autonomic modulation, memory, attention and sensory integration, while NEI has been associated to thyroid modulation and locomotor activity. Although the morphological and hodological aspects of this peptidergic system have been thoroughly examined in rats, there is a paucity of systematic evaluations of this system in mice. This has led to an information mismatch in the literature, as functional data obtained from mice are commonly interpreted using anatomical data from rats, without any confirmation of the transposability of such data. To provide accurate morphological and neurochemical data regarding the MCH peptidergic system in mice, we examined the distribution of MCH and NEI in male and female mice, including animals in all stages of the reproductive cycle, using immunohistochemistry tools. We additionally examined another peptidergic system that spatially correlates to MCH, the orexin system [ORX], to obtain comparative reference. Our results indicate that, although numerous morphological aspects are similar between rats and mice regarding the MCH peptidergic system, important differences were found regarding structures linked to endocrine modulation, in addition to a dampened response to the reproductive cycle in mice, suggesting a decreased participation of MCH and NEI in these functions. Furthermore, the comparison of our results to other mammals suggest that MCH conserved its diencephalic location, but varies between species in terms of dorso-ventral, latero-medial and rostro-caudal distributions. Finally, we propose that MCH and ORX are organized into two chemical domains in the lateral hypothalamus, the LHA shell and the LHA core that may have important implications for the intercommunication between these two neuronal populations.

Title: Leptin promotes growth and bone formation via the PI3Kα signalling pathway

Authors: *D. GARCIA GALIANO[1], S. J. ALLEN[2], K. M. KOZLOFF[3], C. F. ELIAS[2]
[2]Mol. and Integrative Physiol., [3]Biomed. Engin., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Bone metabolism is intimately related to energy balance and fat reserves, and the brain is directly implicated in this regulation. Leptin is secreted peripherally to promote the bone formation via modulation of GHRH-GH-Igf-1 axis. However, more detailed work is required to understand the molecular mechanisms associated with leptin action. In this sense,

phosphatidylinositol 3-kinase (PI3K) pathway plays an essential role in long-term energy homeostasis, mediating leptin and growth factors actions in endocrine modulation. Using mouse models with specific deletion of the PI3K p110α catalytic subunit (PI3Kα) in leptin receptor (LR)-expressing cells ($LR^{\Delta\alpha}$), we observed a decreased body weight and snout-anus distance in $LR^{\Delta\alpha}$ mice respect to floxed controls at postnatal day of 60 (P60). Micro-computed tomography detected a decrease in bone mineral density at trabecular and reduced cortical area in femur of $LR^{\Delta\alpha}$ females (n=6/genotype). Additionally, a significant increase in AgRP transcript in the arcuate nucleus and fiber projections into hypothalamic paraventricular nucleus were observed in $LR^{\Delta\alpha}$ mice (n=6/genotype). Analysis of gene expression at different levels of the growth hormone (GH) axis did not detect differences in hypothalamic GHRH or SST mRNA expression between genotypes at P60. However, a significant reduction in hepatic GH-R and Igf-1 mRNA expression was detected in adult $LR^{\Delta\alpha}$ mice. Reduced growth rate was only detected in sexually mature $LR^{\Delta\alpha}$ females, with no differences in pubertal (P40) stage, suggesting an effect of sex steroids on growth via PI3Kα pathway. Finally, we explored if leptin supplementation can affect the growth rate in pubertal mice. For this, peripubertal females of both genotypes were daily injected with leptin from P35-P55. Leptin supplementation in control females decreased cumulative weight gain but body length was increased at P60. Notwithstanding, leptin treatment had an enhanced effect on weight loss but no changes in growth rate were detected in $LR^{\Delta\alpha}$ females. These data suggest that $LR^{\Delta\alpha}$ mice are unresponsive to leptin's effect on growth rate. Collectively, our findings indicate that the PI3Kα downstream of leptin signaling is required for normal progression of growth and bone formation at pubertal stages.

Title: Prostaglandin E_2 activates melanin-concentrating hormone neurons in diet-induced obesity

Authors: L. FANG, V. LINEHAN, *M. HIRASAWA
Div. of Biomed. Sci., Mem. Univ., St John's, NL, Canada

Abstract: Diet-induced obesity is associated with low-grade chronic inflammation of the hypothalamus, a key brain region for energy homeostasis. However, it remains unclear how this neuroinflammation influences appetite-related neurons. Melanin-concentrating hormone (MCH) neurons are one of the hypothalamic cell groups that promote appetite and weight gain. Therefore, any influence of neuroinflammatory factors on MCH neurons may modulate energy balance. Prostaglandin E_2 (PGE_2) is an important mediator of hypothalamic inflammation under disease states and may also play a role in obesity-related inflammation. Thus, we asked whether PGE_2 modulates the activity of MCH neurons in diet-induced obesity. To answer this question, 3-week old male Sprague Dawley rats were fed *ad libitum* with palatable high-fat diet (HFD) or control chow for >11 weeks. Following the feeding period rats were sacrificed and whole-cell patch clamp recordings were performed on acute brain slices. We found that the resting membrane potential of MCH neurons was depolarized in the HFD group compared to chow controls. This excitatory effect of HFD was mimicked by incubating chow control slices with a low concentration of PGE_2, which was blocked by the EP2 receptor-specific antagonist PF 04418948, but not by antagonists for other subtypes of PGE_2 receptors (EP1, EP3, EP4). HFD-induced depolarization was also reversed by the EP2 receptor antagonist, suggesting a role of PGE_2 in the HFD effect. In support of this, inhibiting PGE_2 production in the HFD brain slice by the COX inhibitor acetaminophen reversed the depolarization of MCH neurons. Using COX-1 and COX-2 specific inhibitors SC-560 and SC-236 respectively, we further determined that COX-2 is responsible for the PGE_2 production in the hypothalamus of HFD-fed animals. In conclusion, our study shows that HFD-induced activation of MCH neurons is mediated by the COX-2/PGE_2 pathway. Given the known role of MCH in promoting positive energy balance, this mechanism may be at least partially responsible for diet-induced obesity. Therefore, elucidating the mechanism behind MCH neuron activation in obese conditions will provide insight into potential new therapies for obesity.

Abstract: Drug addiction is a chronic and relapsing disease resulting from repeated exposure to the drugs of abuse. The sensitivity to drugs of abuse is regulated by many physiological and pathological conditions, particularly the metabolic status of animals. Food restriction increases and over-nutrition decreases the sensitivity to drugs of abuse. However, it is still elusive how the brain circuitry regulating the metabolic status interacts with the reward circuitry. The perifonical/lateral hypothalamus is a critical brain area to regulate both energy homeostasis and food/drug reward. A selective group of neurons exclusively synthesizing the neuropeptide hypocretin (Hcrt, also called orexin) affect food intake and play a prominent role in food award and drug addiction. In this study, by using electrophysiological, immunocytochemical and behavioral methods we examined changes in basic synaptic properties in Hcrt cells and responses of Hcrt neurons to cocaine exposure and acute stress (a cue triggering relapse of cocaine use) in control and diet-induced obesity (DIO) mice. C57/B6 mice at an age of 4 weeks old were divided into two groups: control, fed with a normal diet (ND) for 10-12 weeks; DIO group, fed with a high fat diet (45% calories from fat, Research Diets Inc.) for 10-12 weeks. Whole-cell patch clamp recording was performed in GFP-labeled Hcrt cells in brain slices from both groups. The frequency of mEPSCs was 218.8 ± 39.9 /min (n=12) and 137.4 ± 28.7/min (n=12) in Hcrt cells in ND and DIO mice, respectively. The difference between these two groups is not statistically significant but the trend is obvious (p=0.11, t test). The frequency of mIPSCs was 70.4 ± 13.4 /min (n=12) in Hcrt cells in ND and 68.4 ± 22.5 /min (n=12) in Hcrt cells in DIO mice (p>0.05, t test). In addition, we have examined evoked excitatory postsynaptic currents in Hcrt cells in ND and DIO mice. Under a train of stimulations (100 Hz, 20 pulse) to Hcrt cells, the evoked EPSCs decayed rapidly (within 20 pulses) in these cells in ND mice but did not decay as fast in the DIO group. Since the amplitudes of evoked EPSCs induced by these stimuli decay as the readily releasable pool (RRP) of vesicles in presynaptic terminals are depleted by the rapid, repetitive stimulations, this result and the decrease in the frequency of mEPSCs suggest a possible de-potentiation of presynaptic efficacy in Hcrt neurons in DIO mice. Lastly, our data indicate that the responses of Hcrt cells to cocaine treatments and acute stress were altered as well. In conclusion, our preliminary tests suggest a re-programed Hcrt system by high-fat diet may be responsible for altered behaviors relevant to cocaine reward/abuse in animals.

Title: Anorexigenic effects of substance P in Coturnix japonica

Authors: *C. BUENAVENTURA[1], M. A. CLINE[2], E. R. GILBERT[3]
[2]Animal and Poultry Sci., [1]Virginia Tech., Blacksburg, VA; [3]Animal Sci., Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: When substance P (SP), an 11 amino acid-residue tachykinin that is produced centrally and peripherally, is centrally administered, there is reduced food intake although the mechanism mediating this effect is poorly understood. Hence, the objective of this project was to elucidate the central mechanism associated with reduced food intake using Japanese quail (*Coturnix japonica*) as a model. In Experiment 1, 7 day-old quail were intracerebroventricularly injected with 0, 0.25, 0.5 or 1.0 nmol SP and food and water intake were quantified for 180 min. On a cumulative basis, quail that received 0.5 and 1.0 nmol SP reduced food intake during the entire observation period (50% reduction compared to controls at 30 min post-injection) while those administered 0.25 nmol were not different from vehicle-injected chicks. On a non-cumulative basis, food intake in the 0.5 and 1.0 nmol-injected groups was different from the vehicle-injected group at only 30 min post-injection. Water intake was not affected. In Experiment 2, whole hypothalamus was isolated from injected chicks and real-time PCR performed to measure mRNA abundance of several appetite-associated factors. Quail injected with SP had reduced agouti-related peptide (AgRP) mRNA compared to quail injected with vehicle. In Experiment 3, a comprehensive behavior analysis was performed. Quail that received SP had decreased feeding pecks and reduced locomotion compared with quail that received vehicle. In sum, SP induces a potent anorexia following central injection in quail that coincides with reduced hypothalamic AgRP expression. The effect on food intake may be primary because SP did not affect behaviors that would be competitive with food intake.

Title: Gamma oscillations in the basolateral amygdala and prefrontal cortex support the emotional modulation of memory consolidation

Authors: *V. KANTA, D. PARÉ, D. B. HEADLEY
Rutgers, the State Univ. of New Jersey, Newark, NJ

Abstract: Recently formed memories are labile, but with time can strengthen and become permanent through a process of consolidation. Emotional arousal enhances consolidation, resulting in memories that are vivid and long lasting. This effect is mediated by the basolateral amygdala (BLA) and its strong projections to both the hippocampus and neocortex. While there has been extensive investigation into the electrophysiological mechanisms of consolidation between the hippocampus and neocortex, comparatively little is known about the BLA's role. What is known is that the BLA generates gamma oscillations during emotional arousal, and artificially driving a gamma rhythm in the BLA boosts the consolidation of aversive memories. Thus, gamma oscillations constitute a promising candidate mechanism for mediating the enhancing effects of emotional arousal on memory consolidation. In this study, we examine how the consolidation of emotional experiences affects the interactions between the BLA, ventral hippocampus, and medial prefrontal cortex (mPFC), a neocortical area linked to memory consolidation. In particular, we study how gamma-related activity in these areas is affected during consolidation of both aversive and positively motivated spatial memories. The behavioral tasks we used are inhibitory avoidance and the holeboard foraging task. Preliminary results show that gamma power and coherence between BLA and mPFC (but not ventral hippocampus) increased immediately after training on both tasks. Crucially, its strength correlates with subsequent retention. To establish whether changes in gamma are causally related to memory consolidation, we have developed a closed-loop real-time optogenetic control system that can reliably detect oscillatory bursts in the BLA with frequency and phase specificity. Using this system, we intend to modulate gamma oscillations during the post-training consolidation period. Overall, our results indicate that the coordination of gamma oscillations between the BLA and mPFC supports consolidation of emotional memories.

Title: Stress-induced changes in effective connectivity during the emotional response to threat

Authors: *A. M. GOODMAN[1], M. D. WHEELOCK[2], N. G. HARNETT[1], D. R. HURST[1], T. R. OREM[1], G. DESHPANDE[3], S. MRUG[1], D. C. KNIGHT[1]

[1]Psychology, Univ. of Alabama at Birmingham, Birmingham, AL; [2]Psychiatry, Washington Univ., St. Louis, MO; [3]Electrical and Computer Engin., Auburn Univ. MRI Res. Ctr., Auburn, AL

Abstract: Stress exposure can disrupt emotional learning and regulation processes. However, the neurobiological processes that mediate stress-related dysfunction that impacts learning and memory is not well understood. Studies from our laboratory have shown that conditioned diminution of the emotional response to threat (reduced emotional response to predictable vs unpredictable threat) is a regulatory process supported by a prefrontal cortex (PFC)-hippocampus-amygdala neural circuit during fear conditioning. The current study investigated the hypothesis that stress disrupts the functional connectivity of the PFC-hippocampus-amygdala circuit, and in turn, the dysfunction of this circuit disrupts emotion regulation. 120 right-handed volunteers completed a variant of the Montreal Imaging Stress Task (MIST) followed (20 minutes later) by a Pavlovian fear conditioning procedure during fMRI. Self-reported stress and psychophysiological responses to the MIST were used to assess stress reactivity. Psychophysiological measures and fMRI signal during fear conditioning were used to assess autonomic responses and neural activity underlying conditioned diminution of the emotional response to threat. In order to find task-specific connectivity during the fear conditioning, Granger Causality (GC) values were populated into two different samples based on the predictable (CS+UCS; UCS that follows the CS+) and unpredictable (UCS alone) threat presentations. Analyses of predictable and unpredictable trials of the UCS revealed two main hub ROIs: the dorsolateral PFC (dlPFC) and insula. Presentations of the predictable threat (i.e., CS+UCS) showed greater connectivity than unpredictable threat (i.e., UCS alone) from the dlPFC to dorsomedial PFC (dmPFC), ventromedial PFC (vmPFC), dlPFC, posterior cingulate cortext (PCC), amygdala, and inferior parietal lobule (IPL). Presentations of the CS+UCS showed connectivity from the dlPFC to the insula, PCC, vmPFC, IPL, and amygdala, and from the insula to the dlPFC, PCC, and amygdala. Connectivity during the unpredictable threat was observed from the dlPFC to the vmPFC, dmPFC, dlPFC, insula, PCC, IPL, and amygdala. Stress reactivity (self-reported) did not vary with connectivity during the predicable threat. In contrast, stress reactivity varied with connectivity during UCS alone trials from the insula to the IPL. These findings suggest that the left dlPFC was significantly more involved in top-down regulation of other brain regions during CS+UCS trials compared to UCS alone. Increased connectivity between the insula and IPL may play a critical role in stress-induced changes in the emotional response to threat.

Title: How do rest periods following the end of chronic stress impact fear conditioning?

Authors: *J. M. JUDD, V. SHAH, A. FLEGENHEIMER, B. LE, F. SANABRIA, C. D. CONRAD
Psychology, Arizona State Univ., Tempe, AZ

Abstract: In fear conditioning paradigms, chronic stress enhances fear learning (Conrad *et al.*, 1999), attenuates extinction learning (Izquierdo *et al*., 2006), and impairs recall of extinction (Baran *et al.*, 2009). Chronic stress increases anxiety-like behavior, which remains elevated even after a no-stress period (i.e., rest) prior to the start of behavioral testing (Vyas *et al*., 2004). In other tasks, the effects of chronic stress seem to disappear following a rest period (Conrad *et al.*, 2016). Whether a rest period on fear conditioning and extinction would lead to persistent effects or dissipate is untested. Male Sprague-Dawley rats were chronically stressed by wire mesh restraint (6hr/d/21) or assigned to a non-stressed control group (CON). Fear conditioning occurred within a day (IMM), 3 weeks (REST3), or 6 weeks (REST6) after chronic stress ended. Prior to the start of fear conditioning, rats were acclimated to the training and testing contexts for 10mins/day 3days/context to attenuate the likelihood of chronic stress potentiating fear learning during the training session. Fear conditioning involved the presentation of 3 tone (20sec, 2kHz, 75db)-footshock (1sec, 0.8mA) pairings. Extinction took place over the next two days in a different context than during training and consisted of 15 tone presentations (no footshocks). The duration of freezing to each tone and context (20-secs immediately prior to each tone), and the difference between both durations (difference score) were quantified. During fear conditioning, REST6 acquired the freezing response slower than the other groups; all groups showed similar and elevated freezing by the third tone presentation. In the first extinction session, rats displayed minimal freezing to the context before the first tone presentation, but differences emerged in subsequent context assessments. IMM froze significantly more to context than REST3 and REST6. All groups froze similarly to tones during extinction 1. The difference score for IMM was at zero, indicating similar freezing to tone and context, whereas REST3 and REST6 exhibited positive difference scores, indicating more freezing to tone than to context. CON difference scores were higher than IMM but lower than REST3 and REST6. No significant differences in freezing were detected during the second extinction session and spontaneous recovery. These results suggest that a rest period following the end of chronic stress may lead to

optimal fear conditioning and extinction compared to fear conditioning soon after chronic stress has ended. Establishing whether the IMM performance during extinction reflects generalization is underway.

Title: Midbrain dopamine neurons regulate model-based, not model-free, aversive learning

Authors: *C. Y. PENG, P. JEAN-RICHARD DIT BRESSEL, G. P. MCNALLY
Psychology, Univ. of New South Wales - Kensington Campus, Sydney, Australia

Abstract: Whereas dopamine is well-known for mediating reward learning, its role in aversive learning and threat-related attention is less well understood. Here we used optogenetics and transgenic TH::Cre rats to investigate the causal role of Ventral Tegmental Area (VTA) Tyrosine hydroxylase (TH) neurons in aversive learning under experimental designs enabling concurrent assessment of model-free (simple Pavlovian conditioning) and model-based (punishment) learning. First, we show in simple model-free Pavlovian fear conditioning that optogenetic silencing of VTA TH+ neurons during the conditioned stimulus or unconditioned stimulus has no effect on fear learning, across different asymptotic levels of learning and across differences in strength of positive prediction errors. Then, we show that optogenetic inhibition of VTA TH+ neurons, in the same animals, is sufficient to punish instrumental responding for a food reward. To directly compare the role of VTA TH neurons in these two forms of aversive learning we developed a novel behavioural paradigm that allowed concurrent assessment of model-free aversive learning (fear) and model-based aversive learning (punishment) under identical stimulus and shock contingencies. Using this paradigm we show that optogenetic inhibition of VTA TH neurons augments aversive model-based learning without affecting aversive model-free learning acquired under matched conditions. These findings show that midbrain TH neurons regulate model-based, not model-free, aversive learning.

Title: Safety-signal learning in Hermissenda produced by conditioned inhibition training

Authors: *J. FARLEY
Indiana Univ. Bloomington, Bloomington, IN

Abstract: Previously, we found that conditioned inhibition (CI) learning in *Hermissenda* (*H.c.),* produced by repeated explicitly-unpaired (EU) presentations of light (CS) and rotation (US), fixed ISI of 4.5 min, resulted in increased phototactic behavior and decreased/increased photoresponses and spike activity of ocular Type B/A photoreceptors (Britton & Farley, 1999, *J Neurosci*; Walker et al., 2010, *Front Beh Neuro*). Recent studies (Farley et al., 2017) determined the ionic conductance changes that underlie persistent EU-produced decreases in B cell light-responses and spike frequencies: increases in two somatic K^+ currents (I_A and $I_{K\text{-}Ca}$). These same two K^+ currents are suppressed by CS-US pairing-produced persistent PKC-activity, and underlie the enhanced photoresponses and excitability of B cells that comprise the molecular basis of associative memory in *H.c.* Another often-used CI/safety-signal procedure with vertebrates, more complex than EU-training, is the "Pavlovian Conditioned Inhibition" procedure (Pav CI). Here I report that *H.c.* exposed to Pav CI training show enhanced phototactic behavior, similar to EU-trained animals. Animals in the Pav CI procedure received an initial 2 training days in which a chemosensory cue (scallop extract) was paired with rotation (C+), 25X per session. This was followed by 3 additional training days in which 50 non-reinforced (no rotation) simultaneous compound presentations of the chemosensory cue and light (CL-), intended to establish L as a signal for the "absence of rotation", were added to the C+ trials. A discrimination control group (C+/L-) of animals received the same training as the Pav CI group, except that the non-reinforced light-alone trials (L-) did not include the presentation of the chemosensory cue. During post-training open-field phototactic tests, Pav CI animals clearly moved *towards* the center of the light gradient [pre-post distance scores of (mean +/- sem)]: 4.2 +/-0.8 cm, 3.7 +/- 0.7 cm (retention test days 1 & 2, respectively), similar to EU-animals. In contrast, discrimination control (C+/L-) animals showed only small (< 0.6 cm) non-significant changes in phototaxis. Additional studies showed an acquisition function for Pav CI, as well as "extinction" of Pav CI by non-reinforced light-alone trials.

Title: Neurotoxic damage to orbitofrontal subregions 12 or 13 impairs startle response to fearful and safe stimuli in macaques

Authors: *L. E. MURPHY, C. WYNN, V. WERTMAN, A. M. KAZAMA, J. BACHEVALIER
Emory Univ., Atlanta, GA

Abstract: Dysfunction of the orbitofrontal cortex (OFC) plays a key role in anxiety disorders in humans, characterized by exaggerated anxiety and fear responses to relatively harmless stimuli (Milad & Rauch, 2007). PTSD patients exhibit similar characteristics, and are unable to integrate safety-signal information in the presence of fearful cues, as measured by the safety-signal (AX+/BX-) paradigm (Jovanovic et al., 2012). Previously, we showed that selective damage to OFC area 14 impairs the expression of learned fear and safety cues in macaques on the AX+/BX- task (Kazama et al. 2013). Because the OFC includes several subregions with distinct but complimentary functions, we tested here the effects of selective lesions of OFC areas 12 and 13 on the expression of fear and safety learning and conditioned inhibition. Nine adult rhesus macaques were trained to discriminate between a fear (AX+) and a safety (BX-) cue. Percent fear-potentiated startle (%FPS) measured both the rate of associating the conditioned cues (AX+, BX-) to the unconditioned stimuli (air blast; no air blast), as well as conditioned inhibition during a probe test combining the A and B cues (AB). Subjects then received either bilateral ibotenic acids lesions to OFC area 12, OFC area 13, or sham operations. Following surgery, subjects were then given the probe test with the same cues they had learned pre-surgery. Pre-surgical performance of the 3 groups were similar on both the trials to criterion during training (AX+ and BX- cues) and %FPS during the probe test (X^2=1.00, p=0.61; $F_{2,6}$=1.20, p=0.37, n^2=0.40). A RM-ANOVA comparing the %FPS to each stimulus type (AX+, BX-, AB) post-surgery revealed a trend toward Stimulus X Lesion interaction with a large effect size ($F_{4,12}$=3.00, p=0.06, n^2=0.50), indicating that sham-operated controls again showed good discrimination between the aversive and safety cues and good conditioned inhibition ($F_{2,12}$=4.35, p=0.09, n^2=0.69). By contrast, animals with damage to either OFC areas 12 or 13 did not differentiate between the previously conditioned fear and safety cues, showing impaired expression and consequently no conditioned inhibition in the post-surgery probe test (Area 12 = $F_{2,4}$=0.85, p=0.49, n^2=0.30; Area 13 = $F_{2,4}$=1.77, p=0.28, n^2=0.47). These results suggest that lesions to either OFC areas 12 or 13

significantly impair subjects' ability to retain the emotional valence of conditioned cues and, like OFC area 14, areas 12 and 13 are necessary for the expression of fear and safety learning. Thus, the interactions between OFC areas are important for emotion regulation, and may help elucidate the neural circuity of anxiety disorders.

Title: Early life stress differentially impacts adult fear discrimination and increases alcohol drinking in male and female rats

Authors: *R. A. ZACHARIAS, C. ANDREANSKY, M. H. RAY, M. A. MCDANNALD
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Stress during early life is a risk factor for a number of clinical disorders, such as Post-Traumatic Stress Disorder, depression and substance abuse disorders, which manifest in adulthood. Many of the disorders for which early life stress (ELS) is a risk factor are more prevalent in females, yet there is a dearth of research on how physical ELS may differentially impact males and females later in life. In order to address this significant issue, we exposed rats to ELS to investigate sex-specific behavioral effects in adulthood. Male and female Long-Evans rats were born in the laboratory and weaned on post-natal day 21. Half of the males and females underwent ELS twice daily on post-natal days 26-35, while the other half were non-exposed controls. The ELS procedure consisted of exposure to four types of adverse experiences five times each, including forced cold water swim, tail pinch, cat hair exposure, and restraint stress. Body weights were recorded in order to track physical development. Starting on post-natal day 70, all rats were maintained at 85% of their free body weight and trained to nose poke for pellets. After two days of pre-exposure to three 10-second auditory cues, all rats then underwent 16 days of Pavlovian fear discrimination during which the three different auditory cues predicted foot shock at different probabilities: 0% (safety), 25% (uncertainty), and 100% (danger). After discrimination, rats underwent 6 days of extinction, which consisted of presentations of the three

auditory cues without foot shock. At least 10 days after the conclusion of fear conditioning, all rats were given voluntary, intermittent access to 20% ethanol in 8, 24-hour sessions. Results indicated that ELS impaired physical development, resulting in decreased body weights in both male and female rats compared to their control counterparts. However, no differences in body weights were observed in adulthood. Males exposed to ELS performed similarly to controls during fear discrimination; however, females demonstrated generalized higher fear to both the safety and uncertainty cues compared to their control counterparts during discrimination and continuing into extinction. ELS rats drank more alcohol than controls in initial alcohol drinking sessions, and this effect was present in males and females. Taken together, these data indicate that ELS negatively impacts both males and females, but for fear discrimination this effect is not uniform across the sexes.

Title: An investigation into the long term and cross- contextual effects of fear counter-conditioning via DecNef

Authors: *J. E. STEWART[1], M. KAWATO[2], A. KOIZUMI[3], H. LAU[4]
[1]Computat. Neurosci., ATR, Nara-Shi, Japan; [2]Computat. Neurosci., ATR, Kyoto, Japan; [3]CiNet, NICT, Suita, Japan; [4]Univ. of California, California, CA

Abstract: Acquired fear responses to simple visual stimuli have been successfully reduced by a novel counter-conditioning procedure where decoded neurofeedback (DecNef) was used to pair reward with the multi-voxel neural patterns that represent these stimuli (Koizumi et al., 2016). This procedure could potentially benefit patients with fear-related disorders who cannot tolerate the direct encounters with fear-associated stimuli that occur during conventional fear reduction procedures. However, clinical application of this type of DecNef awaits further investigation to clarify whether the fear reduction effect (1) can be achieved with more naturalistic stimuli, (2) survives changes in context, and (3) is maintained over time. We have therefore begun a new series of experiments where we use angry faces as naturalistic visual stimuli , where we use different odors to manipulate context, and where we re-test fear responses three months after original testing. We aim to examine whether acquired fear responses to angry face stimuli can be

reduced via DecNef counter-conditioning, and whether these potential fear reduction effects are maintained across different odor contexts and over time. The results of preliminary experiments, as well as plans for future experiments, will be discussed.

Title: Modelling the impact of matrix metalloproteinase inhibition on human threat learning

Authors: *F. MELINSCAK[1], A. TZOVARA[1,2], D. R. BACH[1,2]
[1]Div. of Clin. Psychiatry Res., Psychiatric Hospital, Univ. of Zurich, Zurich, Switzerland; [2]Wellcome Trust Ctr. for Neuroimaging, London, United Kingdom

Abstract: Long-term potentiation is a fundamental memory mechanism and requires a signalling cascade that involves matrix metalloproteinase (MMP) 9. We have previously shown that the blood-brain barrier crossing, in vivo and in vitro human MMP inhibitor doxycycline impairs human threat learning (fear conditioning), as assessed by fear-potentiated startle in a retention test 7 days after learning [Bach, Tzovara, Vunder, 2017: Molecular Psychiatry]. Doxycycline also had an impact on skin conductance responses during acquisition, but this impact is not understood quantitatively. Here we harness computational models of aversive learning to derive a formal description of the observed learning trajectory.
Our models are designed to capture activity of the sympathetic nervous system (SNS) upon CS presentation, which is not directly observable. To obtain trial-by-trial estimates of SNS activity, we apply a psychophysiological modelling (PsPM) approach to skin conductance data. We then fit a number of computational associative learning models. Our model spaces encompasses descriptive models from reinforcement learning theory, normative Bayesian learning, and null models. Relative evidence for the models is assessed through Bayesian model selection.
Across all subjects, we find that the learning trajectory of SNS activity is best approximated by Bayesian learning with a beta-binomial model that fully embodies the task structure. The mapping from model onto SNS activity appears to reflect a mixture of the prior mean and entropy, thus replicating our previous work. The same computational model is also the most plausible one in both the placebo and doxycycline group, when analyzing the groups separately. We then proceed to identify variants of this model that may capture the impact of MMP inhibition during learning.

To summarise, we use computational models to link MMP inhibition to behavioural indices of threat learning, in order to capture trial-by-trial dynamics of aversive learning under conditions of impaired long-term potentiation.

Title: Gamma oscillations in BLA - a computational perspective

Authors: *F. FENG[1], D. B. HEADLEY[2], Z. CHEN[1], B. LATIMER[1], A. AMIR[2], D. PARE[2], S. S. NAIR[1]
[1]Electrical and Computer Engin., Univ. of Missouri-Columbia, Columbia, MO; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: The basolateral amygdala (BLA) participates in the formation and expression of emotional memories. Many of the brain regions that project to the BLA exhibit oscillations in the gamma (35-100 Hz) frequency band (Headley and Pare, 2013). In addition to these extrinsic sources of gamma drive, the BLA itself is thought to be capable of generating gamma oscillations on its own. However, the physiological mechanisms that support gamma rhythmogenesis in the BLA are unknown. Similarly, the relative contributions of the intrinsic mechanisms vs. extrinsic drive remain unclear.
We used a biophysical 1000-cell computational model of the BLA to investigate the role of intrinsic mechanisms and state-dependent extrinsic drive on the generation of gamma oscillations. The network model was developed using the known physiological and anatomical properties of the BLA, specifically different single cell types and their neurophysiology, synaptic current dynamics, spatially heterogeneous spatial connectivity, short- and long-term plasticity and neuromodulatory inputs (Rainnie et al., 1993; Woodruff and Sah, 2007; Headley et al., unpublished results).
The model replicated several features of gamma oscillations seen in *in vivo* local field potential recordings from BLA (unpublished data), with a prominent peak in the simulated local field potential at 60 Hz. The firing rates of model principal cells (PNs) and interneurons (ITNs) followed a log-normal distribution with averages of 0.79±0.59 Hz and 20.21±10.4 Hz, respectively, consistent with biological data (Amir et al., 2015). Both PN and ITN inter-spike interval distributions showed exponential decay with coefficient of variation values of 0.6 for

PNs, and 1.3 for ITNs, indicating irregular spiking. Moreover, both PNs and ITNs exhibited weak synchronization to the gamma cycle (vector strength: 0.18±0.1 for PNs, and 0.35±0.04 for ITNs), in agreement with *in vivo* recordings (unpublished data). We also note that, consistent with prior studies, generation of the weak gamma in BLA required that the drive to ITNs come primarily from PNs. On-going work examines the role of underlying biophysical mechanisms and connectivity schemes in the genesis of gamma. In parallel, we are investigating how state-dependent properties of the extrinsic drive, such as its gamma entrainment, produce BLA gamma.

Sch. of Med., Indianapolis, IN; [3]Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Anagin, Inc., Indiana Ctr. for Biomed. Innovation, Indianapolis, IN; [5]Dept. of Psychological and Brain Sciences, Indiana Univ. Bloomington, Bloomington, IN

Abstract: Stimulation of N-methyl-D- aspartic acid receptors (NMDARs) and the resulting activation of neuronal nitric oxide synthase (nNOS) are crucial for fear memory formation. While NMDAR antagonists and NOS inhibitors can disrupt fear conditioning, they also disrupt many other CNS functions. The 95 kDa postsynaptic density protein (PSD95) is a scaffolding protein that links nNOS to NMDARs, which is required for the efficient activation of nNOS. We hypothesized that uncoupling nNOS from PSD95/NMADRs through either systemic and intra-amygdala application will reduce conditioned fear, similar to NMDAR antagonists but without other motor and learning deficits. In this study, we explore this hypothesis by utilizing a compound that disrupts PSD95/nNOS binding, ZL006 for its conditioned fear-attenuating effects

and determining the cellular mechanisms mediating such effects. First, we demonstrate that i.p. injection of ZL006 and not its inactive isomer ZL007, can attenuate fear memory, as measured with auditory fear conditioning. More importantly, unlike NMDARs antagonist MK801, systemic ZL006 is devoid of effects on locomotor activity, social interaction, object recognition memory and spatial memory. We show that co-immunoprecipitation analysis of tissue homogenates taken from rats soon after fear-conditioning showed a robust increase in the amygdala PSD95/nNOS binding, which is blocked by systemic pre-administration of ZL006. Treatment of amygdala slices with ZL006 also impairs long-term potentiation (LTP), the cellular signature of synaptic plasticity in amygdala neurons. Finally, we demonstrate that direct intra-amygdala infusion of ZL006 also attenuate fear conditioning. These findings support the hypothesis that disrupting the PSD95/nNOS interaction downstream of NMDARs reduces fear memory and may represent a novel treatment approach for fear-related disorders, such as post-traumatic stress disorder.

Title: Lateral orbitofrontal cortex regulation of aversive prediction errors

Authors: *M. H. RAY, E. HANLON, M. A. MCDANNALD
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The capacity to correctly discriminate cues signaling danger and safety is crucial and dysfunction of this capacity is a hallmark of anxiety disorders, including PTSD. In real life, cues do not signal danger or safety with complete certainty. Instead, uncertainty is inherent. Furthermore, uncertainty itself is not typically *static*, but is subject to change over time. Making and updating accurate estimates of threat in uncertainty is therefore essential. Here we tested the hypothesis that the lateral orbitofrontal cortex (lOFC) is necessary for employing aversive prediction errors related to changes in uncertainty. Male, Long Evans rats received bilateral neurotoxic lateral orbitofrontal cortex lesions using NMDA. Shams received identical surgical

treatment but did not receive NMDA infusions. Following recovery, rats received fear discrimination in which three different auditory cues were associated with different probabilities of foot shock. Fear to each cue was measured by nose poke suppression. The safety cue never predicted foot shock (p=0.00) while the danger cue always predicted foot shock (p=1.00). For the first 16 sessions, the uncertainty cue predicted would occur on 25% of trials (p=0.25). Rats were then subjected to shifts in the probability of the uncertainty cue in two blocks, both consisting of four sessions each. The first block was designed to induce a large, positive prediction error (Large, +PE block) by shifting the probability from 0.25 to 0.50. The second block was designed to induce a large, negative prediction error (Large, -PE block) by shifting the probability from 0.50 to 0.13.
We found that both Sham and lOFC-lesioned rats acquired the initial discrimination. In the Large, +PE the lOFC-lesioned rats generalized their increase in fear to the danger and safety cues. However, the sham rats did not generalize their increase in fear. In the Large, -PE block both Sham and lOFC-lesioned rats decreased fear to the uncertainty cue. Although now, in Sham rats the decrease was generalized to the danger cue, whereas in the lOFC-lesioned rats no generalization was apparent.
These results suggest that the lateral orbitofrontal cortex is involved in regulating the generalization of positive and negative aversive prediction errors. Being able to accurately and rapidly employ aversive prediction errors is an important part of associative learning. Incorrectly generalizing aversive prediction errors is maladaptive and may be indicative of human anxiety disorders, such as PTSD.

Abstract: Rapid assessment of threat and safety predicting cues is crucial in an ever-changing environment. When safe cues become threatening and threatening cues become safe, flexible reversal of the learned defensive responses is required. Patients with posttraumatic stress disorder (PTSD) generally show higher defensive responses to safe cues, but the crucial ability to update threat learning has not been investigated and may represent an independent objective marker of the disease. Here, we measured skin conductance response and functional resonance magnetic imaging during threat acquisition and reversal in combat veterans with PTSD (VPTSD; N=30), veteran combat controls (VCC; N=30) and healthy human controls (HCC; N=33). We hypothesized that VPTSD would show attenuated updating of learned defensive responses compared to VCC and HCC. Indeed, the reversal learning index (defined as the difference between threat acquisition and threat reversal) was attenuated in VPTSD ($t(61) = -2.10$, $P = 0.04$; Cohen's $d = -0.53$) but also in VCC ($t(61) = -2.15$, $P = 0.04$; Cohen's $d = -0.55$) compared to HCC while there was no statistical difference between veteran groups. In line with previous PTSD imaging meta-analyses we focused our neural analysis on brain regions that have shown hyperactivity (amygdala, insula) and hypoactivity (ventromedial prefrontal cortex, dorsal striatum, dorsal anterior cingulate cortex, thalamus) and found lower neural differentiation between the threatening and safe stimuli during both acquisition and reversal in the combined veteran group compared to HCC in the bilateral caudate nuclei (left: $t(79) = -2.61$, $P = 0.01$, Cohen's $d = -0.59$; right: $t(79) = -2.89$, $P = 0.005$, Cohen's $d = -0.65$) and right thalamus ($t(79) = -2.52$, $P = 0.01$, Cohen's $d = -0.57$). Differential neural activity during threat acquisition and reversal in the dorsal anterior cingulate cortex (dACC) predicted the strength of the reversal learning index in the combined veteran group ($r(48) = 0.3$, $P = 0.03$). In conclusion, the reversal index reduction in VPTSD and VCC scaled negatively with differential neural activity in the dACC, suggesting a potentially protective role of the dACC in restoring learned threat updating.

Title: Mapping the cholinergic engram in fear & anxiety

Authors: *P. M. RAJEBHOSALE[1,2], D. TALMAGE[1,3], L. W. ROLE[1,4]
[1]Ctr. for Nervous Syst. Disorders, State Univ. of New York At Stony Brook, Stony Brook, NY; [2]Program in Neurosci., [3]Dept. of Pharmacol. Sci., [4]Dept. of Neurobio. & Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Anxiety disorders are one of the most common psychiatric diagnoses around the globe and are often comorbid with a variety of other mental illnesses (Kessler et al. 2005). Numerous studies have pointed to smoking cigarettes and nicotine dependence as risk factors for developing anxiety disorders (Moylan et al. 2012); some of the most illuminating studies are those of nicotine dependence in subjects with PTSD (Beckam et al. 1995. Koenen et al. 2005). In the brain, nicotine binds the nicotinic acetylcholine receptor (nAChR), the endogenous ligand for which is acetylcholine (ACh). Additionally, the basolateral amygdala (BLA), which plays an important role in fear learning, receives dense cholinergic innervation from basal forebrain cholinergic neurons (BFCNs). In the process of investigating the role of cholinergic signaling in fear learning and memory, our lab has recently demonstrated that acetylcholine release in the basolateral amygdala (BLA) can contribute to the fidelity of fear memories after an auditory fear conditioning task (Jiang et al. 2016). To further understand the contribution of the BFCN to fear learning and recall, we have developed novel tools for activity-dependent (AD), cell-type specific (Cre dependent), and temporally controlled labeling of neurons (Hereon referred to as ADCD). Here we demonstrate the validity of using these genetic constructs for mapping cell bodies as well as terminal fields of BFCNs activated during fear learning and recall of the fear memory. Upon recall of the fear memory, we discovered BFCNs in the nucleus basalis and substantia innominata (nbM/SI) labeled with the ADCD. This region of the basal forebrain sends dense projections to the BLA. Preliminarily, we observe variations in learning and/or memory between individual animals, which correlate with the number of ADCD positive BFCNs. These data suggest that there might be a correlation between cholinergic activity in the nBM/SI and either the ability of the animal to learn and/or recall the fear memory. *Prima facie*, there also seems to be an anterior-posterior bias to where these activated cholinergic neurons are found within the basal forebrain.

Title: Cued fear memory discrimination and generalization over time

Authors: *J. BEZEK, G. POLLACK, L. WEINGAST, H. BERGSTROM
Psychological Sci., Vassar Col., Poughkeepsie, NY

Abstract: The ability to properly generalize learned stimuli is adaptive, whereas over-generalization is thought to contribute to anxiety disorders and post-traumatic stress disorder. The passage of time is one factor that can influence memory generalization. Fear conditioned contextual stimuli are well-known to generalize over time. Surprisingly little is known about the extent of generalization for auditory fear conditioned stimuli with time. The present study sought to establish an auditory fear conditioned stimulus discrimination gradient at 1-day (recent) and 30-days (remote) following learning. Adult male C57BL/6 mice were fear conditioned with three auditory conditioned stimuli (CS; 75 dB, 5 kHz, 20 s) that each co-terminated with a foot shock unconditioned stimulus (US; 0.5 s, 0.6 mA) in context A. One day after fear conditioning, mice were presented with one of five tones at different frequencies (2, 3, 5, 8, or 12 kHz; 75 dB, 20s) in a novel context (context B). 30 days later, mice were returned to context B and replayed the tone. Results showed mice discriminated most (2, 3 and 12 kHz), but not all (8 kHz), auditory frequencies at the recent frame (24 hrs). Mice were still able to discriminate the same stimuli 30 days later, suggesting a high degree of accuracy for cued fear memory retrieval over time. In a second experiment, the tone (2, 3, 8, 5 and 12 kHz) was played at only the remote time point following learning. In contrast to the first experiment, results showed a flattening of the stimulus generalization gradient, with significant cued-specific generalized responsivity occurring at the 3 kHz frequency. Based on these results, we conclude that the sharpness of the remote auditory cued fear memory generalization gradient depends on pre-exposure to the non-target stimuli at a recent time point following learning. Measurements of Arc/arg 3.1 neuron density at recent and remote time points in the lateral amygdala, temporal association cortex and prelimbic cortex is ongoing.

Abstract: In Pavlovian to instrumental transfer (PIT) a conditioned stimulus (CS) that has been paired with an unconditioned stimulus (US) energizes goal directed behavior. PIT has typically been studied using appetitive reinforcement, and has provided an effective model that has advanced our understanding of the psychobiological substrates of appetitive motivation. However, we still know relatively little about aversive motivation. Aversive versions of PIT typically employ unsignaled active avoidance behavior and demonstrate control over this class of responding by a CS for an aversive US (e.g., shock). The psychological and neural mechanisms underlying aversive PIT are not well understood but early findings indicate it is a unique form of avoidance behavior. In order to further explore aversive PIT we evaluated whether generalization known as acquired equivalence is involved in transfer. In this framework, stimuli that predict the same US come to be treated as similar, increasing generalization between them. To explore if context-shock and tone-shock pairings contribute to this, subjects were exposed to two avoidance chambers during training. In context A (a standard avoidance chamber) shuttling was acquired as a footshock avoidance response using an unsignaled Sidman procedure, whereas in context B (another avoidance chamber with checkered walls and smooth floors), shock was never delivered. A shock-paired CS produced less transfer (i.e., PIT) in context B than in context A. This suggests that at least in part, the aversive PIT effect is driven by the avoidance context and may be due to generalization via shock. We followed this by testing if PIT requires regions of the brain that have been implicated in spatial learning (e.g., hippocampus) and mediated generalization (e.g., entorhinal cortex). Designer hM4Di receptors were used to inhibit these regions during PIT testing, but found no behavioral effect. Subjects then underwent training on a negative patterning task, which studies have found involve both hippocampal and entorhinal regions. Inhibition of these regions via treatment with CNO (the ligand for designer receptors) impaired acquisition of the negative patterning discrimination relative to vehicle controls and a non-viral CNO control group. This pattern of findings suggests that these regions may be involved in learning based on special forms of generalization, but since aversive PIT is a performance phenomenon, these regions are not required.

Title: Retention intervals enhance associative competition produced by a preexposed conditioned stimulus

Authors: *T. SCHACHTMAN[1], D. KLAKOTSKAIA[2], R. A. RICHARDSON[2], A. TAMASI[2], C. BAKER[2]
[2]Psychological Sci., [1]Univ. of Missouri, Columbia, MO

Abstract: Earlier studies have shown that a latent inhibitor is poor at competing for learning with another conditioned stimulus (CS) on a compound conditioning trial. Previous research also has shown that the poor conditioned response (CR) produced to a latent inhibitor can be reversed by a retention interval placed after conditioning and prior to testing the CR (e.g., Bakner et al., 1991). In the present conditioned taste aversion experiments, a CS ("A") was given CS-alone preexposures prior to a pairing of the CS with the unconditioned stimulus as pretraining phases. A compound conditioning phase also occurred in which this CS was able to compete with an added novel CS ("B"). However, prior to the AB-US compound conditioning phase, a retention interval occurred lasting either one day or many days (15 or 21 days). It was found that the lengthy retention interval enhanced the competitive potential of the pretrained CS. These results show that treatments that enhance the expression of a CS-US association can also enhance the competitive ability of the CS. However, a confirmation of the Bakner et al. effect in which the retention interval enhances the CR has not yet been examined in our laboratory using the present procedure.

Title: Affective flexibility without perceptual awareness

Authors: *D. SCHILLER[1], P. HOMAN[3], H. LAU[2], C. M. RAIO[4], D. R. BACH[5], D. CARMEL[6]
[1]Psychiatry and Neurosci. Departments, and Friedman Brain Inst., [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Dept. of Psychiatry, Icahn Sch. of Med. At Mount Sinai, New York, NY; [4]New York Univ., New York, NY; [5]Univ. of Zurich, Zurich, Switzerland; [6]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: In an ever-changing environment, cues that predict threat constantly change – new cues become threatening while old ones become safe. Affective flexibility is the ability to dynamically update our affective responses when threat contingencies change. Yet, confronting threatening cues in order to modify our responses could be difficult. Is it possible to achieve affective flexibility without consciously perceiving the threatening cues? We addressed this question using threat reversal learning with or without perceptual awareness of the conditioned cues, in 101 healthy human participants. To prevent perceptual awareness, we used continuous flash suppression, a technique allowing suppression of stimuli from awareness for long durations (seconds to minutes). Both aware and unaware participants were able to accomplish a dynamic updating process by shifting learned defensive responses from a stimulus that no longer predicts threat to one that does. Baseline anxiety levels scaled negatively with the strength of this updating in unaware participants. A trial-by-trial analysis of individual awareness reports, however, revealed in some participants patterns that appear unlikely under complete stimulus suppression, which conventional analyses for assessing perceptual awareness used to date might easily miss. Nevertheless, our results survived exclusion of the corresponding participants. We conclude that measures of perceptual awareness ought to consider individual trial-wise patterns, and that the successful updating of learned defensive responses requires affective flexibility but not perceptual awareness.

Title: Dopamine D2 receptor upregulation in cholinergic interneurons (CINs) of the nucleus accumbens: Effects on CIN function and Pavlovian incentive motivation

Authors: *E. F. GALLO[1], *E. F. GALLO[1], E. TEBOUL[2], M. BAILEY[3], P. BALSAM[4], J. A. JAVITCH[3], C. KELLENDONK[2]
[1]Psychiatry, [2]Columbia University/NYSPI, New York, NY; [3]Columbia Univ., New York, NY; [4]Columbia University/Barnard Col., New York, NY

Abstract: Alterations in striatal dopamine D2 receptor (D2R) availability are associated with several neuropsychiatric disorders that feature motivational dysfunction. Cholinergic interneurons (CINs), which express D2Rs, account for 2-3% of the striatal cell population, but exert widespread control over striatal circuit function. *In vivo*, CINs exhibit a dopamine-dependent pause in firing activity in response to reward-related stimuli that is deemed critical for cue-reward associations. *In vitro* studies have implicated the D2R in mediating the dopamine-dependent pause recorded in CINs. However, conventional pharmacological tools are limited in their ability to disentangle the specific contribution of CIN D2Rs to the pause and to incentive motivation given that other cell types that operate within striatum to process reward also express D2Rs. Here, we used a Cre-dependent viral strategy to selectively express either D2Rs or EGFP in CINs of the mouse nucleus accumbens (NAc). A general Pavlovian-to-Instrumental transfer (PIT) paradigm was used to measure the motivational influence of reward-associated cues on instrumental responding for food. Our preliminary data show that, during PIT testing, responding during pre-CS+ and the CS+ periods was comparable between D2R- and EGFP-expressing mice. However, D2R upregulation led to reduced overall responding to the CS- compared to controls. This effect was particularly significant in the first of four CS+/CS- presentations. These data suggest that, rather than invigorate responding during a reward-related cue, D2R upregulation in CINs of the NAc may enhance the inhibition of actions co-occurring with a neutral cue. Because reward-related cues in PIT elicit increases in phasic dopamine release in the NAc, we sought to determine whether increased D2R expression in CINs alters their response to dopamine release. To this end, we used a similar approach to express D2Rs or EGFP in CINs of the NAc while expressing ChR2 in midbrain dopamine neurons. Using acute slices, we measured the duration of the pause in CIN firing evoked by 20 Hz photostimulation of dopamine afferents. CINs overexpressing D2Rs showed a significant pause elongation compared to EGFP-expressing CINs (D2R: 2.0 ± 0.30 s; EGFP: 0.76 ± 0.15 s; $p < 0.005$), without altering the average interspike interval. Blocking D2Rs with sulpiride abolished the pause in both conditions, indicating that D2Rs are necessary for the light-evoked pause in CINs. Together, these results suggest that CIN-selective D2R upregulation is associated with a prolonged pause response to burst firing of dopamine neurons, which may underlie the effect on Pavlovian incentive motivation.

Title: Effects of environmental enrichment on sucrose cue reactivity and ventral striatal and cortical DARPP32 and DARPP32Thr34 in rats

Authors: *J. W. GRIMM, E. GLUECK, D. GINDER, J. HYDE, K. NORTH, H. REISTERER, J. SULC, K. JIGANTI
Dept of Psych and Beh Neurosci, Western Washington Univ., Bellingham, WA

Abstract: Background: Acute (17h) or chronic (30d) environmental enrichment (EE) reduces sucrose taking and seeking in rats. Our study examined the effects of acute or chronic EE on sucrose seeking and brain region levels of dopamine- and cAMP-regulated neuronal phosphoprotein molecular mass 32 kDa (DARPP32) and DARPP32 phosphorylated at threonine 34 (DARPP32Thr34). Changes in DARPP32 regulation may reflect altered dopamine (DA) D1 (DAD1) receptor-mediated signaling. Methods: Male Long-Evans rats first underwent 10 days (2h/day) of sucrose self-administration training. Control (CON) subjects remained in standard, single housing for the remainder of the experiment. Other rats experienced overnight (acute) or chronic (30d) EE (ChronicEE). Acute EE was provided immediately after the 10^{th} day of training (Day 1 AcuteEE) or 29 days later (Day 30 AcuteEE). Some rats responded for sucrose cues for 1h (TEST) immediately prior to sacrifice and brain extraction while others were sacrificed at a similar time without testing (NO TEST). Micropunches from several mesocorticolimbic regions were run through the western blot assay to identify intensity of signal for antibody-labelled DARPP32 and DARPP32Thr34. Reported here are results from ventral striatum (nucleus accumbens core and shell) and cortex (anterior cingulate and infralimbic cortices). Results: Regardless of TEST or NO TEST condition, in the nucleus accumbens core DARPP32 signal intensity was reduced by either acute or chronic EE. Acute EE increased the ratio of phosphorylated to total DARPP32 intensity. In the nucleus accumbens shell, DARPP32 signal intensity was reduced only in the NO TEST Day1 AcuteEE condition. There were no significant findings in the anterior cingulate cortex. Regardless of TEST or NO TEST condition, in the infralimbic cortex DARPP32 and the ratio of phosphorylated to total DARPP32 signal intensity were highest in ChronicEE rats. For the nucleus accumbens core, Pearson's r correlations were observed between responding for a sucrose-paired cue and DARPP32Thr34 ($r = -0.36$) and the ratio of the phosphorylated to total protein ($r = -0.44$). All results were statistically significant at $P < 0.05$. Discussion: These results support a role for DAD1 receptor signaling in the anti-craving effects of EE and indicate that targets for further investigation regarding the neurobiology of the anti-craving effects of EE include DARPP32 and DARPP32Thr34 in the nucleus accumbens core and infralimbic cortex. The accumbens core may be especially important due to the correlations between the objective measure of craving and protein signal intensities.

Title: Discovery of dopaminergic circuitry controlling *Drosophila* sleep and other behaviors

Authors: *S. LUU, M. C. W. HO, T. XIE, M. WU
Johns Hopkins Univ., Baltimore, MD

Abstract: Dopamine (DA) is a conserved neurotransmitter that plays crucial roles in regulating neural circuit function and behaviors in both health and disease.[1,2] This includes behaviors such as sleep/wake, arousal, and learning and memory. Genetic tools newly developed by our lab allow for intersectional strategies to target and examine the functions of small subsets of DA neurons on animal behavior.
In our studies, DA neurons are thermogenetically activated using dTRPA1 or silenced with temperature-sensitive Shibire and are assayed for effects on 1) sleep behavior using high-throughput behavioral assays and 2) gustatory learning. We have confirmed that silencing neurons within TH-D8 GAL4 driver with UAS-Shibire^{ts} results in less sleep compared to *iso31*, UAS-Shibire^{ts} control flies, which indicates that some DA neurons could promote sleep, contrary to their role in promoting wakefuless. We are using intersectional techniques to identify the specific neurons within TH-D8 GAL4 that are responsible for this phenotype. We also show that when TH-C1 GAL4 neurons are activated using UAS-dTRPA1, flies showed increased proboscis extension after training compared to *iso31*, UAS-dTRPA1 control flies, suggesting that their learning is impaired. We are using additional tools to identify the specific neurons within TH-C1 GAL4 that affect this type of gustatory learning behavior. Finally, we are also performing an unbiased video screen of various *Drosophila* behaviors using the activation of sparse DA neurons with dTRPA1. Our studies make use of novel genetic tools to dissect the DA circuitry of several fly behaviors including sleep and learning.

Title: Influence of repeated intracranial self-stimulation on brain-wide functional networks

Authors: *T. C. WEIDNER[1,2], D. VINCENZ[1], M. J. BROCKA[1], A. OELSCHLEGEL[1], J. GOLDSCHMIDT[1,2,3], F. W. OHL[1,2,3], M. T. LIPPERT[1,2]
[1]Systems Physiol. of Learning, Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Otto-von-Guericke-University, Ctr. for Behavioral Brain Sci. (CBBS), Magdeburg, Germany; [3]Otto-von-Guericke-University, Inst. of Biol., Magdeburg, Germany

Abstract: Reward learning is a dynamic process supported by the mesolimbic dopamine neurons, which are often encoding reward prediction error. Intracranial self-stimulation allows for associating an operant behavior with the stimulation of these neurons. The technique has been used widely to study the neural basis of learning, addiction and other brain functions. Over the course of the acquisition of self-stimulation behavior during training, the pressing rates increase in a fashion similar to a learning curve. However, the process can also be seen in terms of a developing addiction-like condition. Here, we investigate the brain-wide plastic changes in functional network activity, which accompany this process. We transduced TH::Cre- and DAT::Cre-positive mice with ChR2(H134R) and implanted a fiber into the left VTA. The animals were then trained to perform an intracranial self-stimulation task over the course of two weeks. We subsequently performed regional single-photon emission computed tomography imaging of regional cerebral blood flow (^{99m}Tc-HMPAO SPECT) to investigate the resting state network activity in the absence of optogenetic stimulation. In the control group, mice were implanted with fibers and optogenetically transduced, but did not undergo self-stimulation training nor were they ever stimulated. Both groups showed marked differences in resting state activity levels due to the experience of self-stimulation training. In particular, TH::Cre mice exhibited elevated levels of nucleus accumbens activity in the trained group. In contrast, DAT::Cre mice showed the opposite effect: a suppression of nucleus accumbens activity after training. In general, our findings demonstrate the strong, plasticity-inducing properties of VTA self-stimulation. These effects are particularly pronounced in structures linked to addiction, like nucleus accumbens and prefrontal cortex. Furthermore, the differing cellular composition of the stimulated population in Th::Cre vs. Dat::Cre mice has a strong influence on the resulting plastic changes.

Title: The role of glutamate receptor-dependent signaling in the dopamine system in reinforcement learning

Authors: *P. E. CIESLAK, J. RODRIGUEZ PARKITNA
Inst. of Pharmacol. PAS, Krakow, Poland

Abstract: Midbrain dopamine (DA) neurons, together with the major target of their projections - dopaminoceptive neurons in the frontal cortex and basal ganglia, provide a neural substrate for reinforcement learning and are involved in decision-making and action selection. Activity and plasticity in the DA system is largely dependent on excitatory glutamatergic transmission. Here, we sought to determine the role of glutamate receptors in the DA system by using genetically modified mice with cell-type specific ablation of NMDA or mGluR5 receptors in DA neurons and neurons expressing dopamine D1 receptors. Animals were tested in an adaptive decision-making task, that resembles a 'two-armed bandit problem', in which mouse is required to estimate by trial-and-error expected value of two alternatives associated with different reward probabilities (80% vs 20%). During each session reward probabilities were reversed after 60 trials. In order to maximize the long-term sum of rewards, a mouse had to select alternative with higher success probability and adapt their choices to changes in reward contingencies. We observed that disruption of NMDA receptor-dependent signaling in DA neurons caused an initial impairment in error-driven learning and reduced the likelihood of returning to previously rewarded alternative. Moreover, loss of mGluR5 but not NMDA receptors in D1 receptor-expressing neurons decreased reward sensitivity, and as a consequence frequency of choosing alternative with higher reward probability. Finally, loss of NMDA receptors in DA neurons and mGluR5 receptors in D1 neurons caused a delay in decision time and increased latency to collect reward. In conclusion, our results suggest that glutamate receptor-dependent signaling in the DA system is necessary for quick and optimal decision-making.

Title: Nucleus accumbens expression of pkiα may modulate the motivation to be physically active

Authors: *K. GRIGBSY
Biomed. Sci., Univ. of Missouri, Col. of Vet. Medi, Columbia, MO

Abstract: Despite the depth of knowledge concerning the health benefits exercise, little is known about the genetic factors underlying the motivation to be physically active. Voluntary exercise is known to be driven by the dopamine-reward system, specifically within the nucleus accumbens (NAc), and functions as a marker of positive motivation. To address this topic, our lab has created a selective breeding model in Wistar rats for high (HVR) and low (LVR) voluntary wheel-running behavior to recapitulate the genetic contributions for the motivation, and lack of motivation, to be physically active. Objective: We aimed to elucidate if genetic differences in PKA signaling within the NAc, in particular the role of PKIα (protein kinase inhibitor alpha), influences the motivation to voluntarily wheel-run in our model. Methods: Pharmacological antagonism of PKA in the NAc (analogous to the role of PKIα) of HVR and LVR rats was accomplished with H-89 and overnight wheel-running behavior was monitored. qRT-PCR was used to assess *PKIα, Homer1, ZIF268* and *Arc* mRNA levels in an *ex vivo* preparation of WT, LVR and HVR rat NAc slices following dopamine receptor type-1 (D1R) activation via DRD1 agonist, SKF-38393, and dopamine receptor type-2 activation following DRD2 agonist, Quinpirole. Western blots were used to assess CREB phosphorylation following the same DRD1 activation Results: Intra-nucleus accumbens injections of H-89 increased overnight running in HVR rats at 2.5μg/0.5μl, whereas it decreased running in LVR rats at 10μg/0.5μl. Baseline mRNA expression of *Drd1*, *PKIα,* and immediate early genes similar in WT and HVR rats, and lower in LVR rats. Both WT and HVR rats showed either no or decreased expression following Drd1 activation at 10μM and 20μM. LVR showed increased expression of most genes following Drd1 activation at 20μM. Following Drd2 activation, WT and HVR rat slices showed either no or decreased mRNA expression, whereas LVR tended to show an increase in mRNA expression at 10μM. HVR showed a marked increase in CREB phosphorylation following D1R agonism, with no increase in CREB phosphorylation in LVR slices. Significance: In light of the epidemic rise in physical inactivity worldwide, understanding the molecular and genetic differences between HVR and LVR rats, for instance the role of PKIα and other downstream targets, offers keen insight into the mechanisms underlying the motivation to be physically active.

Title: A novel task to study loss of control over food intake in rodents

Authors: *J. P. VERHAREN[1], M. C. M. LUIJENDIJK[1], L. J. M. J. VANDERSCHUREN[2], R. A. H. ADAN[1]
[1]Brain Ctr. Rudolf Magnus, Translational Neurosci., Utrecht Univ. Med. Ctr., Utrecht, Netherlands; [2]Utrecht University, Fac. of Vet. Med., Utrecht, Netherlands

Abstract: Loss of control over behavior is a hallmark feature of many neuropsychiatric disorders, including bulimia nervosa, addiction, and obsessive-compulsive disorder. The last decades have seen a growing research interest on this topic, and several behavioral tasks for rodents have been developed to model loss of control in human psychiatric diseases. However, these tasks are often complex, and require lengthy training in rodents. Here, we sought to overcome these drawbacks, and developed a novel behavioral task that explicitly tests the ability of a rat to inhibit its urge to consume a visually present sucrose pellet during the playback of an auditory tone. During tone trials, one can distinguish successful behavioral inhibition trials, in which the rat was able to wait with reward consumption until tone termination, and loss-of-control trials, in which the rat retrieved the reward and was therefore punished with footshock. Thus far, we have used this task to study the contributions of midbrain dopamine (DA) and the prefrontal cortex to behavioral (dis)inhibition. In view of the role of dopamine in incentive motivation and impulse control, we first measured the activity of DA neurons in this task, by performing fiber photometry in the VTA of TH::Cre rats. Surprisingly, we found no changes in DA activity during either successful or unsuccessful waiting trials, inconsistent with a role for DA in control over behavior. In line with this finding, pharmacological DA stimulation did not affect performance in the task. Second, considering the role of the prefrontal cortex in behavioral inhibition, we asked which prefrontal subregions are involved in this process. To this aim, we performed pharmacological inactivations of different prefrontal cortex regions (prelimbic, inframlimbic, lateral orbital, and medial orbital cortex) and studied its effect on task performance.In sum, we present a novel task which allows for an investigation of the neural processes behind loss of control over food intake, and show proof of concept by combining it with *in vivo* calcium imaging and neuronal manipulations. In the future, this task may be used to further unravel the complex neural circuitries underlying control over behavior.

Title: Is it possible that non-attractive male mouse could get female mind?

Authors: ***Y. N. OHNISHI**, Y. KAWAHARA, Y. H. OHNISHI, A. NISHI
Kurume Univ. Sch. of Med., Kurume, Japan

Abstract: To attract female is an eternal theme for male. We challenged to search what are criteria of female mice to select a male mouse and the neural network activity when male attracts female. Moreover, we tried to hijack the neural network for making female mice to love a non-attractive male mouse with optogenetic stimulation.At first, we have to confirm whether there are attractive and non-attractive male mice. Because we can not distinguish the difference between any healthy two mice other than their body size. For the purpose, we established the exploring behavior-based monitoring system for checking female preference to male mice. Unfortunately, this method works only one time, but we were able to detect their preference to the specific male mouse and/or avoidance behavior against the non-attractive male mouse. In this condition, we examined (1) whether their preference is common among mice having different genetic background, (2) whether female prefers to the familiar male mouse, (3) whether female prefers to father of her babies, (4) whether female mice prefer the single housing attractive male mouse or female-paired housing non-attractive male mouse, (5) whether testosterone administration changes the non-attractive male mouse into attractive one. Additionally, we measured dopamine levels in the nucleus accumbens, when female mice are encountering with the non-attractive or attractive male mouse. As we found significant difference between them, we will try to mimic the response with optogenetic stimulation and examine their effects on female preference behavior against male mice.

Abstract: Recent work showing that dopamine (DA) transmission is not necessary for all forms of learning has questioned the hypothesis that phasic dopamine corresponds to a reward prediction error signal arising from a classical Model-Free system. This hypothesis has been derived from the observation that in certain individuals known as goal trackers, DA release does not conform to the classical reward prediction error signal and that blocking DA does not impair learning during Pavlovian autoshaping. The Lesaint-Khamassi model has accounted for these observations and has provided a set of experimental predictions to further its validity. Here we test the prediction that individual variability observed during Pavlovian conditioning and associated DA release can be modulated by the length of time in between trials (intertrial interval; ITI). It has been hypothesized that increasing (resp. decreasing) the ITI allows more (resp. less) time to negatively revise the value of the food receptacle leading to increased (resp. decreased) tendencies to track predictive stimuli (i.e., sign-tracking). It is predicted that, with this constant revision of value, DA release to the US will not attenuate during learning as would be expected from classical Model-Free algorithms. To test this prediction we recorded DA release in nucleus accumbens core during a common Pavlovian autoshaping procedure (8 sec lever extension followed by reward) during sessions with either long (120 s) or short (60 s) ITIs. Consistent with model predictions, lengthening the ITI (i.e., 120 s ITI group) increased sign tracking and phasic DA release during the conditioned stimulus (CS; lever extension) and reward delivery (unconditioned stimulus; US). Importantly, phasic DA release to reward delivery was

even present after learning (10 sessions x 25 trials). During conditioning with shorter ITIs (i.e., 60 s groups), goal tracking was more prominent, and DA release to the CS was weaker, and not present at the time of reward delivery after learning. These results validate the initial computational hypotheses, opening new perspectives on the understanding of inter-individual differences in Pavlovian conditioning.

Title: Differential effects of dopamine receptor activation at the nucleus accumbens and the medial preoptic area on male rat sexual behavior expression of sexually exhausted male rats

Authors: L. GUADARRAMA-BAZANTE, *G. RODRIGUEZ-MANZO
Cinvestav-Sede Sur, IPN, Ciudad DE Mexico, Mexico

Abstract: Dopamine (DA) is involved in the control of motivated behaviors such as sexual behavior. Two brain regions are implicated in the dopaminergic regulation of male rat sexual behavior: the medial preoptic area (mPOA) and the nucleus accumbens (NAcc). We have recently reported that systemic administration of the nonspecific DA receptor agonist apomorphine has different effects on copulation of sexually active animals and temporarily sexually inactive males, due to sexual satiety. Thus, apomorphine almost lacked an effect in sexually experienced rats, but had clear facilitative effects on sexual behavior expression of sexually exhausted males. To determine the role played by the NAcc and the mPOA in the mediation of apomorphine-induced effects on copulatory behavior of animals with a distinct sexual condition, different doses of apomorphine (0.6, 2.0, 6.0 µg/animal) were directly infused into the mPOA or the NAcc of either sexually experienced or sexually exhausted males (24h after satiation). Apomorphine delivered to the mPOA did not modify copulation of sexually experienced animals and slightly increased the proportion of sexually exhausted animals exhibiting sexual activity. By contrast, infusion of apomorphine into the NAcc lacked of effects in sexually active rats, but reversed sexual satiety at all doses tested. After the highest apomorphine dose tested (6.0 µg/rat), all the satiated rats achieved ejaculation and resumed copulation after ejaculation and their copulatory parameters were indistinguishable from those

exhibited by sexually experienced control male rats, suggesting a full reversal of the sexual inhibitory state. Data show that activation of dopamine receptors by apomorphine either at the mPOA or the NAcc does not modify copulatory behavior of sexually active male rats. By contrast, in sexually exhausted animals the same apomorphine doses facilitated sexual behavior expression when infused into the NAcc, but lacked of an effect when infused into the mPOA. Results suggest that activation of DA receptors at the NAcc participates in the reversal of the sexual inhibitory state that characterizes sexual satiety, while DA transmission at the mPOA is not involved in this sexual inhibition phenomenon

Title: Coincident and causal contributions of striatal dopamine to cognitive flexibility

Authors: *A. KOCHARIAN[1], A. K. RADKE[2], D. M. LOVINGER[1], Y. MATEO[1], A. HOLMES, PhD[1]
[1]Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [2]Miami Univ., Oxford, OH

Abstract: Striatal dopamine (DA) neurons encode the difference between expected and received reward as prediction errors (RPEs) which work as teaching signals to guide adaptive choices. DA dynamics vary between different striatal regions and few studies have examined the differential contributions of DA release in the nucleus accumbens core (NAcc) and dorsolateral striatum (DLS) to the ability to flexibly update behaviors and revise associations. Here, DA transients were monitored using *in vivo* fast-scan cyclic voltammetry (FSCV) in the mouse NAcc and DLS during performance of a rewarded choice-discrimination and reversal touchscreen task. DA transients in the NAcc were significantly elevated following unexpectedly-rewarded choices during early reversal, but not other task-phases. To assess the causal contribution of DAergic inputs from the ventral tegmental area (VTA) to the NAcc in choice-flexibility, the VTA-NAcc pathway was selectively photosilenced or photostimulated during early reversal. Inhibition of DA cell terminal activity during early reversal significantly increased perseverative errors. Bidirectional effects were not observed with photostimulation at DA terminals as no changes in behavioral performance were observed in this group, suggesting that augmenting DA activity may not be sufficient to facilitate performance, possibly due to a ceiling effect in the measured DA release. Collectively, our data provide further evidence of preferential recruitment of DA

input to the NAcc when expected stimulus-reward contingencies are altered and, importantly, demonstrate a necessary causal role for this DAergic signal for choice behavior to be adapted accordingly. Research supported by NIAAA IRP.

Title: Projection-specific roles of dopamine neurons in decision making

Authors: *M. CARANDINI, S. SCHRÖDER, M. WELLS, C. REDDY, K. D. HARRIS, A. LAK
Univ. Col. London, London, United Kingdom

Abstract: Reward learning and value estimation rely on the phasic activity of midbrain dopamine (DA) neurons. Recent studies suggest that subpopulations of DA neurons with different projection targets could play different roles in these behaviors. To test this hypothesis, we trained mice in a perceptual decision task, and characterized the effects of pairing reward with activation of DA neurons. We then asked how these effects depend on the projection target of the activated DA neurons.
We expressed Channelrhodopsin-2 in midbrain DA neurons of DAT-Cre mice, and implanted optical fibers to stimulate their cell bodies in ventral tegmental area (VTA) or their axon terminals in striatum or medial prefrontal cortex (mPFC). We trained these mice in a perceptual decision task rewarded with water (Burgess et al., bioRxiv, 2016). In each trial, a grating appeared on the left or right side of a monitor, and the head-fixed mouse indicated its position by turning a steering wheel. By varying stimulus contrast across trials we obtained high-quality psychometric curves. After reaching stable task performance, we paired the water reward that followed one choice option with brief optogenetic stimulation.
The effects of DA stimulation depended markedly on the location of the optical fiber. Following stimulation of DA cell bodies in VTA, mice developed a tendency towards choices paired with such stimulations. This tendency affected the psychometric bias parameter, consistent with increased value of the choice option paired with DA stimulation. Following stimulation of DA

terminals in mPFC, we observed a similar, albeit weaker, behavioral effect, which we are further testing using alternative viral methods.
We observed a different effect following stimulation of DA terminals in striatum. The effect depended on which hemisphere was stimulated: mice developed a tendency to respond as if a visual stimulus ipsilateral to the stimulated striatum was present, regardless of stimulus location. This tendency changed both the bias and a lapse parameter of the psychometric function and occurred regardless of which choices (left or right or both) were paired with the stimulation. Thus, the unilateral stimulation of striatal DA terminals could not be interpreted as a change in the value of a choice option.
Together, these results illustrate the roles of DA neurons in driving perceptual choices and indicate that DA neurons projecting to different brain structures could play different roles in decision making under perceptual uncertainty.

Title: The priming effect of rewarding brain stimulation persists with pimozide

Authors: *C. EVANGELISTA, N. MEHREZ, W. G. BRAKE, P. SHIZGAL
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: Instrumental performance is invigorated by prior delivery of free rewards. In previous studies, rats ran faster to receive rewarding electrical brain stimulation in the goal box of a runway after free, non-contingent stimulation ("priming") had been delivered in the start box. Although dopamine is strongly implicated in other forms of incentive motivation, the D2/D4 blocker, pimozide, did not eliminate the effect of priming on runway performance. In the present study, the impact of pimozide on the priming effect was reassessed using an operant chamber and systematic variation of reward cost. Male, Long-Evans rats (n = 8) were implanted with electrodes aimed bilaterally at the lateral hypothalamus and were subsequently trained to lever press for rewarding electrical brain stimulation. A single response on a setup lever triggered its retraction and the extension of a separate "reward" lever, which was armed on a fixed-ratio (FR) schedule (range: FR2-32). The FR requirement increased after every block of 15 trials. Following the completion of the FR, a 0.5-s train of 300-500 μA, 0.1-ms cathodal pulses was

delivered and the reward lever was retracted. After a 30-s inter-trial interval (ITI), the setup lever extended, starting a new trial. Either two or 10 0.5-s trains were delivered during the ITI. Vehicle or pimozide (0.1, 0.2, 0.5 mg/kg) was administered three h prior to testing. Tests were conducted in three-day cycles consisting of a vehicle day, pimozide day, and washout day. Response vigor, measured as the inverse of the latency to complete the FR requirement, decreased as the FR was increased. The curve relating response vigor to the FR was shifted leftward along the FR axis by pimozide, indicating that the drug decreased the effectiveness of the electrical reward. Nonetheless, the priming effect remained intact after drug administration: the boost in response vigor due to increasing the number of priming trains from two to 10 was similar in the drug and vehicle conditions. These results are consistent with the previous finding obtained using the runway task. Pimozide does not appear to alter the priming effect.

Title: Distinguishing movement from prediction signals in midbrain dopamine neurons during Pavlovian acquisition

Authors: *L. T. CODDINGTON[1], J. T. DUDMAN[2]
[1]Neurobio., HHMI Janelia Res. Campus, Ashburn, VA; [2]HHMI, Ashburn, VA

Abstract: Debates about the specifics of mammalian midbrain dopamine (mDA) reward-encoding often turn on the question of whether the signal is structured to affect ongoing behavior or to guide learning for future behavior. Recently, recordings made outside of the context of cue-reward associations suggested that mDA neurons may also represent the initiation of movement. Thus, it was proposed that mDA activity acts to control movement initiation. However, given that movement initiation signals are largely absent in well-trained animals, we note an alternative possibility: in the absence of well-represented goals, self-initiated actions might hold relatively large reward-predictive value. mDA movement initiation signals in relatively untrained animals could then reflect a transient phase in which movements generate relatively strong reward prediction signals in DA neurons. This should be evident during the transition from naivety to the acquisition of appetitive responses during Pavlovian conditioning.
We simultaneously monitored the activity of identified mDA neurons with quantitative measures of appetitive responding (body movements and licking) in head fixed mice during initial acquisition of a Pavlovian conditioned stimulus (CS; a 500 ms pure tone). We observed conditioned approach movements that together with licking served as a sensitive, continuous

learning index. We performed juxtacellular recordings from optogenetically-identified DA neurons in both the ventral tegmental area (n=48) and the substantia nigra (n=85), densely sampled throughout initial learning.
We observed phasic modulations of both SNc and VTA DA neurons to water reward delivery, reward-predictive stimuli, and self-initiated movements, consistent with disparate previous works. Responses to movement initiation were not continuously correlated with parameters of movement, but within individual cells responses to movement, CS-, and US-reward cues were correlated, reflecting a common, predictive signal subject to cell- and state-specific gain factors. CS-responses and modulation of reward encoding by expectation appeared late in acquisition learning, lagging the emergence of associated behavioral changes. Together these data support a model in which the phasic responses of mDA neurons reflect learning and are positioned to play a role in adapting appetitive behavior rather than driving associative learning per se.

Title: Blockade of dopaminergic transients prevents learning driven by changes in reward features

Authors: *C. CHANG, M. GARDNER, M. GONZALEZ DI TILLIO, G. SCHOENBAUM
NIDA, Baltimore, MD

Abstract: Abstract:
Prediction errors are critical for associative learning. Transient changes in dopamine neuron activity correlate with positive and negative reward prediction errors and can mimic their effects. However, while causal studies show that dopamine transients are sufficient to drive learning, they do not address whether they are necessary. Further, the precise nature of this signal is not yet fully established. While it has been equated to the cached-value error signal proposed to support model-free reinforcement learning, cached-value errors are typically confounded with errors in the prediction of reward features. Here we used optogenetic and transgenic approaches to prevent transient changes in midbrain dopamine neuron activity during the critical error-signaling period of two unblocking tasks. In one, learning was unblocked by adding unexpected reward, a manipulation expected to induce errors in predicting both value and reward features. In another, learning was unblocked by switching from one to another equally valued reward, a

manipulation expected to induce errors only in reward feature prediction. Optogenetically suppressing the firing of dopamine neurons in the ventral tegmental area for 5s at the time of the changes in reward prevented unblocking of learning in both tasks. This result suggests that dopamine transients play a general role in error signaling rather than being restricted to only signaling errors in value as currently hypothesized.

Title: Can high fructose corn syrup alter behavioral and neural responses to oxycodone?

Authors: *M. MINHAS, ***M. MINHAS**, E. STROM, C. L. LIMEBEER, F. LERI
Dept. of Psychology & Collaborative Specialization in Neurosci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Objective: The food addiction hypothesis suggests that refined sugars such as high fructose corn syrup (HFCS) can promote addictive-like behaviors. This leads to the prediction that sugars and drugs of abuse interact at both neural and behavioural levels. The present study examined whether rats chronically pre-exposed to high fructose corn syrup (HFCS; 55% fructose to 45% glucose) altered responses to oxycodone (OXY), a widely abused prescription opioid. Since sugars can activate opioid receptors in the ventral tegmental area to enhance dopamine (DA) release in the nucleus accumbens (NAc) to affect reward processes, we investigated whether chronic HFCS pre-exposure affected responses to: OXY- place preference, OXY-induced locomotor sensitization, and OXY-induced elevation in DA concentrations in the NAc. Methods: Male Sprague-Dawley rats received in their home cages: 0% HFCS 24h a day (n = 70); 50% HFCS 24h a day (continuous access group, CONT; n = 84); or 50% HFCS 12h a day (intermittent access beginning 4 h into the dark cycle, INT; n = 28) for 26 days. INT sugar access was employed as it leads to “bingeing” behaviour which is linked to the neural alterations that cause enhancements in reward and motor responses to stimuli. Following a 9-day sugar free period, animals were tested on one of the following: (1) place conditioning (biased design) involving: pre-test, place conditioning (0, 0.16, or 2.5 mg/kg OXY SC; 3 pairings each over 6 days), and a test of preference; (2) locomotor sensitization involving context-dependent treatment with OXY (0, 0.16, or 2.5 mg/kg SC) over 5 days, followed by a 9-day drug-free

period, following which locomotor activity was measured in the drug-paired context, both in the absence and 24 hrs later in the presence of OXY; (3) in vivo microdialysis of extracellular DA in the NAc during a 1hr baseline and 3 hrs following an injection of OXY (0 or 2.5 mg/kg SC). Results: It was found that 0.16 and 2.5 mg/kg OXY produced a place preference, but this was not modified by HFCS pre-treatment. Furthermore, HFCS pre-treatment decreased OXY-induced, but not context-induced locomotion. Microdialysis data revealed that HFCS pre-treatment decreased the OXY-induced dopaminergic response in the NAc.
Conclusion: Taken together, the current experiments indicate that chronic HFCS pre-exposure blunted the psychomotor and dopaminergic response to OXY, but did not alter OXY conditioned locomotion or reward. These results suggest that opioids and sugars interact at both behavioural and neural levels, indicating that nutrition has the potential to influence some responses to opioids, and this may be relevant to the licit and illicit use of these drugs.

Title: The activation of GABA-A alpha1 receptors in the ventral tegmental area potentiates the stimulation of dopamine neurons in the antero-ventral region of the ventral tegmental area induced by lateral septum stimulation

Authors: I. M. VEGA-QUIROGA, H. E. YARUR, *K. GYSLING
Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: The mechanisms controlling activity of dopaminergic neurons in ventral tegmental area (VTA) and the anatomical location of these neurons are relevant for the expression of motivated behavior associated to reward-related signals. Anatomical and neurochemical evidence shows that several brain regions modulate the activity of VTA dopaminergic neurons. However, there is scarce knowledge of how the lateral septum (LS) modulates VTA activity. The evidence showed that LS output is pronominally GABAergic neurons, thus we hypothesized that GABAergic projections from LS to VTA inhibit GABAergic interneurons in the VTA through GABA-A alpha 1 receptors selectivity expressed in these interneurons .We performed *in-vivo* dual-probe microdialysis in anesthetized rats to measure VTA dopamine, glutamate and GABA extracellular levels after stimulating or inhibiting LS. In addition, we combined c-Fos and tyrosine hydroxylase immunohistochemistry with to reveal which VTA dopaminergic neurons

respond to LS stimulation. In addition, we injected biotin-dextran-amine (BDA), anterograde tracer in LS to reveal the topography of LS-VTA connectivity. The presence of indiplon, selective positive GABA-A alpha 1 receptor modulator, in the VTA induced a significant increase in VTA dopamine extracellular levels induced by LS stimulation. Furthermore, we observed thata LS stimulation induced significant c-Fos expression in a subset of dopaminergic neurons in the antero-ventral region of the VTA. Consistently, intra LS BDA injection labelled fibers reaching the antero-ventral region of the VTA. Taken together our data shows that LS modulates dopaminergic activity in the antero-ventral region of the VTA by inhibiting GABAergic interneurons bearing GABA-A alpha 1 receptors.

Title: Spatio-temporally heterogeneous activity of VTA projections to dorsal striatum

Authors: *A. HAMID[1], M. J. FRANK[2], C. I. MOORE[1,2]
[1]Dept. of Neurosci., [2]Brown Inst. for Brain Sci., Brown Univ., Providence, RI

Abstract: Dopamine (DA) is closely involved in both motivation and reinforcement-driven learning. Midbrain DA activity is extensively documented to encode reward prediction errors (RPEs). This RPE message is argued to be redundantly encoded among DA cells, and uniformly broadcast to downstream targets. But, many reports provide evidence for the contrary, suggesting a specialized and heterogeneous DA circuit. First, midbrain DA cells form diverse groups based on forebrain projection-target and biophysical characteristics, and are differentially recruited in response to salient cues, reward cues or aversive cues. Second, within the striatum, DA release is under strong control of local microcircuitry (e.g glutamate, acetylcholine), and the temporal dynamics of *in vivo* DA release are heterogeneous across striatal micro (and macro) domains. A thorough examination of the functional role of region-specific DA activity is lacking, but remains essential for a deeper understanding of flexible decision making.
We performed functional imaging of VTA axons in the dorsal striatum. DAT-cre mice received midbrain infusion of GCAMP6f, and implanted with imaging cannula or GRIN lenses for optical access into the striatum. After recovery from surgery, we imaged large-scale (~2-3 mm area using 1-photon microscopy) or fine scale (using 2-photon microscopy) activity of DA terminals in the striatum during task performance. Preliminary data indicates macro domains of asynchronous DA axon activity across large regions of striatal tissue. These zones are sometimes co-active in a global manner, but were observed to be decorrelated for extended temporal epochs.

Individual DA axons imaged with 2-photon microscopy also revealed spatio-temporal heterogeneity in the activity of neighboring axons separated by a few microns. Striatal DA domains observed to have asychornous spontaneous activity also displayed behaviorally relevant functional heterogeneity, ramping to delayed rewards or phasically responding to juice delivery. Together, our results provide support for distributed, heterogeneous DA signals that may serve local computational requirements.

Title: Midbrain neuronal activity during cue-guided spatial learning

Authors: *Y. KREMER[1], J. FLAKOWSKI[1], C. ROHNER[1], C. LÜSCHER[1,2]
[1]Dept. Basic Neurosciences - Univ. of Geneva, Geneva, Switzerland; [2]Clin. of Neurology, Dept. of Clin. Neurosciences, Geneva Univ. Hosp., Geneva, Switzerland

Abstract: Neurons of the ventral tegmental area (VTA) have been implicated in reward processing, motivation and motor output. Dopamine neurons in particular may encode reward prediction error but also locomotor activity. Stimulating dopamine neurons induces place preference, enhances spatial working memory and modulates hippocampal place fields. However whether spatial locations per se evoke firing in dopamine neurons remains elusive. Here we ask how the mesolimbic network orchestrates neural activity to generate a successful behavioral output based on reward-predicting cues present in the environment.
We designed a spatial task for freely moving mice that allows decoupling of spatial location, cue-evoked responses and reward consumption. Mice first learned to associate a light cue (CS) with the availability of a liquid reward (US). Once this association was acquired, mice could trigger the CS-US sequence by remaining for 2 seconds in a pre-defined, unmarked location in the operant chamber. During the task we recorded single-unit activity in the midbrain (of which a fraction was optogenetically phototagged) to investigate the correlations between the individudal events of the task and the underlying firing patterns contributing to the learning and execution of

the paradigm.
Our recordings show that a large fraction of midbrain neurons encodes motor output related to movement between the different task positions or actions to collect the reward (licking). Dopamine neurons, even though they maintain reliable phasic responses to either the cue, reward delivery or both, show a large diversity in their response magnitudes even at similar stages of learning.
We then trained mice to search for new locations by changing the spatial reward contingencies. In these experiments mice quickly learned to search for new rewarded positions, but the activity of DA neurons was not altered. In a second variation, we asked the mice to perform the task in the absence of light cues, solely relying on spatial information. In these experiments, mice were still able to perform the task although no responses in DA neurons could be detected.
In summary, mice associated spatial positions with the availability of rewards, but DA neurons respond to temporally precise reward-predicting cues rather than to spatial locations predicting rewards. Additionally, even though animals show clear reward expectancy by navigating to these locations, the CS reliably triggers large bursts of action potentials indicating that the spatial location did not devaluate the reward prediction error.

Abstract: Increasing immune system activity is a leading target for cancer therapy. Here, we show that the anti-tumor immune response can be enhanced by activation of the brain's reward system, a key circuitry in positive emotional states. We activated the reward system of tumor-

bearing mice (Lewis Lung Carcinoma) using chemogenetics (DREADDs), and analyzed the effects on tumor growth and anti-tumor immunity. Reward system activation resulted in a 52% ± 15.1% reduction in tumor size. This effect was mediated by a specific reduction in sympathetic activity in the bone marrow, attenuating the immunosuppressive functions of myeloid derived suppressor cells (MDSCs). Given the central role of the reward system in positive emotions, these findings introduce a physiological mechanism whereby the patient's psychological state can impact cancer progression.

Title: *In vivo* electrochemical and optogenetic assessment of the nucleus accumbens in the acquisition, valuation and extinction of avoidance behavior

Authors: *K. J. PULTORAK, S. A. SCHELP, G. P. KRZYSTYNIAK, D. R. RAKOWSKI, B. BUSCH, E. OLESON
Univ. of Colorado Denver, Denver, CO

Abstract: The mesolimbic dopamine (DA) system has historically been implicated in motivational processing under appetitive contexts. Within an appetitive context, mounting evidence supports that transient accumbal DA release events increase in response to reward predictive cues, represent intrinsic reward value, and causally modify reward-seeking. Less, however, is known regarding the role the nucleus accumbens (Nac) plays in an aversive context. Here we sought to investigate the role of DA in the valuation of avoided footshock using fast-scan cyclic voltammetry (FSCV), assess the causal role of DA in valuation though optical stimulation of DA neurons, and further assess the role of DA in the acquisition and extinction of avoidance behavior utilizing optogenetic stimulation. In order to address these research

questions, we first developed a novel behavioral economics task in which rats are provided the opportunity to operantly avoid electrical footshock across epochs wherein unit-price (response requirement/mA shock avoided) increases on a semi-exponential array. In congruence with previous appetitive research, the concentration of DA observed at the avoidance-predictive cue as well as upon successful avoidance scaled in an inversely to unit-price; however, an initial suppression of dopamine release and avoidance was observed at session onset. To assess causality, we optogenetically activated ChR2 expressing DA neurons within the VTA to selectively augment DA release at either cue onset or upon successful avoidance. We observed that augmentation of VTA DA at the cue decreases the maximal price paid to avoid footshock; whereas augmenting release at successful avoidance increases the maximal price paid to avoid footshock. Next we augmented dopamine during the acquisition and extinction of avoidance either at the cue or at successful avoidance. Preliminary data suggest faster rates of acquisition, but slower rates of extinction when dopamine release is augmented at avoidance. Conversely, augmentation at the cue produce slower acquisition, but increased rates of extinction. Finally we sought to evaluate the role of other predominate input structures onto the Nac, most notably the basolateral amygdala (BLA) which has been strongly implicated in anxiety and fear learning. Preliminary data suggest that terminal augmentation of BLA glutamate neurons at the cue suppresses the acquisition of avoidance. Together, these findings suggest that transient, accumbal DA release events play an integral role in the learning, extinction and valuation of avoidance and further demonstrate that BLA-Nac neuronal circuitry influence the acquisition of avoidance.

Title: Food seeking engages distinct calcium responses in direct and indirect pathway striatal neurons

Authors: *T. LONDON, A. KRAVITZ
Natl. Inst. of Health/ NIDDK, Bethesda, MD

Abstract: Feeding is driven by sensory inputs related to food cues and internal hunger signals reflecting nutrient levels and energy balance. Dopamine signaling lies at the nexus of these signals, as dopamine neurons are activated by food cues and are also modulated by hunger

centers in the brain. The striatum plays a role in influencing food reinforcement through the activity of two projection neurons, direct pathway medium spiny neurons (dMSN) and indirect pathway medium spiny neurons (iMSN). These populations express different dopamine receptors, D1 and D2, respectively, and can therefore respond to dopamine differently. Based on literature implicating dMSNs in positive reinforcement and iMSNs in punishment, we hypothesized that dMSNs would be excited by cues, actions directed toward food, and food consumption, while iMSNs would be inhibited during these behavioral events. We examined the role of each neuron type in a modified Pavlovian task, while recording their activity with fiber photometry: a technique that allows for the recording of bulk calcium signals in specific cell populations. Using this technique, we quantified the responses of dMSNs and iMSNs to cues that predict food, movement to the food, and food consumption. We found food seeking behavior activated dMSNs, but not iMSNs. Counter to our hypothesis, food predictive cues did not alter population calcium signals in either pathway; while consumption strongly inhibited calcium signals in both pathways. We conclude that medium spiny neurons respond differently during the phases of food seeking and consumption. Understanding the dynamics of striatal neurons during food seeking and consumption will shed light on how the brain processes food related information, and what drives animals to seek food.

Title: Dynamic changes in striatal dopamine predict reward learning: Evidence from simultaneous PET/MR

Authors: *F. J. CALABRO[1], D. F. MONTEZ[2], V. P. MURTY[2], B. LARSEN[3], J. C. PRICE[4], B. LUNA[5]

Abstract: Dopamine is strongly associated with reward processing in the striatum, but its precise contribution to reward learning in humans has been difficult to characterize. Here, we combined behavioral (reinforcement learning) modeling with simultaneously acquired task fMRI and PET to assess the relationship of dopamine signaling and brain activation to reward related behavior.

A sample of 77 young adults (40 female, ages 18-30) were scanned in a Biograph MMR combined PET/MR scanner, during which subjects performed a rewarded map exploration task in which they attempted to accumulate rewards and learn reward probabilities for each map location. Performance data was characterized using a reinforcement learning (RL) model to assess learning parameters. A bolus/infusion paradigm was used to administer the D2/D3 ligand [^{11}C]Raclopride, and task-related DA was quantified as a change in binding potential (BP) using a modified version of the simplified reference tissue model (SRTM). Task fMRI data was acquired simultaneously, and activation was assessed by comparing BOLD responses among high, low, and no reward trials. Voxelwise analysis of the PET data across the striatum showed significant decreases in BP during task in bilateral portions of the ventral striatum (nucleus accumbens, NAcc) and dorsal putamen, indicating task-related DA release. Notably, the magnitude of DA release was greater among subjects who exhibited reward learning, compared to non-learners, in the NAcc, but not putamen. Furthermore, among learners, DA release in the NAcc was positively correlated with learning rate. DA responses were highly correlated with BOLD reward responses in the NAcc, and this effect was more closely related to parametric prediction error related activation than to reward expectation. Non-learners did not show any relationship between DA and BOLD. Our results provide direct *in vivo* support for dopamine signaling in NAcc contributing to the neural and behavioral indices of reward learning. These data confirm and extend models of reward-related dopamine signaling from rodent and primate studies.

Title: Exploring the mechanism by which optogenetic stimulation of ventral tegmental area dopamine neurons prevents extinction of cued approach behavior

Authors: *C. M. REYES[1], S. M. NICOLA[2]
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Dept. Psychiatry, Albert Einstein Coll Med., Bronx, NY

Abstract: The nucleus accumbens (NAc) and its dopaminergic (DA) innervation from the ventral tegmental area (VTA) are involved in promoting reward-seeking behavior as well as strengthening cue-reward associations. Many NAc neurons exhibit cue-evoked excitations that are required for approach behavior elicited by a reward predictive cue. Additionally, a large body of literature suggests that DA neurons encode reward prediction errors (RPE), which serve to update the current state and alter the strength of cue-reward associations depending on the valence of the RPE (positive or negative). While RPEs presumably lead to changes in response probability, the downstream neural mechanisms from the VTA to NAc mediating this behavior remain unknown.

We hypothesized that DA neuronal activity at the predicted time of reward delivery is sufficient to reinforce cued approach behavior by maintaining the magnitude of cue-evoked excitation of NAc neurons on subsequent trials thereby blocking the transference of a negative RPE. To test this hypothesis we recorded from neurons in the NAc of *Th::Cre* rats expressing channelrhodopsin in VTA DA neurons. Animals were trained on a conditioned stimulus (CS) task in which two distinct auditory tones were presented. One tone predicted availability of a liquid sucrose reward while the other was a non-rewarded. After training, rats were subjected to an *omission* session followed by an *omission + stimulation* session. During *omission* sessions there was a 30 min baseline in the CS task followed by omission of the reward. *Omission + stimulation* sessions introduced a 20 Hz, 1s photostimulation at the predicted time of reward. During *omission* sessions we found a decrease in cue responding and a reduction in the magnitude of cue-evoked excitations of NAc neurons. Additionally, we found that stimulation of VTA DA during *omission + stimulation* sessions was sufficient to prevent extinction. Recording from NAc neurons during *omission + stimulation* sessions revealed short latency firing of NAc neurons during stimulation. In addition, the reduction in cue-evoked excitations during omission was attenuated by stimulation at the time of predicted reward. These results suggest a mechanism by which VTA DA neuronal firing influences subsequent cue-evoked excitations and thus the probability of behavioral response to the cue. Stimulation of VTA DA neurons prevents the extinction of approach behavior and our results suggest that this effect is due to a reduction in the decline in cue-evoked excitations that drive the approach response. Further experiments are underway to investigate if short latency firing is required for the maintenance of approach behavior.

Title: Activation of ventral tegmental CB1 receptors is essential for avoidance learning

Authors: *J. M. WENZEL[1], H. M. DANTRASSY[2], E. B. OLESON[4], J. F. CHEER[3]
[1]Anat. & Neurobio., [2]Anat. and Neurobio., [3]Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Neurobio. and Anat., Univ. of Colorado Denver, Denver, CO

Abstract: The mesolimbic dopamine system plays an integral role in reinforcement learning and a growing body of evidence identifies signal transduction at cannabinoid receptors as a critical modulator of this system. Utilizing an operant footshock avoidance procedure, our laboratory has previously shown that phasic activation of mesolimbic dopamine facilitates lever pressing to avoid footshock. Indeed, dopamine transients within the nucleus accumbens at the presentation of a warning signal preceding footshock delivery predict successful avoidance. Further, optogenetic activation of midbrain dopamine neurons during the warning signal enhances avoidance responding, suggesting a causal role for dopamine in avoidance. Here we examine the role of CB1 activation during learning of the operant shock avoidance task, at three time periods; early, mid and late in training. All rats were initially shaped to press a lever to terminate footshock. Once animals learned to reliably escape footshock, an avoidance contingency was introduced to the task wherein illumination of cue light served as a warning signal, which was presented 2s before the onset of footshock. Execution of a single lever press during this initial 2s interval resulted in the avoidance of footshock, whereas a lever press made after the initiation of shock delivery resulted in escape from footshock. Animals were divided into three groups to determine the effect of ventral tegmental area (VTA) CB1 receptor antagonism either from the start of training (early in training), once animals avoided footshock on ~50% of trials (mid-training), or after rats reached ~80% avoidance (late in training). Intra-VTA delivery of the CB1 antagonist rimonabant completely prevented the development of avoidance behavior when administered before each of the first 10 single daily avoidance sessions. Similarly, once rats learned to avoid footshock approximately 50% of the time, a single rimonabant administration significantly attenuated avoidance, compared to vehicle. However, rimonabant administration had no affect on avoidance behavior when delivered late in training, once rats avoided footshock on ~80% of trials. Thus, intact tegmental CB1 signaling is required for learning operant shock avoidance. However, once animals perform well on the task, CB1 activation is no longer

necessary to maintain high levels of avoidance responding. These data suggest that endogenous cannabinoid signaling exerts a previously unrecognized function in learning, whereby its effects are modulated by experience.

Title: Dopamine activation tracks uncertainty during operant responding

Authors: *P. MASCIA[1], J. BROWN[1], K. NESBITT[2], R. KENNEDY[2], P. VEZINA[1]
[1]Univesity of Chicago, Chicago, IL; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Pavlovian conditioning has been used in animals and humans to associate visual stimuli with different probabilities of reward. Using this approach, stimuli associated with probabilities ranging from 0 to 1.0 have been shown to differentially produce a sustained increase in dopamine (DA) activity. Stimuli associated with the most predictable outcomes (p=0 or 1.0) produce the least sustained activation while stimuli associated with the least predictable outcome (p=0.50) produce the greatest. The resulting inverted U-shaped curve has supported a relationship between sustained DA activation and uncertainty of reward. Here we describe an operant conditioning approach that supports a similar relationship between DA activation and uncertainty of reward and does so over a larger range of reward probabilities. Rats were trained extensively in 1-hr sessions to nose-poke for saccharin on escalating fixed ratio (FR) or variable ratio (VR) schedules of reinforcement using the following succession of ratios: 1, 2, 3, 5, 7, 10, 13, 16, 19, 20. The variance (a measure of uncertainty) associated with the different escalating FR ratios remained at 0 as these programmed a fixed relationship between nose-pokes and payout. On the other hand, the variance associated with the increasing VR ratios increased exponentially as these programmed an increasingly variable relationship. Remarkably, the pattern of DA overflow assessed in the nucleus accumbens with different schedules of reinforcement showed a notable similarity to these flat certainty and exponential uncertainty curves. When tested at ratios 5, 13-16, and 19-20, rats trained under the FR ratios (certain

relationship between nose-pokes and reward) showed little to no increases in DA throughout the sessions. Conversely, rats tested under the VR ratios (uncertain relationship) showed an exponential increase in DA overflow that tracked the variance of the ratios. The greatest overflow was associated with the greatest uncertainty. Notably, changes in DA overflow were not consistently associated with different behaviors (nose-pokes, dipper entries, consumption of saccharin reinforcers) and emission of the latter did not differ between FR and VR rats. These results further support a relationship between uncertainty and DA activation. Because repeated intermittent increases in DA have been implicated in the development of sensitization, these findings provide a likely mechanism for repeated exposure to conditions of uncertainty to promote the maintenance and progression of both drug and behavioral addictions such as pathological gambling.

Title: Differential modulation of striatal dopamine release by nicotinic receptors in adolescent and adult rats

Authors: *M. J. FERRIS, A. NORTH-FENNELL, L. L. SEXTON
Physiol. and Pharmacol., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Variability in the rate in which animals will acquire self-administration of psychostimulants, including nicotine, is a preclinical model for vulnerability to abuse drugs in humans. The variability in animals' acquisition rate can be predicted by individual differences in animals' locomotor response to a novel environment. Therefore, we investigated whether the propensity to explore a novel environment might also predict individual differences in how nicotinic acetylcholine receptors (nAChR) located on dopamine terminals in the core of the nucleus accumbens modulate rapid dopamine signals. We chose nAChRs given their well-documented ability to modulate rapid dopamine signals that are critical for acquisition behavior. Finally, we investigated whether nAChR modulation of dopamine release is similar in adolescent vs. adult rats. We assessed locomotor activity in an inescapable novel environment followed by

measurements of dopamine release using voltammetry in brain slices from adolescent (PD 28-35) and adult (PD 75-80) rats. We found no relationship between the animals' locomotor response to a novel environment and the magnitude of electrically-stimulated dopamine release in the nucleus accumbens of either cohort. In fact, no relationship between these parameters was found when dopamine was elicited under single-pulse conditions and under multiple-pulse conditions across a range of frequencies (5 Hz - 100 Hz). Following assessment of dopamine release, mecamylamine, DHβE, α-conotoxin PIA, and nicotine was bath applied to different slices from the same animal. Only adult animals with low response to a novel environment (LR) showed inhibition in dopamine release to nAChR blockade or desensitization under single pulse and low frequency, multiple-pulse stimulations that reflect tonic firing of dopamine neurons. All adolescent animals regardless of locomotor activity and adult animals with a high response to a novel environment (HR) showed greater facilitation of dopamine release to nAChR blockade or desensitization under multiple-pulse, high-frequency conditions that reflect phasic firing of dopamine neurons. Thus, LR adult animals are more sensitive to the dopamine inhibitory effects of nAChR blockade under tonic firing-like conditions while adolescent and adult HR animals are more sensitive to the dopamine facilitative effect of nAChR blockade under phasic firing-like conditions. The increased sensitivity to nAChR induced facilitation of dopamine signals elicited by phasic-like stimulation parameters may be mechanistically linked to faster and more robust acquisition of drugs of abuse and vulnerability to nicotine addiction.

Abstract: The basal ganglia has been implicated in motivational behavior, reinforcement learning, reward seeking, and action selection. The dual nature of these behaviors, i.e.

encouragement vs. discouragement (motivation), reward vs. punishment (reinforcement learning, reward seeking), go vs. no-go (action selection), has been hypothesized to be represented by two anatomically distinct pathways within the basal ganglia circuit, namely the D1 direct (striatonigral) and the D2 indirect (striatopallidal) pathways, respectively. While there have been a variety of behavioral studies supporting this hypothesis, it is still not known what specific signals are carried by each pathway. To address this issue, we studied the effects of optogenetic excitation of direct or indirect pathway during two behavioral paradigms in mice, i.e. during open-field exploration and an odor-based Go/No-Go task. For excitation of direct and indirect pathways, we injected the virus AAV5-EF1a-DIO- hChR2(H134R)-EYFP into dorsomedial striatum bilaterally in D1-Cre and A2a-Cre mice, respectively. About 3 weeks after injections two optical fibers were implanted at the injected regions.
In the open-field exploration task, mice were left in a rectangular chamber to move freely. Optogenetic stimulation was applied only when the mouse entered a predetermined region of the chamber. Our results showed that D1 mice preferred to spend more time on the stimulated region whereas D2 mice on the non-stimulated. These results are consistent with previously published work and confirm the basic functionality of our optogenetic model.
Using our verified model, we then examined the effects of optogenetic stimulation of direct and indirect pathways on learning by way of the Go/No-Go task, i.e. the speed of learning, the success rate after learning, and the reaction times. We trained mice to identify four odors delivered through an odor port. Two of the odors were used to instruct reward delivery through a water port (Go trial) and the remaining two to wait and not go to the water port (No-Go trial). One of each Go and No-Go odors were primed with optogenetic stimulation during feedback and reward period. Our data showed that neither the speed of learning, nor final task performance (>75% success rate) was significantly altered by optogenetic stimulation in D1 or D2 mice. However, we observed that the latency in initiating the subsequent trial was increased with stimulation of the indirect pathway. Overall, the odor-based Go/No-Go task results do not support the D1/D2 pathway's involvement in reward/punishment or go/no-go signals. However, the open field results are still in accord with a motivation-based signaling.

Title: The effects of d-amphetamine on progressive ratio responding for intracranial self-stimulation and food reinforcment

Authors: M. BAGNALL, G. BOATMAN, *W. D. KLIPEC
Dept. of Psychology and Neurosci., Drake Univ., Des Moines, IA

Abstract: Rats will respond incessantly for continuous intracranial self-stimulation (ICSS) but show rapid extinction following responding for ICSS compared to food reinforcement. Since both food reinforcement and intracranial self-stimulation (ICSS) are associated with dopamine release in the mesolimbic pathways, the different patterns of behavior raise questions about the affective or reward value of ICSS. One of the problems in comparing ICSS with food reinforcement results from deprivation as an establishing operation for food but not ICSS. Here, we have compared responding on progressive ratio schedules of reinforcement, where the response requirement progressively increased within training sessions until the animal reached the maximum fixed ratio (FRMax) before it quits responding (breakpoint). Using ICSS targeted in the medial forebrain bundle and a within subjects design, we have demonstrated the breakpoint for food reinforcement is significantly higher (about FR55-60) than for ICSS (about FR5-6) in either the food deprived state or the sated state. Furthermore, we found that administration of d-amphetamine (1, 3, and 5 mg/kg i.p.), compared to saline and no injection control tests, dramatically increased the FRMax for ICSS but decreased it for food reinforcement. Based on these findings, we are hypothesizing that high, maintained levels of synaptic dopamine produced by both dense ratio schedules of ICSS and amphetamine, leading to response perseveration, are responsible for the paradoxical effects of food and ICSS as reinforcers. More specifically, these data suggest that dopamine release, by leading to the repetition of the response that it follows, may be the physiological mechanism for Skinner's reinforcement principle, rather than a pleasure based reward mechanism.

Title: Time of sucrose access affects differentially binge eating behavior and Per1 in the nucleus Accumbens

Authors: *R. I. OSNAYA[1], M. PALMA GOMEZ[2], C. ESCOBAR[2]
[2]Anat., [1]UNAM, Mexico City, Mexico

Abstract: Binge eating (BE) is characterized by the consumption of large amounts of food within a discrete interval. In rodent models highly palatable foods (fats, sugars), as well as restricted food access promote BE and result in sustained dopamine release and activation of the glutamatergic system within the nucleus Accumbens. We aimed to explore the reciprocal interaction between the circadian system and BE, therefore we exploredthe influence of time of day on the development of BE and how BE can influence the rhythm of Per1 in the nucleus Accumbens. The present study explored the effect of sucrose intake during the rest phase versus the active phase on the development of BE, the influence of restricted food access on the development of BE and its effects on circadian rhythms of general activity, clock protein expression and body core temperature. The temporal expression of dopamine D1 receptor (DR1), GluR1 subunit of AMPA receptor and the clock protein PER1 were assessed in the Nucleus Accumbens and TH in the VTA. One hundred and twelve adult Wistar rats were randomly assigned to Control conditions, Restricted access to sucrose during the day (ZT5; SUC-D) or night (ZT17; SUC-N), restricted food acces to the day (RF-D) or night (RF-N) or the combination of restricted food and sucrose access in the day or night. All animals had ad libitum access to water. The experimental protocol had a duration of 5 weeks with 6 days access to sucrose per week. RESULTS: BE was 250% stronger in the SUC-N vs SUC-D and BE to sugar was not dependent of RF. RF induced overconsumption of regular chow food, an increase in locomotor activity and temperature in anticipation and response to chow access. Food restriction combined with access to sucrose increase the anticipatory response observed in general activity and core temperature. The expression of the clock protein PER1 was increased in the groups who had acces to sucrose and RF during the day and during the night, the expression of TH was also increased in the animals with access to sucrose independently of the time in which they had access to sucrose, DR1 in nucleus Accumbens was increased in the groups who had access to sucrose at night but not in the day. GluR1 was not modified between groups in the night vs. light phase. Overall our results show that BE is influenced by the time of the day, with a higher response in the night; RF can induce anticipatory locomotor activity when it is combined with sucrose access, this may be under control of day-night variations in the expression of PER1, TH and DR1 in brain reward areas. Present data will provide a better insight of factors eliciting BE and other compulsive disorders.

Title: Behavioral and metabolic characterization of eating disorder associated HDAC4-A778-T mutant mice

Authors: *K. C. DAVIS[1], M. Z. KHAN[2], M. L. LUTTER[2], H. CUI[3]
[1]Psychiatry, Univ. of Iowa Dept. of Psychiatry, Iowa City, IA; [2]Psychiatry, Univ. of Iowa, Iowa City, IA; [3]Psychiatry, Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: While eating disorders (EDs) are thought to result from a combination of environmental and psychological stressors superimposed on genetic vulnerability, the neurobiological basis of EDs remains incompletely understood. We recently reported that a rare missense mutation in the gene encoding transcriptional repressor histone deacetylase 4 (HDAC4) is associated with the risk of developing an ED in humans. To understand the biological consequences of this missense mutation, we created transgenic mice carrying this mutation by introducing the alanine to threonine mutation at position 778 of mouse Hdac4 (corresponding to position 786 of the human protein) and performed metabolic and behavioral characterization. Male mice heterozygous for HDAC4A778T did not show any metabolic or behavioral differences. In contrast, female mice heterozygous for HDAC4A778T display several ED-related feeding and behavioral deficits depending on housing condition. Individually housed HDAC4A778T female mice exhibit reduced effortful responding for high-fat diet and compulsive grooming, whereas group-housed female mice display increased weight gain on a high-fat diet, reduced behavioral despair, and increased anxiety-like behaviors. We are now in the process of characterizing homozygous HDAC4A778T mutation carriers and performing comprehensive gene expression profiling in the brain by RNA-Seq to identify the target genes affected by the HDAC4A778T mutation. The mouse line is a novel model of ED-related behaviors and will be a valuable tool to identify potential molecular pathways underlying the neurobiological basis of EDs.

Title: Evaluating sucrose and saccharin value in diet-induced obese rats

Authors: *S. R. BATTEN, J. BECKMANN
Psychology, Univ. of Kentucky, Lexington, KY

Abstract: The incidence of obesity has more than doubled since 1980 in the United States. Despite this increase, the neurobehavioral mechanisms that mediate obesity are largely unknown. Although it is well known that hormonal and metabolic factors influence obesity, recent evidence suggests that obesity may also be influenced by changes in reward sensitivity and associated neurocircuitry, akin to that seen in other 'reward pathologies', like addiction. However, much of this work has relied on the use of caloric reinforcers, potentially confounding metabolic effects from those of reward. The current study seeks to isolate reward changes that may occur during the onset of diet-induced obesity. Specifically, Sprague Dawley rats were trained to baseline on an operant procedure that measures the essential value of reinforcers through economic demand analyses. Baseline results show that rats value sucrose more than saccharin. Following baseline training, rats were fed a low-fat or high-fat diet for 8 weeks. Following the 8-week diet, animals fed the high-fat diet were split into 2 groups based upon weight distribution: obesity prone (top 1/3) and obesity resistant (bottom 1/3). After the split, sucrose and saccharin essential value were reassessed. The results suggest that high-fat diet produced a specific increase in sucrose and saccharin essential value for obesity-prone rats, relative to both obesity-resistant and low-fat controls. The results illustrate that a behavioral economic approach is useful in isolating the effects of diet-induced changes in reward value, and it suggests that changes in reward processes are a prominent factor in the onset of diet-induced obesity.

Title: Identification of transcriptional activity driven by estrogen-related receptor alpha as a novel pathway associated with eating disorder

Authors: *H. CUI[1], K. SAITO[2], K. C. DAVIS[2], E. RODRIGUEZ CRUZ[2], B. TOTH[2], M. LUTTER[1]

Abstract: Eating disorders (EDs) feature serious disturbances in eating behavior and body weight regulation that are associated with a wide range of adverse psychological, physical, and social consequences. Yet, the etiology and pathogenesis of these disorders are not fully understood. We have recently identified a rare missense mutation in Estrogen-related receptor alpha (Esrra) that increases the risk of developing an ED. Interestingly, conventional Esrra-null mice display reduced body weight and decreased energy intake when fed palatable high-fat diet (HFD). However, little is known about the detailed functions of Esrra in the brain. To better understand the physiological function of Esrra in the brain, multifaceted approaches were undertaken. Immunohistochemistry confirmed a wide-spread expression of Esrra in mouse brain, which was significantly upregulated by caloric restriction. Electrophysiological recording revealed that Esrra-null female mice exhibit altered miniature excitatory postsynaptic currents on GABAergic medium spiny neurons in the ventral striatum, a well-known brain region for reward processing. Behaviorally, the Esrra-null mice display a reduced motivation for palatable HFD. Surprisingly, homozygous and heterozygous deletion of Esrra from glutamatergic and GABAergic neurons, respectively, reveal an opposite role of Esrra in excitatory and inhibitory neurons in terms of body weight homeostasis and food intake. The findings shed light on a previously unappreciated role of Esrra in the brain that may confer risk for development of an ED.

Title: Accumbens processing of a food associated cue in a rat model of binge eating

Authors: *J. STAMOS, A. PAWLAK, M. SICHERER, R. PAN, C. STAMOS, J. KULIK, N. BEACHER, N. BELLO, M. WEST
Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: Project Summary:
Binge Eating Disorder (BED) and Bulimia Nervosa (BN) are complex disorders that involve social behavioral and body image components. BN is characterized by repeated episodes of loss

of control over eating followed by unreasonable compensatory behavior. BED is characterized by similar episodes of loss of control over food intake. However there are no unreasonable compensatory behaviors. In addition BED is associated with feelings of diminished self-worth and negative affect. In recent years there has been growing interest in the Nucleus Accumbens (Nac) involvement in eating disorders such as BED and BN. Due to their complex nature a comprehensive animal model of these disorders may not be possible. In this study we use an established rat model of binge eating (BE), which is a key component of both BN and BED, in order to study the contribution of BE behavior to disease pathology. In particular we examine how a history of BE affects Nac processing of a food associated cue. Female Sprague Dawley rats were divided into Binge Eating (BE) and Chow Control (CC) groups (n=9 per group). BE animals were subjected to a six week binge eating pretreatment. This treatment consisted of twice weekly 30 min sessions were BE animals were allowed unlimited access to a mixture of Crisco and sugar (10% sucrose by weight). Following treatment all animals had a 16 microwire array implanted into their Nac. Following recovery from surgery all animals were maintained on the binge regimen and subjected to 10 consecutive daily pavlovian trials where a tone CS was pared with a sucrose US. Each session comprised 56 trials with a variable interval of on average one minute. Behavioral measures such as number of missed trials and latency to head entry were measured over days. Neural data were divided into three phases for analysis: cue processing, approach, and consumption. Neural data from each phase were compared with analogous non-cued behavior. Furthermore, ultrasonic vocalizations (USV) were recorded during each pavlovian session and were compared to USVs recorded in a baseline session. USVs can be used to give an accurate estimation of a rat's affective state and in this context were used to see if a history of binge eating would affect the animal' affective state. Preliminary results indicate that there was an increase in the magnitude of the firing rate in the BE animals in response to the tone CS. Also the change in the magnitude of response to the CS was greater in Nac shell than Nac core in the BE but not CC animals.

Title: Sleep deprivation induces signs of compulsive eating behavior to high fat diet associated with changes in reward brain structures

Authors: *E. N. ESPITIA, C. ESCOBAR
UNAM, Ciudad DE Mexico, Mexico

Abstract: Compulsive Eating Behavior (CEB) is characterized by eating a large quantity of palatable food (rich in fat and/ or sugar) associated with signs of anticipation, progressive escalating consumption, food-directed effort behaviors and binge eating. Sugar and fat are digested and absorptive differently, therefore we proposed that the development of CEB for both components is different. CEB is also related with activation of reward brain structures, and chronic exposition to palatable food causes ΔFOSB accumulation. Sleep deprivation increases signs of hunger and increases food intake. We aimed to explore the differential changes caused by restricted access to a high sugar diet (HSD) or high fat diet (HFD) on the development of CEB. We also explored the influence of sleep deprivation in the susceptibility to develop CEB with both type of diets. The neuronal activation measured by c-Fos and ΔFOSB accumulation was compared in reward brain structures. Rats were housed in a 12:12 h light-dark cycle with chow and water *ad-libitum*. Locomotor activity, body weight and food intake were recorded every week. Rats had restricted access to palatable diets daily for 1 hour during 4 weeks and rats were manteined one more week without diet (abstinence). In the 4th week and abstinence, all indicators of CEB were evaluated. Brains were collected to determine c-Fos activation and the accumulation of ΔFOSB in the nucleus accumbens (Acc) and prefrontal cortex (PFCx). In the HFD group binge eating and anticipation to the 1 h access started in the first week of exposure, while the HSD group started both behaviors in the 3rd week. Both groups developed effort behaviors to obtain the diet, as well as progressive consumption of the diet along the 4 weeks. The c-Fos activation in nucleus accumbens was increased in the HFD group and HFD and HSD ΔFOSB was increased in the Acc. Sleep deprivation promoted binge eating, progressive escalating consumption and high-motivated behaviors for fat, but not for sugar. Anticipation did not occur in these groups. Sleep deprivation does not impaired c-fos activation in Acc neither in PFCx, while ΔFOSB accumulation was higher in the Acc and PFCx from those who were not sleep-deprived. We conclude that HFD induces stronger signs of CEB than HSD and sleep deprivation potentiates signs of CEB only in the HFD group.

Title: Taste reward prediction error signaling in adolescent anorexia nervosa

Authors: *M. DEGUZMAN, M. SHOTT, G. K. FRANK
Psychiatry, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Introduction: Anorexia nervosa is a psychiatric disorder associated with severe low weight and increased mortality rate, yet its underlying neurobiology is not well understood. Recently, we showed that adolescents with anorexia nervosa have elevated brain response in a monetary reward paradigm associated with brain dopamine function. Here, we tested whether adolescents with anorexia nervosa (aAN) also have heightened response to a taste stimulus. Methods: We recruited forty underweight aAN (mean age =16.7±2.5 years, mean BMI =15.9±.9 kg/m^2) and thirty-five healthy weight control adolescents (mean age=15.9±2.5 years, mean BMI =21.1±1.8 kg/m^2). While undergoing functional magnetic resonance brain imaging (fMRI), all subjects learned to associate unique visual stimuli with sweet taste stimuli. Violating learned associations evoked a prediction error (PE), which has been linked with neuronal dopamine response. PE was computationally modeled based on trial sequence and regressed with brain activation. Images were preprocessed in SPM12, mean parameter estimates were extracted from regions of interest using MarsBaR, and statistical group differences were analyzed in SPSS24. Results: In response to unexpected reward receipt, aAN showed greater activation compared to control adolescents in anterior cingulum, substantia nigra, caudate, and insula. aAN showed greater PE signal than control adolescents in caudate and insula regions. Conclusions: These results align with previous findings in adults and suggest the brain reward system in aAN has heightened PE signaling, potentially due to altered dopaminergic function. Similar results using taste or monetary stimuli suggest a generalized alteration of this reward system. Further studies are needed to test whether this brain circuitry can be used to predict treatment outcome or develop therapeutic interventions.

Title: Accumbens mechanisms for cued sucrose seeking

Authors: *A.-C. BOBADILLA, C. GARCIA-KELLER, J. A. HEINSBROEK, M. SCOFIELD, V. CHAREUNSOUK, C. MONFORTON, P. W. KALIVAS
Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: The last 20 years of research supports a perspective that addictive drugs usurp brain circuits used by natural rewards, especially for the dopamine-dependent reinforcing qualities of both drugs and natural rewards. Interestingly, comorbidity between substance use disorders and binge-eating disorders is frequent; the prevalence of lifetime substance use disorders among individuals with binge eating disorders reaches 40.4% in males, and both disorders share common characteristics, like compulsive behavior, binging and distress (Schreiber, Odlaug et al., 2013). Reinstated drug seeking in animal models of relapse relies on potentiated glutamate release from cortical terminals synapsing in the nucleus accumbens core (NAcore) to stimulate metabotropic glutamate receptor5 (mGluR5) on neuronal nitric oxide synthase (nNOS) interneurons (Smith et al. 2014). In contrast to shared dopamine release, reinstated sucrose seeking does not induce glutamate spillover (Gipson et al., 2003). We hypothesized that pharmacologically promoting glutamate spillover in the NAcore would mimic cocaine-induced adaptations and potentiate cued reinstatement of sucrose seeking. We first targeted the astroglial glutamate transporter GLT-1, one of the main regulators of glutamate clearance at the synapse. Blocking GLT-1 transporter to induce glutamate spillover had no effect on sucrose seeking. However, blocking glutamate release-regulating metabotropic glutamate receptor2/3 (mGluR2/3) with selective antagonist LY 341495 potentiated cue-induced sucrose seeking. Although potentiated sucrose reinstatement following mGluR2/3 blockade was reversed by antagonizing mGluR5, direct stimulation of mGluR5 did not affect seeking. Moreover, blocking nNOS activity didn’t prevent the LY 341495-induced potentiation of sucrose seeking. Nonetheless, selective chemogenetic activation of nNOS interneurons in the NAcore potentiated cue-induced sucrose seeking. These data indicate that dysregulated presynaptic mGluR2/3 signaling is a possible site of shared signaling in drug seeking and potentiated sucrose seeking, but that, in contrast to addictive drugs, glutamate spillover due to down-regulated glutamate transport and subsequent activation of nitric oxide synthesis cannot be recruited to promote sucrose seeking.

Title: Ghrelin inhibition of the M-current in KNDy neurons and the impact of 17b-estradiol

Authors: *K. M. CONDE[1,2], T. A. ROEPKE[3]
[2]Dept. of Neurosci. and Cell Biol., [1]Rutgers Univ., New Brunswick, NJ; [3]Animal Sci., Rutgers, The State Univ. of New Jersey, New Brunswick, NJ

Abstract: Dysregulation of the hypothalamic-pituitary-gonadal (HPG) axis is caused by obesity and anorexia and both conditions negatively impact on reproduction (irregular menses, infertility, and miscarriages). The gut peptide, ghrelin, potentially mediates the influences of negative energy states (hunger, fasting) on the neuroendocrine control of reproduction. When empty, the stomach produces ghrelin to drive hunger and initiate feeding behaviors via its cognate receptor, growth hormone secretagogue receptor (GHSR). GHSR is expressed in many neurons known to regulate feeding behavior and reproduction including hypothalamic arcuate (ARC) Kisspeptin/Neurokinin B (*Tac2*)/Dynorphin (KNDy) neurons. Ghrelin signaling in other ARC neurons inhibits the M- current produced by KCNQ (Kv7) channel subunits. We hypothesize that ghrelin's control of KNDy neurons involves targeting the M-current for a dual control of reproduction and energy homeostasis. To test our hypothesis, we utilized intact Tac2-GFP adult female mice to perform whole-cell patch-clamp recordings to elicit the M-current in KNDy neurons using standard activation and deactivation protocols in voltage clamp. We first characterized the activity of the M-current in KNDy neurons using the selective KCNQ channel blocker XE991 (40 μM), which decreased the maximum peak current by 26.4 ± 5.3 pA (*n*=5). Ghrelin perfusion (100 nM) for 10 min suppressed the maximum peak current by 22.4 ± 5.1 pA (*n*=7). Additionally, we have previously reported that 17β-estradiol (E2) increases *Ghsr* expression in KNDy neurons by 6-fold and increases the M-current in NPY neurons. Subsequent experiments will characterize the impact of E2 on the KNDy M-current and ghrelin sensitivity in ovariectomized adult female mice to establish the interaction of E2 and ghrelin signaling in modulating the activity of KNDy neurons.

Title: Medial prefrontal cortex VIP neuron activation suppresses binge-like feeding and interest in novel stimuli in the absence of an effect on food intake

Authors: *B. A. NEWMYER, M. M. SCOTT
Univ. of Virginia, Charlottesville, VA

Abstract: Novelty can be powerful driver of hyperphagia and binge eating: animals sated on one diet cease consumption if presented the same diet but will continue consumption if offered a novel palatable food source, a phenomenon known as sensory-specific satiety. Various central mechanisms driving this reward-seeking behavior synergize within the prefrontal cortex (PFC), and although considerable research exists demonstrating roles for the PFC in hedonistic food intake and food reward valuation, much less has focused on elucidating the upstream mechanisms of PFC modulation. Interneurons expressing vasoactive intestinal peptide (VIP) function as the predominant disinhibitory regulators of PFC pyramidal cells, suggesting a prominent role for this cell population in governing PFC-regulated behaviors. Thus, we sought to elucidate roles for this neuronal population in food reward seeking behavior and non-contingent food intake. We found that increasing mPFC VIP output using a Cre recombinase-dependant stabilized step-function opsin (SSFO) significantly attenuated binge consumption of highly palatable food in transgenic mice expressing Cre recombinase from the VIP peptide locus during the first exposure to this diet, while this stimulation had no effect on subsequent exposures. We also found that SSFO activation of mPFC VIP neurons significantly decreased social interaction behavior as well as novel object investigation. These findings together suggest a role for mPFC VIP neurons in novelty-based reward valuation and provide mechanistic insight into the role of this population in food intake regulation.

Title: Contributions of lateral hypothalamic galanin signaling to feeding and affective behavior

Authors: *E. QUALLS-CREEKMORE[1], M. FRANCOIS[1], A. BRUCE-KELLER[1], C. D. MORRISON[1], H. MUNZBERG[2]
[1]Pennington Biomed. Res. Ctr., Baton Rouge, LA; [2]Pennington Biomed Res. Ctr., Baton Rouge, LA

Abstract: The lateral hypothalamus (LHA) is an important regulator of both feeding behavior and affective states. Activation of GABAergic neurons in the LHA induces robust consummatory and appetitive behaviors. Other research found hypocretin (Hcrt) neurons, also located in the LHA, regulates stress response via activation of the HPA axis and that this response is blunted by leptin signaling from non-Hcrt neurons in the LHA. We recently identified LHA galanin neurons that are non-Hcrt neurons, but innervate Hcrt neurons and modulate motivated feeding via leptin, and further suggests that LHA galanin neurons may also significantly contribute to the regulation of affective behaviors. Indeed we show that a large population of LHA galanin neurons are GABAergic and synthetic activation of LHA galanin neurons (using AAV-hM3Dq and CNO) increases appetitive feeding while also robustly decreasing stress-induced digging behaviors in the marble burying test. Importantly, activation of LHA GABA neurons maintained increases in consummatory and appetitive feeding, but stress-induced digging was conversely increased, suggesting that increased affective behavior was mediated by GABAergic neurons distinct from LHA galanin neurons. To understand if the anxiolytic effect of LHA galanin neurons also involves galanin signaling we synthetically activated LHA galanin neurons chemogenetically in the absence of intact galanin receptor 1 (GalR1) signaling pathway (GalR1KO mice) and tested for operant feeding behavior and anxiety-related behavior in the open field test, elevated plus maze, and marble burying test. We showed earlier that activation of LHA galanin neurons significantly increased operant responding and decreased anxiety-like behavior in all tested paradigms. Importantly, anxiolytic effects were not accompanied by reduced arousal indicated by a modest increase in locomotor activity in the open field test. Preliminary data confirmed that activation of LHA galanin neurons in GalR1-WT mice again promoted anxiolytic behavior in the elevated plus maze and the absence of GalR1 was not able to suppress this anxiolytic effect. Even though analysis is still ongoing, these preliminary data suggest that GalR1 may not be required for the anxiolytic effect. This data suggests LHA galanin neurons and potentially galanin signaling may represent a potential target for the treatment of disorders which present with both feeding and affective disruptions such as anorexia nervosa.

Title: Adolescents show conditioned food aversion: A strategy to study disordered eating?

Authors: E. BURNETTE, G. OCAMPO, R. WANDER, Q. WALKER, N. ZUCKER, *C. M. KUHN
Dept of Pharmacol. and Cancer Biol., Duke Univ. Hosp., Durham, NC

Abstract: Anorexia Nervosa (AN) is the leading cause of mortality due to psychiatric causes. Current animal models focus on anorexia associated with food restriction, extreme stress and or excess physical activity and no current animal model captures the key characteristics of visceral hypersensitivity leading to learned food avoidance, adolescent onset and female dominance. The present study developed a food aversion task that involved no food deprivation to investigate the developmental and sex specificity of conditioned food avoidance (CFA) in adolescent (PN 28-30) and adult (PN 60-62) rats (N = 8-16/group). Rats were placed in novel feeding cage and allowed to eat a novel cereal (Cheerios, Ch) for one hour. Twenty-four hours later, they were injected with saline or LiCl (19 mg/kg) and were allowed to eat a novel, palatable food (Froot Loops, FL). Pica was quantitated in a subset of animals for 1 hr. as a measure of nausea. Twenty four hours later, rats were given the opportunity to eat FL and another novel cereal, Apple Jacks (AJ). Cereal intake (g/kg bw) were quantitated for each cereal. Results were analyzed by 3-way ANOVA (drug x age x sex). LiCl caused pica that was greater in adults than adolescents ($p < .002$ effect of drug, $p < .002$ age x dose). Adolescents ate more of a novel food (Ch) than adults ($p < .001$ for effect of age, $p < .0002$ age x sex). All animals showed marked CFA to FL ($p < .001$ effect of drug), and adolescents showed more CFA than adults ($p < .003$ effect of age, $p < .007$ age x sex x treatment). Furthermore, females generalized the CFA to include a novel food not previously paired with LiCl more than males (AJ) $p < .001$ effect of drug, ($p < .0002$ effect of age, $p < .002$ effect of sex, and there was a trend for greater generalization in adolescents ($p < ;06$ for age x treatment). The results contrast markedly with reports from this laboratory and others of lower adolescent sensitivity in standard conditioned taste aversion tasks, and suggest that this approach may prove useful in characterizing the neural mechanisms responsible for the development of disordered eating in adolescents.

Title: Sex-specific alterations in dopamine transporter function from food restriction and/or exercise are amplified during adolescence

Authors: *T. L. GILMAN, W. A. OWENS, L. METZEL, C. M. GEORGE, L. C. DAWS
Cell. & Integrative Physiol., UT Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Afflicting at least 3 percent of teenagers, eating disorders such as anorexia nervosa, bulimia nervosa, and binge eating disorder entail severe health consequences in addition to their psychological toll. Yet no effective treatments for eating disorders exist. An established regulator of both eating behaviors and physical activity, the dopaminergic system undergoes a sensitive maturation period during adolescence. Eating disorders, which are 2.5-fold more prevalent in females vs. males, typically emerge during adolescence. However, studies into the role of the dopaminergic system in ontogeny of eating disorders are lacking, as are investigations into the adolescent maturation of the dopaminergic system in females. Here we measured function of the dopamine transporter (DAT), a critical regulator of dopaminergic signaling, using both in vivo high-speed chronoamperometry and locomotor assays of cocaine response. Using an activity-based anorexia paradigm we explored how food restriction, exercise on a running wheel, or the combination thereof impacted DAT function in adult (postnatal day 90) and adolescent (postnatal day 30) Sprague-Dawley rats of both sexes. Broadly, rats exposed to both food restriction and free exercise showed leftward shifts in the dose-response to the locomotor response to cocaine, regardless of sex or age. We further observed enhanced locomotion in response to cocaine and heightened striatal function of DAT in females compared to males, and in adolescents compared to adults. Similarly, free running wheel access and restricted food access produced dramatic reductions in adolescent, but not adult, DAT-mediated dopamine uptake. Adolescent females in particular exhibit the most pronounced exercise- and diet-induced decreases in striatal DAT function. Together, these findings suggest that adolescent plasticity of the dopaminergic system confers – particularly in females – vulnerability to eating disorders and persistence of associated unhealthy behaviors (e.g., compulsive exercise). Therefore, drugs that enhance dopamine uptake or otherwise reduce dopamine signaling duration may prove efficacious in the treatment of adolescent eating disorders. Ongoing experiments are evaluating striatal DAT expression, as well as circulating insulin and leptin levels, as both of these metabolic hormones are known to

influence DAT function. Future experiments will examine how adolescent changes in DAT function and sensitivity, as a result of exercise and/or food restriction, affect voluntary access to drugs of abuse or highly palatable foods.

Title: Mechanisms specific to methamphetamine-associated memory disruption by nonmuscle myosin II inhibition

Authors: *M. HAFENBREIDEL[1], S. B. BRIGGS[1], S. KHAN[2], M. D. CAMERON[2], G. RUMBAUGH[3], C. A. MILLER[1]
[1]Neuroscience; Mol. Med., [2]Mol. Med., [3]Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Drug-associated memories, which can trigger relapse, are persistent, long-lasting, and thought to be maintained by learning-induced dendritic spine changes. During learning, dendritic spines undergo actin-dependent structural plasticity, which is then stabilized to maintain concurrent functional changes. We previously reported that depolymerizing actin with the nonmuscle myosin II inhibitor Blebbistatin (Blebb) systemically or in the amygdala (AMY) disrupts methamphetamine (METH)-associated memories. However, similar treatment does not affect cocaine (COC)-associated memories in a condition place preference (CPP) paradigm. One possibility for this difference is the longer half-life of METH, compared to COC, which suggests that longer exposure to COC (i.e. via self-administration) might render the memory susceptible. Therefore, we first assessed the ability of Blebb to disrupt context-induced reinstatement of COC seeking. Consistent with our previous results, intra-AMY Blebb had no effect on context-induced reinstatement of COC seeking. However, a home cage injection of COC (10mg/kg) paired with Blebb, with the goal of briefly reactivating actin dynamics concurrent with NMII inhibition, appeared to diminish context-induced reinstatement when tested on a subsequent day. To further follow up on the possible contribution of a longer half-life to the selective susceptibility of METH memories, we next assessed brain clearance rates of METH and COC with the goal of mimicking METH's clearance rate with COC. Previous work has shown that METH is cleared

slower following behavioral sensitization than following an acute injection. This suggests that previous drug exposure may affect future clearance rates. Therefore, we first determined the clearance rate of METH (2mg/kg) and COC (15mg/kg) on the final day of CPP training. Using mass spectrometry, we found that temporal lobe METH concentrations were approximately 60% higher than COC 15 min post-injection, despite delivering a much higher COC dose. This is consistent with the known function of the N-methyl group on METH to enhance blood brain barrier penetration. As expected, METH cleared slowly, reaching zero by ~8 hrs post-injection. Alternatively, COC concentrations dropped by more than 50% from 15 to 30 min post-injection, and were near zero by ~2 hrs. Programmable mini pumps are now being used to precisely mimic the decay rate of METH with COC in a CPP paradigm. Determining the mechanism that makes METH-associated memories uniquely vulnerable to Blebb disruption may allow for expansion to other drug-associated memories, thus allowing for further application of Blebb's therapeutic potential.

Title: Determining the selectivity of actin depolymerization for disrupting METH-associated memories

Authors: *S. B. BRIGGS, E. YOUNG, M. HAFENBREIDEL, G. RUMBAUGH, C. A. MILLER
Neurosci., The Scripps Res. Institute-Fl Campus, Jupiter, FL

Abstract: We have previously demonstrated that depolymerizing actin in the amygdala (AMY), either directly with latrunculin A (Lat A) or indirectly with the nonmuscle myosin II inhibitor (NMIIi) blebbistatin (blebb), produces a long-lasting and retrieval-independent disruption of the storage of memories associated with methamphetamine (METH) and amphetamine after a single treatment. Thus, depolymerizing actin, particularly through NMIIi, may prove to be a powerful therapeutic approach for targeting relapse-inducing associations. However, because the memories are being targeted in storage, it is important that the effect be selective, so as to not

disrupt other, non-drug memories. To this end, we have established that actin depolymerization delivered prior to testing has no influence on the storage of memories for fear, food reward, cocaine or morphine. In more recent work, we have sought to test the limits of the selectivity of actin depolymerization on the storage of memories that are formed either close in time or at the exact time of METH exposure in the same animal. To achieve this, we first determined the effect of depolymerizing actin on two memories that were formed over consecutive days. We found that when an auditory fear memory was learned prior to a METH-associated memory, Lat A and Blebb treatment had no effect on the fear memory. To more stringently test the selectivity of actin depolymerization for METH associations, an acute METH injection was combined with fear conditioning (FC) to pair two unconditioned stimuli with the auditory cue - METH reward and foot shock. Consistent with selective disruption of METH associations seen in other experiments, the deficits in freezing seen in animals given METH during FC and vehicle at testing was restored to the elevated levels seen in saline-treated FC that received LatA or Blebb. This result is consistent with the notion that the METH association was selectively excised, leaving the fear association intact. Taken together, these data add to the growing evidence of NMIIi's high degree of specificity for METH-associated memories.

Title: BDNF mediates pervasive habit learning following withdrawal

Authors: *E. HARVEY[1], N. ANGELILLIS[2], C. AHN[3], P. J. KENNEDY[1]
[1]Psychology, [2]MIMG, [3]Neurosci., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Research in the field of learning and memory suggests that the brain is composed of multiple memory systems that process and store information concurrently and may act competitively for control over learned behaviors. Among these systems are the hippocampus (HC) and dosrsomedial striatum (DMS), which have been shown to encode information flexibly to support goal-directed behaviors. Another system, the dorsolateral striatum (DLS), encodes information inflexibly and supports behaviors that are "hard-wired" (habits). Previous research from our lab and others suggest that drugs of abuse bias memory function such that the DLS predominates new behavioral learning and selection, even outside of drug-seeking contexts. The neural mechanisms supporting memory system bias following withdrawal from drugs of abuse remains largely unknown. Here we report that following extended withdrawal from chronic

cocaine, rats show a bias towards the use of DLS-dependent learning strategies whereas drug naïve controls demonstrate learning dependent on the HC. We further show that changes in behavioral learning are associated with bidirectional modulation of genes implicated in neuronal plasticity in the DLS and HC. Specifically, we identify brain derived neurotrophic factor (BDNF) as a critical regulator of memory system bias following withdrawal from cocaine and provide evidence for transcriptionally permissive and repressive chromatin states in the DLS and HC, respectively. We further show that viral-mediated overexpression of BDNF in the HC or peripheral treatment with the kappa opioid receptor antagonist (JDTic) throughout cocaine withdrawal restores HC-dependent learning. Our data suggest that chronic cocaine exposure causes lasting changes in transcriptional regulation in DLS and HC memory circuits to support the pervasive use of inflexible, "habit" learning *in lieu* of flexible, goal-directed learning. Ongoing experiments will use chromatin immunoprecitation (ChIP) to directly examine chromatin mechanisms of gene regulation in the DLS and HC following cocaine withdrawal and further investigate mechanisms of JDTic intervention strategies.

Title: Differential regulation of EGR transcription factors in hippocampus following extended access to cocaine self-administration and withdrawal

Authors: *A. GOLD[1], P. J. KENNEDY[2]
[1]Psychology, UCLA, Los Angeles, CA; [2]Psychology, Univ. of California Los Angeles, Los Angeles, CA

Abstract: Accumulating evidence suggests that the transition from recreational drug use to addiction is supported by altered plasticity in distributed brain circuits mediating reward, motivation, decision-making and learning and memory. Early growth response (EGR) family proteins have previously been implicated in a number of learning and memory processes and are thought to be critically involved in the formation of new long-term memories. Using a rat model of extended access cocaine self-administration, we report an increase in gene expression of the EGR family transcription-regulatory factors in the dorsal hippocampus (HC) compared to drug naïve and restricted access controls. These changes are further associated with decreased expression of several histone deacetylases (HDACs), suggesting that cocaine-induced changes in

HC chromatin structure may support activated gene regulation and the strengthening of memories associated with drug-taking. We further show these effects to be temporally specific as expression levels of both EGRs and HDACs return to baseline levels following a 10-day withdrawal period. Our data suggest a cocaine-mediated transcriptional regulatory mechanism that may facilitate hippocampal function and plasticity to strengthen drug-associated memories and contribute to the relapsing nature of drug addiction. Ongoing experiments are investigating the critical role of EGR family proteins in mediating the influence of context/spatial cues in the formation and maintenance of drug-associated memories and relapse.

Title: Fos-expressing neuronal ensembles within the infralimbic cortex mediate extinction of cocaine seeking

Authors: *B. L. WARREN, V. SELVAM, M. VENNIRO, M. MENDOZA, F. R. SOTO DEL VALLE, D. CAPRIOLI, Y. SHAHAM, B. T. HOPE
Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Background: Extinction training weakens operant responding established during previous self-administration training. Extinction memories are thought to be stored within specific patterns of sparsely distributed patterns of neurons called neuronal ensembles. We previously showed that Fos-expressing neuronal ensembles in the infralimbic cortex play a role in extinction of food seeking. We now hypothesize that similar neuronal ensembles may play a role in extinction of cocaine seeking.
Methods: We trained food-restricted Long-Evans rats to lever press for infusions of cocaine for 14 days (3 h/day). On days 1-7 of self-administration, rats self-administered 1.0 mg/kg/infusion. On days 8-14, we halved the dose so that rats self-administered 0.5 mg/kg/infusion. We subsequently exposed rats to 0, 2, or 7 daily extinction sessions to assess Fos expression at three different time points following extinction training. The next day, we exposed all rats to a short 30 min test under non-reinforced conditions and assessed Fos immunoreactivity in the infralimbic cortex. We then used Daun02 inactivation in Fos-LacZ transgenic rats to test whether these Fos-expressing neurons are necessary for extinction recall.
Results: Rats increased their lever pressing for cocaine infusions over the course of self-

administration training. Furthermore, rats doubled their lever pressing when the dose of cocaine per infusion was cut in half. On test day, rats decreased their lever pressing following both 2 and 7 prior extinction sessions. We found maximal Fos expression in the infralimbic cortex of rats exposed to 2 prior extinction sessions. Daun02 inactivation of Fos-expressing neuronal ensembles associated with either self-administration or extinction recall decreased or increased lever presses compared to controls, respectively.
Conclusions: Taken together, these data suggest that neuronal ensembles within the vmPFC mediate recall of extinction of cocaine seeking in rats.

Abstract: Expression of immediate early genes (IEGs) are routinely used as an indicator of strongly activated neurons in rodent behavioral procedures. Our lab and others have shown that neuronal ensembles, identified using the activity marker Fos, mediate relapse to food and drug seeking. To investigate brain-wide circuitry that was activated during behavior, we adapted a whole brain clearing and immunolabeling technique, called iDISCO+, to generate whole brain Fos maps in mice during relapse to food seeking.
We trained mice to lever press for a palatable food pellet reward for seven days. We then tested the mice for relapse to non-reinforced food seeking (30 min test sessions) after 1 or 15 abstinence days in homecage. We transferred these mice (test group) to their homecages immediately after the test session and perfused them 60 min later; we also perfused no-test mice (homecage group) at the same time. We modified the recently published iDISCO+ method for

uniform labeling of the proteins Fos and the general neuronal marker NeuN. We optimized acquisition parameters to image immunolabeled brains using light sheet fluorescent microscopy. We observed reliable food self-administration from the mice, as well as robust relapse to food seeking during both early and late abstinence. We are currently acquiring whole brain Fos data from the experimental brains and optimizing parameters to use the open-source analysis package ClearMap for data analysis. We will quantify Fos expression by brain area, generate distribution maps, and analyze Fos activation patterns across the whole brain.

Title: Examination of the role of prelimbic cortex neuronal ensembles in encoding reinstatement of palatable food seeking in rats using *In vivo* calcium imaging

Authors: *R. MADANGOPAL, C. HEINS, D. CAPRIOLI, B. LIANG, G. BARBERA, L. KOMER, J. BOSSERT, B. T. HOPE, Y. SHAHAM, D.-T. LIN
Natl. Inst. On Drug Abuse IRP, Baltimore, MD

Abstract: *In vivo* calcium imaging of awake behaving rats provides a dynamic, spatio-temporal view of task-related ensemble activity during the course of learning. Previous studies using the rat reinstatement model have implicated prelimbic cortex in reinstatement of palatable food seeking induced by non-contingent pellet priming. However, the underlying neuronal ensemble activity in prelimbic cortex that encodes pellet priming-induced reinstatement is unknown. To this end, we developed a miniature epifluorescent microscope and optimized surgical and behavioral procedures for long-term calcium imaging in prelimbic cortex of awake behaving rats.
We trained food-restricted rats to lever press for a palatable food pellet reward (FR1 reinforcement schedule; 3 pellet reward delivered after presentation of a 10-s discrete cue) in a modified trial-based design (100 trials/session; 20-s lever availability/trial; variable inter-trial interval). Next, we extinguished the rats' lever pressing in the presence of the discrete cue. We then tested the rats under extinction conditions for pellet priming-induced reinstatement (1 priming pellet delivered/trial preceding lever presentation) of food seeking. We observed reliable

food self-administration and extinction of food-reinforced responding in the trial-based procedure. We also observed robust pellet-primed reinstatement under extinction conditions. We are currently recording task-specific *in vivo* neuronal activity in prelimbic cortex during our trial-based task to identify and monitor neuronal ensembles that encode for different phases of food-seeking behavior.

Title: Distinct Fos-expressing neuronal ensembles in the prelimbic cortex mediate cue-induced reinstatement of cocaine and heroin seeking

Authors: *F. RUBIO, R. QUINTANA-FELICIANO, B. L. WARREN, X. LI, K. F. R. WITONSKY, Y. SHAHAM, B. T. HOPE
Behavioral Neurosci. Res. Branch, NIDA IRP, NIH, Baltimore, MD

Abstract: Learned associations between discrete cues (or contexts) and drug effects are thought to be encoded by sparsely distributed patterns of neurons called “neuronal ensembles”. Here, we determined whether cocaine and heroin seeking are encoded by distinct neuronal ensembles within the prelimbic cortex, an area in which increased the number of Fos-expressing neurons was associated with both cue-induced reinstatement of cocaine and heroin seeking.
We train *Fos-lacZ* transgenic rats to self-administer cocaine (1 mg/kg/infusion) and heroin (0.03 mg/kg/infusion) on alternating days (3-h/day; 18-days). During training, the rats were trained to lever press for cocaine or heroin with drug infusions paired with either a 3.5-s continuous or intermittent light cue (counterbalanced). After training, rats receive 10 days of operant extinction training (3-h/day) with both active levers present, but without cues or drugs.
On induction day, the rats were assigned to four groups based on the order of drug-related cues presented during induction day and test day: Cocaine-Cocaine, Heroin-Heroin, Cocaine-Heroin and Heroin-Cocaine. On induction day, the rats lever pressed for 30 min for one of the drug-related cues. Sixty minutes later, we injected the prodrug Daun02 into the prelimbic cortex which reacts with beta-galactosidase protein in the most strongly activated neurons and ablates these neurons. Two days after the induction day, we assess the effects of inactivating the cocaine- or

heroin-reward neuronal ensembles on cocaine or heroin seeking. We will present the data from this study at the meeting.

Abstract: Learned associations between environmental stimuli and rewards drive goal-directed learning and motivated behavior. The prelimbic cortex (PLC) is known to play a role in this type of learning, although there is debate as to its specific role. Learned associations are thought to be encoded by specific patterns of sparsely distributed neurons called neuronal ensembles that are selectively activated by reward-predictive stimuli. We identify these ensembles using the neural activity marker, Fos. We hypothesized that PLC Fos-expressing neuronal ensembles play a causal role in the expression of operant learning. To test this hypothesis, we first trained rats to self-administer palatable food pellets for 1-hr/day over the course of ten days. We observed Fos expression in PLC following this operant training procedure. We then used the Daun02 inactivation method in Fos-LacZ rats and found that selective ablation of PLC neurons that were active during food self-administration training decreased lever pressing during a 30-min test session, suggesting that PLC neuronal ensembles play a causal role in the expression of operant learning. Additionally, the fundamental question of how ensemble neurons are functionally altered during learning, and which of these changes encode learned associations is unknown. To address this question, we examined intrinsic excitability in PLC Fos-expressing ensembles that were selectively activated during food self-administration training in rats. We used Fos-GFP transgenic rats to identify activated ensemble neurons (FosGFP+) and non-activated (or weakly

activated) non-ensemble neurons (FosGFP-) in an *ex vivo* brain slice preparation. Using whole cell recordings of layer V pyramidal neurons, we found increased excitability of FosGFP+ neurons and decreased excitability of FosGFP- neurons following operant training. The increased excitability of FosGFP+ neurons was driven by an increase in steady-state input resistance. The decreased excitability of FosGFP- neurons was driven by an increased contribution of small conductance calcium-activated potassium (SK) channels. To determine if the increased contribution of the SK channel was critical to retrieval of food self-administration memory, we injected the specific SK channel antagonist apamin into PLC and found no effect on lever pressing. Overall, operant training induced bidirectional plasticity in PLC neuronal ensembles and non-ensembles via distinct mechanisms. The increased excitability of Fos-expressing ensembles in PLC may play a role in encoding the self-administration memory, but not the decreased excitability in the surrounding non-ensemble neurons.

Title: Cue-induced reinstatement of cocaine or heroin seeking activates Fos-expressing neuronal ensembles composed of glutamatergic and GABAergic cell types in rat prelimbic cortex

Authors: *R. QUINTANA FELICIANO, F. RUBIO, X. LI, K. F. R. WITONSKY, Y. SHAHAM, B. T. HOPE
Natl. Inst. On Drug Abuse, NIH, Baltimore, MD

Abstract: Learned associations between environmental cues and drugs of abuse play an important role in inducing drug craving and relapse. In recent years, we have demonstrated that neuronal ensembles expressing the neural activity marker *Fos* play a causal role in these behaviors. Here we characterized the cellular phenotypes of *Fos*-expressing neurons in the prelimbic cortex following cue-induced reinstatement of either cocaine or heroin seeking.
For behavior, 28 Long Evans rats (females and males) were trained to self-administer cocaine (1.0 mg/kg/infusion) or heroin (0.03 mg/kg/infusion) on alternating days (9 days per drug). In 3-h daily sessions, the rats were trained to lever-press for one of the drugs; drug infusions were paired with either a 20-s continuous or intermittent light cue. Next, the rats underwent 9 3-h daily

sessions of operant extinction training in the absence of the drug cues. We observed similar levels of lever pressing during cocaine and heroin training and extinction sessions. On the reinstatement test day, two groups of rats were presented with either the cocaine or the heroin-paired cue for 60 min with both heroin- and cocaine-paired levers present. A control group of rats underwent an additional extinction session without the drug cues. Results for the test day showed selective cue-induced reinstatement in both the cocaine cue and heroin cue groups. No increase in level presses was observed in the extinction group.
For *Fos* protein expression, one group of rats was processed for immunohistochemistry 30 min after the 60-min test session. Total numbers of *Fos*-immunoreactive nuclei in prelimbic cortex for both cocaine cue (186±33 nuclei/mm^2) and heroin cue (258±46 nuclei/mm^2) groups were significantly higher than that in the extinction group (74±18 nuclei/mm^2). For double-labeling of *Fos* and cell type markers, a separate group of rats was processed for RNAscope *in situ* hybridization. In rats that reinstated lever pressing for either cocaine or heroin cues, preliminary results indicate that >80% of *Fos*-expressing neurons co-expressed the vesicular glutamate transporter (*Vglut*) while <15% co-expressed the vesicular gamma-aminobutyric acid transporter (*Vgat*).
Overall, we found that cue-induced reinstatement of cocaine or heroin seeking activated prelimbic cortex *Fos*-expressing neuronal ensembles with both glutamate and GABA cell types.

Abstract: Neuropeptide oxytocin (OT) is involved in the regulation of social and non-social behavior. The central nucleus of the amygdala (CeA), part of the limbic system, plays an important role in learning, memory, anxiety and reinforcing mechanisms. CeA has been shown to be rich in OT-receptors. Our previous findings indicated that in the rat CeA OT has a dose dependent positive reinforcing and anxiolytic effect. The aim of our present study was to examine in the CeA the possible effects of OT and dopamine (DA) D2 receptor antagonist sulpiride on reinforcement in place preference test and on anxiety in elevated plus maze test. Male wistar rats were microinjected bilaterally with 10 ng OT (Sigma: O6379, injected in volume of 0.4 µl). In different group of animals 4 µg DA D2 receptor antagonist (sulpiride: Sigma: S7771 dissolved in sterile saline, injected in volume of 0.4 µl) was applied. Other animals received DA D2 receptor antagonist 15 min before 10 ng OT treatment or vehicle solution into the CeA.
Rats receiving 10 ng OT spent significantly longer time in the treatment quadrant during the test session in conditioned place preference test. Prior treatment with DA D2 receptor antagonist blocked the rewarding effects of OT. Antagonist in itself did not influence the time rats spent in the treatment quadrant. In elevated plus maze test, rats receiving 10 ng OT spent significantly longer time on the open arms. Prior treatment with DA D2 receptor antagonist blocked the effects of OT.
Our results show that in the rat CeA OT has positive reinforcing and anxiolytic effects. DA system plays a role in positive reinforcing and anxiolytic effects of OT because DA D2 receptor antagonist can block these actions.

Title: NCS-Rapgef2, the protein product of the neuronal Rapgef2 gene, is a specific activator of D1 dopamine receptor-dependent ERK phosphorylation in mouse brain

Authors: *S. Z. JIANG, W. XU, S. SWEAT, M. EIDEN, C. GERFEN, A. EMERY, L. EIDEN
NIMH/NIH, Bethesda, MD

Abstract: The neuritogenic cyclic AMP sensor (NCS) is encoded by the *Rapgef2* gene. This protein links cyclic AMP elevation to the activation of extracellular signal-regulated kinases 1/2 (ERK) in neurons and neuroendocrine cells (Emery et al., Sci. Signaling 6 (281), ra51, 2013; J. Biol. Chem. 289: 10126, 2014). Cyclic AMP elevation does not cause ERK activation in the human embryonic kidney 293 (HEK293) cells, which are devoid of Rapgef2 protein. Transducing these cells with a vector encoding *Rapgef2* reconstituted cAMP-dependent ERK activation. Mutagenesis of Rapgef2 revealed that its cyclic nucleotide binding domain (CNBD) is necessary for cAMP-dependent activation of ERK. A point mutation of one CNBD residue abrogated cAMP-ERK coupling, while deletion of the CNBD yielded a constitutively active protein. In vivo, RT-PCR analysis revealed two classes of transcripts from the *Rapgef2* gene: one was found in all tissues and one was specific to neuronal and endocrine tissues. In adult mice, expression of the full-length ~167KD Rapgef2 protein (NCS-Rapgef2) was evident only in neuronal and neuroendocrine tissues, corresponding to the expression pattern of the neuronal/neuroendocrine-specific transcript, initiated at an alternative first exon (termed by us exon 1'). In the brain, NCS-Rapgef2 is expressed specially in neurons, with prominent expression in corticolimbic excitatory neurons and striatal medium spiny neurons (MSNs). The expression of NCS-Rapgef2 in the nucleus accumbens (NAc) suggested the possibility of engagement of NCS-Rapgef2 via the dopamine D1 receptor. Rapgef2 dependent ERK activation was confirmed in neuroendocrine NS-1 cells expressing the human DRD1a receptor: treatment with D1 agonist SKF81297 (10 µM) caused cAMP-dependent ERK activation and neuritogenesis, while deletion of the *Rapgef2* gene abolished this effect. In vivo, ERK phosphorylation induced by SKF81297 (2 or 5 mg/kg, ip) was significantly attenuated in the hippocampal dentate gyrus and basolateral amygdala of CamK2α-$Cre^{+/-}$; $Rapgef2^{cko/cko}$ mice, which have forebrain-specific NCS-Rapgef2 ablation. Likewise, SKF81297-induced ERK phosphorylation in NAc MSNs was significantly reduced in $Rapgef2^{cko/cko}$ mice injected with AAV-Synapsin-Cre. Treatment with psychostimulants cocaine (30 mg/kg, i.p.) or amphetamine (10 mg/kg, i.p.) significantly increased ERK phosphorylation in NAc MSNs, which was also blocked by prior injection of AAV-Synapsin-cre. We conclude that D1-dependent ERK phosphorylation in mouse brain requires NCS-Rapgef2 expression, and therefore that ERK-dependent behaviors mediated by the D1 receptor are likely to be NCS-Rapgef2-dependent.

Title: Regional expression of Egr2 in substructures of the reward circuit regulates distinct aspects of cocaine-induced behaviors

Authors: *D. MUKHEREE, B. GONZALES, E. ITSKOVITS, L. IZAKSON, A. ZASLAVER, A. CITRI
Hebrew Univ., Jerusalem, Israel

Abstract: Neuroadaptations underlying maladaptive behavior driven by drugs of abuse have been shown to depend on transcriptional changes in the reward circuit. We thus hypothesized that the information contained in inducible transcription could enable identification of novel molecular substrates driving long term neuroplastic changes affected by drugs of abuse. To this end, we performed high throughput time dependent transcriptional profiling of 7 brain structures in the reward circuit, in response to acute (novel), repeated or challenge (reinstatement) administrations of cocaine. Our results demonstrate that the individual cocaine experiences were characterized by distinct but consistent region specific expression of immediate early genes (IEG), with low inter-individual variability and clear temporal dynamics. Comparing between the experience-induced transcriptomes, we observed the most significant changes in spatiotemporal patterns of expression of *Egr2*, a transcription factor belonging to the Early Growth Response family. Moreover, using machine learning algorithms for supervised classification, we have identified that this region specific expression of *Egr2* was a reliable marker for segregation and unique clustering of the different cocaine experiences much more accurately compared to conventional IEGs like *Arc* and *Fos*. These indications suggested that spatially defined expression of *Egr2* could be playing an important role in encoding the different aspects of a cocaine experience. To test this we performed targeted shRNA mediated knockdown of *Egr2* expression in the distinct anatomical substructures of the striatum, and subjected them to cocaine induced sensitization and place preference behavior. Initial results from such experiments indicated that expression of *Egr2* in the NAc regulates only psychomotor activation but in the DS affected both psychomotor behavior and cocaine induced place preference. In each case, knockdown of *Egr2* expression led to attenuated expression of *Arc* and *Fos* in the manipulated brain regions but no change in other brain areas. Taken together, this study provides a system level description of the spatiotemporal transcriptional architecture induced by distinct cocaine experiences. We report the identification of novel marker *Egr2* that is highly informative regarding the extent of cocaine exposure of mice, and whose region-specific expression is responsible for encoding distinct aspects of cocaine dependent behaviors. However, the underlying cellular mechanisms by which region specific expression of *Egr2* implements the encoding of cocaine induced behaviors is a topic for further investigation.

Title: Retrieval of cocaine and caffeine-associated memory selectively alters early gene expression in the prefrontal cortex and nucleus accumbens of mice

Authors: J. P. PRIETO[1], J. MUÑIZ[2], B. GONZALEZ[2], J. L. CADET[3], M. SCORZA[1], F. J. URBANO[4], *V. BISAGNO[2]

Abstract: Caffeine is the world's most popular psychostimulant and is frequently used as an active adulterant in many illicit drugs including cocaine. Previous studies have shown that caffeine, acting as an adulterant, can potentiate the stimulant effects of cocaine and cocaine-induced drug seeking behavior. However, little is known about the effects of this drug combination on reward-related learning, a key process in the maintenance of addiction and vulnerability to relapse. The goal of the present study was thus to determine if caffeine can enhance cocaine-conditioned memory and lead to differential mRNA expression in the nucleus accumbens (NAc) and prefrontal cortex (PFC). Mice were treated with caffeine (5 mg/kg, CAF), cocaine (10mg/kg, COC), or their combination (caffeine 5 mg/kg + cocaine 10 mg/kg, CAF+COC) in a Conditioned Place Preference (CPP) test. NAc and PFC tissues were dissected immediately after the CPP test or after a single conditioning session for mRNA expression analysis. CAF+COC induced a marked change of preference to the drug conditioned side of the CPP and a significant increase in locomotion compared to COC. Gene expression analysis of early genes as well as dopamine and adenosine receptor subunits revealed up-regulation of D1 receptor subunit, cFos and FosB in the NAc, and cFos, EGR1 and NPAS4 in the PFC of the CAF+COC animals. With a single conditioning session, CAF+COC induced changes only in D1 receptor subunit (up-regulation) in the NAC and cFos (down-regulation) like the CAF group,

whereas in the PFC, we observed increased expression of D1, D2 and A1 receptor and cFos in both CAF and CAF+COC groups. Interestingly, we found that NPAS4 gene expression was increased only in the PFC of the CAF+COC. Our study provides evidence that caffeine acting as an adulterant is capable of potentiating reward-associated memories elicited by cocaine. This is associated with specific changes in early gene expression that were observed only in groups that received the combination of both psychostimulants in the context of CPP memory retrieval. These results highlight the importance of caffeine in the maintenance of cocaine addiction probably by neural plasticity mechanisms linked to strengthening learning associated with the drug-environment.

Title: Acute nicotine disrupts consolidation of contextual fear extinction and alters long-term memory-associated hippocampal kinases

Authors: *S. GADIWALLA[1], T. J. GOULD[1], M. G. KUTLU[1], J. TUMOLO[2], B. GARRETT[2]
[1]Penn State Univ., University Park, PA; [2]Dept. of Psychology, Neurosci., Temple Univ., Philadelphia, PA

Abstract: Long-term memory consolidation and its cell-signaling cascades are regulated by nicotinic acetylcholine receptors (nAChRs). Evidence showed that nicotine, an agonist of nAChRs, has enhanced hippocampus dependent fear learning by altering phosphorylation patterns of several cell-signaling kinases that are involved in the consolidation of long-term memories including ERK1/2 and JNK1. In addition, past work has indicated that acute nicotine impairs contextual fear extinction. However, the effects of nicotine administration on cell signaling pathways during acquisition and consolidation of fear extinction memories are unknown. In this study, we examined the effects of acute nicotine on the phosphorylation of

dorsal and ventral hippocampal ERK1/2 and JNK1 during contextual fear conditioning. Our results showed that acute nicotine administered immediately, and 30 minutes, but not 6 hours following extinction impaired contextual fear extinction. This suggests that acute nicotine injections within the memory consolidation window disrupts the consolidation of contextual fear extinction memories. We also found that acute nicotine administered prior to extinction sessions downregulated the phosphorylated forms of ERK1/2 in the ventral hippocampus, but not dorsal hippocampus, and JNK1 in the dorsal and ventral hippocampus during the consolidation phase on the 3rd day of extinction, results which were not present on the 1st extinction day. Finally, our results showed that acute nicotine injections immediately after each session upregulated the phosphorylated form of ERK1/2 in the ventral hippocampus, but did not affect dorsal hippocampal ERK1/2 phosphorylation or phosphorylated form of JNK1. In summary, these results illustrate that acute nicotine impairs contextual fear extinction potentially by altering molecular processes responsible for the consolidation of extinction memories.

Title: Activity changes surrounding cerebellar perineuronal nets in cocaine induced preference memories

Authors: *J. GUARQUE-CHABRERA[1], I. GIL-MIRAVET[2], M. MIQUEL[3]
[1]Psychobiology, Univ. Jaume I, Villarreal, Spain; [2]Univ. Jaume I, Castellon, Spain; [3]Jaume I Univ., Castellon, Spain

Abstract: Perineuronal nets (PNNs) are a critical part of synaptic plasticity machinery. A PNN is an aggregation of extracellular matrix molecules (versican, aggrecan, neurocan, brevican, hyaluronan, tenascin-R, link proteins, and semaphorin 3A) in a net-like manner that envelopes the perikaryon and proximal dendrites of special subsets of neurons. Since PNNs begin to form at the end of the brain development and because of the stability of its components, they have been proposed as a candidate mechanism for learning and memory storage. In the adult brain, PNNs create the conditions to restrict synaptic plasticity modifications. Given that addiction could be considered the result of pathological learning, PNNs are considered to contribute to the maintenance of drug-induced conditioned memories after prolonged drug abuse. Drug-induced

plasticity changes in PNNs in relation to addiction are receiving increasing support but still very few studies are focused on animal models of drug addiction. Previous studies from the lab showed that after the infralimbic deactivation PNNs were upregulated in the dorsal cerebellar cortex. Also, the infralimbic cortex and the dorsal cerebellum seem to be part of a functional and structural network which would work on restraining goal-directed behavior when drug-cue associations are acquired. Therefore, PNNs in this network might be an important mechanism for storage of drug-induced conditioned memories. The present research aimed to assess whether an infralimbic deactivation would affect glutamatergic activity surrounding PNNs in the dorsal granule cell layer. We used vGluT1, vGluT2 expression in order to estimate changes in neural activity. Our results indicated that in the sham group cocaine-induced preference conditioning was accompanied by an upregulation of PNN expression and a significant increase in the glutamatergic activity. However, the infralimbic deactivation reduced significantly glutamatergic activity around the fully condensed PNNs. These findings suggest that the infralimbic cortex has the capacity to regulate activity in the dorsal cerebellar cortex.

Title: Modeling drug seeking using zebrafish

Authors: *G. BOSSE, R. T. PETERSON
Univ. of Utah, Col. of Pharm., Salt Lake City, UT

Abstract: America is in the midst of a major opioid addiction crisis owing to the alarming increase in opioid overdose-related fatalities. One of the main challenges is that no treatment is currently available to cure this addiction, as replacement therapies are the only viable options. Drug addiction is a state defined by compulsive engagement in naturally rewarding behavior or drug use, despite adverse consequences. The zebrafish (*Danio rerio*) has become an excellent tool to study mental health disorders, due to its physiological and genetic similarity to humans, ease of genetic manipulation, and feasibility of small molecule screening. Zebrafish have been shown to exhibit characteristics of addiction to drugs of abuse in non-contingent assays, including conditioned place preference. However, thus far, a single contingent assay has been reported for only one type of consumption abuse.
Using inexpensive electronic, mechanical, and optical components, we developed an automated

opioid self-administration assay for zebrafish. Thus, enabling us to measure drug seeking and gain insight into the underlying biological pathways. Zebrafish trained in the assay for five days exhibit robust self-administration, which is dependent on the function of the μ-opioid receptor. In addition, as with other animal models, we can also use a progressive ratio protocol to test our conditioned fish and they also continue to seek the drug despite an adverse consequence. Furthermore, fish trained in our assay also showed signs of stress and anxiety upon withdrawal of the drug. Finally, we validated our assay by confirming that self-administration in zebrafish is dependent on several of the same molecular pathways as other animal models.
Given the ease and throughput of this assay, it will enable the identification of important biological pathways regulating drug seeking and could lead to the development of new therapeutic molecules to treat addiction.

Title: Higher anhedonia during withdrawal from initial opiate exposure predicts lower levels of subsequent morphine self-administration in rats

Authors: *Y. SWAIN[1,2], P. MUELKEN[2], A. SKANSBERG[1,2], M. KRUEGER[1,2], D. MOTZ[1,2], Z. HAAVE[3,2], M. G. LESAGE[1,4,2], J. C. GEWIRTZ[1,3,2], A. C. HARRIS[1,4,2]

Abstract: Understanding factors contributing to individual differences in opioid addiction vulnerability is essential for developing more effective preventions and treatments. Opiate withdrawal leads to negative affective (emotional) symptoms including anhedonia. The role of

withdrawal in individual differences in addiction vulnerability is unclear, with some findings indicating that greater withdrawal sensitivity is associated with lower addiction vulnerability and other findings indicating the opposite. The goal of the current study was to evaluate the ability of anhedonia during initial opiate withdrawal to predict individual differences in subsequent addiction vulnerability as measured using i.v. morphine self-administration (MSA) in rats. Rats were first tested for withdrawal sensitivity following acute injections of morphine (i.e., “acute dependence”), measured as elevations in intracranial self-stimulation (ICSS) thresholds (anhedonia-like behavior) during naloxone-precipitated and spontaneous withdrawal. Rats were then catheterized and allowed to acquire MSA (0.2 mg/kg/infusion, 2 hour/day sessions). Greater escalation (sensitization) of naloxone-precipitated withdrawal across repeated morphine injections and greater peak spontaneous withdrawal severity were both associated with lower infusion rates during acquisition of MSA. These data support some previous studies indicating an inverse relationship between withdrawal sensitivity and drug use propensity, and suggest that high anhedonia during withdrawal from initial opiate exposure could be protective against subsequent opiate addiction. These findings also establish a model that could be used to understand the behavioral and neurobiological mechanisms underlying individual differences in opiate addiction vulnerability.

Title: The role of the paraventricular nucleus of the thalamus in the augmentation of heroin seeking induced by chronic food restriction

Authors: *A. CHISHOLM, D. RIZZO, N. GONZALEZ, C. MCANULTY, E. FORTIN, A. BUMBU, U. SHALEV
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Drug addiction is a chronic disorder that is characterized by compulsive drug seeking and involves switching between periods of compulsive drug use, abstinence, and relapse. In both human addicts and animal models of addiction chronic food restriction has been shown to increase rates of relapse. Previously, our laboratory has demonstrated a robust increase in drug seeking following a period of withdrawal in chronically food-restricted rats compared to sated rats. To date, the neural mechanisms that mediate the effect of chronic food restriction on drug

seeking have not been elucidated. However, the paraventricular nucleus of the thalamus (PVT) appears to be a promising candidate to investigate. The PVT is uniquely placed to contribute to both homeostatic control and drug seeking systems. Thus, the objective of the current study was to study the effect of PVT activation on heroin seeking under food restriction conditions.
Prior to heroin self-administration training, male Long Evans rats were injected with a viral vector carrying an excitatory Designer Receptor Exclusively Activated by Designer Drug (DREADD) into the PVT. Next, rats were trained to self-administer heroin over the course of 10 days (0.1 mg/kg/infusion; i.v.). Following training, rats were removed from the operant conditioning chambers and placed into drug withdrawal for 16 days. Over the withdrawal period, rats were exposed to a mild food restriction (90% of baseline body weight) or were given unrestricted access to food. On the 14^{th} and 16^{th} day of the withdrawal period, two drug-seeking tests were conducted in which rats were injected (i.p.) with either CNO (6 mg/kg), to activate the DREADDs, or vehicle, 20 minutes prior to test. Injectors' placement was verified using immunohistochemistry.
All rats reliability learned to self-administer heroin. As expected, food-restricted rats demonstrated an augmented heroin seeking during the heroin-seeking test in comparison to sated rats. Preliminary results suggest that PVT activation may reduce heroin seeking in food-restricted rats.
These results suggest that PVT activity appears to play a role in heroin seeking. Furthermore, PVT activity may modulate the augmentation of heroin seeking following chronic food restriction.

Title: The effect of NMDA antagonists on the reinforcing properties of oxycodone and nalbuphine in rhesus macaques

Authors: *K. L. NICHOLSON, K. L. SHELTON, M. L. BANKS
Pharmacology/Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Therapeutic use of prescription analgesics has more than quadrupled in the last decade and concomitantly the incidence of prescription opioid abuse has also doubled. Interestingly,

some studies suggest that NMDA antagonism can decrease the reward-related effects of opioid agonists as has been shown in rodents. Using a behavioral economic approach, we examined the impact of co-administration of the NMDA antagonist ketamine on self-administration levels of the opioid medications oxycodone (high efficacy mu agonist) and nalbuphine (low efficacy mu agonist) to assess its potential as an abuse-deterrent adjunctive therapy. Adult male rhesus monkeys were surgically implanted with indwelling intravenous catheter and trained to self-administer 100 mcg/kg/infusion ketamine during daily 3-hr operant sessions under a fixed ratio (FR) 50 schedule of reinforcement. Initially, dose effect curves were determined for ketamine, oxycodone and nalbuphine alone under the following FR schedules: 10, 20, 50, 100 and 200, presented in a counterbalanced order for periods of 4 consecutive days. Subsequently two doses of oxycodone (3 or 10 mcg/kg/infusion) or nalbuphine (1 or 3 mcg/kg/infusion) were tested under the same FR schedules in combination with varying proportions of ketamine. Demand curves relating drug intake to FR and measures of reinforcement were generated for oxycodone and nalbuphine alone as well as in the presence of ketamine. Each drug alone, ketamine, nalbuphine and oxycodone, functioned as a reinforcer. Ketamine increased measures of reinforcement for oxycodone and nalbuphine. Unlike previous work utilizing pretreatments with NMDA antagonists, concurrent administration of ketamine failed to attenuate and actually increased total opioid intake at one or more doses of ketamine. These findings, combined with our previous findings in measures of antinociception (Cornelissen et al., 2017) suggest the combination of ketamine and opioids provides limited therapeutic potential either as an adjunctive analgesic or as an abuse deterrant. However, because ketamine itself has abuse liability, studies examining the effects of the unscheduled NMDA antagonist memantine in combination with each of the opioid drugs are ongoing.

Title: Effects of heroin intake on prosocial behavior in rats

Authors: S. E. TOMEK, G. M. STEGMANN, *M. OLIVE
Psychology, Arizona St Univ., Tempe, AZ

Abstract: Clinical studies show a negative correlation between heroin use and levels of prosocial behaviors. Laboratory rats are capable of prosocial or empathy-like behavior. For

example, under normal conditions, when a rat is placed in the vicinity of another rat that is confined to a plastic restrainer, it will release or “rescue” the confined rat. The present study utilized this paradigm to determine the effects of heroin intake on prosocial behavior in rats. For two weeks, rescuer rats were given the opportunity to release their cagemate, and the occurrence and latency to free the confined rat was recorded. After rescuing behavior was established, rats were randomly assigned to self-administer either heroin (0.06 mg/kg/infusion, i.v.), or sucrose pellets (45 mg) as a control, for 10-14 days. Next, rats were retested for rescuing behavior once daily for 3 days, during which they had a choice between freeing the trapped cagemate or continuing to self-administer their respective reinforcer. Results indicated that the proportion of rats in the sucrose group that continued to rescue their cagemate instead of self-administering sucrose was 76%, whereas the proportion of rats in the heroin group rescuing their cagemate was 0%, and these rats continued to self-administer heroin instead. Thus, rats with a history of heroin self-administration show deficits in prosocial behavior, consistent with specific diagnostic criteria for opiate use disorder. Since activity in the insular cortex is known to be correlated with both drug craving and important abilities needed for social interaction, future studies are planned to attempt to restore prosocial behavior following heroin intake using chemogenetic approaches.

Title: Endomorphin analog ZH853 shows reduced locomotor activation and physical dependence relative to morphine

Authors: *A. T. AMGOTT-KWAN[1], T. J. HUNTER[1], A. K. FEEHAN[1], J. E. ZADINA[1,2,4,3]

Abstract: Morphine remains the gold standard for treatment of moderate and severe pain, but its clinical use is limited by severe side effects. The current opioid epidemic further emphasizes the

need for safer alternative analgesics with reduced abuse potential. Our lab previously characterized endomorphin analog ZH853 as a potent agonist of the mu-opioid receptor (1). ZH853 provides more potent or equipotent and longer-lasting analgesia as compared to morphine in neuropathic, inflammatory, post-operative, and visceral pain models (2). ZH853 also showed reduced side effects including reduced respiratory depression, motor impairment, tolerance, hyperalgesia, and glial activation (1). The transition from casual drug use to addiction is thought to be initially motivated by the rewarding properties of the drug resulting from mesolimbic dopamine activation. Continued drug use is later maintained by physical dependence and reward tolerance resulting from allostatic dysregulation (3). The reduced reward of ZH853 was recently supported by a lack of conditioned place preference and self-administration (1). Here we further demonstrate the reduced abuse liability of ZH853 by assessing locomotor activation and physical dependence. Opioid-induced locomotor activity in mice indicates mesolimbic dopaminergic activation, which is associated with reward (4). Acute subcutaneous administration of morphine, but not equi-antinociceptive doses of ZH853, induced locomotor activation in CF1 mice, suggesting differential dopaminergic activation. Chronic escalating doses morphine, but not ZH853, produce naloxone-precipitated jumping and weight loss, indicators of physical dependence. These data suggest the potential of ZH853 to provide long-term pain treatment with reduced abuse liability relative to morphine.

Title: VK4-116, a highly selective and metabolically stable dopamine D3R antagonist, selectively inhibits oxycodone reward without compromising oxycodone's antinociceptive effects in rats

Authors: *Z.-B. YOU[1], G.-H. BI[2], V. KUMAR[2], E. L. GARDNER[2], Z.-X. XI[2], N. H. AMY[2]

Abstract: The recent epidemic-like increase in prescription opioid misuse and abuse is a serious challenge to public health worldwide. Exploring potential pharmacotherapies for prescription opioid abuse has become a major focus in recent drug abuse research. We have recently developed a highly selective and metabolically stable dopamine D3 receptor antagonist - VK4-116, which significantly inhibits oxycodone-induced conditioned place preference, hyperactivity and locomotor sensitization (Kumar et al., J Med Chem, 2016). However, it is unknown whether this compound is similarly effective in other oxycodone-induced addiction-like behaviors and whether it interacts with oxycodone's analgesic effects. In the present study, we found that: 1) VK4-116 pretreatment (5-25 mg/kg, i.p.; 15 min prior to testing) significantly inhibited oxycodone self-administration in rats that had already acquired self-administration behavior; 2) VK4-116 pretreatment significantly inhibited oxycodone-induced drug-seeking following behavioral extinction; 3) repeated pretreatment with VK4-116 (5, 15 mg/kg, once daily for 5 consecutive days) dose-dependently blocked acquisition of oxycodone self-administration in drug-naïve rats; 4) VK4-116 pretreatment inhibited naloxone-precipitated conditioned place aversion; and 5) VK4-116 pretreatment at doses of 5 or 15 mg/kg (i.p., 15 min before oxycodone) showed no effects on the antinociceptive action of oxycodone as assessed by hot-plate testing. At 25 mg/kg, VK4-116 significantly potentiated oxycodone's antinociceptive effects. Together, our findings indicate that VK4-116 may serve as a novel promising medication for the treatment and prevention of prescription opioid abuse with potential benefit of augmenting the analgesic effects of prescription opioids. Title: Preconception opiate exposure enhances the rewarding effects of cocaine in offspring

Authors: *F. M. VASSOLER, A. M. TOORIE, E. M. BYRNES
Dept. of Biomed. Sci., Tufts Univ. Cummings Sch. of Vet. Med., North Grafton, MA

Abstract: The United States is in the midst of an opiate epidemic, with abuse and misuse of prescription and illegal opioids increasing steadily over the past decade. A growing body of evidence describes that environmental exposures, such as opioids, can impact the physiology and behavior of subsequent generations. The current study was designed to test the hypothesis that maternal or paternal exposure to opioids prior to pregnancy alters abuse liability in subsequent generations. Female or male adolescent rats were administered morphine at increasing doses (5-25 mg/kg, s.c.) or saline for 10 days (P30-39). Animals then remained drug free for at least 3 weeks. During adulthood (P70-P90), animals were bred with drug-naïve partners. Male and female adult offspring (F1 animals) were tested for either morphine or cocaine self-administration acquisition, progressive ratio, extinction, and reinstatement (0.75-morphine and 0.5-cocaine mg/kg/infusion). In addition, mu-opioid receptor expression levels as well as β-endorphin peptide levels were measured in the nucleus accumbens and ventral tegmental area. There were both drug- and sex- dependent effects on all phases of the self-administration paradigm that indicate decreased morphine reward and attenuated relapse-like behavior and yet increased cocaine reward and enhanced relapse-like behavior in Mor-F1 animals compared with Sal-F1 animals. Additionally, both receptor and cognate peptide levels were altered in Mor-F1 animals. The results demonstrate that even limited opioid exposure during adolescence can have lasting effects across multiple generations.

Title: Craving and addiction severity in rat models of heroin and cocaine sequential polydrug abuse

Authors: *E. CRUMMY
Univ. of Washington, Seattle, WA

Abstract: Polydrug abuse is commonly observed in drug abusers with reports of 30% to 80% of heroin addicts also using cocaine (Leri et. al, 2003); heroin abusers all also 15x more likely to develop addictions to cocaine (National Survey on Drug Use and Health, 2011-2013). While high prevalence of concomitant and sequential drug abuse has been reported, polydrug abuse, especially sequential abuse, is relatively understudied and little is understood about the mechanisms underlying craving and addiction severity resulting from polydrug use. Initial

studies in our lab have found decreased use of cocaine in rats alternatively self-administering cocaine and heroin compared to rats self-administering cocaine alone, but consistent heroin use in polydrug users versus single users of heroin. When examining incubation of craving, however, incubation was observed in polydrug users for both heroin and cocaine, comparable to craving behavior demonstrated in single use of heroin or cocaine across ten sessions. To further characterize if cocaine and heroin use recruited different circuits, rats self-administered cocaine and heroin on alternating days for a total of eight sessions, then were either placed in their home cage or allowed to continue to self-administer cocaine for a thirty day period. Rats demonstrated craving after a thirty day withdrawal period from heroin, regardless of access to cocaine, suggesting separate circuitry is involved in craving for these drugs and consistent with previous reports of selective reinstatement for heroin or cocaine when administered priming injections (Leri & Stewart, 2001). Experiments are currently underway to further characterize the impacts of polydrug use history and prolonged exposure to drug on craving and addiction severity. Using self-administration threshold paradigms to assess maximal prices that rats are willing to take to maintain initial drug consumption levels.

Title: Striatal medium spiny neurons regulate reinstatement of heroin-seeking

Authors: *T. J. O'NEAL, S. M. FERGUSON
Neurosci., Univ. of Washington, Seattle, WA

Abstract: Lethal heroin overdoses have risen dramatically in recent years, and the difficulty faced by individuals attempting to abstain from use has exacerbated this. Indeed, nearly 90% of heroin users will relapse within 3 months of abstinence, and the likelihood of successful, long-term abstinence decreases with each relapse. Although the rewarding effects of heroin are known to act primarily through mu opioid receptor-mediated modulation of dopaminergic transmission within the cortico-basal ganglia network, the circuit perturbations that contribute to reinstatement of heroin-seeking remain poorly understood. Notably, glutamatergic projections from the ventral subiculum to the nucleus accumbens (NAc) have been shown to mediate reinstatement of heroin-seeking, but the NAc contains two homogeneously interspersed populations of GABAergic output neurons: D1 receptor-expressing medium spiny neurons (D1-MSNs) and D2 receptor-

expressing MSNs (D2-MSNs). D1-MSNs and D2-MSNs have differential downstream and local projection pathways, and the role of each cell type in heroin-seeking is not clear. To begin to address this, rats underwent surgery for implantation of indwelling jugular catheters and stereotaxic surgery for infusion of a retrograde CAV-Cre virus into either the ventral tegmental area (VTA) or ventral pallidum (VP) along with infusion of an AAV-DIO-hM4Di virus into the NAc to allow pathway-specific manipulation of D1-MSNs and D2-MSNs, respectively. Rats were trained to self-administer heroin (0.075 mg/kg/infusion) on an FR1 schedule using an intermittent-access paradigm (5 min ON, 25 min OFF; 6 hr total) for 10 days, during which drug delivery was signaled by a cue light. Following training, rats underwent extinction testing in the self-administration chambers in the absence of heroin or cue light availability. To assess the role of D1-MSNs and D2-MSNs in heroin-seeking, rats then underwent cue-induced reinstatement tests following injection of clozapine-N-oxide (CNO; 5 mg/kg) to selectively inactivate these circuits. Inhibition of D1-MSNs significantly attenuated heroin-seeking following CNO injection. Currently, the role of D2-MSNs in cued-reinstatement is under investigation, as well as the effect of stimulating D1-MSNs or D2-MSNs using an AAV-DIO-hM3Dq virus, both of which will offer additional insight into how these distinct pathways regulate heroin-seeking during abstinence.

Title: The contribution of 6-acetylmorphine to the rewarding effects of heroin

Authors: *A. S. KVELLO[1], F. BOIX[1], J. M. ANDERSEN[1], J. MORLAND[2], I. BOGEN[1]
[1]Dept. of Forensic Sci., Oslo Univ. Hosp., Oslo, Norway; [2]Norwegian Inst. Publ. Hlth., Oslo, Norway

Abstract: Background: The acute behavioral effect of heroin is mainly mediated by its first metabolite, 6-acetylmorphine (6-AM). However, 6-AM's implication in the rewarding properties of heroin remains uncertain. The current study aimed to examine the contribution of 6-AM to heroin reinforcement and reward. **Methods**: Male C57BL/6J mice were tested for conditioned place preference (CPP) induced by equimolar doses (1.25-5 µmol/kg) of heroin or 6-AM, administered prior to conditioning for three consecutive days. A CPP test was performed on the fourth day. The locomotor activity of the animals was recorded during each 20 min conditioning

session. To further investigate the individual contributions from heroin and 6-AM to heroin-induced reward, additional mice were pretreated with a 6-AM specific antibody (anti-6-AM mAb; 10-200 mg/kg) 24 hours before subjected to the same experimental procedure as described above, but using only a dose of 2.5 µmol/kg heroin or 6-AM. **Results**: Both heroin and 6-AM produced CPP in mice. However, heroin CPP scores (367 and 381 s) were twice as high as 6-AM CPP scores (159 and 168 s) induced by doses of 2.5 and 5 µmol/kg, respectively. Locomotor sensitization was seen after heroin and 6-AM doses of 2.5 and 5 µmol/kg, but not after 1.25 µmol/kg, and was more profound in the heroin group compared to the 6-AM group. We found no correlation between the expression of CPP and locomotor sensitization. Pretreatment with anti-6-AM mAb prior to heroin and 6-AM injections blocked the expression of both CPP and locomotor sensitization to both opioids, however, a high mAb dose (200 mg/kg) was required to block heroin-induced CPP. **Conclusions**: Altogether, our results suggest that heroin holds a higher rewarding potential compared to 6-AM, and that CPP and locomotor sensitization are two phenomena mediated through different mechanisms in the rodent brain.

Title: An investigation of the reinforcing effects of diazepam and midazolam in rats trained to self-administer heroin

Authors: *S. L. SMITH[1], S. HOLLAND[1], R. A. GRAY[2], D. J. HEAL[1]
[1]Renasci Ltd, Nottingham, United Kingdom; [2]Sovereign House, Vision Park, GW Pharmaceuticals, Cambridge CB24 9BZ, United Kingdom

Abstract: Although benzodiazepines (BDZs) have reinforcing effects in humans (eg Griffiths et al, 1984, Psychopharm **84**:147-54; Braun et al, 2008, Eur Neuropsychopharmacol **18**:723-8) and are recreationally abused, very few published studies exist that describe the reinforcing effects of the BDZs in rats. We have addressed this deficiency by investigating whether diazepam and/or midazolam serve as positive reinforcers in rats trained to self-administer heroin.
Mildly food-restricted, male, Sprague-Dawley rats were initially trained to lever-press for food rewards before being surgically implanted with in-dwelling jugular catheters. Rats were allowed to self-administer heroin (15µg/kg/inj) on a fixed ratio (FR3) schedule of reinforcement in 2hr training sessions. After establishment of consistent heroin self-administration, the rats were subjected to saline extinction. The reinforcing effects of diazepam (1, 3, 4.5 or 10µg/kg/inj) and

midazolam (0.3, 1, 1.5, 2.25 or 3μg/kg/inj) were then evaluated on a FR3 schedule in 2hr sessions. In the first part of the experiment, if a BDZ served as a reinforcer (>6 inj/session) in an individual rat, a 4hr progressive ratio (PR)/break-point analysis was performed. Results are mean ± SEM.
Heroin maintained self-administration in rats (17.6±0.5 inj/session, n=39) at levels significantly greater ($p<0.001$) than saline (3.7±0.2 inj/session, n=39). Diazepam served as a positive reinforcer in 50% (4/8) and 43% (3/7) rats at 3 and 10μg/kg/inj, respectively, and midazolam in 29% (5/17) and 69% (11/16) rats at 1 and 1.5μg/kg/inj, respectively. When the group mean results were analysed diazepam (3μg/kg/inj) [7.0±2.1 inj/session, n=8] and midazolam (1.5μg/kg/inj) [7.3±1.3 inj/session, n=16] maintained self-administration at levels significantly greater than saline ($p<0.05$). The number of infusions of all doses of diazepam and midazolam were significantly ($p<0.001$) lower than heroin. The break-points for responding (mean lever-presses/inj) for diazepam were 18.9±2.8 (n=4) and 13.0±1.0 (n=3) at 3 and 10μg/kg/inj, respectively. For midazolam, they were 17.1±2.8 (n=3) and 13.2±0.7 (n=5) at 1 and 1.5μg/kg/inj, respectively. All benzodiazepine break-points were significantly ($p<0.05$) lower than heroin (39.4±6.9, n=10).
This study is the first to systematically investigate whether BDZs substitute for heroin in rats, and compare their reinforcing effects relative to heroin. Diazepam and midazolam maintained self-administration at some, but not all, doses in heroin-maintained rats indicating their reinforcing effects are weak in this species. This was confirmed by their low break-points for drug reinforcement.

Title: The selective M_5 negative allosteric modulator ML375 attenuates remifentanil self-administration without blocking morphine-induced analgesia in rats

Authors: ***B. GUNTER**[1,3], R. W. GOULD[1,3], M. P. MILLER[1], M. BUBSER[1,3], C. W. LINDSLEY[1,3,2], C. K. JONES[1,3]

[1]Pharmacol., [2]Chem., Vanderbilt Univ., Nashville, TN; [3]Vanderbilt Ctr. for Neurosci. Drug Discovery, Nashville, TN

Abstract: Opioid use disorder (OUD) has reached epidemic proportions in the United States. Yet, current treatment options remain limited to opioid maintenance and detoxification strategies, which are associated with high rates of relapse, abuse potential, and other adverse side effects. Accumulating evidence suggests that selective inhibition of the M_5 muscarinic acetylcholine receptor (mAChR) subtype may provide a novel approach for the treatment of OUD. M_5 is the only mAChR subtype expressed on midbrain DA cell bodies and selective activation of M_5 increases midbrain DA cell firing and DA efflux in the nucleus accumbens; effects that are blunted or absent in the M_5 knockout (KO) mice. Furthermore, M_5 KO mice exhibit reduced morphine place preference without affecting morphine-induced analgesia. Recently, we reported the successful discovery and optimization of a novel series of highly selective M_5 negative allosteric modulators (NAMs), represented by the M_5 NAM tool compound ML375. Previously, we have demonstrated that ML375 acutely attenuates both the reinforcing effects and relative reinforcing strength of cocaine. In the present studies, we determined whether ML375 would also attenuate opioid self-administration in rats without blocking opioid-induced analgesia.

Male Sprague-Dawley rats were trained to self-administer remifentanil under a fixed ratio schedule of reinforcement and the ability of ML375 to attenuate the reinforcing effects of remifentanil at each unit dose was then evaluated. The effects of ML375 were also determined when rats responded under a progressive ratio (PR) schedule for remifentanil alone and in combination with cocaine. Finally, the potential analgesic effects of ML375 alone and in combination with morphine were assessed using a hot plate apparatus.

ML375 reduced remifentanil self-administration at each dose under a FR 10 schedule. Furthermore under a PR schedule, ML375 reduced the reinforcing strength of remifentanil. Isobolographic and dose-addition analysis of the effects of ML375 on remifentanil/cocaine combinations suggests ML375 attenuates the supra-additive effects of a single remifentanil/cocaine combination. Finally, our preliminary data indicate that ML375 does not have analgesic properties when administered alone, nor does it have any effect on morphine-induced analgesia.

Taken together, these results suggest that selective negative allosteric modulation of the M_5 mAChR receptor may represent a promising novel pharmacotherapy for the treatment of OUD.

Title: Effect of blockade of mu, delta, and kappa opioid receptors on context-induced reinstatement of oxycodone seeking

Authors: *J. K. HOOTS[1], I. FREDRIKSSON[1], C. CIFANI[1,2], S. ADHIKARY[1], Y. SHAHAM[1], J. M. BOSSERT[1]
[1]Behavioral Neurosci., NIDA/NIH, Baltimore, MD; [2]Sch. of Pharm., U Camerino, Camerino, Italy

Abstract: Background: High relapse rates perpetuate prescription opioid addiction, which drives the current drug overdose epidemic in the US. This relapse often occurs after exposure to places previously associated with opioid use. Here, we describe a rat model of context-induced reinstatement of oxycodone seeking after repeated cycles of drug self-administration and extinction-induced abstinence. We also determined the role of mu, delta, and kappa opioid receptors (MOR, DOR, KOR) in this reinstatement. Methods: We trained rats to self-administer oxycodone (0.1 and 0.05 mg/kg/infusion; 7-10 days/dose, 6-h/d) in Context A; lever pressing was paired with a discrete cue. Next, we extinguished the lever pressing in the presence of the discrete cue in Context B for 8-11 days (6-h/d). We then tested the rats for reinstatement of oxycodone seeking in both contexts under extinction conditions (1-h/day). Next, we re-trained the rats to self-administer oxycodone in Context A, re-extinguished their lever pressing in Context B, and re-tested them for reinstatement in both contexts. Prior to testing, we injected (s.c) the rats with vehicle or antagonists of MOR (naltrexone; 0.5 or 1.0 mg/kg), DOR (naltrindole; 7.5 or 15 mg/kg), or KOR (LY2456302; 5 or 10 mg/kg). Results: We observed reliable context-induced reinstatement of oxycodone seeking after repeated cycles of drug self-administration and extinction. Systemic injections of naltrexone, but not naltrindole or LY2456302, decreased this reinstatement. Conclusions: We established a rat model of context-induced relapse to oxycodone seeking after repeated cycles of drug self-administration and abstinence and demonstrated a role of MOR but not KOR or DOR in this relapse.

Title: Cannabidiol blocks morphine place preference in mice

Authors: J. R. MARKOS[1], H. M. HARRIS[1], W. GUL[2], M. A. ELSOHLY[2], *K. J. SUFKA[1]
[1]Dept. of Psychology, [2]Res. Inst. of Pharmaceut. Sci., Univ. of Mississippi, Oxford, MS

Abstract: This study determined whether the cannabis constituent cannabidiol attenuates the development of morphine reward in the conditioned place preference paradigm. Mice received either saline or morphine in combination with increasing doses of cannabidiol using 3 sets of conditioning trials. After drug-place conditioning, morphine mice displayed robust place preference that was dose-dependently attenuated by cannabidiol. Further, the dose of cannabidiol that was effective against morphine reward was void of rewarding and aversive properties. The finding that cannabidiol blocks opioid reward suggests that this compound may be useful as an abuse deterrent.

Title: Time-of-day effects on heroin intake

Authors: *A. A. COFFEY, J. FANG, P. S. GRIGSON
Penn State Col. of Med., Hershey, PA

Abstract: Addiction is a chronic disease characterized by multiple relapses. In the United States, heroin abuse is increasing dramatically. Circadian rhythms govern more than just sleep, and there is mounting evidence of circadian effects on drug abuse. For example, most heroin overdose hospitalizations occur in the early morning hours. There also are circadian effects on metabolism of drugs and dopamine release/reuptake, potentially changing the rewarding properties of drugs of abuse across the 24 hour cycle. Interestingly, cocaine intake in rats is highest mid-light cycle and mid-dark cycle and lowest early light and early dark cycle. However, time-of-day effects on heroin self-administration have not been assessed in rats.
Previously, we have shown that rats self-administering heroin during their inactive light cycle reverse their sleep patterns relative to rats self-administering saline during the light cycle and rats

self-administering heroin or saline during the dark cycle. This reversal persisted for 4 days after the rats no longer had access to heroin. In the current study, we sought to investigate whether this circadian disruption affects drug intake, motivation to take drug, and relapse-like behavior. Over 18 trials, 38 male Sprague-Dawley rats were trained to self-administer heroin for 6 hours daily during the second half of either their inactive light cycle (n=17) or their active dark cycle (n=21). Motivation to take drug was tested using a progressive ratio schedule of reinforcement for one trial during the third week of acquisition. Rats were then tested in an extinction paradigm where no drug was available, followed by 13 additional days of abstinence, and an extinction/drug-induced reinstatement test. Rats with dark cycle access to heroin took more drug than those with light cycle access, but there was no difference in the motivation to take drug between the groups. Dark access rats also failed to extinguish seeking across the second extinction test, however, there was no difference between the groups in drug seeking during reinstatement. Understanding the circadian effects on drug intake has the potential to inform risk factors for worsening drug addiction and relapse, particularly if circadian disruption feeds into this process.

Title: *In vivo* electrochemical assessment of dopamine release during conditioned withdrawal in heroin dependent rats

Authors: *S. SCHELP, K. PULTORAK, E. OLESON
Univ. of Colorado, Denver, Denver, CO

Abstract: The centers for disease control and prevention reports that heroin abuse has doubled for Americans aged 18-25. Drugs of abuse, such as heroin, are commonly thought to increase the concentration of dopamine (DA) in the nucleus accumbens core (NAcc), although their effects on phasic DA release events remains to be fully characterized. In contrast, when an addicted subject is withdrawn from a substance such as heroin, there is a clear suppression of phasic DA activity in the NAcc. Heroin withdrawal presents characteristic symptoms, most predominately increased craving for the drug, which contributes to further abuse. While withdrawal symptoms

have been shown to be conditioned to previously neutral stimuli through classical conditioning, there is a lack of electrochemical evidence of conditioned withdrawal and its effects on non-drug related stimuli. Here, we explored how conditioned withdrawal in heroin addicted rats affects DA. We provided rats 23 hour access to IV heroin over 28 days. The 28 days are split into four blocks of increasing doses ranging from 0.06 mg/kg to 6 mg/kg to more accurately simulate the progression of heroin addiction. During the 28 day history, circadian changes in heroin, food, and water intake were altered and overall consumption of heroin increased. We then, investigated how conditioned withdrawal affects cue-evoked dopamine release in the NAcc using fast scan cyclic voltammetry (FSCV) during conditioned suppression of food maintained responding. Here, animals were first trained to respond for food under an FR1 schedule for 3 consecutive days where food availability was predicted by a cue-light placed above the lever. This was followed by 3 consecutive days of conditioned withdrawal training where a tone was conditioned to naloxone-precipitated withdrawal. On test day, animals responded for food under normal conditions, but the withdrawal associated tone was presented concurrently with cue-light onset during 33% of trials. By simultaneously presenting the withdrawal paired tone with the food predictive cue light we observed a substantial suppression of DA concentration at the cue light relative to non-paired trials. After conditioned withdrawal test day sessions, IV 6 mg/kg heroin was administered followed by 1.0 mg/kg naloxone methiodide and 1.0 mg/kg naloxone HCl during FSCV to determine if peripheral nervous system inputs contribute to withdrawal induced DA suppression. These data demonstrated that conditioned suppression of food maintained responding induced by conditioned heroin withdrawal is accompanied by a transient suppression in dopamine concentration.

Title: Sex differences in gene expression in the amygdala in morphine dependence and withdrawal

Authors: *S. J. O'SULLIVAN[1], J. PARK[1,2], J. GORKY[1], C. C. THEISEN[3], B. A. REYES[4], E. J. VAN BOCKSTAELE[4], J. S. SCHWABER[1]
[1]Pathology, Anatomy, & Cell Biol., Thomas Jefferson Univ., Philadelphia, PA; [2]Chem. and Biomolecular Engin., Univ. of Delaware, Newark, DE; [3]Neurobio. & Anat., [4]Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Opioid withdrawal is characterized by dysphoria, nausea, anxiety and fear. The negative reinforcement theory of addiction postulates that avoidance of these negative physical and emotional symptoms drives drug-seeking. The amygdala plays a central role in this context as it is a limbic structure responsible for fear and anxiety that also processes autonomic inputs, generates autonomic outputs, and has consistently demonstrated involvement in addiction and motivated behaviors. The organization of gene networks that underlie amygdalar function in opioid dependence and withdrawal reveal genetic network behaviors and specific pathological drivers that contribute to the observed drug-seeking behavior via negative reinforcement. We use a combination of laser capture microdissection and microfluidic RT-qPCR to accurately assay 96 transcripts at both the single-cell and tissue level in morphine-dependent and withdrawn rats. Previous experiments at the single-cell level in the Central Nucleus of the Amygdala (CeA) demonstrated global transcriptional shifts along with cell type-specific gene alterations—especially in stress-related and inflammatory genes. We are building on these studies by analyzing putative sex differences in transcriptomes within the CeA as well as the Basolateral Nucleus of the Amygdala (BLA) following chronic morphine exposure and naltrexone-precipitated withdrawal in male and female rats. Addiction mechanisms at large, and transcriptional networks specifically, that differ between the sexes not only offer a novel view of opioid addiction, but may also provide insight into potential targets for intervention.

Title: ΔFosB expression in human postmortem brain tissue from opioid overdoses

Authors: *L. JABBOUR, F. CARTEE, M. CAISSE, K. HAYNES
Franklin Pierce Univ., Rindge, NH

Abstract: Background: ΔFosB is a truncated form of FosB, a transcription factor from the Fos family of transcription factors. It is established that ΔFosB, normally absent in brain tissue, accumulates following conditions of prolonged exposure to drugs of abuse. It has also been shown to be up-regulated following abuse of natural rewards and under chronic stress. ΔFosB is believed to be a molecular switch for establishing long lasting changes in gene expression following abuse, however, these changes have only been described in animal models.

Objective: We hypothesize that ΔFosB has an equivalent role in the human brain. Our objective is to characterize its expression in the human brain tissue obtained at autopsy of opioid overdoses.
Methods: We obtained post-mortem brain tissue from 24 cases of opioid overdose and 4 control cases, age and sex-matched, where death was not caused by a drug overdose. The brain tissue was immediately fixed in 10% formalin and subsequently dissected. We used immunohistochemistry to evaluate *in-situ* protein expression in various regions of the mesolimbic system. We used microtubule-associated protein (MAP) and a neuronal specific nuclear protein (NeuN) as a positive control, and ran a slide with no primary antibody for every assay conducted.
Results: We observed positive staining for ΔFosB in the nucleus accumbens and more specifically, between the islands of Calleja. We have also tested amygdala but at time of abstract submission, we had seen expression following one assay but were not able to replicate this result, so we cannot confirm expression in amygdala.
Conclusion: We confirm expression of ΔFosB in the nucleus accumbens as seen in animal models exposed to opioids.
Current and Future Studies: We are further characterizing expression of ΔFosB in the amygdala, hippocampus, caudate, putamen, and other regions of the mesolimbic dopamine system. Moreover, we are concurrently working on isolating RNA for quantitative PCR.

Title: A subtype-selective neuropeptide FF receptor antagonist attenuates morphine withdrawal syndrome

Authors: *D. H. MALIN, J. ELAYOUBI, M. M. HENCEROTH, J. R. CAMPBELL, C. MADISON, C. P. WARD
Human Sciences,, Univ. of Houston Clear Lake, Houston, TX

Abstract: Considerable evidence suggests the neuropeptide FF (NPFF) and related peptides exert anti-opiate actions, particularly at the supra-spinal level. Ventricular administration of NPFF antagonists or antibodies attenuates morphine tolerance and dependence, suggesting that the NPFF family contributes to these disorders. On the other hand, NPFF appears to exert pro-

opiate activity, particularly at the spinal level. Lameh *et al*, JPET 334: 244, 2010, suggested that activating the FF2 NPFF receptor subtype is responsible for pro-opiate effects, while activating the FF1 receptor subtype is responsible for anti-opiate effects. They also showed that the compound AC262620 selectively inhibits the FF1 receptor subtype. This experiment tested the hypothesis that the FF1 receptor is a major contributor to opiate dependence and subsequent withdrawal syndrome. The subjects were 18 male Sprague-Dawley rats. Osmotic minipumps infused each rat for seven days with morphine sulfate at a constant rate of 0.6mg/kg/hr. On the seventh day of infusion, morphine infusion was terminated by pump removal. After 23 hours, rats were injected i.p. with 10mg/kg of AC262620 (generously donated by Acadia Pharmaceuticals) or with saline/DMSO injection vehicle alone. Beginning forty-five minutes later, subjects were observed under blind conditions for 20 minutes on a standard checklist of somatically expressed morphine withdrawal signs. Student's t-test revealed a highly significant reduction in total morphine withdrawal signs from the vehicle control group to the AC262620 group, $t(16)=3.798$, $p=.001$. Differences in individual categories of signs were also significant in shakes, $t(16)=2.63$, $p=.009$ and in tremors, $t(16)=2.67$, $p=.0085$. Reductions in instances of writhes and vacuous chewing also approached significance, $p=.083$ and .093, respectively. These results are consistent with an earlier experiment where AC262620 administered to morphine-dependent rats reduced subsequent naloxone-precipitated withdrawal after a much lower rate of morphine infusion. Taken together, these findings support the hypothesis that NPFF or related neuropeptides contribute to opiate dependence and withdrawal syndrome through the FF1 receptor.

Title: Exploring mechanisms for the effect of social environment on morphine response

Authors: *S. BATES[1], M. A. EMERY[2], C. T. HORRAX[5], P. J. WELLMAN[3], S. EITAN[4]
[2]Psychology, [1]Texas A&M Univ., College Station, TX; [3]Texas A&M Univ., College Sta, TX;

[4]Dept of Psychology, Behavioral & Cell. Neurosci Program, Texas A&M Univ., College Station, TX; [5]Neurosci., Texas A&M, College Station, TX

Abstract: Drug abuse is strongly influenced by socio-environmental factors. Our previous studies demonstrated that social housing conditions alter the propensity to acquire morphine reward and dependence in adolescent mice. Morphine-treated animals that are housed only with other morphine-treated animals (referred to as 'morphine only' animals) acquire morphine CPP significantly faster than morphine-treated animals which are housed with drug-naïve mice (referred to as 'morphine cage-mates'). Similarly, morphine only animals extinguished their morphine place preference at a markedly slower rate than the morphine cage-mates. This indicates a stronger and more robust acquisition of morphine CPP in animals housed with only other morphine-treated animals than in animals housed with drug-naïve animals. Lastly, morphine only animals display distinctly greater morphine withdrawal symptoms than morphine cage-mates. These results demonstrate that being housed with drug-naïve animals has a protective effect on development of opioid dependence, as well as the acquisition and maintenance of opioid reward. This further supports the notion that social conditions alter the propensity for developing opioid addiction.

Despite the preponderance of behavioral evidence, little is known about the mechanisms mediating the differential effects of social housing. In the current study, we explored possible mechanisms for the role of social environment on morphine response. In order to investigate this, we conducted qRT-PCR on gene targets that were identified using RNA-Seq. We also utilized DREADD technology to manipulate a novel DRG neuron subtype that was shown to be activated during social grooming.

We found that several genes were differentially altered between animals that were treated with the same drug, but that were housed differently (i.e., animals that were treated with saline or morphine and housed in 'only' conditions, or in mixed cages). These genes are from a variety of families and have diverse functions. Moreover, we identified a novel DRG neuron subtype that, when inhibited, decreases the protective effect of being housed with drug-naïve animals. Here, we report potential mechanisms for our social housing effect. In the future, more work should be done involving the targets identified here to develop a richer understanding of the role the social environment plays in morphine response. It is our hope that this will lead to better, more successful treatments for opiate use.

Title: Changes in ventral tegmental area serum- and glucocorticoid-inducible kinase 1 (SGK1) catalytic activity and phosphorylation alter drug-related behaviors

Authors: *M. A. DOYLE[1], V. BALI[2], S. KASKA[3], S. E. COOPER[1], M. S. MAZEI-ROBISON[2]
[1]Neurosci. Program, [2]Dept. of Physiol., [3]Dept. of Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Drugs of abuse are known to regulate activity of the mesolimbic dopamine system. Specifically, drug-induced changes in ventral tegmental area (VTA) cellular activity and gene regulation contribute to behavioral outputs associated with addiction. Our previous work has shown that serum- and glucocorticoid-inducible kinase 1 (SGK1) phosphorylation and catalytic activity are increased by chronic, but not acute, administration of cocaine and morphine. However, the functional significance of these changes in drug-related behaviors remains unclear. Thus, we have created novel viral constructs to overexpress SGK1 mutants in the VTA of adult mice, and I am assessing the impact of altered VTA SGK1 activity on drug reward via cocaine conditioned place preference (CPP) and voluntary morphine intake using a two-bottle choice task. Intra-VTA infusion of a catalytically inactive SGK1 mutant (K127Q) significantly decreased morphine intake and there was a similar non-significant trend for decreased cocaine CPP, suggesting that decreasing VTA SGK1 activity is sufficient to decrease drug reward and intake. I am now extending these studies by investigating the role of SGK1 Ser78 in drug-related behaviors, as phosphorylation of this site is increased by drugs of abuse. Intra-VTA infusion of SGK1 S78A, a mutant that prevents phosphorylation at S78, significantly decreased cocaine CPP as well as morphine intake and preference. Conversely, mice with VTA overexpression of SGK1 S78D, a mutant that mimics phosphorylation, exhibited a trend for increased morphine intake and preference. These data suggest that alteration of VTA SGK1 S78 phosphorylation is sufficient to modulate drug reward and/or intake. To more fully understand the role of VTA SGK1 in behaviors relevant to addiction, we have developed cre-dependent constructs to virally overexpress SGK1 mutants in a cell-type specific manner to determine whether SGK1 activity in DA or GABA neurons drives the observed behavioral effects. These studies, along with experiments utilizing a floxed-SGK1 mouse model, will allow identification of the specific cells and circuits that are critical for SGK1-mediated effects on drug behavior. Additionally, I have established a protocol for mouse cocaine self-administration and I am using this paradigm to determine whether alteration of VTA SGK1 activity is sufficient to modify operant drug intake or drug-seeking behavior, expanding our findings to more translationally-relevant models of addictive behavior. In summary, our goal is to characterize the role of VTA SGK1 activity in drug-related behaviors in order to assess SGK1's feasibility as a novel therapeutic target for addiction.

Title: Determination of circuit-specific morphological adaptations in ventral tegmental area dopamine neurons by chronic morphine

Authors: K. WHEELER[1], S. E. COOPER[2], *M. S. MAZEI-ROBISON[3]
[1]Neurosci., [2]Neurosci. Grad. Program, [3]Physiol., Michigan State Univ., East Lansing, MI

Abstract: Opiate drugs are the leading treatment for severe or chronic pain in the USA despite their extremely addictive properties. Chronic opiate exposure induces unique neuroadaptations in the mesocorticolimbic system, particularly in ventral tegmental area (VTA) dopamine (DA) neurons. For example, opiates reduce VTA DA neuron soma size, a change correlated with increased DA activity and reward tolerance. Prevention of this morphological change is sufficient to rescue the morphine-induced changes to behavior, suggesting its direct involvement in addiction-related processes. While VTA DA structural and functional plasticity are central to morphine reward and addiction, the molecular mechanisms driving these neuroadaptations remain elusive due to two main sources of VTA heterogeneity: multiple cell types and diversity within cell type based on projection target. To better understand the circuit-based consequences of morphine-induced neuroadaptations, we compared the morphology of VTA DA neurons that project to the nucleus accumbens (NAc) and medial prefrontal cortex (mPFC) in sham and morphine treated mice. We used stereotaxic bilateral infusion of retrograde Cre-dependent viral constructs (AAV2/5-DIO-eYFP and AAV5-DIO-mCherry) into DA neuron Cre-driver lines (tyrosine hydroxylase (TH)-Cre or dopamine transporter (DAT)-Cre). We found significant differences in basal soma size between established VTA subregions and therefore compared morphology within subregions for the remainder of the study. Chronic morphine treatment in TH-Cre mice significantly reduced the soma size of NAc medial shell-projecting neurons, but conversely had no effect on NAc lateral shell/core-projecting neurons. Interestingly, mPFC-projecting neuron soma size increased following chronic morphine treatment, despite the fact that the basal soma size of these neurons was larger than that of NAc-projecting neurons in sham-treated mice. We are now examining VTA DA neurons in DAT-Cre mice for validation of

morphine effects across DA-specific mouse lines commonly used in addiction research. Thus far, these data suggest that the unique morphological effect of chronic opiates on VTA DA morphology occurs within a distinct VTA DA population, and therefore direct manipulation of specific microcircuit/s may be critical to reverse the negative effects associated with chronic opiate use.

Title: Determination of the upstream kinases responsible for increased phosphorylation of serum and glucocorticoid-inducible kinase by drugs of abuse

Authors: *V. BALI[1], M. A. DOYLE[2], S. E. COOPER[2], S. KASKA[3], M. S. MAZEI-ROBISON[1]
[1]Dept. of Physiol., [2]Neurosci. Program, [3]Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Drugs of abuse alter the activity and output of dopamine neurons in the ventral tegmental area (VTA), which contributes to addiction-related behaviors. Our lab has previously shown that serum- and glucocorticoid-inducible kinase 1 (SGK1) phosphorylation and catalytic activity are increased by chronic administration of cocaine and morphine. Further, using viral-mediated overexpression studies, we have recently observed that decreasing VTA SGK1 catalytic activity decreases drug reward and intake, and that altering VTA SGK1 phosphorylation specifically at serine 78 (S78) is sufficient to modulate cocaine reward and morphine intake, as measured by conditioned place preference and a two-bottle choice task, respectively. However, little is known about regulation of SGK1 S78 phosphorylation, aside from its robust increase by drugs of abuse. Therefore, the aim of my study is to identify the kinases responsible for SGK1 S78 phosphorylation, as this may serve as a novel node for therapeutic intervention. Using *in silico* approaches, I identified promising candidate kinases, namely: glycogen synthase kinase 3 beta (GSK3β), cyclin-dependent kinase 5 (cdk5), extracellular signal-regulated kinase 5 (ERK5), and ERK1/2. As a first screen, I utilized the Neuro2A mouse neuroblastoma cell line and established an induction protocol that robustly increases both SGK1 catalytic activity and S78 phosphorylation. Briefly, I found that 24-hour serum starvation followed by re-feeding with complete media supplemented with epidermal growth factor or insulin for 1 hour significantly increased S78 SGK1 phosphorylation and

catalytic activity, as measured by phosphorylation of N-myc downstream regulated gene (NDGR) protein, the only known SGK1-specific substrate. I then evaluated the role of candidate kinases using pharmacological inhibitors: roscovitine (cdk5), GSK3β inhibitor XXVII (GSK3β kinase), U0126 inhibitor (ERK1/2) and BIX02189 (ERK5). My preliminary data indicate that inhibition of either cdk5 or GSK3β can dose-dependently decrease SGK1 catalytic activity and S78 phosphorylation. I am now completing a similar study to determine the potential roles of ERK1/2 and ERK5. Importantly, all of the inhibitors used in this study have been validated *in vivo*, so I will next test whether intra-VTA infusion is sufficient to prevent the cocaine- and morphine-induced increase in SGK1 S78 phosphorylation, as well as associated behavioral changes. Together, my work seeks to characterize the regulation of SGK1 S78 phosphorylation in drug-related behaviors to identify a potential novel pharmacological target for improved treatment of addiction.

Title: Determination of the morphine-induced transcriptome in ventral tegmental area dopamine neurons

Authors: *S. E. COOPER[1], K. WHEELER[2], M. MAZEI-ROBISON[3]
[1]Neurosci. Grad. Program, [2]Neurosci. Program, [3]Dept. Physiol., Michigan State Univ., East Lansing, MI

Abstract: Opiate exposure induces neuroadaptations in the mesocorticolimbic system, and in particular in ventral tegmental area (VTA) dopamine (DA) neurons. In rodents, chronic morphine reduced VTA dopamine (DA) neuron soma size, which directly correlated with increased DA activity and decreased reward, and prevention of this morphological change was sufficient to rescue the morphine-induced physiological and behavioral changes. While VTA DA structural and functional plasticity are central to morphine reward and addiction, the molecular responses driving these neuroadaptations remain elusive. To date, studies of drug-induced changes in VTA gene expression have been limited to the homogenization of the entire VTA,

which includes GABAergic and dopaminergic (tyrosine hydroxylase (TH)-positive) neurons. While several candidate genes have been identified with this approach, it is unknown whether these changes occur specifically in DA neurons and contribute to the structural neuroadaptations. To determine morphine-induced gene expression changes specifically in VTA DA or GABA neurons, we utilized Translating Ribosome Affinity Purification (TRAP). We crossed DA- (TH- or dopamine transporter (DAT)-Cre) and GABA-specific (vesicular GABA transporter (vGAT)-Cre) driver lines with Rosa26 EGFP-L10a mice, thereby allowing isolation of mRNA from VTA DA (THEGFP-L10a and DATEGFP-L10a) and GABA (vGATEGFP-L10a) neurons. In both DA-specific lines, we found significant enrichment of TH and DAT mRNA and depletion of GABAergic markers glutamic acid decarboxylase (GAD) and vGAT in bound fractions compared to input controls, consistent with successful purification. We first examined morphine-induced changes in the expression of candidate genes such as serum and glucocorticoid-regulated kinase 1 (SGK1). While SGK1 was induced by morphine treatment in the input control, consistent with whole VTA expression studies, this change was not detected in the bound, DA-specific, fraction. Thus, we hypothesize that the morphine-induced increase in SGK1 expression is driven specifically by VTA GABA neurons, which we will test using vGATEGFP-L10a mice. Given evidence that morphine-induced changes can be limited to specific cell types, we are now completing RNA sequencing analysis on samples from THEGFP-L10a and DATEGFP-L10a as an unbiased approach to identify changes that occur specifically in VTA DA cells. In this way, we hope to identify novel mechanisms that underlie opiate-induced neuroadaptations in the VTA in order to develop innovative targets for improved therapeutics.

Title: Functional μ-opioid- galanin Gal_1 receptor heteromers in the ventral tegmental area as targets for opioid use disorders

Authors: *N. CAI[1], E. MORENO[2], C. R. QUIROZ[1], W. P. REA[1], A. SEYEDIAN[1], C. LLUÍS[2], E. CANELA[2], V. CASADÓ[2], S. FERRE[1]
[1]NIDA/NIH, Baltimore, MD; [2]Neurobiologia Mol. Departament de Bioquímica i Biomedicina Mol., Univ. de Barcelona, Barcelona, Spain

Abstract: We recently demonstrated that μ-opioid- galanin Gal_1 receptor heteromers localized in the ventral tegmental area (VTA) constitute a target for the treatment of opioid use disorders. These heteromers can underlie previously described antagonistic interactions between the opioid and galanin systems, by which galanin antagonizes μ-opioid receptor-mediated signaling. We first detected μ-opioid-Gal_1 receptor heteromerization in mammalian transfected cells and obtained a specific peptide that disrupted the heteromerization and a negative crosstalk, by which galanin counteracted MAPK activation induced by the endogenous opioid agonist endomorphin-1. The negative crosstalk therefore constituted a biochemical property of the μ-opioid-Gal_1 receptor heteromer, which could also be identified *in situ* in VTA slices and *in vivo* with microdialysis experiments. Thus, galanin completely counteracted somatodendritic dopamine release induced by the local infusion of endomorphin-1. Both *in situ* and *in vivo* galanin-opioid interactions were also selectively counteracted by application of the disruptive peptide, demonstrating their dependence on μ-opioid-Gal_1 receptor heteromerization. These results indicated that dopaminergic cell function in the VTA is modulated by a predominant population of μ-opioid receptors forming heteromers with Gal_1 receptors. Using transfected mammalian cells, we are now addressing two questions in relation to opioid addiction in the frame of μ-opioid-Gal_1 receptor heteromers. First, based on the proof of concept that receptor heteromerization can change the properties of orthosteric ligands binding to any of the two molecularly different receptor units, we are screening μ-opioid ligands, with the aim of finding receptor agonists with lower affinity or efficacy or receptor antagonists with higher affinity for the μ-opioid receptor when forming heteromers with Gal_1 receptor. Second, based on the proof of concept that products of polymorphic variants of receptor genes can lead to different biochemical properties of receptor heteromers, we are investigating if the product of the single-nucleotide polymorphism rs1799971 (A118G) of the μ-opioid receptor gene induces significant changes in the functional and pharmacological properties of the μ-opioid-Gal_1 receptor heteromer. This common polymorphism, which results in the substitution of an asparagine for an aspartate in a putative extracellular glycosylation site, has been repeatedly associated with increased vulnerability to opiate abuse, but the mechanisms behind the putative loss of function of the modified μ-opioid receptor remain still to be established.

Abstract: Opiate addiction, a chronic relapsing disease, places a large societal and financial burden on our country. In particular, the fundamental issue for the therapeutic treatment of opiate addiction is the persistence of drug craving and seeking, leading to high rates of relapse following drug abstinence. These behaviors are characterized by long-lasting behavioral and cellular plasticity in key regions of the mesolimbic dopamine system, such as changes to the structure of and dendritic spine density on medium spiny neurons in the nucleus accumbens (NAc). To date, the cellular and molecular mechanisms governing opiate-induced structural plasticity remain undetermined. Following heroin self-administration, we find that expression of the essential actin-binding protein drebrin is decreased in the NAc, an effect that is transcriptionally regulated through the binding of HDAC2 at the drebrin promoter. Using viral-mediated gene transfer, the overexpression of drebrin attenuated, while CRISPR-Cas9 deletion exacerbated, heroin-primed (but not sucrose-primed) relapse-like behaviors. In addition, drebrin overexpression produced a downward shift, while CRISPR-Cas9 produced an upward shift, in within-session dose-response curves, demonstrating that drebrin regulates the reinforcing properties of heroin. The restoration of drebrin levels following heroin self-administration reversed the heroin-induced decrease in spine density and reductions in AMPA and NMDA receptor conductances. Taken together, these data demonstrate an essential role for drebrin in mediating the molecular mechanisms underlying opiate-induced behavioral and structural

plasticity. An understanding of these cellular responses will help lead to therapeutic interventions to prevent relapse.

Abstract: Abuse of prescription drugs is a major epidemic in the United States, accounting for over 19,000 deaths in 2014. Massachusetts alone, accounted for 1,200 of these fatalities. The combination of imaging methods and animal models has allowed identification of circuits of addiction and novel biomarkers that could guide clinical intervention. The present studies measure changes in brain function and structure using multimodal imaging in male rats exposed to two weeks of twice daily (2.5 mg/kg/injection) treatments of oxycodone (OXY). The treatments were conducted in a two-chamber testing arena to establish condition place preference. At the end of two weeks, vehicle controls (n = 10) and OXY treated rats (n = 10) were imaged in a 7.0T Bruker Biospec scanner using diffusion weighted imaging (DWI), resting state functional connectivity (fcBOLD) and quantitative, ultra-short time to echo contrast enhanced imaging (QUTE-CE). All voxel based measures for each modality were registered to a rat MRI atlas with 172 segmented, annotated brain regions. DWI and quantitative anisotropy was used to follow neuroadaptation or changes in gray matter microarchitecture in the mesencephalic dopaminergic system, limbic cortex and hippocampal complex. Resting state fcBOLD showed altered connectivity between these different brain regions while QUTE-CE showed changes in capillary density across several brain areas involved in pain processing between vehicle controls and OXY treated animals.

Title: Getting out of the net: Chronic escalating doses of morphine induces morphological changes in perineuronal nets and axonal guidance in substantia nigra in adolescent female rats

Authors: *R. GAGLIA[1], P. GONZALES[2], G. S. LARMOUR[1], M. T. BARDO[3], D. B. VAZQUEZ-SANROMAN[1]

Abstract: Mechanisms underlying adolescent morphine withdrawal in females are not fully understood. Changes in structural neuroplasticity can occur in GABAergic parvalbumin (PRV) positive neurons, which are enveloped by structures of the extracellular matrix called perineuronal nets (PNNs). In the current study, rats received chronic escalating morphine doses during the adolescent period, followed by immunofluorescence measurements for PNN morphology and expression in orbitofrontal cortex (OFC) and substantia nigra (SN). Adolescent female Sprague Dawley rats (PND 34) were administered increasing doses of morphine (5 to 25 mg/kg, s.c.) every 12 hours, for 6 consecutive days. Control rats received saline. On day 6, naloxone (2 mg/kg, i.p.) was injected 2 hr after the last morphine administration and somatic signs of withdrawal were recorded. We found that adolescent morphine escalating dose treatment resulted in the development of morphine dependence as measured by increased withdrawal signs (defecation, digging, mastication and grooming). A one-way ANOVA revealed a significant increase in the perimeter of PNNs [$F(1,76)=11.85$, $p<0.001$], and a reduction on the number of PNNs [$F(1, 3) = 25.36$, $p < .05$] and PNN intensity in SN [$X^2(1)= 8.96$, $p<0.05$] in the morphine-naloxone group compared to saline controls. Moreover, the morphine-naloxone group displayed a significant reduction in the number of PNNs in OFC [$F(1, 3) = 25.36$, $p < .05$]. These results indicate that morphine dependence produced by escalating dose treatment, followed by precipitated withdrawal, remodels PNNs surrounding GABA interneurons in SN and its indirect connections to OFC, suggesting a new possible cellular target where morphine-induced neuroplasticity takes place.

Title: Perineuronal nets and neuronal cilia abnormalities in insular cortex of adolescent female rats treated with chronic escalating doses of morphine

Authors: *D. B. VAZQUEZ SANROMAN[1], R. GAGLIA[2], P. GONZALES[3], G. S. LARMOUR[1], M. T. BARDO[4], N. F. WILSON[1]
[1]Anat. and Cell Biol., Oklahoma State Univ., Tulsa, OK; [2]Anat. and Cell Biol., Oklahoma State Univ. Ctr. For Hlth. Scienc, Tulsa, OK; [3]Biol., Tulsa Community Colleague, Tulsa, OK; [4]Dept Psychol, Univ. Kentucky, Lexington, KY

Abstract: A negative emotional state resulting from withdrawal stress is common in opioid users, yet few studies have examined the effects of morphine withdrawal on extracellular matrix elements and neuronal cilia, both critical organelles that facilitate interactions between the cell and its environment in response to stressful events. Since the insular cortex (IC) is a key brain structure involved in the modulation of negative emotions, this study investigated morphine dependence produced by chronic escalating doses, followed by precipitated withdrawal, on perineuronal nets (PNNs) and neuronal cilia length in the IC. Adolescent female Sprague Dawley rats (PND 34) were administered increasing doses of morphine (5 to 25 mg/kg, s.c.) every 12 hours, for 6 consecutive days. Control rats received saline. On day 6, naloxone (2 mg/kg, i.p.) was injected 2 hr after last morphine administration. Somatic signs of morphine withdrawal were recorded and brains extracted for immunofluorescence analysis. We found that morphine escalating dose treatment resulted in the development of morphine dependence as measured by increased withdrawal signs (defecation and chewing). A Mann-Whitney test indicated that number of PNNs was significantly lower for morphine-naloxone rats (Mdn=10) than for saline rats (Mdn=21), $U= 3.15$, $p<0.05$. Moreover, we found that morphine-naloxone treated rats showed a significant increase in parvalbumin expression [$X2(1)= 7.91$, $p<0.01$]. Also, a separate Mann-Whitney test revealed that neuronal cilia length was significantly increased for morphine-naloxone rats (Mdn=9) compared to saline rats (Mdn=5), $U= 9.15$, $p<0.05$. The current findings demonstrate that the negative emotional state induced by precipitated opioid withdrawal is associated with neuronal cilia elongation and PNN remodeling in IC, perhaps suggesting a novel cellular target for treating opiate dependence and withdrawal.

Title: Contribution of oxygen and hyperbaric pressure to hyperbaric oxygen (HBO_2) suppression of naloxone-precipitated withdrawal in morphine-dependent mice

Authors: *R. M. QUOCK[1], P. N. MAHARAJ[1], S. N. DEWALD[1], E. K. HEATH[1], A. L. BREWER[1], D. Y. SHIRACHI[2]
[1]Psychology, Washington State Univ., Pullman, WA; [2]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: Treatment with hyperbaric oxygen (HBO_2) has been reported to moderate signs of opiate withdrawal in human subjects [Epifanova *et al*., *Anesteziol. Reanimatol.* (3):34-9, 1995]. We recently reported that both 30- and 60-min treatments with HBO_2 suppressed naloxone-precipitated withdrawal signs in morphine-dependent mice [Nicoara *et al*., *Brain Res*. 1648:434-7, 2016]. Work in our laboratory seeks to identify possible mechanisms for the biomedical effects of HBO_2. This follow-up study was conducted to investigate the relative individual contributions of oxygen and hyperbaric pressure to suppression of withdrawal signs by HBO_2 treatment. Male NIH Swiss mice received s.c. injections of morphine sulfate or saline twice a day for 4 days, the daily morphine dose increasing progressively from 50 mg/kg on day 1 to 125 mg/kg on day 4. On day 5, different groups of animals were treated with normobaric air (NBA), normobaric 100% oxygen (NBO_2), hyperbaric air (HBA) or hyperbaric 100% oxygen (HBO_2) for 30 min. Normobaric was set at 1.0 atmosphere absolute (ATA), while hyperbaric was set at 3.5 ATA. Ninety min after NBA, NBO_2, HBA or HBO_2 treatment, opioid withdrawal was precipitated by i.p. injection of 5.0 mg/kg naloxone, and withdrawal signs—withdrawal jumping, wet-dog shakes, forepaw tremors, rearing, and defecation—were videorecorded for 30 min and later counted. Results showed a main effect of oxygen on rears, a main effect of hyperbaric pressure on tremors, and main effects for both oxygen and hyperbaric pressure on fecal boli. No significant results were found for withdrawal jumping or wet-dog shakes. Based on these

findings, the suppressant effect of HBO_2 on opioid withdrawal appears to be attributed to an effect of either oxygen or hyperbaric pressure or both, depending upon the specific endpoint under investigation. This intriguing result should be further studied to identify the neurochemical effects of both oxygen and hyperbaric pressure separately and in combination.

Title: Thalidomide-induced suppression for naloxone-precipitated withdrawal signs in morphine-dependent mice

Authors: *A. BREWER, P. K. MAHARAJ, S. N. DEWALD, E. K. HEATH, R. M. QUOCK
Psychology, Washington State Univ., Pullman, WA

Abstract: Chronic morphine treatment has been shown to increase glial activation in a pro-inflammatory manner in the hippocampus, posterior cingulate cortex and spinal cord indicating that glia may be involved in some aspects of morphine tolerance and dependence [Song and Zhao, *Neurosci. Res.* 39:281-86, 2001]. Glial inflammatory response causes an increase in the release of proinflammatory cytokines. Levels of tumor necrosis factor-α (TNFα) are reportedly elevated in the periaqueductal gray (PAG) of animals undergoing opioid withdrawal; moreover, microinjection of TNFα into the PAG induces withdrawal-like symptoms [Hao *et al*., *Neuropsychopharmacology* 36:664-76, 2011], suggesting TNFα may underlie some aspects of opioid withdrawal. Thalidomide has been shown to be a putative inhibitor of TNFα production in cell culture [Deng *et al*., *J. Invest. Dermatol.* 121:1060-65, 2003] and in human patients [Bauditz *et al*., *Gut* 50:196-200, 2002]. In order to investigate the role of TNFα in opioid withdrawal, male NIH Swiss mice received s.c. injections of morphine sulfate or saline twice a day for 4 days, the daily morphine dose increasing progressively from 50 mg/kg on day 1 to 125 mg/kg on day 4. On day 5, opioid withdrawal was precipitated by i.p. injection of 5.0 mg/kg naloxone.

Sixty min prior to the naloxone injection, different groups of mice were treated with either 65 mg/kg thalidomide or 30% DMSO vehicle. Withdrawal was videorecorded and assessed over a 30-min period using 5 different behavioral endpoints: withdrawal jumping; wet dog shakes; forepaw tremors; rearing; and defecation. Results showed that naloxone caused an increase in frequency of forepaw tremors and withdrawal jumps compared to saline-treated controls. Pretreatment with thalidomide reduced naloxone-precipitated withdrawal jumping, rearing, tremors and defecation but not wet-dog shakes. These findings support the working hypothesis that thalidomide can reduce certain physical signs of withdrawal in animals undergoing precipitated withdrawal. Further research will investigate whether thalidomide-induced inhibition of TNFα production is causally related to thalidomide suppression of opioid withdrawal.

Title: Bidirectional effects of opioid self-administration on medial prefrontal cortex $GABA_BR$-GIRK signaling

Authors: *E. M. ANDERSON, L. FRIEDRICH, D. GOMEZ, M. C. HEARING
Dept. of Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Drug addiction is marked by subtle yet pervasive disruptions in cognitive function that facilitate its development and contribute to a high rate of relapse in addicts, even after sustained periods of abstinence. The prefrontal cortex (PFC) is a critical substrate for many higher-order cognitive functions, including decision making, inhibitory behavior, and processing of reward-related information. Physiological and functional abnormalities in medial PFC (mPFC) neurotransmission produced by repeated drug exposure have long been touted as an underlying factor in the development and persistence of addicted behavior. Layer 5/6 pyramidal neurons in the mPFC provide a key source of glutamate to limbic structures that mediates response to natural reward and drugs of abuse. Unlike psychostimulant exposure on mPFC pyramidal neuron physiology, almost nothing is known regarding the effects of opioids on mPFC pyramidal neuron physiology and inhibitory signaling. The present study sought to examine the impact of intermediate (10-14 d) and more prolonged (40+ d) opioid self-administration on Layer V/VI

pyramidal neuron intrinsic excitability and $GABA_BR$-GIRK signaling within sub-regions of the mPFC. Whole-cell recordings in acute-isolated brain slices from adult C57BL/6 mice showed that somatodendritic currents mediated by $GABA_B$ and GIRK1 are diminished 10-14 d and 40-45 d following intermediate remifentanil (0.05 mg/kg/inf) self-administration in the prelimbic cortex (PrL). These reductions were paralleled by increased reductions in the current required to evoke an action potential (increased excitability) and increased spike firing activity. In contrast, preliminary data indicate that more prolonged self-administration enhances $GABA_B$-GIRK signaling and reduces excitability of pyramidal neurons in the PrL. These data indicate that bidirectional alterations in GIRK signaling may represent early neuroadaptation critical for promoting opioid-seeking behavior during early drug use as well as reductions in mPFC function often associated with more habitual drug use. To this end, future studies will determine the anatomical and efferent selectivity of these adaptations within the mPFC and examine whether GIRK channels represent a potential therapeutic target for disrupting opioid relapse.

Title: Cell-type and pathway-specific plasticity in the NAc following opioid self-administration

Authors: A. MADAYAG[1], L. FRIEDRICH[2], *M. C. HEARING[3]
[1]Pharmacol., UNC Chapel Hill, Chapel Hill, NC; [3]Dept. of Neurosciences, [2]Marquette Univ., Milwaukee, WI

Abstract: Unlike psychostimulants, little is known of opiate-induced synaptic plasticity at excitatory synapses in the nucleus accumbens (NAc) and its relevance to drug-seeking. Medium spiny neurons (MSNs), the principal NAc cell-type, typically express either the dopamine receptor 1 (D1-MSNs) or dopamine receptor 2 (D2-MSNs), the presence of which determines cell physiology and contribution to drug-related behaviors. BAC transgenic mice expressing fluorescent proteins under the control of D1R or D2R promoters were used in combination with whole-cell electrophysiology recordings in acute brain slices to identify opiate-induced plasticity in NAc shell and core MSN glutamate signaling following 10-14 d and 45 d withdrawal from remifentanil self-administration. AMPAR/NMDAR (A/N) ratios and AMPAR-mediated miniature excitatory postsynaptic currents (mEPSCs) were increased in D1-MSNs of the NAc

shell, whereas mEPSCs were reduced in D2-MSNs following 10-14 d of home-cage abstinence. Preliminary data examining cell- and pathway-specific plasticity using ex vivo optogenetic stimulation and retrograde tracers indicates that infralimbic-to-NAc shell synaptic strength and transmitter release probability is enhanced at D1-MSNs that project to the ventral pallidum. Interestingly, unlike non-contingent opioid exposure, mEPSC signaling is also elevated in D1-MSNs of the NAc core, suggesting that using a model of drug administration that requires performance of an operant task engages opioid-induced plasticity within this region. These data identify novel cell-type and pathway-specific alterations in synaptic strength and transmission that are distinct and overlapping in locus and timeline from those produced by psychostimulants and non-contingent opioid exposure. Future experiments will examine potential mechanisms underlying the cell-type plasticity and determine the relevance of cell- and pathway-specific plasticity in relapse behavior.

Title: Opioid-induced adaptations in the neuropeptide Y system in the rat locus coeruleus

Authors: *C. C. THEISEN[1], B. A. S. REYES[2], E. J. VAN BOCKSTAELE[2]
[2]Pharmacol. & Physiol., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Opioid addiction is a serious public health problem in the United States, with over 2.5 million people currently addicted to heroin or prescription opioids. Stress is implicated as a risk factor in vulnerability to opioid abuse and relapse. Recently, neuropeptide Y (NPY) has emerged as a neurochemical mediator of stress resilience. Treatment with NPY prevents and reverses hyperarousal, anxiety, and depression-like behavior rat models of post-traumatic stress disorder, while low levels of NPY are associated with stress vulnerability. In healthy subjects, NPY levels are positively correlated with feelings of dominance, confidence, and superior performance under stress. Interestingly, male rodents exhibit a 2-fold increase in plasma NPY following stress exposure compared to females, indicating NPY may be a mediator of sex differences in stress resilience. Such studies suggest NPY modulates stress resilience, and aberrant NPY activity may increase susceptibility to stress-related psychiatric illness, particularly in females. Here, we investigate adaptations in the endogenous NPY system following chronic morphine exposure and naltrexone-induced withdrawal in the LC of male and female Sprague Dawley rats. Rats were

implanted with placebo or slow release morphine pellets (2 x 75 mg) to induce morphine dependence. After 6 days, rats received i.p. saline or naltrexone (100 mg/kg) to induce acute withdrawal. Rats were euthanized 30 minutes post-injection, and brains were harvested and dissected. Western blot analysis indicated baseline NPY levels were comparable in males and females. Unpaired t-tests for placebo and morphine rats revealed chronic morphine exposure caused significant decreases in LC NPY expression in males ($P < 0.01$) and females ($P < 0.01$). However, ANOVA of male and female placebo, morphine, and withdrawal groups, showed sex differences in the effect of morphine exposure and withdrawal on NPY. A post-hoc Tukey's test found chronic morphine exposure led to a larger decrease in NPY levels in females, compared to morphine-treated males ($P < 0.01$). Additionally, in males, withdrawal from morphine caused a greater decrease in NPY levels, compared to chronic morphine exposure alone ($P < 0.05$). The decrease in NPY levels observed in males subjected to withdrawal was not significantly different from the decreased levels in females exposed to chronic morphine alone. These findings demonstrate significant and sexually dimorphic adaptations in NPY signaling following chronic opioid exposure and withdrawal, and have important implications for the development of therapeutics to target the NPY system and increase resilience and resistance to relapse.

Title: Modeling functional genetic variation at the mu opioid receptor using human stem cells

Authors: *A. HALIKERE[1], J. C. MOORE[2], M. SWERDEL[3], J. A. TISCHFIELD[2], R. P. HART[3], Z. PANG[1]
[1]Dept. of Neurosci. and Cell Biol., CHINJ, RWJMS, Rutgers Univ., New Brunswick, NJ;
[2]Genet., RUCDR/Infinite Biologics, The Human Genet. Inst. of New Jersey, Piscataway, NJ;
[3]Cell Biol. and Neurosci., The Human Genet. Inst. of New Jersey, Rutgers Univ., Piscataway, NJ

Abstract: Significant genetic variability in the mu opioid receptor (MOR) is thought to impact individual responses to opioid drugs. The most common single nucleotide polymorphism (SNP) rs1799971 in the MOR (OPRM1 A118G) replaces an asparagine with an aspartate at position 40 (MOR N40D) of MOR. Previous functional studies investigating the effect of N40D on the

signaling profile of the mu opioid receptor have been controversial and unclear, largely due to the lack of an effective system to model this SNP. To develop a more simplified and species-specific system to provide new insight into the molecular and cellular consequences of OPRM1 A118G, we used CRISPR/Cas9 gene editing to generate two sets of isogenic human stem cell lines carrying homozygous N40 or D40 alleles from which we generated homogeneous populations of human induced neuronal cells (iNs) for functional analyses. Isogenic D40 MOR expressing iNs consistently manifest a stronger suppression of inhibitory synaptic release than N40 MOR human neuronal cells, suggesting acute signaling may be enhanced. Moreover, our data also suggest that MOR N40D variants may regulate MOR function differentially in long term exposures. Specifically, N40 MOR iN cells regained sensitivity to DAMGO following chronic (7 days) agonist exposure whereas D40 MOR iNs failed to show re-sensitization, suggesting potential differences in membrane recycling dynamics. Not only do isogenic cell lines exhibit consistent synaptic phenotypes, but patient derived induced pluripotent stem cell-derived iN cells exhibit similar cellular and synaptic differences in MOR regulation as well, providing strong evidence to support these new insights on MOR function. Our data illustrates the strength of using human pluripotent stem cells to isolate cellular and molecular mechanisms underlying human genetic variation.

Title: Examinations of morphine-induced withdrawal and its related comorbidity

Authors: *C.-Y. OU[1], C.-W. WU[2], A. HUANG[3]
[1]Dept. of Psychology, Fo Guang Univ., Jiaosi, Taiwan; [2]Dept. of Pharm., Keelung Hospital, Ministry of Hlth. and Welfare, Keelung City, Taiwan; [3]Fo Guang Univ., Yilan County, Taiwan

Abstract: Establishing morphine induces withdrawal symptoms and its related comorbidity such as anxiety behavior is a crucial to understand the brain mechanism of drug addiction. This present study addresses this issue. In the beginning of this experiment, all of rats were given a morphine-withdrawal procedure. During this period of time, rats were intraperitoneally injected a specific dose of morphine in the morning and then injected another different dose of morphine in the afternoon as following. Respectively, on Day1, they were given 5 mg/kg morphine and 10 mg/kg morphine. On Day 2, rats were given 15 mg/kg and 20 mg/kg morphine. On Day 3, rats were injected 25 mg/kg and 30 mg/kg morphine. On Day 4, rats were given 35 mg/kg and 40

mg/kg. On Day 5, all rats were given 50 mg/kg morphine and three hours later, all rats were given 2mg/kg naloxone to form withdrawal effects. After 15 minutes, rats were randomly tested anxiety behaviors and motor function in the zero maze and in the open field test. The results indicated that morphine group can induce withdrawal sign in the higher lose weights and stronger anxiety behaviors in lower crossing numbers and lower spent time in the central square. However, non-significant differences for spent time in open arm and staring latency time between morphine and control groups, indicting morphine group has no anxiety behaviors occurred in the zero mazes. In the open field test, morphine group showed a lower total distance travelled than control group, indicating morphine withdrawal effect might reduce motor function during the withdrawal phase. The present findings might offer some insights for interventions in morphine's withdrawal symptoms and its comorbidities. These data should be discussed further.

Title: Reconsidering the definition of the tVTA (tail of the ventral tegmental area) or RMTg (rostromedial tegmental nucleus)

Authors: *F. FAIVRE[1], C. FILLINGER[1], D. DANIEL[1], J. KAUFLING[2], E. DESCHATRETTES[3], D. PLASSARD[4], P. ROMIEU[3], J. SWILLER[3], P.-E. LUTZ[1], C. SANDU[1], C. THIBAULT-CARPENTIER[4], D. MASSOTTE[1], P. VEINANTE[1], M. BARROT[1]

Abstract: In the past decade, a new mesopontine structure was described in the rat brain: the tail of the ventral tegmental area (tVTA) or rostromedial tegmental nucleus (RMTg). This brain region attracted a lot of attention as it densely innervates the VTA and substantia nigra,

providing the most potent inhibitory GABA control of dopamine systems. It was also proved to be the anatomical target by which opiates recruit dopamine systems. The tVTA is the main output of the lateral habenula, and its relay toward dopamine systems. It controls avoidance behaviors and aversive responses, encodes reward prediction errors··· However, this structure is not yet present in rat and mouse brain atlases, and some questions regarding the definition and boundaries of the tVTA remain. The aim of our study was to reconsider and compare these definitions (neurochemical, anatomical, functional and genetic) in the rat brain. First, we did a side-by-side comparison of the various parameters defining the tVTA, by doing immunohistochemistries based on different protein markers of the tVTA: μ opioid receptor, glutamate decarboxylase 67, NeuN, and c-Fos and FosB/ΔFosB after acute administration or self-administration of cocaine. The results allowed us providing a stereological analysis and a 3D reconstruction of the structure. In a second step, we verified, by tract-tracing, the lateral habenula-tVTA-VTA connections. The results show that: 1) the various neurochemical markers of the tVTA define a bilateral structure with same localization and boundaries within the midbrain; 2) the tVTA contains about 2500 neurons per side and most of them can be recruited by cocaine (~60%); 3) the neurochemistry-based and connectivity-based definitions are not matching perfectly, and the neurochemical definition seems to be more relevant.

Title: The tail of the ventral tegmental area: aversive drugs, painful stimuli, stressful stimuli, opioid withdrawal and conditioned taste aversion

Authors: *M. BARROT[1], F. FAIVRE[1], I. YALCIN[1], M.-A. MULLER[2], D. MASSOTTE[1], M. MAJCHRZAK[2], M.-J. SANCHEZ-CATALAN[3]

Abstract: The tVTA (tail of the ventral tegmental area) or RMTg (rostromedial tegmental nucleus), is a GABA mesopontine structure controlling dopamine neurons. It has been implicated in the control of aversive responses, and the stimulation of the LHb/tVTA pathway favors avoidance behaviors. These data suggested an important role of the tVTA in the response to aversive situation. The goal of our study was first to test the influence of various aversive stimuli on the Fos induction in the tVTA in rats and, in a second time, to evaluate the behavioral consequences of a tVTA lesion on opiate withdrawal and on lipopolysaccharide (LPS) and lithium chloride (LiCl) induced conditioned taste aversion (CTA). We tested different types of aversive stimuli, including electric foot shock, pain, predator odor... and we used the response to amphetamine as positive control to compare the Fos responses. We show that only repeated foot-shocks (but not single ones) induced Fos in the tVTA. Naloxone-precipitated opiate withdrawal was also able to induce Fos in mu-opioid receptor positive and negative tVTA cells, which is supportive of both direct and indirect tVTA recruitment. Finally, a bilateral lesion of the tVTA had no impact on CTA and on the behavioural signs of precipitated opiate withdrawal. In conclusion, while stimulation of the tVTA favors avoidance behaviors, our data show that the processing of aversive information may not be a characteristic of the tVTA and that the tVTA does not necessarily process behavioural responses to all aversive stimuli.

Title: Serotoninergic projections to the OFC and BLA modulate reversal learning

Authors: *D. TAPP, M. MCMURRAY
Psychology, Miami Univ., Oxford, OH

Abstract: Behavioral flexibility, the ability to adapt to changing reward contingencies, is a critical aspect of choice behavior. Such ability is disrupted in numerous psychiatric disorders, such as substance abuse disorders, attention deficit disorder, and obsessive-compulsive disorder. The orbitofrontal cortex (OFC) and the basolateral amygdala (BLA) have been implicated as key regulators for this behavior. Additionally, the neurotransmitter serotonin is known to influence behavioral flexibility, and is disrupted in numerous psychiatric disorders. While serotonin and these brain regions have been examined separately, they have yet to be directly linked in this behavioral context. Using a rat model, this study examined such a relationship by selectively leisoning serotoninergic projections to the OFC, BLA, or both regions with a SERT-conjugated

Saporin, and assessing behavioral flexibility in a probabilistic spatial reversal-learning task. Preliminary results indicated that the loss of serotonergic projections to either the OFC, BLA, or both impaired behavioral flexibility. Based on these results, we determined that serotonin regulates reversal learning through its action in the OFC and BLA. Therefore, the serotonergic system may serve as a future therapeutic target for diseases in which behavioral flexibility is impaired, and may explain the effectiveness of serotonin modulators in the treatment of these diseases.

Title: Action-specific reinforcement and update by direct- and indirect- pathway striatal projection neurons

Authors: *S. NONOMURA[1], K. NISHIZAWA[2], K. KOBAYASHI[3], Y. SAKAI[1], Y. KAWAGUCHI[4], A. NAMBU[4], K. YAMANAKA[5], K. ENOMOTO[1], Y. ISOMURA[1], M. KIMURA[1]

Abstract: In order to reach a goal, we take an optimal action by flexibly selecting it from a large number of repertoire based on learning from positive and negative outcomes of our decision. On this occasion, proper assignment of reinforcement to specific decision and action is critical but it is generally difficult. Although the basal ganglia are thought to play major roles in these processes, neuronal basis remains largely unclear. We addressed this issue by focusing on the roles of direct and indirect pathways. We used transgenic rats (Long Evans) expressing Cre recombinase under the promotor of tachykinin receptor 1 (TAC1-Cre rat, for direct pathway) or dopamine D2 receptor (Drd2-Cre rat, for indirect pathway). We injected adeno-associated virus (AAV) vectors that express channelrhodopsin2 (ChR2) in a Cre-dependent manner unilaterally into the dorsomedial striatum (DMS). A 32-ch silicon probe was inserted vertically into the

DMS, and an optic fiber was introduced obliquely to illuminate LED light (460 nm for ChR2, < 2 mW) at the recording sites. Neurons were identified as direct- (dSPNs) or indirect- (iSPNs) pathway striatal projection neurons based on the excitatory response evoked by LED light. Rats performed a free choice task for probabilistic reward under head-fixed condition: they held a lever with right forearm at the center position, pushed or pulled it after visual GO signal, and kept it in the target zones for more than 300 ms to wait for reward (R+) or no-reward (R–) tones and actual outcomes. PUSH and PULL were assigned as either high-value (reward at 80% of trials) or low-value (20%) for 40-60 trials, then action-outcome contingency was reversed. We identified 52 dSPNs from 4 rats and 42 iSPNs from 5 rats. We observed (1) Most iSPNs (37/42) were activated by (R–), whereas most dSPNs (42/52) were activated by (R+) ; (2) Responses of iSPNs to (R–) and those of dSPNs to (R+) occurred preferentially after either PUSH or PULL (32/37, 87% of iSPNs and 32/42, 76% of dSPNs) and the other neurons exhibited similar responses after PUSH and PULL; (3) (R–) responses of iSPNs with preferred action were larger when it was followed by switch choices in the next trial than by stayed choices (22/32) whereas these responses with non-preferred action did not change according to subsequent switch or stayed choses. Our results indicate that direct and indirect pathways of the basal ganglia reinforce and update chosen actions in differential manner. They provide a new insight into neuronal mechanisms of action-specific reinforcement and selection in the basal ganglia, and implications for understanding neuronal basis of basal ganglia disorders.

Title: Neuronal activity in the primate amygdala during economic decisions

Authors: *A. JEZZINI[1], C. PADOA-SCHIOPPA[2]
[1]Washington Univ. In St Louis, Saint Louis, MO; [2]Washington Univ. in St Louis, Saint Louis, MO

Abstract: Experimental and theoretical results of recent years suggest that different groups of neurons in the orbitofrontal cortex (OFC) participate in the formation of good-based economic decisions. In contrast, relatively less is known about the contribution of other areas to this mental

process. A primary candidate is the amygdala, which, together with OFC, is the only brain area where lesions affect performance in reinforcer devaluation tasks. Other research groups found value-coding cells in this area (Paton et al 2006; Grabenhorst et al 2012). However, differences in experimental design and data analysis prevent direct comparisons with our results. In this study, we recorded from the amygdala of rhesus monkeys engaged in a juice choice task.
The experimental design was as in studies of OFC (Padoa-Schioppa and Assad, 2006). In each session one animal chose between two juices offered in variable amounts. Juice quantities varied from trial to trial, and the animal indicated its choice with a saccade. Choice patterns presented a quality-quantity trade-off, and the subjective relative value of the two juices was derived from a sigmoid fit on a session-by-session basis.
We recorded and analyzed the activity of 397 neurons. Firing rates were examined in several time windows. A "trial type" was defined by two offers and one choice (e.g., [1A:3B, A]). A "neuronal response" was defined as the activity of one cell, in one time window, as a function of the trial type. Task-related responses were identified with an ANOVA ($p<0.001$) and regressed against a large number of variables potentially encoded in this region. These included offer value, chosen value, other value, total value, etc. (19 total).
Two procedures for variable selection (stepwise and best-subset) identified three variables that best explained the whole population: offer value, chosen value and chosen juice. Remarkably, these are the same variables previously identified in OFC. The most notable difference between the two areas appeared to be the prevalence of different cell groups. Specifically, chosen value cells were much more prevalent in the amygdala, while offer value cells were much more prevalent in the OFC.

Title: The effect of serotonin 5-HT_4 receptor antagonist on discounting of reward value in decision making

Authors: F. AKIZAWA[1], T. MIZUHIKI[2], R. KUBOKI[1], *M. SHIDARA[2]
[1]Grad Sch. of Comprehensive Human Sci., Univ. of Tsukuba, Tsukuba-shi, Ibaraki, Japan;
[2]Univ. Tsukuba, Tsukuba-shi/Ibaraki, Japan

Abstract: When we choose an action from some alternatives in order to acquire reward, we usually compare each reward value that depends on the balance between reward amount and the cost to obtain it. Previous studies have shown that animals and humans tend to choose smaller immediate reward than larger delayed reward when the serotonin (5-HT) level in the brain decreases, suggesting that serotonin modulates the temporal discount factor of the reward value when getting reward after waiting. On the other hand, it is said that basal ganglia-thalamocortical loop is involved in the reward-based decision-making and 5-HT might modulate the function of some of the loop structures. Recently, Hori et al. (2016, the 39th Annual Meeting of the Japan Neuroscience Society) reported that 5-HT4 receptor antagonist increased the temporal discount factor of reward value in the reward delay task. Since 5-HT4 receptors are largely distributed in striatum of macaque monkeys, this suggests the role of 5-HT4 receptor in the basal ganglia on the temporal discount factor in the reward-based decision-making. Here, we used a decision-making schedule task to assess the role of 5-HT4 receptor on choices depending on reward value. In the task, a monkey was required to choose one of two alternatives. Two kinds of choice cue presented side by side on the monitor were randomly picked up from 16 different combination of reward amount and schedule: 1, 2, 3 or 4 drops of liquid reward by 1, 2, 3 or 4 repeats of a bar-release trial. Brightness and length of the choice target indicates the amount of reward and the number of trial, respectively. Following a choice of one target by touching either left or right bar in front of the monkey, the chosen reward schedule task (consisted of a bar-release trial detecting the target color change from red to green) was started. After the monkey learned this task, we administrated 5-HT4 receptor antagonist GR125487 (1 mg/kg a day) or vehicle systemically and compared the discount factor between two conditions. The value of discount factor k was estimated by fitting the monkey's choice probabilities using exponential discounting model of reward value. Preliminary data from one monkey showed that the discount factor k was higher in GR125487 administration than in control condition. Moreover, in GR125487 administration, the discounting of reward value in schedule task part measured by error rates was also larger than that in control condition. These results suggest that 5-HT4 receptor in basal ganglia may play a role in regulating the discounting of reward value in decision making processing.

Title: Encoding expected reward value for formulating goal-directed decision in the rostro-medial caudate and the ventral pallidum

Authors: *A. FUJIMOTO[1], Y. HORI[1], Y. NAGAI[1], K. W. MCCAIRN[2], T. HIRABAYASHI[1], E. KIKUCHI[1], M. TAKADA[2], T. SUHARA[1], T. MINAMIMOTO[1]
[1]Dept. of Functional Brain Imaging Res., Natl. Inst. of Radiological Sciences, QST, Chiba, Japan; [2]Primate Res. Inst., Kyoto Univ., Inuyama, Japan

Abstract: The limbic basal ganglia networks are conjectured to mediate neural activity underlying reward prediction and goal-directed behavior. Having recently demonstrated that the rostromedial caudate (rmCD) is essential for normal goal-directed decision based on reward size (Nagai et al., 2016), the ventral pallidum (VP)—an area that is reciprocally connected with the rmCD—has also been implicated in reward-based neural processing. How rmCD and VP interact, however, and formulate value-based decisions remain unclear. To address this, we recorded neuronal activity from the rmCD and the VP from rhesus monkeys (N=2), while they performed the 'reward-size' task (Minamimoto et al., 2009). In this task, the monkeys performed an instrumental action (lever release < 1 sec after a 'go' signal) following presentation of a cue associated with the reward size (1, 2, 4, or 8 drops of juice). Both rmCD (39/107) and VP (63/105) transiently encoded the expected reward size following a cue presentation. Neuronal latency for the value coding in the rmCD neurons was significantly longer than the VP neurons (rmCD: 235 ms, VP: 115 ms, $P < 0.01$), suggesting faster recruitment of the VP rather than the rmCD in the value expectation process. To examine the causal role of these two regions, we inactivated bilateral VP by local infusion of $GABA_A$ receptor agonist (muscimol) in one monkey, and compared the behavioral effects with those from rmCD inactivation (N=2, Nagai et al., 2016). Silencing in either structure impaired the normal relationship between error rate and reward size, while the VP inactivation resulted in higher error rates than the rmCD inactivation. These results imply that both the rmCD and the VP encode an expected reward signal, which is critical for formulating decisions in goal-directed behavior. In conclusion, the VP encodes reward and goal-directed behavior in a complex, reciprocating manner, with rmCD.

Title: Probing the motivational control of decision making in mice using an in-house automatized, high throuhput behavioral task

Authors: *C. SCHREIWEIS, M. GACOIN, G. PENDERIA, J. DAUNIZEAU, E. BURGUIÈRE
Brain and Spine Inst. (ICM), Paris, France

Abstract: Anticipated costs and benefits of cognitive control are predicted to be strategically balanced. The expected value of control (EVC), a measurement of worthiness of investing executive resources in a decision, has been suggested to be computed by the anterior cingulate cortex (ACC), a pathologically deviating activation of which is associated with disorders such as ADHD and OCD. Recent neurocomputational studies predict that choices are only executed once passing a critical decision threshold, which can be dynamically adjusted, involving the basal ganglia. Here, we study the motivational control of decision making in mice, using an ecologically designed decision making task, during which task difficulty and reward amounts vary. Subjects live in the operant chambers during the behavioural task, where every event is automated through an in-house software management of the task (e.g. stimulus presentation, food delivery, optogenetic stimulation). Preliminary data suggest that task performance negatively correlates with increasing difficulty levels and drops during the inactive time of day (daytime), strongly supporting the automatized, high-throughput, ecological task design. In a first version of the task, we additionally observed an interference of conflicting learning strategies: during early task performance, the acquisition of the quality of stimuli was overlaid by a win-stay/lose-shift strategy. In the future, we will apply in vivo electrophysiological recordings and optogenetic modulation to test our working hypothesis that costs of decision making is encoded by active, prefrontal cortical inhibition of premature selection in basal ganglia.

Title: Different time courses of explore-exploit decisions in primate amygdala, striatum, and orbitofrontal cortex

Authors: *V. D. COSTA, B. B. AVERBECK
Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Many decisions involve a tradeoff between exploiting existing knowledge of the world to obtain rewards right now, versus exploring something unknown to gain a potential advantage in obtaining future rewards. This is referred to as the explore-exploit dilemma. Managing this tradeoff is important in dynamic environments, where new options periodically become available or the values associated with familiar options change over time. In both cases, uncertainty increases the value of exploration. While motivational circuits facilitate exploitation of learned appetitive and aversive associations, much less is known about how these circuits contribute to explore-exploit decisions. In the present study we combined single-unit recordings of neural activity from the amygdala, ventral striatum (VS), and orbitofrontal cortex (OFC) in three rhesus macaques with computational modeling of the monkeys' behavior on a multi-arm bandit task. During the task, the monkeys learned to choose between three, probabilistically rewarded images. Periodically one of the choices was replaced with a novel image the monkey had not yet associated with reward. This explicitly induced an explore-exploit tradeoff, forcing the monkeys to choose between exploring the novel option or exploiting their existing knowledge about the two familiar options that remained available. We first used a Partially Observable Markov Decision Process model to quantify the value of choosing each option in terms of its immediate expected value (IEV), and an associated exploration bonus (BON). The IEV reflected the likelihood that a choice would be rewarded on the current trial, while the BON quantified the relative difference in the total number of future rewards to be gained by choosing to explore an option rather than exploiting alternative options (i.e. the BON is inversely related to uncertainty). We then used chosen value estimates derived from the POMDP to predict neural activity during the task. The overall representation of the IEV of the chosen option did not differ between the three brain regions, however, the representation of the chosen IEV occurred earliest in the amygdala and prior to when the animals made their choice. This contrasted with the onset

of IEV representations in VS and OFC that arose after the animals had made their choice. There was an overall stronger representation of the BON in the amygdala than in the VS and just as we saw for encoding of the chosen IEV, the onset of the chosen BON representation occurred earlier in the amygdala compared to the VS and OFC. These results imply that the amygdala plays a critical role in regulating explore-exploit decisions during reinforcement learning.

Title: Ventral tegmental area hypoactivity may contribute to altered age-related risk-based decision making

Authors: *V. L. TRYON, S. J. Y. MIZUMORI
Psychology, Univ. of Washington, Seattle, WA

Abstract: Normal cognitive aging can result in altered decision making behavior even in the absence of neurodegenerative disease (e.g. Fletcher & Rapp, 2013). We previously showed that aged rats exhibit increased probability discounting; that is, they decrease their choice of a risky reward when the reward is not guaranteed. This observed increase in discounting with age was partially due to a decrease in sensitivity to positive reinforcement, as measured by win-stay behavior. The goal of the current study was to assess whether age changes in midbrain ventral tegmental area (VTA) neural responses to rewards could contribute to the observed changes in probability discounting. Midbrain dopamine (DA) neurons in particular are known to be important for encoding reinforcing stimuli. DA function declines across the life-span, and this decline has been correlated with age-related cognitive deficits (Backman et al., 2006). We used a task designed to test aged (27-30 months) and young (9-12 months) rats' preference for a lever that lead to a large reward with varying probability (the 'risky' option) or a lever that lead to a small reward 100% of the time (the 'certain' option). Pressing the certain lever led to the delivery of 1 sugar pellet 100% of the time while pressing the 'risky' lever led to 4 sugar pellets with varying probability across trial blocks. The descending probabilities associated with the risky lever were 80% and 20%. Each session consisted of 4 blocks of trials, a forced choice

block followed by a free choice block for each probability condition. Each forced choice block contained 10 trials in which one lever came out at a time to inform the rat of the current reward probability. Next were 20 free choice trials in which both levers were made available, and rats were free to choose amongst the 2 options. Once rats exhibited stable performance on the task, they were implanted unilaterally with a 6 tetrode array aimed at the VTA. Analysis of the neural data revealed that putative DA neurons recorded from aged rats had significantly reduced baseline firing rate and did not respond to reward-predictive or rewarding stimuli. Additionally, aged non-DA neurons responded to reward-predictive stimuli, but there were proportionally fewer neurons recorded from aged rats relative to young rats, and the aged phasic response was significantly reduced. While the in-vivo electrophysiological data from young and aged rats' VTA are preliminary, the striking lack of dynamic range in VTA neurons of aged rats supports the view that a functional decline in these neurons may contribute to their altered risk-based decision making.

Title: Social influences on control signals in human and monkey anterior cingulate cortex (ACC) in a simulated stock market

Authors: *A. W. HUTTUNEN[1], M. L. PLATT[2]
[1]Wharton Sch., [2]CCN, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Suboptimal decision-making can have devastating effects on an individual's social and financial well-being. Understanding the neural mechanisms underlying poor financial decisions - especially in social contexts - would provide critical insight into both clinical (e.g. gambling addiction, Parkinson's Disease) and healthy populations (e.g. investor 'herding' and stock market bubbles) that are adversely affected by such biases. Evidence suggests that biases such as loss aversion arise from competing valuation systems in the brain, whereby the 'low-cost' heuristic process wins out over the more effortful goal-directed computational strategy. Dorsal anterior cingulate cortex (dACC) is hypothesized to exert control over these two neurally dissociable systems by estimating the expected value of control (EVC), or the potential benefit of employing the more effortful or cognitively demanding strategy (Hayden, Pearson, & Platt, 2011; Shenhav, Botvinick, & Cohen, 2013). Given that anterior cingulate gyrus (ACCg) is commonly implicated in social value conflict monitoring and observational learning, we hypothesized a similar role for ACCg in exerting control over valuations of social information.

Based on our previous research demonstrating that rodents exhibit behavioral biases similar to humans when 'trading' with other rodents (Huttunen & Bowman, In Prep.), we developed a similar simulated stock market task to investigate whether the neural systems underpinning suboptimal social information evaluations in herding and bubbles are also evolutionarily conserved across human and nonhuman primates. Changes in the quantity and quality of the social information individuals used during the formation of market bubbles were evaluated with behavioral and eye-tracking measures in humans and monkeys. Furthermore, high resolution intracranial recordings in monkeys provides direct comparison of activity in ACCg and dACC during trading. Our model suggests that ACC plays a critical role in evaluating the amount of weight placed on social information during simulated trading decisions. Moreover, mistakes in maximizing expected value of social information, such is the case in 'herding', parallel mistakes in maximizing expected value of reward. In both cases, greater cognitive control leads to a higher proportion of optimal outcomes.

Title: Environmental valence modulates dorsal raphe serotonin and GABA neural dynamics

Authors: *C. SEO[1,2], M. JIN[1], A. K. RECKNAGEL[1], E. WANG[1], C. M. BOADA[1], N. A. KRUPA[1], Y.-Y. HO[1], D. A. BULKIN[1,2], M. R. WARDEN[1,2]

Abstract: Elevated forebrain serotonin (5-HT) has been associated with an array of inactive behavioral phenotypes that includes behavioral inhibition, learned helplessness, and the enhanced ability to wait patiently for rewards. Likewise, reduced 5-HT has been associated with active behavioral phenotypes including faster acquisition of conditioned avoidance behavior and the inability to inhibit premature responses in reward tasks. Although 5-HT neural activity during active/inactive behaviors is broadly consistent, modulation of 5-HT activity by the quality of the current environment is not well understood. Here, we investigated whether active/inactive neural dynamics in the dorsal raphe nucleus (DRN), the primary source of 5-HT to the forebrain, are modulated by environmental valence. Using fiber photometry, we recorded population activity from DRN 5-HT and GABA neurons while mice were actively behaving in rewarding and aversive environments. We first recorded neural activity while mice were subjected to the tail suspension test (poor environment), explored an open field (neutral), and were allowed to engage in free running behavior on a running wheel (good). Surprisingly, neural dynamics in dorsal raphe 5-HT and GABA populations were strongly modulated by environmental valence. 5-HT and GABA neural activity increased during struggling in the tail suspension test, did not systematically fluctuate during the open field test, and decreased during wheel running. These data suggest that environmental valence may play a role in modulating DRN neural dynamics, but leave open the possibility that gross behavioral differences might underlie this effect. We therefore subsequently tested these mice in cued approach and avoidance behaviors, in which they were required to cross a chamber either to obtain a reward or avoid a shock. When mice engaged in these visually indistinguishable running behaviors, DRN GABA neurons continued to be strongly modulated by environmental valence. DRN GABA neural activity increased during running to avoid the shock (bad environment) and decreased during running to obtain the reward (good environment), consistent with the neural dynamics observed during the tail suspension test and running wheel. DRN 5-HT neural activity was systematically suppressed during running in both good and bad environments. We are currently investigating the causal role of these neural populations in approach and avoidance behaviors with optogenetic control. These data support a major role for environmental valence in modulating dorsal raphe neural dynamics during active and inactive behaviors.

Title: Multisensory decision making in rats and underlying neuronal mechanisms

Authors: *N. NIKBAKHT, M. ADIBI, D. ZOCCOLAN, M. E. DIAMOND
Neurosci., SISSA, Trieste, Italy

Abstract: How the brain merges information across sensory modalities to form unified percepts has been the object of debate. Here, we investigated multisensory integration in rats through an orientation categorization task. Rats encountered a grating disc composed of alternating ridges in white and grooves in black. Rats used either their vision (V), or whiskers and snout (Touch; T), or both modalities together (VT). At every trial, the grating disc was rotated to a different orientation spanning a range of 180 degrees. Rats learned to lick one spout for orientations 0±45°(horizontal) and the opposite spout for orientations 90±45° (vertical). Psychometric curves of correct responses versus the orientation showed on averaged across rats, performance was similar across V and T conditions, while individual rats had different comparative V and T performances. Irrespective of their relative V and T performances, all rats performed best in the VT condition, indicating multimodal enhancement. To quantify this enhancement, we computed the performance expected by optimal linear integration of V and T signals in the frameworks of Bayesian decision theory and information theory; both analyses revealed rats combined vision and touch better than could be accounted for by a linear interaction. High-speed video did not reveal difference in the way rats interacted with the object across modalities that may explain the supralinearity. To further investigate how the combination of sensory information from the two modalities gives rise to a decision, we trained rats in a similar task where the categorization boundary for V (at 25°) was different from that of T (65°). Two auditory tones were associated with each modality. Rats successfully learned to categorize orientations according to distinct visual and tactile boundaries, as revealed by a shift in their psychometric curves for V and T conditions. However, in VT condition, rats did not generalize the learned rule to the combination of V and T information. Extracellular recordings in the posterior parietal cortex (PPC) revealed for the majority of neurons task-related firing rate was invariant across the 3 conditions. For 251 out of 622 neurons, the firing rate was best accounted for by behavioral choice while in 185 neurons, activity was best accounted for by stimulus orientation. For the majority of neurons, orientation tuning was congruent across the 3 conditions. Neurometric curves for V, T, and VT trials were consistent with the observed higher performance on multimodal trials. Because PPC expresses activity ranging from stimulus-related to choice-related we suggest that it is involved in supramodal percept-to-choice transformation.

Title: Subcallosal anterior cingulate cortex, ventral striatum, and amygdala encode distinct aspects of reward

Authors: *M. E. YOUNG, K. D. ESANNASON, S. TAMANG, C. P. MOSHER, P. H. RUDEBECK
Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Dysfunction within the circuits linking subcallosal anterior cingulate cortex (ACC), ventral striatum (VS) and amygdala is related to changes in affect, most notably anhedonia, a loss of positive affect from rewarding events. However, a mechanistic understanding of how the subcallosal ACC interacts with VS and amygdala during the anticipation and receipt of reward in normal function is lacking. Previous work has shown that lesions of the subcallosal ACC affect autonomic arousal in anticipation of rewards, suggesting that this part of the prefrontal cortex may influence reward processing in VS and amygdala during the anticipation of reward. Here we investigated how neurons in subcallosal ACC, VS, and amygdala interact while monkeys anticipate and then receive reward. Two rhesus macaques were trained to perform Pavlovian and instrumental trace conditioning tasks while single-unit and local field activity in subcallosal ACC, VS, and basolateral amygdala were recorded. Autonomic measures of arousal, such as pupil diameter and continuous EKG, and task-related behavioral responses were also continuously collected. We found that monkeys showed elevated behavioral (anticipatory licking) and autonomic (pupil size) responses in anticipation of rewards, which were modulated by each animal's individual reward preferences. Neurons in subcallosal ACC, VS, and amygdala encoded the upcoming reward during the stimulus and trace intervals, and this activity was similarly modulated by individual reward preference. However, the timing of these responses differed between areas, with amygdala neurons signaling reward value first, followed then by subcallosal ACC and last by VS. Notably, there was a large increase in the proportion of VS neurons encoding the anticipated reward just prior to reward delivery during the trace interval. In

conclusion, we found that neuronal activity in subcallosal ACC, VS, and amygdala correlates with sustained behavioral and autonomic responses in anticipation of rewards, and that these responses occur on different time scales. We are now exploring how these areas interact as a functional circuit by looking at measures of oscillatory coherence and spike-spike correlations within and between subcallosal ACC, VS, and amygdala.

Title: Optogenetic dissection of temporal dynamics of amygdala-striatal interplay during risk/reward decision-making

Authors: *D. A. BERCOVICI[1], D. E. MOORMAN[2], M. TSE[3], S. B. FLORESCO[3]

Abstract: Assessing costs and benefits associated with different options that vary in terms of reward magnitude and uncertainty is an adaptive behaviour which motivates us to select the optimal course of action. Previous studies using reversible inactivation have shown that the basolateral amygdala (BLA) to nucleus accumbens (NAc) pathway plays a key role in promoting choice towards larger, riskier rewards. Neural activity in the BLA and NAc show distinct, phasic changes in firing prior to action initiation and following action outcomes. Yet, how temporally-precise patterns of activity within BLA-NAc circuitry influences choice behavior is unclear. We assessed how optogenetic silencing of BLA projection terminals in the NAc altered action selection. Rats that received intra-BLA infusions of AAV encoding for the inhibitory opsin eArchT were well-trained on a probabilistic discounting task, where they chose between a smaller/certain reward and a larger reward delivered in a probabilistic manner, with the odds of obtaining the larger reward changing over blocks of trials (50-12.5%). During testing, discrete 5-7s pulses of light (532 nm) were delivered via fiber optic ferrules into the NAc to suppress activity within BLA terminals during specific task events. These included periods “prior to choice” or during different “choice outcomes” (receipt of large rewards, small rewards or reward omissions). Discrete optogenetic suppression of activity in BLA inputs to the NAc prior to choice reduced selection of the more preferred option, suggesting that at this time, activity within

this pathway biases choice towards more preferred rewards. Suppression of BLA inputs during reward omissions increased risky choice during the low-probability block, indicating that activity in this circuit after non-rewarded actions serves to modify subsequent choice behavior. In contrast, silencing during rewarded outcomes did not reliably affect choice behaviour. In vivo electrophysiological studies confirmed that, in rats infused with eArchT within the BLA, local laser light application within the NAc markedly reduced firing of NAc neurons evoked by BLA stimulation. Collectively these data clarify how patterns of activity in BLA-NAc circuitry convey different types of information that guide optimal action-selection in situations involving reward uncertainty.

Title: Dorsal and ventral regions of the medial prefrontal cortex play dissociable roles in regulating risk/reward decision making during a “Blackjack” task guided by external cues

Authors: *M. VAN HOLSTEIN[1], S. B. FLORESCO[2]
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Univ. British Columbia, Vancouver, BC, Canada

Abstract: We often face decisions requiring a choice between options that vary in terms of reward magnitude and uncertainty. Moreover, the relative amount of uncertainty associated with different options can vary. For example, an experienced blackjack player knows the odds of winning a hand are larger when the dealer is showing a “6” compared to an “ace”. Studies with humans often present choices between taking a gamble and choosing a safe alternative, with explicit cues informing participants about the probabilities of winning a gamble prior to the decision. Functional neuroimaging studies using these tasks have revealed a role for the nucleus accumbens (NAc) and distinct parts of the prefrontal cortex (PFC), in particular the ventromedial PFC (vmPFC) and anterior cingulate (AC) cortex in risky decision making. Preclinical studies with rodents have provided additional insight in the neural basis of risk/reward decision making. The probabilistic discounting task is one common way to assess risky decision making wherein rats must use internally-generated information to identify when odds associated with each option change. To bridge this gap between assays in rats and humans we developed an operant assay we

refer to as the “Blackjack” task. In this task, animals are presented with a choice between a small/certain (1 pellet) and a large/uncertain (4 pellet) option. The odds of obtaining the large reward vary across trials, and are signaled by an auditory cue: Prior to a choice, one of two tones signalled that the odds of obtaining the larger reward were either good (50%) or poor (12.5%). Under control conditions, well-trained rats selected the large reward option more often when the odds were good vs poor (~70% vs 20%). We recently revealed distinct roles for subregions of the NAc in this form of decision making. Inactivation of the NAc shell increased risky choice when the odds were poor, suggesting it regulates suppression of suboptimal choices. Inactivation of the NAc core caused a more general disruption in using discriminative cues to guide appropriate responding. In the present study we assessed the involvement of two key cortical inputs to the NAc: the infralimbic (IL) and AC cortex. Inactivation of the IL increased risky choice in a manner similar to inactivation of the NAc shell. However, unlike inactivation of the NAc core, inactivation of the AC resulted in a decrease in the large reward option when the odds were good, suggesting it promotes selection of beneficial choices. Collectively, these data show that the IL and AC play unique roles when using cues to guide decisions associated with uncertainty, similar to the roles the vmPFC and AC might play in humans.

Title: Modulation of probabilistic discounting and reversal learning by dopamine within the medial orbitofrontal cortex

Authors: *N. L. JENNI[1], Y. T. LI[2], S. B. FLORESCO[3]
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Weighing the value of a reward against its likelihood of delivery in order to optimize long-term utility is a necessary component of adaptive decision making. The medial subregion of the orbitofrontal cortex (mOFC) plays a key role in this form of cognition, as inactivation of this subregion in rats alters both risk/reward decision making and cognitive flexibility involving reward uncertainty (probabilistic reversal learning). The mOFC receives dopaminergic input from midbrain neurons, yet whether dopamine (DA) modulates mOFC function has been virtually unexplored. Here, we assessed how DA D_1 and D_2 receptors in the mOFC may

modulate adaptive decision making in the face of probabilistic outcomes. One series of experiments assessed risk/reward decision-making using a probabilistic discounting task, while another set of studies assessed probabilistic reversal learning. Separate groups of well-trained rats, received intra-mOFC microinfusions of selective D_1 or D_2 antagonists or agonists prior to task performance. Our results indicate that blocking mOFC D_1 receptors reduced risky choice, driven by an increase in lose-shift behavior. Interestingly, excess stimulation at the D_1 receptor did not alter choice behavior. Blockade of D_2 receptors increased, while stimulation of D_2 receptors reduced risky choice, with this reduction once again driven by increased lose-shift behavior, suggesting that mOFC DA receptors play an important role in mitigating sensitivity to non-rewarded actions to maintain optimal choice biases during risk/reward decision making. Blockade and stimulation of D_1 receptors in the mOFC reduced the number of reversals completed, but this may be accounted for by a more basic impairment in probabilistic reinforcement learning, as blockade of D_1 receptors increased errors specifically during the initial discrimination of the task. In contrast, blockade of D_2 receptors increased while stimulation of D_2 receptors reduced the number of reversals completed. Again, these effects were apparent during the initial discrimination of the task. Across both behaviours, we found that D_1 and D_2 receptors within the mOFC play dissociable and opposing roles in different forms of reward-related action selection. Together, these findings highlight a novel role for mOFC DA in guiding behavior in situations of reward uncertainty. Elucidating how DA within different nodes of mesocorticolimbic circuitry influences action selection in these situations will expand our understanding of the mechanisms regulating optimal and aberrant decision-making.

Title: Local androgen synthesis in the male rat brain and its modulation of behavioral flexibility

Authors: *R. J. TOMM[1], H. R. SCHWEITZER[1], D. J. TOBIANSKY[3], G. K. KACHKOVSKI[1], C. MA[2], H. H. ADOMAT[4], E. S. GUNS[4], S. B. FLORESCO[5], K. K. SOMA[6]
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Dept. of Psychology, The Univ. of British Columbia, Vancouver, BC, Canada; [4]The Prostate Ctr. at Vancouver Gen. Hosp., Vancouver, BC, Canada; [6]Psychology, [5]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Androgens are known to regulate sexual and aggressive behavior in males. However, little attention has focused on the effects of androgens on higher-order cognition and executive function. Androgens are produced in the gonads but are also produced locally in the brain, which might be particularly important when systemic androgen levels are low. Here, we examined the effects of gonadectomy (GDX) and/or an androgen synthesis inhibitor (abiraterone acetate, ABI) on different forms of behavioral flexibility in adult male Long-Evans rats. Rats received either GDX or sham surgeries and then were housed for 5 weeks, to allow for possible upregulation of local androgen synthesis after GDX. Five days prior to the commencement of behavioral training, rats received daily treatments of either vehicle or ABI (40 mg/kg, p.o.), a compound that is used to treat patients with prostate cancer and crosses the blood-brain barrier. Behavioral flexibility was assessed using operant-based assays. Separate groups were tested on either a strategy set-shifting task or a spatial reversal learning task. The strategy set-shifting task required rats to disengage from a previously correct (but now incorrect) visual-cue based discrimination strategy, and acquire and maintain a new egocentric spatial response strategy. GDX or ABI did not affect the ability to learn an initial, visual-cue based strategy. However, during the shift to an egocentric response strategy, ABI treatment (but not GDX alone) caused an apparent improvement in behavioral flexibility, by reducing the number of errors made before reaching criterion. In a separate group of rats trained on a reversal learning task, we found a similar effect, in that only ABI reduced perseverative-type errors during the reversal. In both studies, GDX+vehicle subjects performed similarly to SHAM+vehicle subjects, suggesting that neural androgen synthesis were mediating these effects. Taken together, these data suggest that neural T synthesis may serve to increase persistence of behavior, which can in some instances supress behavioral flexibility. These data provide evidence for the behavioral functions of neural androgen synthesis in mammals. Ongoing work will measure a panel of sex steroids using LC-MS/MS in multiple brain regions that regulate behavioral flexibility. Furthermore, we will examine the effects of GDX and ABI on dopamine signaling, which plays a critical role in behavioral flexibility.

Title: Active versus passive avoidance is differentially regulated by nucleus accumbens core and shell

Authors: *P. T. PIANTADOSI[1], D. C. M. YEATES[2], S. B. FLORESCO[3]
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Defensive behavior is an adaptive construct that enables organisms to escape or avoid potential threat. These behaviors include defensive reactions, during which behavior is suppressed in order to passively avoid a threatening situation, and defensive actions, during which behavior is produced to actively avoid danger. However, in naturalistic settings, inhibiting motor output in a context where actively avoiding may be more advantageous, or vice versa, could result in aversive consequences. Such inappropriate allocation of defensive behavior has been suggested to underlie pathological avoidance in neuropsychiatric conditions where active avoidance is abnormally elevated (e.g. depression), or response-inhibition (passive avoidance) is diminished (e.g. substance abuse). This dichotomy of active versus passive behavior may be differentially regulated by the major subdivsions of the nucleus accumbens, the core (NAcC) and shell (NAcS), which are known to control flexible action selection in the appetitive domain. Here we examined the contribution of these NAc subregions to cued active/passive avoidance behavior using a novel, operant-based Go/No-Go task. Rats were extensively trained to produce an active avoidance response (press a lever to avoid up to 3 foot-shocks over 10 s; AA) during presentation of one 15 s auditory cue, or a passive avoidance (withhold pressing for 15 s to avoid foot-shock; PA) in response to another auditory cue. Inactivation of either NAcC (n = 10) or NAcS (n = 11) (via infusion of baclofen/muscimol) impaired AA, resulting in more failures and shocks received, without altering escape behavior (i.e. lever-presses after delivery of foot-shock). In contrast, PA was disrupted by inactivation of the NAcS, but not NAcC, reflecting a deficit in response-inhibition that manifested as more passive avoidance failures, lever-presses during a passive failure, and locomotion. To examine the contribution of monoaminergic signaling to AA/PA performance, high-performing rats were administered a systemic dose of D-amphetamine (1 mg/kg). This dose did not affect AA performance, but disinhibited behavior, increasing PA failure (but leaving the number of passive presses intact) and locomotion, suggesting that rats remained sensitive to the instrumental punisher despite behavioral disinhibition. These results provide insight into the ventral striatal regulation of complex avoidance behavior, supporting previous work suggesting that the NAcS is part of an AA circuit, and adding to a growing literature indicating that the NAcS inhibits inappropriate or punished behavior, while the NAcC promotes flexible approach behavior.

Title: Functional encoding of inhibitory control in rats in the variable delay-to-signal task

Authors: *M. ESTEVES, A. M. CUNHA, J. S. REIS, A. ALMEIDA, N. SOUSA, H. LEITE-ALMEIDA
ICVS, Sch. of Medicine, Univ. of Minho, Braga, Portugal

Abstract: The nucleus accumbens (NAcc) is widely known to be associated with critical aspects of decision-making, namely motivation and reward. Although not completely clear, this region has also been linked to behavioral inhibition, for which associations with the prefrontal cortex seem to have an important role. NAcc oscillatory activity was registered in Wistar-Han rats implanted with nichrome single wire electrodes during the execution of an impulsivity task - Variable Delay-to-Signal (VDS). During 10 training sessions animals learnt to nosepoke a small aperture after a 3s delay (signaled with a light) to earn a sugared pellet. Premature nosepokes (during the delay) were punished with a timeout and no reward was provided. On the last session (test), premature responses were allowed (i.e. not punished) and delays were variable. The test started with 25 trials of 3s delays, followed by 70 trials of variable (6 and 12s) delays and finally the 25 trials with 3s delays were repeated. While the training construct reflects action impulsivity, the VDS test is more akin to delay tolerance and correlates with the delay discounting behavior. Local Field Potentials (LFPs) were acquired during the task performance,

amplified and band-pass filtered. Processing was performed in Matlab using the Chronux toolbox and included downsampling, referencing, artifact removal, event alignment, power estimation using a multitaper method and averaging. NAcc power showed frequency-dependent variations around the time of nosepoke, particularly an increase in the lowest frequencies. This activity peak preceded the premature responses but was simultaneous with the timed responses. Furthermore, power in high frequencies was elevated approximately 750ms before premature responses. Our results indicate that the activity state in the Nacc conditions animals' inhibitory capacity suggesting that this area is critically involved in impulsive behavior.

Title: Opposite role of left and right nucleus accumbens in impulsive and habit to goal-directed decision-making

Authors: *A. FERREIRA CUNHA, M. GUIMARÃES, M. ESTEVES, F. TEIXEIRA, A. SALGADO, A. RODRIGUES, N. SOUSA, A. ALMEIDA, H. LEITE-ALMEIDA
Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal

Abstract: Nucleus accumbens (NAcc) is highly involved in impulsive and habit-based/goal-directed decision-making. Curiously, such involvement appears to be lateralized, particularly in the case of impulsivity. Indeed, decreased expression of glutamate decarboxylase, markers of dendritic spines and microtubules, as well as decreased gray matter density in the left (but not in the right) NAcc were associated with high trait impulsivity (Caprioli et al 2014). In this study, we analyzed if the depletion of dopaminergic efferences to the left and right NAcc affected

distinct aspects of decision-making. Wistar-Han male rats, 8 weeks-old, received an injection of 6-hidroxydopamine in the left (6-OHDA-L) or right (6-OHDA-R) NAcc (AP: 1.2, ML: +/- 2.1, DV: 7.0). Control animals were injected with vehicle in the same coordinates. After 3 weeks, rats were trained in an operant chamber to perform an action (lever press) contingent with an outcome (reward). The action/outcome ratio was sequentially increased across sessions up to a random ratio of 20 lever presses/outcome (RR20). An early devaluation session was performed at this stage. In the following 6 sessions, animals were trained in a RR20 schedule (habit formation) and finally a late devaluation test was performed. Two more RR20 sessions were done, in the end of which a contingency of one of the levers was degraded for 2 sessions. Animals performed 3 extra sessions of RR20 in the non-degraded lever and in the end a devaluation test. Then animals were tested in the Variable-delay-to-signal test (VDS; Leite-Almeida et al. 2013) for impulsive behaviour. In a second experiment, a group of animals performed only the VDS test. No differences were found between groups in the learning phase of both operant tasks. However, 6-OHDA R (contrary to Sham or 6-OHDA L) animals do not degraded the contingency in the first day of the test neither devaluate the reward when only one lever was present, indicating a impairment in the shift from habit towards goal-direct behaviour in this group. In opposition, in the VDS test, 6-OHDA-L group manifested higher delay intolerance, as observed by a rampant accumulation of premature responses during the large delay trials (6 and 12 s), than 6-OHDA-R or Sham animals. Additional tests demonstrate that these alterations are not the result of impaired motivation, anxiety-like behavior nor motor problems. Our results demonstrate an opposite involvement of the NAcc in the manifestation of impulsive and goal-directed behaviors and that such is associated with a differential contribution of the left and right mesolimbic dopaminergic projections. Follow up studies will assess the specific involvement of D1 or D2 cells.

Title: Visual two-arm bandit reinforcement learning in rodents

Authors: *G. M. ZABALA-ALEMAN[1,2,3], J. DU HOFFMANN[1,4,5], Y. CHUDASAMA[1,4,5], B. B. AVERBECK[1,2]

Abstract: Reinforcement learning (RL) is the behavioral process of learning to make choices to gather rewards and avoid losses. RL is often studied in the context of two-armed bandit tasks, in which subjects have to make choices between a pair of options. After each choice, they receive an outcome. By integrating the outcomes over trials they can learn which choice is most rewarding, and choose that option in the future. In rodents, choices in such tasks are often between levers or ports in different locations within an operant box. The neural circuitry that underlies learning about which port or which lever is most rewarding has been examined. In studies using primates and humans, choices are often between visual objects whose location varies trial-by-trial. Recent evidence suggests that the neural circuitry that underlies learning to select rewarding actions is different than the neural circuitry that underlies learning to select rewarding objects. Therefore we developed a rodent two-armed bandit task using a touchscreen platform in which rodents (N = 12 rats) initiated a trial by nose-poking a food magazine located opposite the visual display. Two different geometric objects were presented on the left and right side of the touchscreen. The animals then approached the touchscreen and made a choice by nose-poking one of the two visual objects. A response to the correct object was rewarded with 10% sucrose liquid reward. A response to the incorrect object was not rewarded. On average, the animals acquired the stimulus-reward association within 5 days, selecting the rewarded object more than 80% of the time. We subsequently reversed the stimulus-reward contingencies such that the animal had to reverse their preference. The animals successfully reversed their preference within an average of 9 days and switched to selecting the newly rewarded object. Following the initial reversal, the animals were then subjected to three additional reversals using the same pair of visual objects. The animals took an average of 7 days to reverse. Future experiments will examine the neural circuitry underlying these behaviors.

Title: Behavior-dependent limbic-cortical interactions in a Cyfip1 knockout rat model of psychiatric risk

Authors: *J. HECKENAST[1,3], S. TRENT[2], J. HALL[2], L. WILKINSON[2], M. W. JONES[3]
[2]Neurosciences & Mental Hlth. Res. Inst., [1]Cardiff Univ., Cardiff, United Kingdom;
[3]Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Cyfip1 gene dosage is reduced in 15q11.2 deletion syndromes, which are associated with a range of developmental, intellectual and psychiatric symptoms. While the neural bases of these symptoms are unknown, abnormal limbic-cortical interactions feature in other psychiatric patients and genetic risk factor carriers, in other rodent models, and are increasingly thought to contribute to cognitive deficits. We are using a novel line of Cyfip1 heterozygous knockout rats (Cyfip1±) to define the consequences of Cyfip1 knockdown for brain function and behavior.Eight wildtype (WT) and 5 Cyfip1± littermates were trained on a rewarded alternation T-maze task invoking working memory, a process consistently impaired in psychiatric disorders. Chronically implanted microelectrode arrays were used to simultaneously record local field potentials (LFP) from dorsal and ventral CA1 of the hippocampus (CA1), medial prefrontal cortex (PFC), nucleus accumbens and amygdala during maze performance and subsequent sleep.Choice accuracy on the task was unimpaired in Cyfip1± rats (88±5%, WT 79±4%; $p>0.05$), and LFP spectral profiles also appeared normal, showing CA1 and PFC 5-10Hz theta power similar to WT. This suggests that local networks remain broadly intact in Cyfip1± rats.However, using spectral coherence to infer functional interactions between CA1 and PFC indicated that theta coherence in Cyfip1± rats was more sensitive to cognitive context than in WT. The difference in coherence between sample and choice phases on the T-maze was significantly higher in Cyfip1± than WT ($p<0.05$). This result is reminiscent of an fMRI study in which schizophrenia risk allele carriers showed increased limbic-cortical coupling, with no impact on task performance[1].Introducing a 5min delay to the task reduced choice accuracy to chance levels and abolished the context dependence of CA1-PFC coherence in both groups, suggesting that rats may no longer engage CA1-PFC under these conditions. Current analyses are quantifying CA1-PFC interactions during sleep in Cyfip1± rats.These findings indicate that impaired neural network activity during a working memory task is a consequence of reduced Cyfip1 gene dosage, and may be an important component of the pathophysiology underlying psychiatric conditions.1. Title: Ventral hippocampus olm cells control type 2 theta oscillations and response to predator odor

Authors: *S. MIKULOVIC[1], E. RESTREPO[2], S. SIWANI[2], A. B. TORT[3], K. KULLANDER[2], R. N. LEAO[4]
[1]Uppsala University, Neurosci. Dept., Uppsala, Sweden; [2]Uppsala Univ., Uppsala, Sweden; [3]Brain Institute, UFRN, Natal, Brazil; [4]Brain Inst., UFRN, Natal, Brazil

Abstract: The dorsal and ventral hippocampus exert cognition and emotion-related functions, respectively. Since both regions display rhythmical activity, specific neural oscillatory pacemakers could underlie their functional dichotomy. Type 1 theta oscillations are strongly observed in the dorsal hippocampus during movement and exploration and are independent of cholinergic transmission. In contrast, type 2 theta depends on acetylcholine and appears when animals are exposed to emotionally laden contexts (e.g. predator odor tests). However, despite its involvement in emotions, the source of type 2 theta has never been attributed to the ventral hippocampus. Here we show that optogenetic activation of oriens-lacunosum moleculare (OLM) interneurons in the ventral hippocampus drives type 2 theta oscillation. We also show that OLM-driven type 2 theta oscillations can coexist with type 1 theta oscillation. Moreover, we found that type 2 theta generation is associated with increased risk-taking behavior in response to predator odor. These results demonstrate that two theta oscillation subtypes predominate in different hippocampal regions that underlie distinct cognitive functions.

Title: The macaque medial prefrontal cortex neurons respond rapidly and strongly to images of snakes and emotional faces of conspecifics

Authors: *H. NISHIMARU, H. TRONG DINH, J. MATSUMOTO, Y. TAKAMURA, Q. VAN LE, E. HORI, T. ONO, H. NISHIJO

Abstract: Primates devote considerable attention to snakes and conspecific faces. However, neuronal mechanisms of rapid detection of such biological stimuli are still unknown in primates. It has been shown that subcortical visual system including the superior colliculus, pulvinar and amygdala, provide the neural substrate that allows rapid visual detection of snakes and emotional faces. In our previous study, we have shown that monkey pulvinar neurons respond more quickly and more strongly to snakes and faces than to other stimuli (Le et al. PNAS 2013, Nguyen et al. Eur J Neurosci 2013). The medial pulvinar and amygdala send robust inputs to the medial prefrontal cortex (mPFC), a cortical area that has been implicated in the allocation of attention to biologically important stimuli. These neural connections suggest that the mPFC is also involved in the rapid detection of such stimuli. In the present study, we report that monkey mPFC neurons responded more rapidly and more strongly to snakes than to other potential predators, and to emotional faces of conspecifics than to neutral faces of conspecifics and faces of humans. Neuronal responses in the monkey mPFC were recorded while monkeys discriminated 8 categories of visual stimuli (snakes, monkey faces, human faces, raptors, carnivores, non-predators, monkey hands, simple geometrical patterns). Of 538 mPFC neurons recorded, 93 responded to the visual stimuli. The responses to snakes and monkey faces were unique in that; 1) the ratios of neurons that responded best to snakes and monkey faces were larger than other categories, 2) mean response latencies were faster to snakes and monkey faces than those to other categories, and 3) neuronal responses to snakes were unaffected by low pass filtering of the images, but were decreased by high pass filtering. These results provide neurophysiological evidence that the mPFC is involved in coarse and rapid visual information processing of snakes and monkey faces. Furthermore, they suggest that ecological and social selective pressures shaped the PFC, a cortical area that has greatly expanded in primates.

Title: Tactile stimulation of the face and body elicit neural activity in the monkey amygdala

Authors: *J. MORROW[1], C. P. MOSHER[2], K. M. GOTHARD[3]
[1]Neurosci., Univ. of Arizona, Tucson, AZ; [2]Advanced Hlth. Sci., Cedars Sinai Med. Ctr., Los Angeles, CA; [3]Univ. Arizona, Col. Med., Tucson, AZ

Abstract: Recent studies from our laboratory reported the presence of neurons in the monkey amygdala that respond to tactile stimuli. The majority of tactile neurons had bilateral, composite receptive fields (i.e., a receptive field covering multiple, non-contiguous areas on both sides of the face). In this initial report, only the face was tested for tactile responsiveness. The restriction of tactile stimulation to only the face leaves questions about how (or if) the primate amygdala represents the rest of the body. To address this issue, we designed a solenoid controlled air puff apparatus that delivered highly controlled innocuous tactile stimulation via small nozzles to 16 different areas of the face and body. The nozzles were aimed bilaterally to the lower muzzle, upper muzzle, brow, ear, neck, upper forearm, lower forearm, and the back of the hand. Air puffs of 1 s duration were delivered to each location 15-20 times at a pressure of approximately 0.14 MPa. Neurons in the amygdala responded to tactile stimulation both on the face and body. Of the 37 neurons recorded, 7 responded to stimulation of the face while 6 responded to air puffs delivered to different parts of the body. Unlike neurons typically seen in primary somatosensory cortex, some tactile neurons in the amygdala exhibited composite receptive fields spanning distant locations on the head and body (e.g., brow and hand). While a majority of tactile receptive fields on the face and neck were symmetrical (7/10) we found no bilateral receptive fields on the limbs. Ongoing experiments will determine whether neural responses to touch on the body and limbs differ from touch on the face and whether there are significant differences in the properties of the receptive fields for these regions (e.g., size, symmetry, and continuity). These data support the idea that the amygdala is involved in processing touch stimuli regardless of where on the body the stimulation occurs.Supported by a Medical Research Grant from an Anonymous Foundation

Title: Neurons in the primate amygdala respond to tactile, auditory, and visual stimuli

Authors: *P. E. ZIMMERMAN[1], J. MARROW[1], C. P. MOSHER[2], K. M. GOTHARD[3]
[1]Univ. of Arizona, Tucson, AZ; [2]Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Univ. Arizona, Col. Med., Tucson, AZ

Abstract: The primate amygdala receives input from all sensory modalities; however, the majority of neurophysiological studies in primates are limited to the domain of vision. A smaller number of studies showed that auditory stimuli also elicit responses from neurons in the primate amygdala. Recently, our laboratory reported neurons in the amygdala that responded to tactile stimuli. Given that the amygdala receives inputs from areas with different levels of sensory integration, we sought to assess the extent to which neurons in the amygdala respond to tactile, visual, and auditory stimuli. We recorded the responses of single units in the amygdala to neutral stimuli across these three domains. Only neutral, non-social stimuli were used in order to eliminate possible confounds with responses elicited by the valence/value or social salience of stimuli. Of 103 recorded neurons, 28 cells responded to a single modality, while 16 and 7 cells responded to two and three sensory modalities respectively. The most common multisensory neurons responded to visual and tactile stimuli (9 cells). Fewer neurons responded to visual-auditory (3) and auditory-tactile (4) stimulus combinations. Albeit preliminary, these data indicate that a large subset of neurons in the amygdala are multisensory. Ongoing experiments will compare responses to neutral stimuli with responses elicited by stimuli of species-specific, socio-emotional value (such as facial expressions, social calls, and grooming). These data will help establish the role of the amygdala in integrating unconditioned stimuli with low or high socio-emotional value across sensory domains.

Title: Oxytocin (intranasal or bilateral microinjections) enhances the selectivity of amygdala neural responses in a social discrimination task

Authors: *P. PUTNAM[1,2], P. E. ZIMMERMAN[2], L. J. YOUNG[3], K. M. GOTHARD[2,2]
[1]Neurosci., [2]Dept. of Physiol., Univ. Of Arizona, Tucson, AZ; [3]Dept. of Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: The amygdala in primates is crucial for the evaluation of social stimuli, and contains neural specializations for the individuation of conspecifics, the discrimination of facial expressions, and the detection of important social signals such as eye contact. Previous studies have shown that unilateral injections of Oxytocin (OT), a hormone and neuromodulator, into the primate basolateral amygdala increased the frequency of pro-social decisions and attention to a social partner[1]. It has also been reported that intranasal administration of OT increases blood flow in the amygdala of humans performing social tasks[2]. Despite numerous reported behavioral effects of OT, little is known about the underlying neural mechanisms by which OT modulates social cognition. To investigate the effect of OT administration on neural responses in the primate amygdala we recorded neurons from a monkey who received OT (or vehicle control) through intranasal nebulization, or direct bilateral microinjections into the amygdala. During recording the monkey discriminated between the identities of conspecific monkeys, presented in videos. Videos of objects were used as non-social controls. Using the depth of selectivity index[3] we found that intranasal administration of OT increased the selectivity of amygdala neurons for monkey identity when compared to saline inhalation ($p=0.0135$ using a Wilcoxon rank sum test). Ongoing experiments will determine whether intra-amygdala microinjection of OT can yield similar results and whether the effect of OT on social behavior can be localized to specific neuroanatomical substrates. *This work was supported by the Silvio O. Title: Stable changes in H2A.Z binding and acetylation during memory formation and maintenance

Authors: ***K. NARKAJ**[1], A. AZAM[1], A. ANGCO[2], K. SERVADO[2], I. B. ZOVKIC[3]

Abstract: Memory formation is a protracted process that initially involves the hippocampus and becomes increasingly dependent on the cortex as the memory ages. Existing research has implicated stable changes in DNA methylation as a contributor to this process, whereas changes in histone modifications are typically found to be transient. Here, we investigated whether histone H2A.Z, a newly identified epigenetic regulator of learning and memory, is stably modified in the hippocampus and the cortex at delayed time points after learning. Mice were exposed to contextual fear conditioning and brains were collected either 24 hours or 30 days after learning. Using chromatin immunoprecipitation, we quantified H2A.Z and acetylated H2A.Z (AcH2A.Z; a positive marker of transcription) binding on memory-related genes. After 24h, we observed increased levels of H2A.Z acetylation on immediate early genes in fear conditioned mice in the hippocampus, demonstrating the persistence of this epigenetic modification beyond the initial consolidation window (up to 6h). 30 days after training, we detected lasting changes in both H2A.Z binding and H2A.Z acetylation in the medial prefrontal cortex (mPFC), particularly on synapse-related genes. Previously, we showed that H2A.Z in both the hippocampus and the cortex is transiently modified after learning. Here, we show that H2A.Z is stably regulated, but that this regulation is gene-specific, such that changes associated with immediate-early genes are no longer evident at 30 days, whereas, changes associated with synaptic genes persist to support memory maintenance.

Abstract: Molecular mechanism of long-term memory has been extensively studied in the context of hippocampus-dependent recent memory examined within several days; however, months-old remote memory maintained in the cortex for long-term has not much been investigated at molecular levels yet. Various epigenetic mechanisms are known to be important for long-term memory, but whether and how 3D chromatin architecture contributes to neuronal plasticity and memory consolidation are largely unknown. To assess memory upon perturbation of crucial 3D chromatin controller, here we utilized the conditional knockout (cKO) mice, in which CCCTC-binding factor (CTCF) is lost in neurons during adulthood. This enabled us to circumvent the lethal effect of CTCF deletion during the embryonic or postnatal development. Our CTCF cKO mice were viable for more than 8 months and showed normal recent memory in contextual fear conditioning and spatial water maze task. However, they surprisingly showed remarkable impairments in remote memory in both tasks. Underlying the remote memory-specific phenotypes, we found that loss of CTCF disrupts cortical long-term potentiation (LTP) but not hippocampal LTP. CTCF knockdown in cultured cortical neurons altered the expression of hundreds of genes, some of which we uncovered to be regulated by neuronal activity. These results suggest that remote memory storage in the cortex requires CTCF-mediated chromatin regulation in neurons while recent memory formation in the hippocampus does not.

Title: Role of nuclear receptor Nr4A in hippocampus dependent memory formation: A single-cell RNA seq approach

Authors: *S. CHATTERJEE[1], M. E. GAINE[1], E. BAHL[2], J. J. MICHAELSON[2], T. ABEL[1]
[1]Dept. of Mol. Physiol. and Biophysics, [2]Dept. of Psychiatry, The Univ. of Iowa, Iowa City, IA

Abstract: New experiences are initially encoded as labile short-term memories, which are converted into stable long-term memory by gene transcription-dependent processes. Gene expression after learning involves a transient wave of transcription that is critical for memory consolidation. Following early transcriptional activity, learning also induces persistent long-lasting transcriptional changes that are reported to be involved in the storage of long-term memory. Increased transcript levels of 13 nuclear receptors, including all 3 members of the Nr4A subfamily, have been identified after learning. In this study, we show that transgenic mice expressing a dominant-negative form of NR4A (Nr4ADN) in forebrain neurons are impaired in long-term spatial memory consolidation. RNA sequencing from dorsal hippocampus after spatial object recognition task shows downregulation of genes related to long-term spatial memory and glutamate receptors. Differential splice variants, miRNA and long non-coding RNA expression is presently been analyzed. We are also using single cell RNA seq approach to measure gene expression from specific CA1 neurons responsive to learning from control and Nr4ADN mice. To measure mutant Nr4A occupancy on gene promoters, we are using YFP sorted cells (Nr4ADN fused with YFP) from dorsal hippocampus to perform X-ChIP and CUT & RUN. Therefore, the present study investigates the mechanism of Nr4A function and further underscores the importance of Nr4A during hippocampus dependent memory storage.

Title: Hippocampal 5-HT2A receptors regulate Rac1 activity for forgetting of contextual fear memory

Authors: *L. JIANG[1], Y. YIN[2], R. MAO[3], L. XU[4]
[1]Dali university, Yunnan, China; [2]The third People's hospital of Yunnan province, Kunming, China; [3]Key Lab. of Animal Models and Human Dis. Mechanisms, [4]Kunming Inst. of Zoology, the Chinese Acad. of Sci., Kunming, China

Abstract: Excessive fear can lead to mental disorders such as phobias and posttraumatic stress disorder. Serotonin is an ancient neurotransmitter, involved in modulating the acquisition of conditioned emotional memory such as fear and anxiety. The serotonin 2a receptor (5-HT2aR) may be one of the important postsynaptic targets to mediate such effects. Here, we investigated whether activation of hippocampal 5-HT2aR in rat could contribute to the hypermnesia of contextual fear. We found that spaced but not massed training of contextual fear conditioning caused up-regulation the expression of 5-HT2aR in the hippocampus and heightened contextual fear. Intrahippocampal injection of the 5-HT2aR antagonist MDL11939 weakened contextual fear in spaced training, while 5-HT2aR agonist TCB-2 heightened contextual fear in massed training rats. Furthermore, we found that TCB-2 induced obvious inhibition of Rac1 activity in the hippocampus. Our study firstly demonstrates that contextual fear memory in rats is actively regulated by 5-HT2aR in the hippocampus. We propose that forgetting of contextual fear is modulated by counteracting components of a molecular pathway involving 5-HT2aR, Rac1 and cofilin. Our data suggest that this pathway could provide a suitable target for therapeutic treatment of emotional disorders

Title: Association between completeness of context memory formation and the number of cells incorporated into hippocampal neuronal ensembles after learning

Authors: *J. A. LEAKE[1], R. ZINN[3], L. H. CORBIT[2], B. VISSEL[3]
[1]The Univ. of Sydney, Sydney University, Australia; [2]The Univ. of Sydney, Sydney, Australia; [3]The Univ. of Technol. Sydney, Sydney, Australia

Abstract: In a contextual fear conditioning paradigm, animals require a minimum period of time in the context prior to shock to display substantial conditioned fear at test. This period is thought to be necessary for animals to form an integrated representation of the context, which then comes into association with the shock. According to this model, longer placement shock intervals support the generation of a more complete contextual representation within the hippocampus. Yet, the neural underpinnings of this increasing completeness have yet to be systematically investigated. In the present study, we tested the hypothesis that the placement shock interval controls memory completeness by limiting the number of cells activated and incorporated into the memory circuit during learning. Consistent with this, we found that longer intervals were associated with increasing numbers of immediate-early gene expressing cells within the hippocampus across an extensive PSI range. This suggests that the hippocampus continues encoding information many minutes into a learning session, and that the number of cells activated during learning may be a correlate of the completeness of memory acquisition.

Title: Up-regulation of dorsal hippocampal kappa-opioid receptors modulate fear memory intensity during consolidation in rats

Authors: *T. C. DE LIMA[1], F. VANZ, 88040-970[2], M. A. BICCA[3], M. GIACHERO[2], L. J. BERTOGLIO[2]
[1]Univ. Federal de Santa Catarina, Florianopolis, Brazil; [2]Pharmacol., Federal Univ. of Santa Catarina, Florianopolis, Brazil; [3]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Kappa-opioid receptors (KORs) are expressed in brain regions involved in aversive memory consolidation, including the dorsal hippocampus (DH). The present study sought to investigate the contribution of DH KORs to contextual fear memory consolidation. Male Wistar rats were conditioned to the context A with one shock (0.7 mA) and received a bilateral infusion into the DH of vehicle (VEH) or the selective KOR antagonist *nor*-Binaltorphimine (*nor*-BNI 1, 3 or 10 nmol/hemisphere) 0 or 6 h later. In certain experiments, *nor*-BNI was infused immediately after an unpaired shock (immediate shock). Test session was performed one (test A1) and seven (test A2) days after the conditioning day. Freezing behavior was measured as an index of memory retention. In the KORs immunoblotting analysis, animals were conditioned (except the *naive* group) and the DH was dissected 0, 1, 3 or 6 h later. Finally, animals were conditioned (context-shock pairing) or just exposed to contextual (context no-shock) or aversive (immediate shock) components, and the DH was dissected 1 h later. In experiment 1, infusion of *nor*-BNI 3 or 10 nmol immediately after conditioning increased freezing time in both tests A1 and A2 when compared with respective VEH groups (Test A1: VEH = 40 + 5%, *nor*-BNI 3 = 80 + 5%, *nor*-BNI 10 = 68 + 6%; Test A2: VEH = 36 + 4%, *nor*-BNI 3 = 69 + 3%, *nor*-BNI 10 = 65 + 4%). Moreover, *nor*-BNI 3 nmol infused 6 h after the conditioning session (experiment 2) or immediately after the immediate shock (experiment 3) had no effect on freezing behavior ([VEH = 38 + 9% vs. *nor*-BNI 3 = 39 + 6%] and [VEH = 11 + 2% vs. *nor*-BNI 3 = 12 + 2%], respectively). In experiment 4, contextual conditioning induced an increase in DH KORs immunoblotting content in groups 1 and 3 h when compared with *naive* or 0 h groups (Naive = 100 + 11%, 0 h = 101 + 12%, 1 h = 163 + 21%, 3 h = 171 + 17%). Finally, in experiment 5, shock-context group, but not context or immediate shock groups, showed DH KORs immunoblotting content increased 1 h after training session (Naive = 100 + 13%, Context no-

shock = 147 + 13%, Context-shock pairing = 171 + 24%, Immediate shock = 114 + 8%). Altogether, these results suggest that DH KORs are up-regulated during an associative aversive experience, with their activation playing an important modulatory role in contextual fear memory consolidation. Title: Selective PKR inhibition restores short-term memory deficits in apoE4-carrying mouse

Authors: D. IBGHI[1], *V. TAUPIN[2,1], P. BERNARDELLI[2], N. MOINDROT[1], P. GONIOT[1], E. GENET[1], C. VINCENT[1], V. ROUDIERES[1], V. FLEURY[1], A. KRICK[2], M. LOPEZ-GRANCHA[1]
[1]Neurodegeneration Research, Neurosci. Therapeut. Area, Sanofi, Inc., Chilly-Mazarin, France; [2]Sanofi R&D, CHILLY-MAZARIN, France

Abstract: Alzheimer's disease (AD) pathogenic mechanisms such as high brain levels of Aβ species, neuroinflammation, or presence of the main risk-promoting allele apoE4 lead to activation of the protein kinase R (PKR). PKR is a pro-apoptotic kinase that is activated by auto-phosphorylation, leading to phosphorylation of the translation initiation factor eiF2α. Phosphorylated eiF2α (peiF2α) selectively stimulates the translation of ATF4, a repressor of CREB-mediated memory function.
In AD patients, activation of PKR was evidenced by elevated levels of both phosphorylated PKR (pPKR) and peiF2α in brain. Increased pPKR was confirmed in CSF from AD individuals and it has been associated to faster cognitive decline.
In apoE4 carriers, enhanced pPKR levels have been seen in lymphocytes. Also, the presence of apoE4 has been associated with overexpression of ATF4 in brain. In agreement with these findings, mice carrying the human apoE4 isoform show both cognitive impairment and increased levels of pPKR and peiF2α in brain, when compared to apoE3 mice.
Here, we show that subchronic oral treatment with a brain blood barrier permeable selective PKR inhibitor (SAR439883) restores short-term memory deficits in apoE4 mice. This pro-cognitive effect was associated with highly selective, robust and dose-dependent inhibition of

PKR activity in the brain, as measured by both the PKR occupancy and the reduction of peIF2α levels. Remarkably, these effects were achieved from the lowest tested dose of SAR439883 with free brain concentration of 0.1 µM corresponding to 34 % PKR occupancy, which was consistent with the efficacy seen in vitro.
Our results indicate that PKR overactivity is strongly involved in the apoE4-mediated short-term memory deficits in mice. Moreover, they suggest that PKR inhibition could be a potential strategy for the treatment of diseases leading to memory impairment.

Title: Cognitive responses to recurrent administration of intraperitoneal lipopolysaccharide

Authors: *B. J. KUPFERSCHMID[1], P. J. ROWSEY[2]
[1]Univ. of Michigan-Flint, Flint, MI; [2]The Univ. of North Carolina at Greensboro, Greensboro, NC

Abstract: Older individuals are susceptible to infections and recurrent infections are not uncommon. While an infection in older individuals may result in a decline in cognitive functioning, minimal literature exists on the impact of recurrent infections on cognitive

responses. In animals, symptoms of infections such as anorexia and cognitive changes, can be mimicked by administration of Lipopolysaccharide (LPS), a component of the cell wall of gram-negative bacteria. To model a recurrent infection, we examined the effects of intraperitoneal administration of 300 μg/kg LPS (n=5) or saline (n=5) for three consecutive days, followed by two weeks of rest and three additional days of LPS/saline injections. Aged (22 months) male Brown-Norway rats were trained 5 hours after injections for 6 days in the Morris water maze (MWM), a hippocampal-dependent test of spatial learning. Animals were assessed on days five and six of each week. Outcomes measured were spatial learning, food intake, and weight. Directional heading error (DHE), the degree of error in heading toward a hidden platform, and swim time latency were measured as indicators of spatial learning. Probe trials were conducted to assess retention. To determine if outcomes varied between the weeks, all outcomes were analyzed using week as a binary variable. LPS treated animals consumed less food ($p = .003$) and lost more weight than controls ($p = .001$). LPS treated animals also exhibited greater DHE over both weeks ($p = .062$) and while not significant, the LPS group took longer to reach the platform. Although there was not an experimental effect for probe trials, the experimental group travelled less in the correct quadrant. While there were no differences in treatment effect on spatial learning indicators or weight change between the two weeks, there were significant differences in treatment effect on mean food intake ($p < .0001$) with the experimental group increasing intake during week two. Despite some improvement in sickness responses in aged rats, as evidenced by food intake, recurrent exposure to LPS resulted in a trend toward spatial learning deficits including impaired directional heading. These results suggest that older individuals may be more at risk for cognitive impairment following recurrent infections.

Title: Acute exposure to acetaminophen impairs object recognition memory in mice

Authors: *T. M. MILEWSKI[1], S. PATEL[1], C. A. STAPF[1], S. N. WIERBOWSKI[1], P. T. ORR[1,2]
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: The over the counter drug acetaminophen has been used for decades, but recent reports suggest that it has significant effects on cognition. Acute exposure to acetaminophen decreases emotional pain (Dewall et al, 2010) and dulls emotional processing (Durso, Lutterell &Way, 2015) in humans. However, it is not currently known if such acute exposure affects

memory. In this study, we show a dose-dependent impairment on hippocampal memory formation in an object recognition task in mice. 40 male mice were injected with vehicle, 10mg/kg, 50mg/kg, or 100mg/kg of acetaminophen immediately following training in a hippocampal-dependent object recognition memory task. Mice receiving 10 mg/kg of acetaminophen showed a significant preference for the novel object ($t(9) = 2.308$, $p = .046$), demonstrating intact memory for the familiar object, whereas there was not a significant novelty preference in the mice receiving 50 mg/kg ($t(9) = 1.618$, $p = .14$) or 100 mg/kg ($t(9) = .24$, $p = .816$) of acetaminophen. Subsequent to behavioral testing, brain samples were taken for analysis of cell-signaling events downstream of acetaminophen injection. Overall, these data demonstrate that acute, post-training exposure to 50 mg/kg or 100 mg/kg acetaminophen is sufficient to disrupt hippocampal-dependent memory consolidation.

Title: Microanatomy of fear memory consolidation and extinction within sub-regions of the prefrontal cortex and amygdala revealed by Arc and pERK/MAPK activity

Authors: *A. JACQUES[1,3,4], N. CHAAYA[1,3,4], A. BATTLE[2,3,4], L. R. JOHNSON[1,3,4,5]

Institute, Queensland Univ. of Technol., Woolloongabba, Australia; [5]Ctr. for the Study of Traumatic Stress, Dept. of Psychiatry, USU Sch. of Med., Bethesda, MD

Abstract: Post-traumatic stress disorder is a memory-based disorder characterized by enhanced responses to perceived threats and a reduction in the ability to extinguish fearful memories. The generation of fearful or threat memories involve aspects of Pavlovian association between unconditioned, aversive (US) and conditioned, neutral (CS) stimuli. In order to understand the micro-anatomical organization of fear / threat memory processes and guide the development of brain region focused treatments for PTSD, a complete understanding of the micro-anatomical and molecular events underlying threat memory consolidation and extinction is required. Following Pavlovian fear conditioning (CS+USx3), we performed an ‘extended extinction’; rats received 3 days (d) of 20xCS, then 3d home cage prior to a fear memory test (3xCS). Phospho-ERK/MAPK (pMAPK) and Arc protein (Arc/Arg3.1) are sequentially activated markers of

neuroplasticity in response to memory. We investigated Arc and pMAPK immunoreactivity to measure micro-circuit localization of memory in the basolateral amygdala (BLA) known for its role in extinction and the infralimbic cortex (IL) reported to modulate the formation of new extinction memories, in fear memory and 'extended extinction' recall conditions. The relative contribution of pMAPK and Arc were measured in left and right hemispheres respectively (n = 40 animals). Initial results indicate numerically similar contributions of pMAPK and Arc activity in neurons occurring during extinction memory recall within the BLA and IL. Initial investigation also reveals specific sub regions and cortical layers differ in expression of pMAPK and Arc during extinction memory recall. These findings begin to identify the spatial and temporal properties of extinction memory micro-circuits and increase understanding of the mechanisms of pathological fear.

Title: Hookworm infection attenuates hippocampus-dependent learning by inhibiting memory consolidation

Authors: *Z. KOLO[1], T. M. BROMBACHER[1], K. S. DE GOUVEIA[1], L. CRUYWAGEN[1], F. BOOLEY[1], M. DARBY[1], F. BROMBACHER[2]

Abstract: Previous studies have demonstrated the importance of IL-4 producing T cells in the meninges on cognitive function following hippocampal-dependent spatial learning and memory using Morris water maze task. This study aims to investigate the role of neuro-immune interactions on spatial learning and memory following infection with N.brasiliensis, a model of the hookworm N. Americanus. Cognitive function was investigated in mice using the Morris water maze. Mice were given 4 trials a day for 4 consecutive days and trained to locate a circular platform placed approximately 0.5 cm below water level in a circular Morris water maze. On tests of anxiety, thigmotaxis, percent immobility and immobility frequency were increased, while movement was significantly reduced in response to training.Distance swam, swim speed, and latencies to platform during acquisition were similar across groups, with fewer platform crossings by infected mice compared to naive during reference memory. These results correlated directly to reduced brain derived neurotrophic factor (BDNF) with infection, increased macrophages with training and infection, as well as increased microglia with training, but not

infection. Both speed and distance swam were ruled out as factors for any cognitive differences in this study. Because infection plays a role in anxiety defining behavior, we conclude that anxiety interferes with memory consolidation during the acquisition phase of the task as characterized by impaired reference memory, and reduced BDNF. We also conclude that an increase in macrophages due to infection inhibits learning whereas an increase due to training enhances learning. However, the presence of macrophages during infection may also play a role in enhanced learning. Infection alone dampened production of IL-4 by macrophages, while infection with training, showed increased IL-4 production. Overall, we conclude that hookworm infection is detrimental to learning and memory by means of inducing anxiety that interferes with memory consolidation, and that macrophages recruited during infection impair reference memory possibly by production of both IL-4 and IL-13 that in above baseline levels affect memory consolidation without "harming" acquisition. In addition to showing the involvement of microglia in cognitive function we also show that their numbers are reduced during hookworm infection. We show that IL-13, but not necessarily IL-4 appears to steer microglia driven learning and memory in the absence of infection.

Title: High demand of hippocampal glucose and lactate during memory formation in early development

Authors: *E. CRUZ[1], A. TRAVAGLIA[2], C. M. ALBERINI[3]
[1]Ctr. for Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY; [3]Ctr. for Neural Sci., [2]New York Univ., New York, NY

Abstract: Hippocampal glycogenolysis and astrocyte-neuronal lactate metabolic coupling are necessary in the adult rat hippocampus for the consolidation of inhibitory avoidance (IA) memory as well as for in-vivo hippocampal long-term potentiation. Here, we investigated the role of hippocampal glucose and lactate metabolism in memory consolidation during early

development. Specifically, we focused on rats at postnatal day 24 (PN24), a young age when rats have just acquired the ability to form strong and long lasting hippocampal-dependent memories. Quantitative polymerase chain reaction array (qPCR-array) of dorsal hippocampal RNAs revealed that 40 out of 84 glucose metabolism-related genes were up-regulated in PN24 rats compared to the adult rats (PN80). In addition, IA training led to significant increases in both hippocampal extracellular glucose and expression of the glucose transporters (GLUT1 and GLUT3) in PN24 rats. Inhibition of hippocampal glycogenolysis with 4-dideoxy-1, 4-imino-D-arabinitol (DAB), or knockdown of GLUT3 or lactate transporters (Monocarboxylate transporters 1, 2, and 4) impaired IA memory formation in PN24 rats. Unlike in adult rats, both, D-glucose and L-lactate persistently rescued these memory impairments. Furthermore, higher levels of D-glucose and L-lactate were required to rescue the memory impairments of PN24 rats compared to adults, suggesting that the developing hippocampus requires higher levels of these metabolic substrates to form long-lasting memories. We conclude that hippocampal metabolic requirements and possibly mechanisms underlying memory formation during development differ from those of adults.

Title: Alcohol exposure during gestational development alters spatial extinction behavior in adult male and female rats

Authors: *C. M. MAGCALAS[1], J. WAGNER[2], D. D. SAVAGE[2], D. A. HAMILTON[1]
[1]Psychology, [2]Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: Prenatal alcohol exposure (PAE) is associated with structural and physiological changes that impact the central nervous system and can result in persistent negative consequences in a broad spectrum of cognitive and behavioral domains including deficits in motor behavior, social behavior, and behavioral flexibility. Previous studies have characterized the influence of PAE on spatial navigation acquisition and extinction through various behavioral paradigms including the Morris water task (MWT). The current study focuses on examining the behavioral consequences of PAE on spatial extinction behavior through the use of the MWT.

Pregnant rat dams voluntarily consumed saccharin (SAC) water containing 0% or 5% ethanol (EtOH) for 4 hours per day during the entire gestational period. Male and female pups matured and were tested in the MWT in adulthood (>90 days old). In order to assess extinction behavior the animals were tested in a 5-day hidden platform protocol. Days 1-4 of the hidden protocol consisted of 12 training trials. At the end of day 4, the animals were tested in 3 consecutive no-platform probe trials to assess extinction behavior. Day 5 began with one no-platform probe trial to assess spontaneous recovery followed by 12 retraining trials. All of the animals successfully learned the hidden platform goal location during the initial training period. All of the male animals (PAE and controls) failed to extinguish, which was evident by the consistent short latency to reach the learned target location. The control females successfully extinguished, but the ethanol exposed females failed to extinguish the learned behavior. These outcomes suggest that animals exposed to moderate levels of ethanol during gestation have intact spatial acquisition abilities, but may have distinct extinction behaviors that may be sex specific and can be influenced by PAE. [Supported by grant AA019462 to DH].

Title: How much gestational noise stress impairs reproduction activates HPA axis and damages behavior in mice

Authors: *Z. JAFARI, J. MEHLA, B. E. KOLB, M. H. MOHAJERANI
Dept. of Neurosci., Univ. of Lethbridge, CCBN, Lethbridge, AB, Canada

Abstract: Maternal stress is a common adversity during pregnancy. Noise exposure is a known environmental pollutant whose adverse effect on health has been less studied. We used “noise” as a gestational stress compared with physical stress to explore the effect of stress during gestation on hypothalamic-pituitary-adrenal (HPA) axis activation, cognitive performance, and behavior in the dams and their offspring. Noise stress caused higher rates of resorbed embryos

and reduction of litter, as well as an increase in anxiety-like behavior and reduced time spent exploring new environment compared to the physical stress and control groups. It also severely impaired the HPA axis activation, as well as cognitive, memory, and balance function as large as or stronger than the physical stress in both mothers and offspring. Both prenatal stresses also caused a strong susceptibility to environmental experiences as stressful conditions in the offspring. The findings suggest the significance of conservation against loud noise exposure in daily living, as well as need to further notice to the different aspects of gestational stress on health.

Title: Acute restraint stress impairs object recognition memory in female mice

Authors: C. A. STAPF[1], K. N. WALTER[1], K. E. TALERICO[1], *P. T. ORR[2,1]
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: It has been well established that hippocampal-dependent memory formation in rodents is affected by acute and chronic stress. However, this has been established primarily in male rodents, even though hippocampal-dependent tasks, such as object recognition, are sensitive to steroid hormones such as estradiol and progesterone, which cycle in intact females. Given the recent decision by the National Institutes of Health to highlight sex as a biological variable in biomedical research, it is critically important to establish baseline effects such as this in females. In this study, we examined intact female mice to determine if acute restraint stress impaired performance on a novel object recognition memory task, as it does in male mice. Adult (8 week old) intact female mice were trained in an object recognition task and subsequently restrained for 1 hour. During testing, control (unrestrained) mice showed a significant preference for the novel object ($t(11)=2.368$, $p=0.037$) suggesting intact memory. Restrained mice did not show a preference for the novel object ($t(12)= -.189$, $p=0.854$), suggesting a lack of memory. Two weeks after behavioral testing, mice were again restrained for one hour and hippocampus was dissected out for analysis of cell-signaling cascades. Acute restraint stress significantly impairs hippocampal-dependent consolidation of object recognition memory in intact female mice.

Title: Phases of the estrous cycle modulate renewal of appetitive and fear behavior

Authors: *E. HILZ, M. MONFILS, H. LEE
Psychology, Univ. of Texas At Austin, Austin, TX

Abstract: The gonadal hormone estradiol has been shown to increase synaptic plasticity in the hippocampus, an area of the brain known to play an important role in contextual information processing. The hippocampus mediates both renewal and memory retrieval of conditioned fear after extinction, but little research has examined if natural fluctuations in estradiol across the estrus cycle modulate the expression of contextual learning and memory. In the present experiment, we examine whether the level of estradiol present during extinction - either low-estradiol during the metestrus/diestrus (M/D) phases of the estrous cycle or high-estradiol during the proestrus (P) phase of the estrous cycle - plays a role in contextual renewal of appetitive and fear behavior. Female and male Sprague-Dawley rats were exposed to both appetitive and fear acquisition and extinction procedures and tested for renewal of conditioned behavior in an ABBA design (i.e., acquisition in context A, extinction in context B, and test in both contexts A and B). Appetitive results suggest that if female rats were in the P phase during extinction, they show significantly higher renewal of behavior in the original training context as compared to the females that were in M/D phase during extinction. Male rats did not significantly differ from either group. Preliminary results suggest that the estrous cycle may modulate renewal of extinguished fear differently. In general, our results suggest that estradiol levels might modulate contextual information processing during extinction.

Title: Anterior thalamus regulates interactions between hippocampus and retrosplenial cortex

Authors: *N. A. KAMBI, J. M. PHILLIPS, Y. B. SAALMANN
Dept. of Psychology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Episodic memory is the capacity allowing us to consciously remember objects and events from our personal past. A large body of evidence suggests that the hippocampus and retrosplenial cortex play an important role in episodic memory. However, the nature of interactions and the information flow between these brain regions for supporting episodic memory and spatial processing remains unclear. The anterior thalamus is reciprocally connected with both the hippocampus and retrosplenial cortex, and anterior thalamic lesions can give rise to memory deficits. We thus hypothesized that the anterior thalamus supports episodic memory by regulating information transmission between the hippocampus and retrosplenial cortex. To test our hypothesis, we simultaneously recorded spikes and local field potentials (LFPs) from the anterior thalamus, hippocampus (subiculum) and retrosplenial cortex of two macaques performing a visuospatial episodic-like memory task. We used diffusion MRI to target linear electrode arrays to interconnected sites of this hippocampo-thalamo-cortical network (1mm isotropic, 60 diffusion directions, b=1000s/mm^2 and NEX=14, using a 3T GE MR750 scanner and 16-channel receive-only head coil), and structural MRI of electrodes in situ to confirm electrode positions (0.5mm isotropic). Our preliminary electrophysiological data show bidirectional conditional Granger causal influences in the 5-15Hz range between the hippocampus and retrosplenial cortex during memory retrieval. During this time, neurons in the anterior thalamus (ventral division) responded preferentially to particular learnt visual scenes. We also measured increased coherence between thalamic spikes and the LFPs in both the hippocampus and retrosplenial cortex, in the 5-15Hz range. Further, the anterior thalamus showed increased conditional Granger causal influences on the hippocampus and retrosplenial cortex in the same frequency range. These preliminary data suggest that the anterior thalamus regulates information transmission between the hippocampus and retrosplenial cortex based on episodic memory demands. The underlying mechanisms appear to include the anterior thalamus synchronizing activity between the hippocampus and retrosplenial cortex. Overall, this study supports an important role for the anterior thalamus in the extended hippocampal system supporting episodic memory.

Title: Neuronal activity in the retrosplenial cortex of rats performing a visuospatial attention task

Authors: *E. HWANG[1], F.-C. YANG[3], T. K. JACOBSON[1], R. D. BURWELL[2]
[1]CLPS, [2]Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI;
[3]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Research in primates and rodents has addressed the role of the retrosplenial cortex (RSC) in a variety of spatial functions including navigation, contextual learning, and the integration of information across spatial reference frames. Anatomical studies of the rodent brain show that RSC is connected with other regions that process spatial information for a variety of purposes, including the hippocampus (navigation and spatial memory), postrhinal cortex (POR, representation of context), and posterior parietal cortex (PPC, visuospatial attention and action selection). An open question is what *core function* of RSC could support the variety of spatial information processing observed in related brain regions. We hypothesize that RSC supports online integration of information across space, time, contexts, and reference frames for use by other brain regions for a variety of functions. To address this hypothesis, we recorded from the RSC in rats performing the visuospatial attention (VSA) task. This task is a purely visual task that was adapted from the five choice serial reaction time task (Bari et al, 2008) for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze (Jacobson et al., 2014). The task involves top-down and bottom-up visuospatial attention, multiple spatial reference frames, and the processing of reward. The animals are trained to attend to three locations and to approach the spot that is briefly illuminated (see figure). Trials alternate east to west. Approach to the correct location is followed by reward. Task epochs included pre- and post-stimulus, pre- and post-selection, and reward. We found that the majority of recorded RSC cells signal both allocentric and egocentric location and also integrate outcome with multiple task events. Additionally, RSC activity increases as the rat progresses through different task epochs, suggesting integration of information across task epochs. Analyses of neuronal correlates will be presented and patterns of selectivity in RSC will be compared with those of the PPC and POR recorded in rats performing the same VSA task.

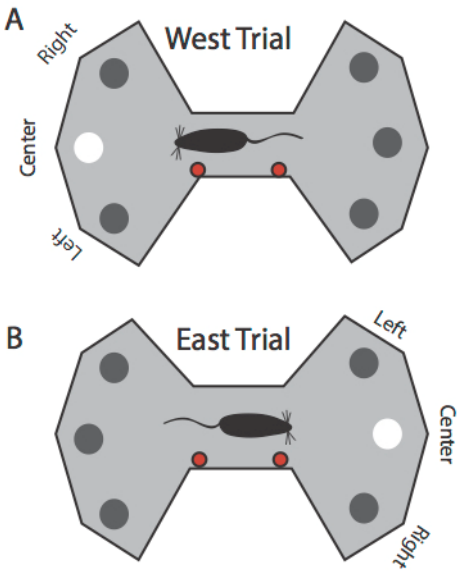

Fig 1. Shown above is an animal in ready position. A shows animal approaching correct stimulus on the West trial and B on the East trial. Animals are rewarded at the reward port (red dots).

Title: Object-location conjunctive coding in the parahippocampal network

Authors: *V. J. ESTELA[1], A. FAROVIK[2], R. D. BURWELL[2]
[1]Neurosci., [2]Cognitive Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: The formation of episodic memories requires a network capable of representing objects within a complex context, allowing for recollection of events in time and space. These contexts consist of items, places, patterns, as well as the specific spatial arrangement of these elements. Structures in the medial temporal lobe, specifically the perirhinal (PER) and postrhinal (POR) cortices, are crucial for contextual learning. Our overarching hypothesis is that the POR integrates object information from the PER with spatial information from the posterior parietal and retrosplenial cortices to represent the spatial layout of objects, patterns, and features in the local environmental context. Further, we hypothesize that the hippocampus (HC) relies on contextual representations from the POR for associative learning and episodic memory. Prior studies reported that both the POR and HC exhibit object-location conjunctive coding (Furtak, et al., 2012; Komorowski, et al., 2009). Such conjunctions could be considered a signature of context representations, but they could also reflect associative learning. Indeed, object-location conjunctions emerge with learning in the HC. The timing of emergence of object-location conjunctions in the POR is unknown. One possibility is that the object-location conjunctions in the POR reflect a complete representation of the local spatial environment, whereas the HC uses this representation of the spatial environment or context for episodic memory and in the formation of associative memories. If our hypothesis is correct, object-location conjunctions should be present in the POR before they emerge in the HC. To test this prediction, we will record in the POR and HC during performance on the location biconditional discrimination (locBCD) task in the floor projection maze. In this task, presentation of a pair of objects alternates between the east and west sides of a bowtie-shaped maze. The east-west location determines which of the two objects is correct. Finding object-location conjunctions in the POR prior to the HC would be consistent with the interpretation that object-location conjunctive coding in the HC relies on POR representations of context. Future studies will address this interpretation in circuit analysis experiments that utilize dual-site recording of the POR and HC as well as experiments that combine electrophysiology and optogenetics in rats performing the locBCD task.

Title: Bio-plausible models of ACC function in a novel probabilistic reversal learning task

Authors: *R. M. FRANCIS[1], R. A. WIRT[2], J. M. HYMAN[3]
[1]Psychology, UNLV, Las Vegas, NV; [3]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: The anterior cingulate cortex (ACC) is often associated with learning and decision-making due in part to its vast array of behaviorally-related electrophysiological signals. Most notably, some ACC neurons carry signals that classify outcomes as either rewarding or non-rewarding, here called outcome-tracking signals. Additionally, experimental evidence suggests that the ACC generates the feedback-related negativity signal (FN), which is an event-related potential modulated by the probability of receiving different outcomes. Currently, the roles of ACC outcome-tracking signals and the FN in learning, decision-making, and ultimately preference formation are unknown. Here we report a novel behavioral task that helps to better characterize these processes. Our probabilistic reversal task allowed us to observe the formation of different behavioral preferences within rodent subjects multiple times in a single session. This task featured two ports, one with a 75% probability of yielding a reward, and the other with a payout probability of 25%. On *cued* trials, subjects were randomly prompted to nose-poke at one of the two ports. This action would trigger one of two feedback scents to be pumped directly into the port. One scent signaled that reward in the form of a sugar pellet would follow 1 second later, and the other scent signaled that no reward would be available on that trial. After every four *cued* trials, there was a *probe* trial where both ports would be active. *Probe* trial choices permitted us to assess the degree of behavioral preference for the 75% port and how preference was affected by recent *cued* trial outcomes. We set a behavioral preference criterion of three consecutive *probe* trial choices of the 75% port ($p<.05$). Once this threshold was met, the reward probabilities of the two ports were reversed, the threshold counter was wiped, and the task continued. Some subjects achieved up to 5 reversals in a single 1-hour session. We created a series of computational models to characterize behavioral transitions between preferences that existed before and after reversals. Some models used mechanisms based on ACC outcome-tracking signals and the FN to assess whether these models outperformed conventional models' ability to fit the data. Analyses revealed that the bio-plausible models (featuring outcome-tracking signals and FN homologues) more accurately predicted when behavioral preferences formed in comparison to their conventional versions, suggesting that these outcome-related ACC signals have a specific relationship, and actually play an integral role in decision-making and preference formation.

Title: Expectation and outcome representations combine to create a novel signal in ACC neurons underlying the FN

Authors: *J. M. HYMAN[1], C. B. HOLROYD[2], J. K. SEAMANS[3]
[1]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV; [2]Univ. of Victoria, Victoria, BC, Canada; [3]Psychiatry, UBC, Vancouver, BC, Canada

Abstract: The function of the anterior cingulate cortex (ACC) remains controversial, yet many theories have emphasized its importance in dynamically changing environments where expectations are frequently violated. This view is motivated in part by observations of a human event-related potential termed the feedback-related negativity (FN) that is evoked over the ACC whenever such violations occur. Although the FN is thought to depend on prediction errors, it is not clear how predictions and prediction errors are encoded in ACC and how they lead to an FN. To address these issues we recorded from ACC neurons while rats performed a task identical to one that reliably evokes a robust FN in humans. On each trial the rats were cued to perform a nose poke (NP) at one of 3 ports (each with a different payout probability) at which point a feedback scent was delivered informing the rat whether the trial would be rewarded or not. A subset of ACC neurons was found that encoded expected outcomes according to recent outcome history. Specifically, responses during the NP mimicked responses to either the positive or negative feedback scents on trials preceded by many rewarded or non-rewarded outcomes respectively. The representation of expected outcomes persisted throughout the trial until the actual outcome feedback scent was delivered, at which point the ensembles shifted from representing the expected to actual outcome on incongruent trials. This shift occurred at the same point in the trial where an FN-like response was observed in ACC field potentials (Warren et al., 2015). Thus the present study identified the requisite neural components of prediction error signaling in ACC and demonstrated the novel way in which they interact to produce an FN.

Title: It's about time: Electrophysiological evidence for temporally mediated consolidation of spatial memories

Authors: *R. A. WIRT[1], L. A. CREW[1], K. R. ZHA[1], N. L. KAPLAN[1], R. M. FRANCIS[1], J. M. HYMAN[2]

Abstract: Formation and retrieval of new spatial information is highly dependent on the hippocampus (HC), but over time these memories become increasingly reliant on other areas, including the anterior cingulate cortex (ACC) (Bontempi et al., 1999). We hypothesized that if this were the case then the retrieval of older spatial memories would engender different

interactions between the HC and ACC than more recent memories would. Specifically, there should be changes in synchrony between these two areas and the direction of the interactions should shift from the HC leading for recent memories to the ACC leading for more remote retrieval. To assess this, we recorded both single units and local field potentials from the ACC and HC as animals were exposed to unique spatial environments and then re-exposed to those same environments at differing time delays (1-14 days). Behavioral data revealed a significant decrease in exploration-related movement as early as the second exposure regardless of the delay period, indicating that the animals quickly became familiar with the environments. We found that neural synchrony between the ACC and HC was significantly stronger on the remote retrieval days, despite no discernible behavioral differences from recent retrieval days. These effects were found in theta and gamma band coherence, phase synchrony, and ACC unit phase locking to HC theta. Time-lag correlation analysis revealed that while on days 1-7 HC theta activity led the ACC, on day 14 this effect reversed and theta in the ACC now led the HC. Additionally, there were no significant changes in ACC-HC synchrony until 14-days after initial exposure regardless of the number of previous experiences, supporting the conclusion that the operative variable affecting these interactions was the passage of time. We also observed increases in bilateral ACC synchrony on day 14, which may be indicative of an ACC mediated retrieval of remote memories. These results reveal a clear electrophysiological signature of spatial memory consolidation to the ACC, and they pinpoint that the observed changes were due to time passing and not other possible factors.

Title: Familiarity-induced activity patterns in the LEC and PER in the absence of a functional hippocampus

Authors: *L. MAHNKE[1,2], E. ATUCHA[1,2], T. KITSUKAWA[3], M. SAUVAGE[1,2,4,5]

Abstract: Recognition memory relies on the recollection and the familiarity processes. It is a consensus that the hippocampus supports recollection, but a major debate remains whether this brain area also supports familiarity or whether the parahippocampal region does, especially the perirhinal (PER) and the lateral entorhinal (LEC) cortices. Using a high resolution molecular imaging technique based on the detection of the immediate-early gene *Arc*, closely tight to synaptic plasticity, memory performance and commonly used to map activity in the medial temporal lobe, we recently showed that the PER and the LEC are selectively recruited during familiarity-only judgements in rats with intact hippocampal function, while the hippocampal subfields CA1 and CA3 are not (see Atucha et al., *submitted*). However, it remained unclear whether this recruitment was completely independent of the hippocampus. To address this question, we imaged brain activity in the PER and the LEC of rats with lesioned hippocampus performing a delay non-match to sample memory task, as performance under these conditions rely on familiarity (Fortin et al., *Nature*, 2004), and investigated whether activity patterns in the PER and the LEC were affected when hippocampal function was compromised. Preliminary data indicate this is not the case, suggesting that familiarity-induced patterns of activity detected in the LEC and the PER are independent of the hippocampus, and giving further support to the claim that the PER and the LEC support familiarity and not the hippocampus.

Title: Identifying olfactory neural circuits in adult *Drosophila* using high-speed whole brain functional imaging (SCAPE)

Authors: *N. MISHRA[1], W. LI[2], E. S. SCHAFFER[1], V. VOLETI[2], E. M. HILLMAN[2], R. AXEL[1]

Abstract: While imaging small brain regions or even single neurons has revealed a lot about neural processing, the insights we gain from looking at larger populations are very different. Imaging neurons across the brain affords us the possibility to observe the relationship of activity in one part of the brain versus another. Toward this goal, we are using high-speed light sheet microscopy to do pan-neuronal calcium imaging in adult *Drosophila*.
We use Swept Confocally Aligned Planar Excitation (SCAPE) microscopy to observe the activity at single-cell resolution across the entire brain volume at speeds up to 20 volumes per second. Due to SCAPE's unique optical set up, a form of light-sheet imaging that uses a single objective lens and a novel scanning-descanning approach, we are able to do high-speed volumetric imaging in a non-transparent animal. During our in vivo imaging, flies expressing pan-neuronal GCaMP are subjected to an odor stimulus controlled via an olfactometer while performing tracked locomotive behavior on an air-supported ball. We test the performance of SCAPE by seeing activity distributed across the brain as our flies navigate a virtual environment. The spatiotemporal capabilities of this methodology will allow us to subsequently study the neural dynamics of more complex behaviors and internal states.

Title: Cholecystokinin from entorhinal cortex switches long-term potentiation in hippocampus

Authors: *J. SU[1], W. YE[2], J. HE[1]
[1]City Univ. of Hong Kong, Hong Kong, China; [2]Guangzhou Inst. of Biomedicine and Hlth., Guangzhou, China

Abstract: Our earlier studies showed that activation of cholecystokinin (CCK) neurons that originated from the entorhinal cortex (EC) induces long-term potentiation (LTP) and neuroplasticity in the auditory cortex. Lesions in EC or hippocampus will lead to memory deficits which have received intensive studies. In the present study, we found CCK peptide knockout mice (CCK-KO) showed severe deficits in spatial memory and hippocampal CA3-CA1 LTP formation induced by high-frequency (HF) electrical stimulation (ES) in vivo. We also found the same HF ES stimulation still induced CA3-CA1 LTP in CCK B-receptor knockout mice (CCKBR-KO), which exhibited normal spatial memory, while CCK A-receptor antagonist Devazepide totally blocked the LTP formation. We thus hypothesize that CCK released in respond to HF ES stimulation participates in LTP formation, the effect of which is mediated by CCKAR in hippocampus CA3-CA1 pathway. We further injected Cre-dependent ChR2-eYFP virus into either hippocampus or EC of CCK-Cre mice, and applied light stimulation in hippocampus. While HF light stimulation of CCK positive neuron in hippocampus, followed by low frequency (LF) ES stimulation of CA3, did not induce LTP, the same HF light manipulation of CCK positive projections from entorhinal cortex initiated LTP in CA3-CA1 pathway. Increased CCK concentration was also detected in hippocampus after HF light stimulation of these EC-originated terminals. We explain that HF stimulation of the EC originated CCK terminals induced CCK release in hippocampus, and LF ES stimulation of CA3 could induce LTP in the presence of CCK. The enhanced connectivity within hippocampus induced by this HF light-stimulation protocol was further supported in a spatial fear memory test, in which the CCK-Cre mice showed fear against both the footshock-given region and the HF light-paired region.

Title: Impaired performance in an object place paired associate task by a rat model of moderate prenatal alcohol exposure

Authors: *L. M. SANCHEZ[1], J. K. GOSS[1], J. WAGNER[2], S. DAVIES[2], D. A. HAMILTON[1], D. D. SAVAGE II[2], B. J. CLARK[1]
[1]Psychology, Univ. of New Mexico, Albuquerque, NM; [2]Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Memory impairments, including spatial and object processing, are often observed in individuals with Fetal Alcohol Spectrum Disorder. Although there is currently no consensus regarding the neuroanatomy for these memory deficits, much attention has been directed towards the hippocampus, which displays significant alterations after prenatal alcohol exposure (PAE). The parahippocampal cortex, which forms a major input-output relationship with the hippocampus, has a role in processing information about spatial locations and environmental features such as landmarks and objects. In the present study, we tested a moderate PAE rat model (Savage et al., 2010) in an object-place paired associate (OPPA) task, which has previously been shown to require hippocampal and parahippocampal processing. In brief, the OPPA task was composed of training rats to discriminate between an identical pair of objects presented in 180° opposite arms of a radial arm maze. Animals were given a total of 10 trials per day over 14 days of training and were rewarded with a piece of cereal after the correct selection of an object. Thus, animals were required to select a particular object on the basis of spatial location. We observed that PAE rats (n = 16) made significantly more errors than saccharin control rats (n = 16) during acquisition of the OPPA task. In Experiment 2, animals were trained in a reversal task which required rats to once again discriminate between identical pairs of object presented in 180° opposing arms. Although the same objects were used as in Experiment 1, the opposite object was rewarded in each arm. Rats were therefore required to flexibly learn a new object-place paired association. Again, animals were given a total of 10 trials per day over a 14 day training schedule. In the reversal task, PAE and saccharin control rats performed comparably, however there were mean differences in acquisition performance on days 7 through 12. Following the reversal task, in which training is halted and restarted in 96 hours to test for memory, PAE rats showed a significant, but mild decrease in performance. In Experiment 3, rats performed an object discrimination task in which rats were trained in a single maze to accurately select a rewarded object from a pair of objects. In this task, moderate PAE and saccharin control rats exhibited comparable performance. The observations of impaired performance, slower learning, and lack of flexibility by moderate PAE animals is discussed in relation to theories of the hippocampal-parahippocampal and limbic system basis of object-place memory.

Title: Reduced spatial coding of hippocampal place cells following moderate prenatal alcohol exposure

Authors: *R. E. HARVEY, J. K. GOSS, T. RIGG, L. E. BERKOWITZ, L. M. SANCHEZ, J. L. WAGNER, D. D. SAVAGE, D. A. HAMILTON, B. J. CLARK
Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: A common behavioral manifestation of prenatal alcohol exposure (PAE) is the loss of spatial memory, which is marked by a general inability to recognize familiar places and to accurately navigate from one location to another. Spatial deficits in PAE have been linked to the hippocampus, which displays reduced synaptic plasticity in moderate PAE models. In vivo electrophysiological recordings from the hippocampus have shown that specific neurons called place cells within CA1, CA3, and dentate gyrus subregions fire when animals enter specific regions of the environment. Each hippocampal place cell fires in a different location indicating that a large population of these cells cover the spatial layout of the environment. It is currently unknown if hippocampal deficits observed PAE animals negatively impact place cell firing. Thus, we performed electrophysiological recordings from the hippocampi (CA1 and CA3) of moderate PAE adult rats (Savage et al., 2010) and saccharin control adult rats. Rats were implanted with high density tetrode arrays aimed at the CA1 and CA3 regions. Following implantation, rats were trained to complete laps on a narrow linear track across multiple 10 - 20 minute sessions while single unit and local field potentials were recorded. Around 200 hippocampal neurons were identified as place cells based on their spatial and firing characteristics. Our results show that hippocampal place cells from PAE rats have severe spatial coding impairments such as reduced spatial information content, increased sparsity, and expanded firing field widths which indicate a lack of place cell spatial specificity. Further, indicative of network deficiencies, PAE rats have reduced theta phase locking and theta power compared to saccharin control rats. In sum, the failure of hippocampal place cell firing to selectively discriminate between spatial locations combined with altered local field potentials provides a potential mechanism to explain spatial memory impairment after PAE.

Title: Sex specific spatial navigation and spatial memory impairment in the TgF344-ad rat model of Alzheimer's disease

Authors: *L. E. BERKOWITZ, S. M. THOMPSON, E. N. DRAKE, J. T. MADDEN, E. A. SNEDDON, R. E. HARVEY, B. J. CLARK
Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: Spatial navigation and memory are impaired in early stages of Alzheimer's disease (AD), and may be a defining behavioral marker of preclinical AD. The advent of transgenic murine and rat models have proved valuable for aspects of neuropathological mechanisms in brain regions involved spatial cognition. Nevertheless, the translational significance resultant from these models may not represent that found in humans given limited pathological expression. However, the TgF344-AD rat model of AD expresses the full spectrum of AD pathology and may serve as a better rodent model for elucidating behavioral markers. In addition, TgF344-AD rats have been shown to exhibit reference memory impairment, though this has not been comprehensively assessed at early age points. This study aimed to characterize spatial memory in TgF344-AD at early ages and over time. TgF344-AD (n=16) and Fischer 344 (n=12) male and female rats were assessed in three paradigms of the Morris Water Maze at 4.3-5.5, 8.7-9.9 and 10.3-11.5 months of age. Measures of escape latency, preference score and search error were obtained. Navigational strategies characterized from swim paths were also obtained. Results indicate that TgF344-AD females exhibited navigational deficits as early as 4.5 months while TgF344-AD males showed impairments at 10.5 months. Furthermore, TgF344-AD males demonstrated acute reference memory impairments at 10.5 months whereas TgF344-AD females were no different from controls. Across all time points, cued navigation, spatial working memory and reference memory remained largely intact between subjects. Overall, these results indicated that TgF344-AD rats exhibit comparable deficits to those found in individuals with MCI and provides further evidence of sexual dimorphisms of AD. Future studies elucidating neurobiological mechanisms of spatial navigation impairment in preclinical AD would therefore benefit from using this model.

Title: Brainwide coherent theta oscillations during visual and olfactory guided spatial learning and memory

Authors: *A. SHERIFF[1,2], L. M. KAY[1,2]
[1]Dept. of Psychology, [2]Inst. for Mind and Biol., The Univ. of Chicago, Chicago, IL

Abstract: Spatial learning and memory (SLM) has been widely studied in basic research of the hippocampus (HPC) primarily using visual cues. However, in navigation nocturnal rodents use multiple orientation mechanisms from multiple sensory sources, including odors. A recent proposal suggests that olfaction evolved primarily in the context of spatial navigation. Therefore, the rodent SLM model may be more ethologically valid when adding olfactory-spatial cues rather than using solely visual-spatial cues. Coherent neural oscillations underlie several component processes involved in SLM (e.g., perception, attention, and memory). However, while theta oscillations (4-14 Hz) are widely implicated in SLM, research on coherent oscillatory activity across widely distributed brain regions implicated in SLM is sparse. In this study, we used behavioral and electrophysiological methods with aims of 1: comparing SLM in rodents across visual and olfactory modalities; and 2: assessing the roles of coherent theta oscillations across olfactory-limbic and neocortical brain areas during SLM with olfactory vs. visual cues. We appetitively conditioned Long Evans rats to a single location within a four-arm radial maze to a learning criterion of 9 out of 10 correct trials using allocentric visual or olfactory cues. Preliminary data suggest rats learn the task faster when olfactory cues are present. Recordings of the local field potential (LFP) were made in olfactory-limbic and neocortical areas simultaneously during the navigation task: olfactory-limbic - olfactory bulb, piriform cortex, entorhinal cortex, HPC; neocortical - primary visual cortex, secondary motor cortex, medial parietal association cortex, primary somatosensory cortex. We performed within-subject comparisons of theta power and coherence during SLM. For electrophysiological analysis, rats were trained to a novel location each day for 4 consecutive days- two consecutive days with visual spatial cues and two consecutive days with olfactory spatial cues, with order counter-balanced across subjects. Theta coherence and power were analyzed in relation to SLM and correct vs. incorrect trials. Theta power increased in all regions while rats ran during the task, and V1M showed increased theta power during sessions with visual spatial cues. Theta coherence between pairs of brain regions fluctuated with SLM and in regards to correct vs. incorrect trials. Granger causality was used to assess directionality of coherence between all

pairs. Ubiquitous and modality-specific physiological features of SLM are elucidated by expanding analysis of SLM to olfactory cues and widely distributed theta coherence.

Title: Spatiotemporal patterns of cortical voltage activity during sharp-wave ripples: Implications for memory consolidation theory

Authors: *J. KARIMI, M. NAZARI, B. L. MCNAUGHTON, M. H. MOHAJERANI
Neurosci., Canadian Ctr. For Behavioral Neuroscience/Univer, Lethbridge, AB, Canada

Abstract: The coordination of cortical up-states and hippocampal sharp-wave ripples (SWR) during slow wave sleep is believed to play a major role in the consolidation of recently acquired memories. Electrophysiological studies have extensively investigated the interaction of cortex and hippocampus during SWR, but the spatial distribution of SWR-up-state interaction across the cortical mantle is not known well. fMRI studies in monkeys have identified regions in the so-called default mode network which show high co-activity with SWRs (Kaplan et al., 2016), but fMRI suffers from the low temporal resolution. Therefore, we investigated how a large portion of the cortex interacts statistically with SWR using wide-field optical imaging of cortical voltage responses combined with extracellular recording of SWR and multi-unit activity (MUA) in CA1. Voltage-sensitive dye recording allowed us to capture cortical activity with high spatiotemporal resolution. Mice were imaged under urethane anesthesia as a model of slow wave sleep. We found that the activities of areas adjacent to the midline sinus, especially retrosplenial cortex (RSC) show the strongest correlation with SWRs. We also parsed the hippocampal activity around SWRs into 3 different clusters based on the pattern of hippocampal MUA activity and found distinct cortical response patterns corresponding to each of these groups. In general, the cortical activation tended to either lead, lag, or be coincident with the peaks of the SWR in these three clusters. Previously it was found that midline cortical reactivation of recent memory traces is strongest during periods of high up-down state transitions (Johnson et al., 2010). We speculate that the variable temporal relationships observed here may reflect the degree of consolidation of

different memory patterns: for well consolidated memory cortical activation may lead hippocampus whereas for the newest memories, that still depend on hippocampus, cortex would follow. This predicts a range of temporal interactions on average, which is what we observe.

Title: Differential genes expression following EGb treatment and conditioned suppression in the amygdaloid complex and dorsal hippocampal formation

Authors: *S. M. CERUTTI[1], C. R. ZAMBERLAM[2], J. M. CERUTTI[3]
[1]Univ. Federal De Sao Paulo, Sao Paulo, Brazil; [2]Federal Univ. of Sao Paulo, Diadema, Brazil; [3]Federal Univ. of Sao Paulo, São Paulo, Brazil

Abstract: Studies in our laboratory have shown that fear conditioning is associated with changes in gene expression of NMDA, 5-HT_{1A} and $GABA_A$ receptors in the dorsal hippocampal formation (dHF). This study assessed the effects of treatment prior to conditioning with EGb on differential *Grin2b,* Girn2a*5htr1a*, *Gfap* and *Gabraa*-α5 gene expression in the dorsal hippocampal formation (dHF) and amygdaloid complex (AC) of the rats submitted to the acquisition of the conditioned suppression of a lick response. Adult male *Wistar* rats were treated before conditioned fear with EGb or vehicle and were fear conditioned in a lick-operandum chamber. Each rat was placed in the chamber to acquisition of licking responses (1° to 5° days). In the 6°day, thirty minutes after the administration of drug or vehicle, each rat was submitted to four tone-footshock (CS-US) pairings. The suppression of licking response was calculated for each rat, in 10 trials CS presentation in the Acquisition Test (8°day). All rats had acquisition of fear memory but, in minor dose, EGb-treatment reduced the suppression ratio. The gene expression analysis, using qPCR, in the DH samples showed that 500 $mg.Kg^{-1}$ EGb treatment resulted in the overexpression of *Gabra5* ($Re_{Gabraa\text{-}\alpha5}$=268 ddCT), *Gabra1* ($Re_{Gabraa\text{-}\alpha1}$=4.879 ddCT), *Grin2b* ($Re_{Grin2b}$=382 ddCT) and *Gfap (*$Re_{Gfap}$=2.404 ddCT) in the DH after retention test when compared with control group (Re=676; 56; 180; 1268 and 63 respectly) (p<0,0001). In the AC, 500$mg.Kg^{-1}$ EGb resulted in upregulation of *5htr1a* (Re=187, p< 0.05) and *Gabraa*-α1 (Re=76; p< 0.0001) compared with control group (Re= 48 and 46, respectively). Conversely, 250 $mg.Kg^{-1}$ EGb treatment resulted in the downregulation of Re_{Grin2b}=0,1; $Re_{Gabraa\text{-}\alpha1}$=0,5 and

$Re_{Gabraa\text{-}\alpha5}$=1,7 ($p$<0,0001) in the AC when compared to the control group (Re=1,00; 4,6 and 13, respectively). Moreover, treatments with 1000 mg.Kg^{-1} EGb resulted in downregulation of $Re_{Gabraa\text{-}\alpha1}$=2,25 and $Re_{Gabraa\text{-}\alpha5}$=7,3; p<0,0001). One-way ANOVA followed by a *post hoc* Bonferroni test was performed to evaluate the relationships between the expression levels and groups. The results from gene expression analysis in the DH and AC shown the modulatory effects of EGb treatment and indicate the involvement of 5HT1AR, GABAA and NMDA-GluN2B receptors in the effect of standardized extract of *Ginkgo biloba* L. on acquisition of conditioned fear in a dose-dependent and structure-dependent manner (CEUA N. 3298260514).

Title: Physiological characteristics and functional role of ventral hippocampus projecting cells

Authors: *M. R. LOPEZ[1], H. ZURITA[1], B. HARLAND[2], K.-C. LEONG[1], A. J. APICELLA[1], I. A. MUZZIO[1]
[1]Biol., Univ. of Texas At San Antonio, San Antonio, TX; [2]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Many psychopathologies such as post-traumatic stress disorder and specific phobias are typified by failures of extinction and fear generalization. Therefore, understanding the underling circuit abnormalities that lead to these psychopathologies is of critical importance. The hippocampus is thought to provide a contextual “gating” mechanism that determines whether fear or extinction should be expressed in particular contexts; however, no direct physiological evidence supports this theory. The ventral hippocampus (VH) is in a key position to control this contextual “gating” through its projections to the basolateral amygdala (BLA), an area involved in associative fear learning, and the prelimbic (PL) and infralimbic (IL) cortices, regions in the medial prefrontal cortex (mPFC) involved in fear expression and extinction, respectively. However, since single cells in the VH have broadly tuned fields (e.g., cells fire in large areas of space), it is unclear how they provide specific contextual information during learning and retrieval. Our lab recently demonstrated that although single VH cells lack precise spatial tuning, the population activity in the VH contains contextual information. Critically, ventral patterns of

activity are ideal to support generalization processes. This raises the question of whether the VH projection neurons are comprised by distinct cell-types and/or provide the same computational information to the different target regions of the fear/extinction circuitry. To test this, we first used retrograde fluorescent beads to identify ventral projecting cells to mPFC and BLA. We found that these different projecting cells conform segregated cell-types with almost no overlap. Then, we began to characterize their physiological and anatomical properties using whole cell patch clamp. Our preliminary data suggest that ventral cells projecting to mPFC burst and display temporal summation, whereas cells projecting to amygdala display regular firing and no temporal summation. We are currently trying to elucidate the distribution and electrophysiological properties of cells projecting to PL and IL cortices. To further characterize the functional role of VH in generalization processes, we are also using chemogenetic silencing of specific projecting cells in combination with single unit recordings from ventral area CA1. These results will provide important information about how the VH provides contextual gating of fear- and extinction- related behaviors.

Title: Chronically reactivating positive and negative memories to modulate hedonic and social behaviors

Authors: *E. DOUCETTE, E. MERFELD, Y. ZAKI, S. L. GRELLA, N. J. MURAWSKI, M. SHPOKAYTE, S. RAMIREZ

Abstract: Chronic stress in mice induces variety a of anxiety- and depressive-like phenotypes at the neuronal, circuit, and behavioral levels. More specifically, social and hedonic-like states are dramatically impaired across many psychiatric disorders, though the underlying mechanisms

sufficient to precipitate or alleviate such impairments remain largely unknown. Here, we utilize an activity-dependent and inducible tagging strategy to modulate hippocampus cells processing positive, neutral, or negative memories prior to chronic immobilization stress exposure. We hypothesized that chronic positive memory stimulation is sufficient to mitigate the effects of stress, while chronic negative memory stimulation is sufficient to mimic such effects in a number of behavioral assays (e.g. exposure to female, resident intruder, social interaction). We find that chronically stimulating hippocampus cells processing a positive memory in male mice is sufficient to increase hedonic-like activity, as measured by time spent interacting with a female mouse, and those effects remain unaltered by chronic stress. We also find that chronic stimulation of cells processing a negative memory is sufficient to impair social behaviors in both the resident intruder and social interaction assays. The magnitude of these effects is comparable to the impairments seen in chronically stressed animals receiving neutral memory stimulation pre-stress. Furthermore, chronically stimulating cells processing a negative memory followed by chronic stress produces larger impairments than stress alone in a subset of social behaviors. Our current experiments focus on interrogating the neural circuitry underlying each phenotype by measuring levels of neurogenesis, dendritic spine growth and retraction, and circuit-wide activity contributing to hedonic and social behaviors. Together our results connect chronic memory modulation with discrete maladaptive behavioral states and simultaneously provide a mechanistic basis for inducing a defined set of behavioral impairments.

Title: Inhibiting ensembles in the hippocampus and amygdala to suppress reinstatement-induced fear

Authors: *Y. ZAKI, E. DOUCETTE, S. L. GRELLA, N. J. MURAWSKI, E. MERFELD, M. SHPOKAYTE, S. RAMIREZ
Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Post-traumatic stress disorder (PTSD) is a condition that precipitates from a highly aversive experience and is manifested by overgeneralized fear in innocuous situations. Interestingly, a striking proportion of patients who undergo exposure therapy - which can lead to the suppression, or "extinction," of the original fear memory - are highly vulnerable to relapse, especially when the conditioned stimulus is delivered outside a clinical context. Here, we seek to interrogate the neural substrates supporting the acquisition of fear as well as the subsequent extinction of fear to gain a causal understanding of its underlying neural components. We used a combination of activity-dependent labeling of neuronal ensembles in multiple brain regions associated with fear-related behaviors (basolateral amygdala, BLA; dorsal dentate gyrus of hippocampus, dDG) and further manipulated these ensembles using optogenetics to probe the changes that a fear memory undergoes during extinction and during fear reinstatement.
We first tagged BLA cells processing a contextual fear memory in mice. All subjects then underwent extinction learning, and had the tagged fear ensemble in the BLA inhibited either during a shock in an unconditioned context (serving to reinstate the original context-specific fear) or during a fear recall test in the original conditioned context the day after. We found that while inhibition of the original fear ensemble in the BLA was not enough to prevent reinstatement, inhibition of that ensemble during the recall test was enough to actively disrupt fear expression in the conditioned context. This suggests that the original fear ensemble in the BLA contributes to a context-dependent fear response following shock-induced reinstatement, providing key evidence that the neural correlate of fear reinstatement may be a reemergence of the original fear memory trace. In the dDG, we observed that the original fear ensemble was preferentially reactivated during the fear recall session, but not during reinstatement. To further investigate the changes that occur in the brain during reinstatement, our current work focuses on inhibiting the hippocampal fear ensemble during the fear recall test to assess whether that ensemble continues to be instrumental in the contextual fear response following reinstatement.

Abstract: Cognitive and emotional disruptions underlie many stress disorders and are also known to affect hippocampus function. The dorsal hippocampus is thought to processes spatial, temporal, and contextual information whereas the ventral hippocampus is thought to mediate stress and emotional aspects of learning and memory. Here, we asked if artificial activation of positive or negative memories in the dorsal or ventral hippocampus could promote appetitive or aversive-related behaviors. We also examined if chronic activation of a fear memory is sufficient to mimic extinction-like reductions in fear responses. We first infused an activity-dependent AAV9-c-Fos-tTA-TRE-ChR2 into the dorsal or ventral dentate gyrus (DG), which allowed for optical control over DG neurons expressing the immediate-early gene c-Fos in a doxycycline(Dox)-dependent manner. Mice received a positive, negative, or neutral experience while off Dox to tag cells processing a discrete memory. Next, mice underwent a battery of behavioral tests to measure appetitive and aversive responses during light-on and light-off epochs. Our findings are threefold: 1) activation of dorsal and ventral hippocampus cells were sufficient to drive freezing, avoidance, and preference; 2) the ventral, but not dorsal, hippocampus was sufficient to modulate anxiety-like states; 3) and finally, chronic activation of the dorsal hippocampus cells produced extinction-like reductions in fear responses, whereas ventral hippocampus stimulation induced a context-specific enhancement of a fear memory. Together, we demonstrate functionally overlapping and segregated roles of the dorsal and ventral hippocampus and that artificially activating positive and negative memories are sufficient to mitigate or mimic stress-related behavioral states.

Title: Activating ventral hippocampus to amygdala terminals processing fear and reward

Authors: *M. SHPOKAYTE, S. L. GRELLA, Y. ZAKI, N. J. MURAWSKI, E. DOUCETTE, E. MERFELD, S. RAMIREZ
Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Projections from the hippocampus to the amygdala code for a variety of contextual information associated with positive and negative valences. Previous studies have focused on stimulating cell bodies in the hippocampus or amygdala during events of opposing valences and have revealed that a discrete set of hippocampus cells can "switch" which valence-specific behavior they drive, while such responses in the amygdala appear to be more hardwired. However, the flexibility of hippocampus-amygdala terminals in processing both reward and aversion remains untested. Here, we utilize the activity dependent and inducible cfos-tTA system for tagging cells processing positive or negative memories in ventral CA1 terminals onto the basolateral amygdala of c57BL/6 mice. Following tagging, the capability of these terminals to drive preference or aversion was assessed. Next, the animals were exposed to either a negative or positive experience while the hippocampus terminals processing the opposite valence were optogenetically activated. We find that optogenetic stimulation of hippocampus to amygdala terminals is sufficient to switch the terminals' capacity to drive reward to fear and vice versa. Our ongoing experiments are focused on anatomically tracing projection-specific targets of positive and negative memory hippocampus terminals and testing their role in modulating a battery of behavioral states. Understanding the intricacies of the hippocampus to amygdala circuitry in relation to the malleability of memories may have clinical value for the treatment of psychiatric disease-related states.

Title: Reactivating hippocampus-mediated memories to disrupt the reconsolidation of fear

Authors: *S. L. GRELLA, Y. ZAKI, N. J. MURAWSKI, E. DOUCETTE, E. MERFELD, M. SHPOKAYTE, S. RAMIREZ
Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Background: Fear conditioning has been used to model memory and stress-related behaviors in rodents. While fear is often adaptive, dysregulation of fear circuits can lead to maladaptive states comprising mood and anxiety disorders. A promising prospect of attenuating the strength of fear memories is through the disruption of reconsolidation - a process by which activated memories are susceptible to modification, thus allowing for subsequent manipulation (e.g. enhancement / disruption). In previous studies, interventions such as protein synthesis inhibitors and beta-blockers have been used to target and disrupt conditioned fear during the reconsolidation process. Here, we propose a novel intervention based on the hypothesis that optogenetic reactivation of a previously formed, hippocampus-mediated memory during reconsolidation will alter and disrupt the original fear memory, thereby reducing the behavioral expression of fear. **Method:** We combined the use of the activity-dependent inducible c-Fos-tTA system for neuronal tagging in c57BL/6 mice to tag dorsal dentate gyrus (dDG) cells active during a positive or neutral experience, and channelrhodopsin 2-mediated optogenetics. Mice were fear-conditioned and given a 20-minute recall session the following day. During recall, we optically stimulated the dDG during the first or last 10 minutes of the session when the reconsolidation window is thought to be open – to reactivate the tagged dDG-mediated positive or neutral memories. Mice then received extinction training and were tested for stress-induced reinstatement on subsequent days. **Results:** Artificial reactivation of both positive and neutral memories during reconsolidation resulted in faster rates of extinction learning and the attenuation of stress-induced reinstatement. However, these effects transpired more quickly with the reactivation of a positive memory compared to the reactivation of a neutral memory. Moreover, artificial reactivation of a positive memory during reconsolidation of a fear memory resulted in real-time decreases in freezing during reactivation whereas reactivation of a neutral memory did not produce similar decreases in freezing. **Significance:** This work highlights the therapeutic value of memory modulation as a viable treatment for the suppression of fear responses, implicating dDG cells as specific nodes of intervention.

Title: Neuronal activity in the amygdala and hippocampus during and after optogenetic stimulation of the basolateral amygdala in awake rats

Authors: *N. S. AHLGRIM[1,2], C. R. GALLOWAY[1], Y. CHUNG[3], K. PARK[3], J. R. MANNS[1]
[1]Psychology, [2]Grad. Program in Neurosci., [3]Emory Univ., Atlanta, GA

Abstract: The amygdala is known to modulate memory consolidation via its direct and indirect projections to the hippocampus. Although this modulation is most often studied in conjunction with emotional arousal, like during fear conditioning and acute stress, recent work has shown that activity in the basolateral amygdala (BLA) can also modulate emotionally neutral memory. We have previously found that brief electrical stimulation of the BLA enhances recognition memory for individual objects, a phenomenon that is dependent on the intermediate hippocampus. Further, electrical stimulation to the BLA increases synchrony between the CA3 and CA1 subfields of the hippocampus. To better characterize the activity in the BLA that produces the enhancement of memory and to determine whether these effects are attributable to activation of glutamatergic projection neurons in the BLA, the current study used optogenetic stimulation in place of electrical stimulation. Optogenetic stimulation facilitated simultaneous recordings of single-unit and oscillatory activity in the amygdala and hippocampus. Putative glutamatergic neurons were transfected with the depolarizing Channelrhodopsin [ChR2(H134R)] ion channel, and transfected neurons were stimulated across a range of frequencies. Simultaneous stimulation and recording in the amygdala allows for on-line verification of how amygdala activity changed as a result of optical stimulation. Optogenetic stimulation of the BLA elicited spiking and oscillations in local field potentials that were entrained to the stimulation frequency. Our protocol of simultaneous neural recordings from the amygdala and hippocampus in an awake animal will enable direct analysis of single-unit and oscillatory activity in the amygdala during memory tasks, which projects to and modulates the hippocampus. The current experiment lays the foundation for the long-term goal of the project, which is to understand how these two regions communicate and what neural activity is required to enhance the consolidation of specific memories.

Title: Conjunctive coding in the primate entorhinal cortex

Authors: *M. L. MEISTER[1,2], E. A. BUFFALO[1,2]
[1]Physiol. and Biophysics, [2]Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA

Abstract: Primate entorhinal cortex neurons respond to the appearance of visual stimuli in the context of visual recognition memory or association tasks in which the neural responses are typically analyzed during time periods lasting about 0.5 seconds. Given the heterogeneity of entorhinal response types identified *in vitro,* including responses that continue many seconds after stimulation, it is possible that distinct cell classes could also be observed *in vivo* across longer time periods. Here, we recorded the responses of individual neurons (n = 349) while monkeys freely viewed large, natural scene stimuli. Monkeys were allowed to view the scenes for up to 5 seconds, and up to 120 distinct scenes were presented within each session. Results revealed that entorhinal neurons exhibit vastly distinct responses locked to the onset of visual stimuli, both enhanced and reduced firing rates, with some neurons returning to baseline firing rate quickly, and others showing an exceptionally long decay, continuing well over 1 second after stimulus onset. Responses spanning this dynamic range were reliably encountered across experimental sessions and animals, suggesting distinct cell types.
To determine whether these separate cell types reflected anatomical specificity or differed in other aspects of their response profile, we compared the properties of cells with “Brief” vs. “Sustained” responses (responses that respectively returned to baseline firing rate within 0.5 sec or no sooner than 1.5 sec following image onset). Compared to Brief cells, Sustained cells included a significantly greater proportion of cells located in superficial cortical layers which provide the predominant cortical input to the hippocampus. Additionally, Sustained cells were more likely to show consistent spatial activity that reflected the location of the monkey’s gaze within the image. Notably, there was no difference in the proportion of spatial Sustained cells that showed enhanced compared to reduced firing rate at stimulus onset.
Together, these findings reveal an association between cells with an exceptionally long response decay after the appearance of an image, spatial coding, and location in the superficial cortical layers. Because the entorhinal cortex is important for memory, we speculate that these exceptionally long responses may provide necessary drive to create a sustained binding state, or

memory “chunk,” linking across time spatially separate elements encountered during visual exploration of an image. Future research distinguishing these diverse cell types offers a potentially powerful, new way to enhance our understanding of the neural mechanisms that underlie memory.

Abstract: Pattern separation, which refers to the process of orthogonalizing overlapping inputs into distinct memory representations, has been shown to be affected in healthy elderly individuals as well as in individuals with mild cognitive impairment who may go on to develop Alzheimer’s disease. Research using functional imaging in humans has implicated substructures of the hippocampus, specifically CA3 and Dentate Gyrus (DG), as being particularly important for pattern separation, with deficits in nondemented older adults associated with increased CA3/DG activity (Lacy, et al., 2011; Yassa et al., 2010). Single unit recordings in rodents have implicated the DG in pattern separation and have suggested that CA3 representations more likely reflect pattern completion mechanisms, i.e., the retrieval of a memory with partial input (Neunuebel and Knierim, 2014). Monkeys, which can be trained to perform similar, if not identical, behavioral tasks as those used in human subjects, provide an avenue for clarifying this issue and assessing the neurobiological underpinnings of this ability at the level of cells and

circuits. Here, we adapted the mnemonic discrimination task from the human literature for use with rhesus macaques. This task provides a useful behavioral assay of pattern separation. Five monkeys were trained on a sequential delayed match to sample task with centrally located images. Subjects indicated the detection of a match by touchbar release. Each trial could include repeated nonmatching stimuli (ABBA design) and extend to a potential length of six nonmatching stimuli. Human-validated distracter items from the human mnemonic discrimination task that varied parametrically across five levels of similarity to the target item were used as critical lure stimuli. All monkeys were able to perform this task successfully. Notably, monkeys displayed similar behavioral performance to humans, in that performance varied predictably along with the increasing similarity of the lure to the target. These results demonstrate the applicability of the mnemonic discrimination task as a platform for further neurophysiological studies targeting single units in specific hippocampal subregions in the primate.

Title: Eye movements temporally organize spatial representations in the primate hippocampus

Authors: *S. D. KOENIG[1], E. A. BUFFALO[2,3]
[2]Physiol. and Biophysics, [3]Washington Natl. Primate Res. Ctr., [1]Univ. of Washington, Seattle, WA

Abstract: Single unit recordings in rodents have identified place and time cells in the hippocampus that are hypothesized to support the spatial and temporal aspects of episodic memories. However, it is not fully understood the extent to which similar representations exist in the primate hippocampus. Notably, studies in monkeys have identified neurons in the hippocampus and entorhinal cortex that are modulated by gaze location rather than the monkey's physical location (Rolls, 1999; Killian et al., 2012). In addition, saccadic eye movements modulate the activity of single hippocampal neurons (Sobotka et al., 1997) and the phase of the hippocampal local field potential (Hoffman et al., 2013; Jutras et al., 2013), suggesting that the temporal properties of active sampling of the environment via saccades plays an important role in hippocampal activity. To further explore how these representations are related to eye movements, we recorded the activity of 347 hippocampal neurons from two monkeys as they freely viewed complex images. We found that 31% of these neurons were significantly modulated by viewing location; these neurons were spatially stable across the recording session and had significant ($p < 0.05$) spatial information scores.(Skaggs et al., 1993) Surprisingly, each view-modulated neuron appeared to reach its maximum firing rate at a distinct time relative to the start of a fixation into the neuron's firing field. Across the population of view-modulated neurons, the latency of the peak response tiled the full duration of a fixation (~200 msec), suggesting that these responses may reflect sequential firing. Taken together, these data provide further support for the idea that neurons in the primate hippocampus are modulated by eye movements and show selectivity for viewing location. Furthermore, these data demonstrate that

eye movements temporally organize hippocampal activity across the extent of a fixation, potentially allowing information to be integrated across successive eye movements.

Abstract: Decades of studies have shown that the hippocampus plays an important role in memory in humans, monkeys, and rodents, but we do not yet have a full understanding of how transient neuronal activity in the hippocampus supports mnemonic function. Here, we investigated activity in the monkey hippocampus related to spatial memory performance. Monkeys were trained on a spatial delayed-alternation task in a visually rich virtual Y-Maze, in which the previous trajectory must be remembered in order to make a correct response. Hippocampal neurons were simultaneously recorded from more than 60 channels using a chronically implanted microdrive with independently movable electrodes (Gray Matter Research). The electrodes targeted the full anterior-posterior and medial-lateral extent of the

hippocampus, spanning the dentate gyrus, CA3, CA1, and subliculum.
Preliminary results indicate that single units show reliable responses to multiple distinct features of the task. Hippocampal neurons demonstrate discrete spiking in each phase of the task, including the center stem, choice point, reward locations, and delay period. Notably, these neural representations include place cells with consistent responses to the position of the monkey's virtual avatar relative to maze landmarks. Over the aggregate ensemble, the observed hippocampal activity spans all task events, bridging discrete features within one network.
To determine whether visual features of the maze influence network activity in addition to task structure, we compared neuronal activity across distinct environments with the same spatial dimensions. Neural responses were strikingly consistent across repeated sessions in a particular environment during a single day. When a visually distinct environment was interposed between the two repeated environments, a subpopulation of hippocampal cells showed marked shifts in response profile. These alterations included changes in whether a neuron was active in the task and in the location of a neuron's place field. Taken together, these findings show that robust, task dependent activity in the monkey hippocampus can be elicited using a virtual reality memory paradigm. Further, environmental context biases which neural ensemble will be active, even with a consistent task structure.

Title: Modified firing in hippocampal area CA2 in a mouse model of schizophrenia during social tasks

Authors: *M. L. DONEGAN[1], F. STEFANINI[1], Y. ZAFRINA[2], S. FUSI[1], J. A. GORDON[3], S. A. SIEGELBAUM[1]

Abstract: Social interaction and bonding are crucial elements of mammalian survival, providing a support system for offspring survival, offering increased security, and reducing the expenditure of resources. Neuropsychiatric diseases, such as autism and schizophrenia, often present with disruptions in social behavior that are poorly understood. Recent work on area CA2 of the

hippocampus has shown that CA2 is necessary for the formation of social memory. Moreover, brains from individuals with schizophrenia show specific reductions in parvalbumin-positive (PV) interneurons in CA2. Despite these findings linking CA2 to social memory, the neural firing patterns underlying these memories have yet to be understood. The Df(16)A+/-mouse line is a mouse model of schizophrenia that recapitulates a microdeletion on the 22q11 chromosome, which confers a 30-fold increased likelihood of developing schizophrenia in humans. These mice show deficits in social memory, as well as an age-dependent loss of PV interneurons specific to CA2 (similar to the human results), and a hyperpolarization of the CA2 pyramidal neuron resting potential recorded in slices. While these physiological changes have been investigated in vitro, their in vivo consequences on CA2 firing have not been examined.To characterize CA2 firing during social behavior we recorded extracellularly from the CA2 region of both wild-type and Df(16)A+/- mice during a modified 3 chamber social interaction task during which the mice interact with 1) an empty chamber 2) novel objects 3) littermates and 4) novel mice. In wild-type animals, CA2 firing is highly heterogeneous, with CA2 spatial firing patterns highly unstable from session to session. Interestingly, about 10% of cells in CA2 are only active during the social sessions. A different subpopulation shows is an overall firing rate increase around the novel animal. Despite altered inhibition and resting potential, CA2 pyramidal cells from Df(16)A+/- mice show no change in either average or peak firing rate during this task. Interestingly, CA2 spatial firing patterns of the Df(16)A+/- mice are more stable across the different sessions, with the cells having fewer firing fields compared to their wild-type counterparts. Such changes in single cell firing patterns may interfere with the ability to decode novelty, social information, and spatial information from CA2 population activities and therefore ultimately to extract this information from downstream neurons. These findings suggest a possible role for CA2 neuronal activity in social memory, and that changes in CA2 firing may play a role in the social deficits seen in the Df(16)A+/- mice.

Title: Organization of CA2 projections to ventral CA1 neurons

Authors: *E. W. BUSS, F. LEROY, S. A. SIEGELBAUM
Dept. of Neurosci., Columbia Univ., New York, NY

Abstract: Axons of CA2 pyramidal neurons have a diverse pattern of innervation, providing synaptic input both onto dorsal CA1 (dCA1) as well as ventral CA1 (vCA1) neurons. Additionally, dorsal Ca2 (dCA2) and vCA1 pyramidal neurons are important for social memory processing and storage; however, the functional synaptic connectivity of this circuit remains poorly understood. Given the evidence of distinct functional domains along the dorsoventral axis in CA1 as well as cell type heterogeneity among CA1 pyramidal neurons, we sought to determine how these projections are integrated into the circuit. Using optogenetic stimulation of CA2 fibers, we characterized strong, excitatory projections to the vCA1, displaying a distinct pattern of innervation. Although it remains unclear how CA2 output influences behavior, this offers a potential social memory circuit.

Title: CA2 circuits controlling social behaviors

Authors: *F. LEROY[1], J. PARK[1], T. MEIRA[1,2], E. W. BUSS[1], S. A. SIEGELBAUM[1]
[1]Neurosci., Columbia Univ., New York, NY; [2]Life and Hlth. Sci. Res. Inst. (ICVS),, Sch. of Medicine, Univ. of Minho, Braga, Portugal

Abstract: The hippocampal CA2 area lodged between CA3 and CA1 integrates inputs from the entorhinal cortex, the dentate gyrus, CA3 as well as the supramammillary nucleus, the medial septum and the raphe. Its output remains, however, poorly understood. We characterized strong CA2 projections to the ventral CA1 area (vCA1) and the lateral septum (LS) and have been probing their respective behavioral function by silencing each set of terminals. CA2 and vCA1 were recently shown to be necessary for social memory. We find that dorsal CA2 projects to and excites ventral CA1, providing a potential social memory circuit. We further find that dorsal CA2 excites dorsal LS (dLS). Moreover this projection is not involved in social memory but acts to enhance social aggression through a disinhibitory circuit: CA2 excites dLS, which inhibits ventral lateral septum (vLS), thereby relieving tonic inhibition of the aggression-promoting hypothalamic VMHvl area. This is agreement with studies showing that deletion of the arginine

vasopressin 1b receptor (AVPR1b), which is highly enriched in CA2, reduces social aggression. Our results show that activation of AVPR1b on CA2 presynaptic terminals enhances CA2-LS excitatory synaptic transmission and that selective blockade of these receptors inhibits social aggression. Although it remains unclear how CA2 outputs and their modulations by vasopressin control different social behaviors, our study, together with previous results, suggests a close relationship between social memory and aggression. We are currently investigating the behavioral effect of silencing the CA2-vCA1 projection to explore whether differential neuromodulation of divergent projections from a single brain region may selectively recruit memory versus aggressive social behaviors.

Title: The hippocampal CA2 region plays a dynamic role in social memory

Authors: *T. MEIRA[1,3], F. LEROY[1], S. SIEGELBAUM[1,2]
[1]Neurosci., [2]Pharmacol., Columbia Univ., New York, NY; [3]Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Medicine, Univ. of Minho, Braga, Portugal

Abstract: The hippocampus is an extensively studied structure with a well-defined role in declarative memory. Studies over the past decade have revealed specific roles of certain hippocampal subregions in different aspects of memory storage and recall. Nevertheless, the function of the CA2 field is largely unknown. Recently, the importance of CA2 in social memory was directly demonstrated using a genetically engineered mouse line that allowed for the selective silencing of CA2 pyramidal neurons (PyNs). However, this approach depended on the irreversible and long-term inactivation of CA2 through expression of the tetanus toxin light chain, which may have led to long-term effects on neural circuitry outside of CA2 that consequently caused the social cognition deficits. To further explore how CA2 is acutely involved in social memory, we have been using pharmacogenetic tools that enable us to control the activity of CA2 in a defined temporal manner. We expressed the inhibitory hM4Di

DREADD selectively in CA2 PyNs by injection of a Cre-dependent AAV into the CA2 region of adult *Amigo2*-Cre mice, where Cre expression is largely restricted to CA2 PyNs. In acute hippocampal slices from viral-injected mice, application of the DREADD agonist clozapine *N*-oxide (CNO) reliably hyperpolarized the PyNs membrane, reducing excitability. We first examined the effects of acute CA2 silencing using the direct interaction test of social memory, in which a subject mouse is exposed to a novel juvenile stimulus mouse for 2 min in trial 1 and then re-exposed to the same stimulus mouse in trial 2 after a 30 min inter-trial interval. Social memory is normally manifest as a decrease in social exploration from trial 1 to trial 2 as a result of decreased social novelty. Intraperitoneal injection of CNO 30 min prior to the test caused a profound decrease in social memory, demonstrating the importance of dynamic on-line CA2 activity. Experiments are currently underway to examine whether CA2 is selectively required for memory storage, consolidation and/or retrieval.

Ctr., New York, NY; [5]Skirball Inst. of Biomolecular Med., New York Univ. Langone Med. Ctr., New York, NY; [6]Otolaryngology, NYU Med., New York, NY; [7]Neurosci. Inst., New York Univ., New York, NY

Abstract: Oxytocin receptor (OXTR) signaling has been implicated in many aspects of social behavior, with loci throughout the mammalian brain. Consistently, one major effect of oxytocin signaling is to refine inhibitory tone, along with excitatory output. We report that within area CA2, a hippocampal subregion recently implicated in social memory, OXTR signaling stimulates both excitatory and inhibitory neurons, while sculpting output to CA1. Exogenous application of an oxytocin receptor agonist (TGOT) or optogenetic stimulation of

endogenous oxytocinergic fibers in CA2 can drive otherwise quiescent pyramidal cells to become excited. In all CA2 pyramidal neurons tested (adult mice), OXTR stimulation caused significant depolarization. This depolarization was accompanied by an increase in whole-cell membrane resistance, suggesting modulation of a potassium conductance. Indeed, TGOT-induced depolarizations were blocked by application of retigabine (100 μM), an opener of the KCNQ potassium channel responsible for the M-current. In response to TGOT application, CA2 pyramidal cells depolarize and enter into a burst-firing mode. Bursting in CA2 pyramidal cells was accompanied by a decrease in action potential amplitude and after-hyperpolarization (AHP) magnitude, facilitating high-frequency burst activity. Both phenomena rely on phospholipase C (PLC) activation, while the effects on spike and AHP magnitude depend on protein kinase C (PKC) activation. Pharmacological inhibition of the M-current and activation of PKC recapitulate the effect of OXTR stimulation in CA2 pyramidal cells. PV+ interneurons in CA2 were also depolarized by OXTR stimulation that depended on M-current inhibition. Blockade of inhibition during OXTR agonist application altered burst duration and frequency, suggesting that CA2-mediated inhibition is important in shaping the response to OXTR stimulation. Indeed, our optogenetic experiments suggest that the burst structure, shaped by CA2-mediated inhibition, is optimal for excitatory charge transfer onto CA1 pyramidal cells. We find evidence for a similar molecular mechanism at play in CA1 fast-spiking interneurons, suggesting that OXTR-mediated inhibition of M-current may be a modulatory motif throughout the brain. Further, our results suggest that oxytocinergic modulation of CA2 may impact not only CA2-dependent social memory, but more broadly, hippocampal information transfer via CA1.

Title: The contribution of hippocampal oxytocin receptors to social memory processing

Authors: *T. RAAM
Ctr. for Regenerative Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: The trisynaptic hippocampal pathway DG-CA2/3-CA1 plays a critical role in processing contextual information by encoding distinct representations in non-overlapping ensembles of neurons, a process known as pattern separation. Recent studies suggest a role for the dorsal CA2/3 subregion in processing social memories, raising the question of how the same hippocampal sub-regions process social information. Based on the enrichment of receptors for

the social hormone oxytocin (Oxtrs) in the DG-CA2/3 axis, but not CA1, and the critical role oxytocin plays in social memory, we hypothesized that Oxtrs in dorsal DG-CA2/3 are essential for social memory processing. Here we employ pharmacological and genetic tools to demonstrate the necessity of Oxtrs in dDG and dCA2/3 for social memory, but not object memory. Further, we utilized ensemble mapping techniques to demonstrate that Oxtrs are necessary for population-based encoding of social stimuli in CA3. Optogenetic terminal-specific silencing revealed roles for distinct dCA2/3 outputs to downstream limbic regions in discrimination of objects and social stimuli. Together, these studies begin to elucidate how an evolutionarily conserved neuromodulatory hormone, oxytocin, utilizes a basic memory processing circuit in the hippocampus to modulate social behavior.

Lab., [4]Natl. Inst. of Env. Hlth. Sci., NIH, Research Triangle Park, NC

Abstract: Hippocampal pyramidal cells (PCs) are critical for certain forms of learning and memory, and work from our lab and others has shown that PCs in CA2 are required for social cognition and behavior. Permanently silencing CA2 PCs in mice impairs social memory, and we found that chemogenetically increasing or decreasing CA2 PC activity increases or decreases sociability, respectively. Further, mice lacking Regulator of G-Protein Signaling 14 (RGS14), a protein that is highly enriched in and restricted to CA2 PCs, learn faster than wild-types (WTs) in the Morris water maze spatial memory test. CA2 PCs in these RGS14 knock-out (KO) mice have increased excitability and a capacity for LTP at CA3 □CA2 synapses in stratum radiatum, where LTP normally does not occur. Although the enhanced spatial learning abilities of the RGS14 KO mice suggest a role for CA2 PCs in at least one hippocampus-dependent behavior, the role of CA2 PCs in fear conditioning is unknown. Fear conditioning, a form of associative

learning, involves the hippocampus and extrahippocampal brain structures such as the prefrontal cortex and amygdala. Because we found that chemogenetic modification of CA2 PC excitability altered prefrontal cortical activity, we asked how modifying CA2 PC activity would affect fear conditioning. We expressed Gq- or Gi-coupled DREADDs in CA2 PCs and administered CNO before the shock-tone-context pairing. On subsequent days, we measured freezing behavior in the same context but without the tone (contextual fear) or in a new context but in the presence of the tone cue (cued fear). We found that activation of CA2 PCs during the shock pairing resulted in increased freezing behavior in male and female mice upon cue presentation. Because both Gq DREADD expression and RGS14 deletion increases CA2 PCs activity, we also measured conditioned fear responses in RGS14 KO mice. We predicted that, similar to Gq-DREADD-expressing mice, RGS14 KO mice would show enhanced freezing behavior. Indeed, RGS14 KO mice had increased freezing upon cue presentation relative to WTs. Interestingly this effect was only seen in female KO mice. Emerging evidence from our lab suggests that sex differences arise following manipulations of CA2 activity; for instance, chemogenetic inhibition of CA2 PCs during the shock pairing resulted in increased freezing in the associated *context* in female, but not male, mice. These findings support the conclusion that CA2 PC activity plays a functional role in the corticolimbic circuitry that includes prefrontal cortex and amygdala. Given the behavioral sex differences in the Gi-DREADD and RGS14KO mice, we propose that the function of CA2 PCs in this circuitry may be sexually dimorphic.

Abstract: The hippocampal CA2 regions has been shown to be involved in social and contextual memory.

Still, the way these memories are encoded by it remains, for the most part, unknown.
We expressed GCaMP6s in the CA2 of vasopressin 1b receptor promoter- driven *Cre* recombinase-expressing knock-in mice and imaged the calcium transients in selective pyramidal neurons within the CA2 subfield of socially behaving mice. We used behavioral paradigms such as object and social habituation-dishabituation and social recognition discrimination to map the neural response to the stimuli presented.
Our results indicate the cells are responsive to both social and non-social stimulation. We observe an increased number of calcium events upon presentation of the novel stimulus and a subsequent decrease when the stimulus is removed from the cage. Moreover, upon repetitions of both social and non-social stimuli, neural representation becomes sparser and activity is attenuated in a stimulus-specific manner. Although the cells response to both stimuli, they response significantly more when the social stimulus is presented.
Our preliminary results suggest a preferred social encoding by these vasopressin 1b receptor-expressing pyramidal neurons.

Abstract: The CA2 region of the hippocampus, unique in its synaptic mechanisms and cellular properties, has been shown to encode spatial features in the environment to a lesser extent than its neighboring CA1 or CA3 subregions. Moreover, CA2 neurons change their representation of the environment through time, or when social or novel stimuli are introduced to the environment. To further investigate the way the neurons of the CA2 encode objects in their environment, we

selectively imaged pyramidal neurons of the region by expressing the calcium indicator GCaMP6s in vasopressin 1b receptor (Avpr1b) promoter-driven Cre recombinase transgenic mice. This technique allowed us to image the calcium transients of these CA2 subfield cells as mice performed an object habituation-dishabituation paradigm. Our results suggest that CA2 pyramidal neurons are most sensitive to the initial presentation of a novel object in the environment, with sparser neural representation upon repetitions and decreased population response. Moreover, upon presentation of a second novel object, activity remains low. Our data suggest that the tuning of vasopressin 1b receptor-expressing pyramidal neurons to an object presented is invariant to the object's features.

Title: How dynamic inhibitory control of CA2 pyramidal cell output influences CA1 activity

Authors: *R. A. PISKOROWSKI[1], K. NASRALLAH[2], L. THERREAU[1], V. ROBERT[1], V. CHEVALEYRE[1]

Abstract: The hippocampus is a critical structure for memory formation. Area CA2 has recently emerged as an important region in the control of hippocampal activity and social memory formation. However, how CA2 neurons precisely integrate in the hippocampal network is still unclear. In area CA2, the density of interneurons, and in particular, parvalbumin-expressing (PV+) interneurons is very high. Furthermore, while CA2 pyramidal cells are highly resistant to synaptic plasticity, the inhibitory transmission in this region is highly plastic, and mediated by delta opioid receptor (DOR) activation. Here, we use opto- and chemo-genetics to examine how PV+ interneuron transmission and plasticity controls CA2 pyramidal neuron input and the consequences this has on CA1. Using inhibitory DREADD expression, we found that transmission from PV+ interneurons largely contributes to the spontaneous inhibitory transmission in CA2 and to the feed-forward inhibition between CA3 and CA2. Furthermore,

silencing PV+ interneurons strongly increased the amplitude of excitatory potential from CA3. This manipulation also prevented by occlusion DOR-mediated long-term depression of inhibitory transmission (iLTD). Likewise, we found that excitatory synaptic input from the supramammillary hypothalamic input is also tightly controlled by PV+ inhibitory transmission, and this input is equally sensitive to DOR-mediated iLTD. We then investigated how plasticity in area CA2 influences CA1 activity following stimulation of CA3 inputs. We found that induction of DOR-mediated iLTD in area CA2 resulted in a significant increase in the excitatory drive onto CA1 neurons. We then used a transgenic mouse line to selectively express cre recombinase in CA2 pyramidal neurons to express in order to use optogenetics to study the connection between CA2 and CA1. We found that excitatory transmission from CA2 is larger onto deep compared to superficial CA1 neurons. We also found that CA2 pyramidal neurons strongly target an unusual group of CA1 pyramidal neurons with soma located in stratum radiatum. In addition, we found that feed-forward inhibition between CA2 and CA1 normalizes the net excitatory drive onto the deep and superficial CA1 neurons. In conclusion, we found that feed-forward inhibition mediated by PV+ interneurons controls both the input and the output of CA2 pyramidal neurons. This inhibitory transmission acts to normalize the strength of the excitatory drive between CA2 and different subclasses of CA1 pyramidal neurons.

Title: Differential contributions of dorsal and ventral CA3 to social memory

Authors: *M.-C. CHIANG[1,2], A. J. Y. HUANG[1], R. BOEHRINGER[1], D. POLYGALOV[1], T. OHSHIMA[2], T. J. MCHUGH[1]

Abstract: Social memory is crucial for normal daily life in many animals, including rodents and primates; however, the neural circuits underlying these processes are not fully understood. Recent results have suggested an important role of the hippocampus in social memory, particularly the CA1 and CA2 subregions. Here we employ circuit genetics to address the potential contribution of the hippocampal regions upstream of CA1 and CA2, the CA3 and the dentate gyrus (DG). We applied region specific *N*-methyl-$_D$-aspartate receptor subunit 1 (NR1) knockout (KO) approaches to test the contribution of plasticity in CA3 and the DG in social

memory. We found that CA3 NR1-KO mice demonstrated an impairment of social memory, while DG NR1-KO mice were indistinguishable from controls. We next applied the designer receptors exclusively activated by designer drugs (DREADD)-based chemogenetic approach in the CA3 specific Cre-transgenic mouse to differentiate the contribution of the dorsal CA3 versus the ventral CA3 in social memory. Our results provide the evidence of differential roles of hippocampal CA3 in social memory across the dorsal-ventral axis.

Abstract: The retrosplenial cortex (RSC) is one of the major cortical outputs of the hippocampal formation and as such, has been implicated in memory formation and recall. Further, the RSC is one of the cortical structures important for spatial navigation, containing neurons responsive to the animal's trajectory and head direction. Given its close functional and anatomical connections with the CA1 region an important question is how manipulations of neuronal activity in the RSC and/or CA1 influences these processes. Here we combine transgenic mice expressing the Cre recombinase specifically in the RSC or CA1 pyramidal cells with Cre-dependent AAV vectors expression Gi-DREADD to inducibly inhibit neuronal activity in each region while monitoring in vivo physiology. We found CNO-mediated silencing of RSC activity leads to changes in hippocampal activity supporting its role in memory consolidation.

Title: Characterization of a novel hippocampal-septal circuit

Authors: *H. HE[1,2], K. OKANOYA[2], T. J. MCHUGH[1,2]
[1]RIKEN, BSI, Saitama, Japan; [2]The Univ. of Tokyo, Tokyo, Japan

Abstract: The connections between the hippocampus and medial septum (MS) are crucial for integration of sensory and motor information in memory and the generation of the theta oscillation. While recent work has uncovered specific roles for ascending cholinergic, glutamatergic and GABAergic inputs from the MS to the hippocampus in these processes, much less is known about the role of the descending hippocampal efferents. Here we use transgenic and viral methods to identify and characterize a novel descending projection pathway from the hippocampal CA2 region to the MS. We find that optogenetic manipulation of these axons alters the animals' exploratory behavior and use in vivo physiological recordings to uncover the physiological consequences of these circuit manipulations.

Title: Head direction cells in mice are referenced to gravity

Authors: *H. CHAM[1], J. LAURENS[1], D. E. ANGELAKI[2], J. DICKMAN[3]
[1]Neurosci., [2]Dept of Neurosci., [3]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Head direction cells (HDC) form a “neural compass” of the local environment and play an important role in spatial navigation. Recent evidence reported that head direction cells in bats were 3D spatially tuned, suggesting that their neural response was modulated by the tilt relative to gravity (Finkelstein et al., 2015). Furthermore, we have identified gravity-referenced tilt signals in the anterior thalamus (ATh) of macaques (Laurens et al., 2016). However, ATh neurons in our previous study were not specifically identified as HDC. Furthermore, it remains unknown whether these navigation circuit neurons encode a 3D neural compass. Here, we examined whether HDC in the ATh of mice encode tilt information and determine whether the tilt encoding is referenced to gravity.

We recorded the response of ATh head direction cells in mice (n = 6) by manipulating the restrained animals’ 3D head orientation using a multi-axis motion stimulator. Neural activity was recorded using a chronic tetrode implant. Head direction responses were measured separately when animals moved freely in a circular arena. We recorded the response of 153 cells, out of which 32 (21%) were identified as HDC and 121 (79%) were non-HDC.

The majority of ATh cells (97/153, 63%) had a preferred direction of tilt orientation. In addition, both HD cells (21/32, 66%) and non-head direction cells (76/121, 63%) responded to tilt (Chi Square: p = 0.9). We then examined whether the tilt encoding was referenced either visual or gravity cues. First, we found that the tuning curves of these neurons were similar in both the light and the dark in terms of: preferred direction (r = .60, $p < 10^{-3}$), tuning width (r = .42, $p < 10^{-3}$), minimal firing rate (r = .95, $p < 10^{-5}$), and maximum firing rate (r = .96, $p < 10^{-5}$). Next, we measured the neural response tuning after placing the visual and gravity reference frames in conflict by tilting the visual surround while gravity remained constant. We found that cell responses were better correlated when computed in a gravity reference frame as compared the visual reference frame (Wilcoxon signed rank: $p < 10^{-4}$).

These results are the first to demonstrate tilt encoding of HDC in a land-dwelling animal. Our data suggests that tilt-sensitive ATh neurons use the gravity signal as a reference. The finding that tilt encoding is referenced to gravity highlights the role of the vestibular system in establishing self-orientation during navigation.

Title: Neural encoding of azimuth by head direction cells during rotation in three dimensions; and interaction with gravity responses

Authors: J. LAURENS[1], H. CHAM[1], *J. DICKMAN[2], D. E. ANGELAKI[3]
[1]Neurosci., [2]Dept. of Neurosci., [3]Dept of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Here, we examined whether head direction cells (HD) in the Anterior Thalamus (ATh) of mice encode a 3D neural compass. We recorded the responses of HD cells across a broad range of 3D head orientations during continuous motion stimulation in 2D tilt and 1D azimuth. We observed that the 3D HD responses can be decomposed into: (1) a 'gravity' component during head tilt in vertical planes previously observed in bats, primates and rodents (Finkelstein et al. 2015, Laurens et al 2016, and companion poster: Cham et al. 2017), and (2) an 'azimuth' component where HD encode head orientation in the horizontal plane when animals are upright. Previous studies have suggested that the azimuth plane may follow an animal's plane of locomotion when walking on vertical surfaces (Calton et al 2005; Wilson et al. 2016) or that azimuth and pitch may form a toroidal geometry (Finkelstein et al. 2015). However, a general understanding of neural encoding of azimuth though the whole 3D orientation space has yet to be described.

We recorded the activity of 99 ATh neurons during a passive rotation protocol across the whole 3D orientation space. We observed that 35/99 neurons had significant ($p<0.05$) azimuth tuning during this passive rotation protocol and were classified as HD cells. Nineteen of the thirty five neurons also exhibited a significant gravity tuning, and an additional 34/99 cells were tuned to gravity but no azimuth.

We observed, in agreement with Finkelstein et al. 2015 in bat HD cells, that the azimuth preferred directions (PD) reversed when animals were pitched beyond 90° upward or downward (but not rolled). In contrast, the PD for these cells didn't reverse when animals were rolled left or right up to 150°. We observed intermediate PD shifts for 90° to 150° tilt around intermediate (pitch/roll) axes. Azimuth tuning in upside-down orientation (>150° pitch or roll) was weak and variable. We propose a geometrical definition of azimuth during 3D rotation that accounts for these results and is compatible with the topologies proposed by Finkelstein et al. 2015 and Wilson et al. 2016.

We also found the same pattern of azimuth tuning in a subgroup of 19 gravity-tuned HD cells. The azimuth and gravity tunings interacted in these cells to form a preferred 3D orientation, which we described and modeled . Finally, we verified that this pattern of 3D orientation tuning uncovered during passive movements of the head-fixed animals persists during active exploration in 3D space in unrestrained freely-moving mice.

Title: Comparison of medial entorhinal and nucleus reuniens projections in ca1

Authors: *D. MAISSON, A. L. GRIFFIN
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Our lab has demonstrated that the ventral midline thalamic nucleus reuniens (Re) plays a vital role in spatial working memory (SWM) and oscillatory synchrony between the dorsal hippocampal (HPC) CA1 sub-region and the medial prefrontal cortex (mPFC) (Hallock et al., 2016), likely due to its extensive anatomical connectivity with both structures. Previous work has demonstrated that stratum lacunosum-moleculare (SLM) of CA1 receives dense projections from both Re and MEC. Considering these findings and that these pathways are both critical for SWM, the current study aims to characterize the shared and differential points of synaptic contact of the projections from each structure. This study used two distinct adeno associated viral vectors, each tagged with a different fluorophore, to compare the extent of overlapping innervation from Re and MEC to CA1. Within a given rat, a viral vector tagged with GFP was injected into the Re and one tagged with tdTomato was injected into the MEC. We allotted 6 weeks for expression of the fluorophore along the extent of the membrane and imaged the terminals in CA1 using confocal microscopy at multiple magnifications. Consistent with previous findings, our preliminary data show that stratum SLM receives projections from both the Re and the MEC. Interestingly, within SLM, we found expression of terminals from both structures in close proximity, which is suggestive of dual innervation from Re and MEC onto the same neuronal compartments. Future work will be aimed at identifying whether these two projection pathways converge on dendritic spines of pyramidal neurons, inhibitory interneuron dendrites, or both.

Title: Distinct spatial working memory correlates of prefrontal and hippocampal projections to the nucleus reuniens

Authors: *Z. M. GEMZIK, J. J. STOUT, M. T. GAYLORD, D. MAISSON, A. L. GRIFFIN
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Spatial working memory (SWM) requires the encoding, maintenance and retrieval of spatially relevant information that is then used to successfully navigate toward a goal and relies both on the medial prefrontal cortex (mPFC) and hippocampus (HPC). Due to reciprocal mPFC and HPC connections, the ventral midline thalamic nucleus reuniens (Re) is ideally situated to orchestrate mPFC-HPC interactions. Indeed, our lab has shown that suppression of Re cell body activity is critical for mPFC-HPC synchrony and SWM (Hallock et al., 2016). However, it is not yet clear what distinct roles the specific inputs into the Re have on particular phases of SWM. In order to address this question, we used archaerhodopsin (pAAV5-CAG-ArchT-GFP) for temporally selective optogenetic terminal suppression of either mPFC or dorsal subiculum (dSub) projections to the Re during either the cue-guided, memory-guided, or delay/maintenance phase of the Delayed Non-Match to Position (DNMP) task. Rats were injected with virus in either the mPFC or the HPC; for all rats, the fiber was implanted into the Re. This approach allowed us to selectively suppress terminals from either structure to the Re during each phase of DNMP (sample, choice, delay, and entire-trial). Our data show a significant impairment when mPFC terminals were suppressed during the choice phase but not sample, delay, or entire-trial phases of the task. Conversely, suppression of dSub terminals led to a trending deficit exclusively during the sample phase. These results suggest that the mechanisms underlying encoding may be supported by the HPC-Re-mPFC pathway whereas retrieval may be supported by the and mPFC-Re-HPC pathway.

Title: Oscillatory synchrony within the hippocampal-thalamo-prefrontal circuit during spatial working memory

Authors: *A. C. GARCIA, A. L. GRIFFIN
Univ. of Delaware, Newark, DE

Abstract: Spatial working memory-guided behavior in rodents has been shown to be supported by oscillatory synchrony between the hippocampus and the medial prefrontal cortex (mPFC). Extracellular recordings of local field potentials in dorsal hippocampus and mPFC have shown increased coherence in the theta band (4-12 Hz) when animals are required to apply spatial working memory (WM) toward a decision-making process. However, anatomical connections between hippocampus and mPFC are not bi-directional and are limited to a monosynaptic pathway extending from hippocampus to mPFC, primarily via its ventral subregion. The nucleus reuniens (RE) of ventral-midline thalamus is not only reciprocally connected with both hippocampus and mPFC, but has also been shown to be necessary for spatial WM-guided behavior. Furthermore, pharmacological inactivation of RE during a delayed-alternation task on a T-maze led to concomitant disruptions in theta coherence, theta-gamma phase-amplitude coupling, and directionality between dorsal hippocampus and mPFC when rats were required to emit a spatial WM-guided response (Hallock et al., 2016). To begin to understand how RE participates in hippocampal-mPFC interactions during spatial WM, we recorded local field potentials in dorsal hippocampus, RE, and mPFC during the delayed non-match to position task (DNMP) on a T-maze. The DNMP task requires encoding trial-specific information during the sample phase, maintenance across a delay period, and retrieval-guided decision making during the choice phase. We hypothesized that inter-regional oscillatory synchrony would be increased for the choice phase compared to the sample phase. In line with previous reports, we observed higher hippocampal-mPFC theta coherence during the choice phase compared to the sample phase (O'Neill et al., 2013). Additionally, coherence between RE and mPFC showed increases in both the theta frequency and the slower delta frequency (2-5 Hz) for the choice phase compared to the sample phase. Furthermore, these choice phase-specific increases in synchrony were not observed when animals performed the task poorly. Although coherence between RE and hippocampus showed peaks at theta, we did not observe any differences between sample and choice. The delta/theta coherence between RE and mPFC during the choice phase may serve to

co-modulate ensembles in mPFC that support spatial WM representations (Fujisawa et al., 2011). Further analyses will examine and characterize cross-frequency coupling and directionality within this tri-regional circuit during spatial WM.

Title: Posterior parietal and retrosplenial cortices map the position of a pursuit target

Authors: *D. A. NITZ[1], A. S. ALEXANDER[3], J. TUNG[2]
[2]Cognitive Sci., [1]Univ. of California San Diego, La Jolla, CA; [3]Boston Univ., Boston, MA

Abstract: Rats in the wild travel in packs and hunt small prey, activities that require pursuit of a moving target. In the laboratory, our previous work has shown that rats in an open arena will pursue a laser target moving in random trajectories. Rats also execute shortcut trajectories during stereotyped laser paths interspersed amongst the random paths. The present work examined neural activity in the posterior parietal cortex (PPC) and retrospenial cortex (RSC) that registered the position of the moving target relative to the animal's head during active pursuit. Data indicate that, after controlling for the PPC and RSC correlates for the animal's movement (linear and angular velocity), neurons in the PPC and RSC encode the position of the laser target relative to the animal, at least within a 40 cm long by 60 cm wide spatial window extending out from the rat's head. Sub-populations of neurons in both regions encoded the distance of the laser target irrespective of angular offset, or exhibited laser target receptive fields that were biased according to the distance and angle of the laser target relative to the animal's head. We conclude that both RSC and PPC can effectively generate a mapping of target position that is integrated within an encoding of the animal's current linear and angular velocity.

Title: Representation of navigational distance in the retrosplenial cortex

Authors: *A. S. ALEXANDER[1], D. A. NITZ[2]
[1]Boston Univ., Boston, MA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: Recent work has demonstrated that retrosplenial cortex (RSC) neural ensembles encode a multitude of spatial variables relevant to effective navigation, including: location and heading orientation in the environment, position within known routes, and the current or upcoming action state of the animal. However, accurate spatial mapping and movement also likely requires a representation of the animal's distance from fixed environmental points or landmarks. Recent work in humans traversing virtual environments indicates that BOLD activation in RSC can track distance information. Distance encoding likely requires neural circuitry sensitive to external location, heading, and egocentric relationship to other environmental locations or landmarks. The confluence of projections that reach RSC would potentially produce neurons simultaneously sensitive to these spatial variables, as RSC is reciprocally connected to sub-cortical structures known to represent spatial location and heading in the external world and cortical regions that process sensory information such as the positions of visual stimuli relative to the animal. Here we report that RSC ensembles encode the animal's distance from fixed points in well-known routes. This form of spatial representation is constructed from spatial activation profiles of individual RSC neurons that exhibit symmetrical patterns around individual points within the trajectory. Aligned symmetrical firing rate profiles could be utilized to accurately decode the animal's distance from these points of symmetry, effectively yielding a metric of the animal's distance from all points in the environment. We observed this form of spatial representation across multiple routes and explored distance encoding in RSC during free exploration. The current data indicates that RSC neurons generate a unique representation of navigational distance, including distance from a trajectory start point. Thus, this property is in line with deficits to path integration and topographic disorientation following damage to the region.

Title: Creating spaces: Posterior parietal cortex and hippocampal mapping of environmental subspaces

Authors: *L. E. SHELLEY, D. A. NITZ
UCSD, La Jolla, CA

Abstract: The present study examined posterior parietal cortex and hippocampal representations of an environment divided into subspaces. While numerous studies have outlined posterior parietal cortex route mapping as well as hippocampal place mapping in various situations, the current study examined environmental subspace representations using a task-defined, behavioral rule to demarcate the division of a room into two subspaces, rather than a concrete feature or visible dividing line. During initial training, rats traversed a T-shaped track that was placed in one of four locations. Each rat learned to run up the stem of the 'T' and either turn left or right depending on the location of the track's choice point in the room. Rats were trained to turn left when the track was placed in one half of the room, and to turn right when placed in the other half. This rule divided the overall room into two subspaces in the absence of any physical boundary line. Behavioral results suggested that rats are capable of learning such logical fragmentation, as evidenced by high accuracy during probe trials in which the track was placed in novel locations. Furthermore, although performance in all track positions was significantly above chance, accuracy was dependent on the track's proximity to the fragment boundary, as shown by worse performance for track locations near the boundary. This was likely due to increased ambiguity in turn choice with less spatial separation between a track location requiring a left turn and one requiring a right turn. After rats were trained, neurons in both the hippocampus and posterior parietal cortex were recorded during task performance. Spatial firing patterns of neurons in both brain regions followed the track space in each of the four positions, an effect that was expected for posterior parietal cortex neurons, but was unexpected in the hippocampus. Furthermore, posterior parietal cortex ensembles discriminated between the animal's ultimate left vs right turning behavior at earlier stages in each trial than did the hippocampal population firing patterns. Findings from the present study suggest that rats are capable of learning a spatial division into subspaces that is rule-induced, and that posterior parietal cortex and hippocampal neurons modulate their typical firing patterns in a novel way to map environmental subspaces.

Title: Enriched environment alters the epigenetic profile in the hippocampus and mitigates memory deficits induced by early postnatal lead exposure in a sex-dependent manner

Authors: *V. SINGH, G. VARMA, J. SCHNEIDER
Anatomy, Pathology and Cell Biol., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Being raised in an enriched environment improves cognitive functions and presents a potential social intervention strategy to mitigate cognitive/behavioral deficits associated with developmental disorders. However the molecular mechanisms underlying the structural and functional effects on the brain induced by an enriched environment remain poorly understood. Developmental exposure to the environmental toxicant lead (Pb) results in behavioral and cognitive impairments that can persist lifelong, both in humans and animal models. No current therapies have been effective in reversing the neurological damage and functional deficits induced by Pb exposure. The purpose of this study was to investigate the extent to which environmental enrichment could mitigate memory consolidation/recall deficits and further modify altered epigenetic marks in response to developmental Pb exposure. Following an early postnatal exposure (EPN) to Pb (birth through weaning), male and female Long Evans rats were randomly housed under non-enriched (standard housing, 3 rats/cage) or enriched (large enclosures, 6 rats/cage, equipped with variety of toys, running wheels etc., changed 3 times/week) conditions. Non Pb-exposed controls were housed under similar conditions. At PND55, the animals were tested for associative memory deficits using a trace fear conditioning paradigm. Memory deficits were observed only in non-enriched EPN females. Enriched EPN females performed similar to non Pb controls suggesting that living in the enriched environment mitigated the cognitive deficit induced by Pb exposure. To gain insight into possible epigenetic mechanisms underlying these results, we examined global DNA methylation (mC) and hydroxymethylation (hmC) levels in the CA1 region of the hippocampus. Non-enriched EPN females had globally reduced mC and hmC levels. Enriched EPN females and controls had similar mC and hmC levels and higher than those in non-enriched EPN females. Exposure to Pb differentially altered expression levels of DNA methylation-related genes in EPN male and females and environmental enrichment tended to normalize these levels, making them

comparable to controls. Further studies aimed at understanding gene level functional networks/mechanisms and their functional significance are in progress.

Title: Grid cell representation across a multi-level maze

Authors: *P. A. LACHANCE[1], S. S. WINTER[2], M. L. MEHLMAN[1], J. S. TAUBE[1]
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Successful navigation in the real world requires understanding of three-dimensional (3D) space, though most navigation research focuses on exploration in two-dimensional (2D) arenas. Evidence for neural processing of 3D space can be found in studies examining head direction (HD) cells, which encode the instantaneous orientation of an animal's head. HD cells in the rat translate their 2D representations in accordance with movement from a horizontal to a vertical plane of locomotion. Bat HD cells show firing rate modulation in response to head rotations about the yaw, pitch, and roll axes. Studies have also been undertaken to examine 3D representations in grid cells, which represent 2D space with periodic firing fields that form a repeating hexagonal pattern across an arena. However, 3D grid cell studies have used arenas that force an animal to change its vertical position either continuously or in tandem with a change in horizontal position. The current study sought to evaluate grid representations as female rats explored the same horizontal arena at different vertical heights. Grid cells in the medial entorhinal cortex were monitored as a rat explored a gray square arena (baseline: 1.2 x 1.2 x 0.5 m). Following this, a slightly smaller arena with clear plastic walls was placed into the larger arena, and the rat was allowed to explore this environment within the smaller arena (lower: 1 x 1 x 0.5 m). For the third session, the clear-walled arena was lifted 0.5 m above the floor (upper: 1 x 1 x 0.5 m), such that the rat could look out and see the baseline arena below while still exploring within a familiar but now vertically displaced arena. Grid cells appeared to maintain the size, spacing, and orientation of nodes across the lower and upper locations. However, the grid phase was offset between sessions, such that there was no overlap between lower and upper level grid nodes. This finding indicates that grid cells might integrate vertical displacement into their spatial representations, resulting in a 3D grid pattern transected by the two horizontal planes

explored in this study. Alternatively, the rats could have perceived the upper level as a novel context, resulting in the observed shift in grid patterns.

Title: Are head direction cell responses commutative on a 3D surface?

Authors: *J. R. DUMONT[1], P. A. LACHANCE[1], J. L. MARCROFT[1], N. R. BOVIO[1], S. S. WINTER[2], J. S. TAUBE[1]
[1]Psychological & Brain Sci., Dartmouth Col., Hanover, NH; [2]The Jackson Lab., Bar Habor, ME

Abstract: An animal's perceived sense of orientation depends upon the head direction (HD) system, which is comprised of HD cells that discharge when an animal faces a particular direction in the environment; i.e., the preferred firing direction (PFD). While most research has focused on the neural properties of HD cells in the horizontal plane, animals navigate through 3D terrains. Previous research examining HD cell responses in 3D has lead to two competing models in predicting how HD cells respond in different planes: 1) the 'rotational plane model', which postulates that as a rat moves from a horizontal surface onto a vertical one, the cell will transform its frame of reference to its current plane of locomotion by rotating the horizontal plane by 90° into the vertical plane. Thus, a cell's PFD in the vertical plane can be treated as a rotational extension of the floor, where the animal shifts its reference frame to align with its current plane of locomotion; 2) the 'mosaic model', which is based on recent findings showing that as rats traverse across vertical corners of a cuboidal structure, HD cells shift their PFDs by 90° across vertical boundaries (90° CCW shift for leftward crossings and 90° CW shift for rightward crossings). PFD shifts did not occur across horizontal boundaries. Both these models make different predictions about how HD cells would respond once they reach the top (horizontal) surface following routes across vertical boundaries. The rotational plane model predicts that if an animal always rotates its plane of locomotion (along with the cell's PFD) onto the next surface, then the cell will fire in a different direction compared with the floor when the animal reaches the top surface - depending upon the path taken (i.e., firing is not commutative). In contrast, the mosaic model predicts that a cell's PFD would remain the same when the rat travels from the floor onto a vertical surface and then across a second vertical surface before

reaching the top surface (i.e., firing is commutative) because the model argues that cells' PFDs will shift by 90° around the vertical corner, but not around the horizontal corner. To test whether cell responses are commutative, we recorded HD cells from the anterodorsal thalamus while rats traveled different paths to reach the top surface of a cube (floor -> wall -> top vs. floor -> wall -> side wall -> top). Our results indicate that the majority of HD cells shifted their PFDs by 90° around vertical corners such that the cells responses on the top surface remained similar to that on the floor regardless of the path taken by the rats - thus demonstrating commutativity. These results are more consistent with the mosaic model than the rotational plane model.

Title: The dorsal striatum and medial precentral cortex are functionally and anatomically integrated into the head direction cell circuitry

Authors: *M. L. MEHLMAN[1], S. S. WINTER[2], S. VALERIO[3], J. S. TAUBE[1]
[1]Dartmouth Col., Hanover, NH; [2]The Jackson Lab., Mount Desert, ME; [3]Natl. Inst. of Hlth. and Med. Res., Bordeaux, France

Abstract: Head direction (HD) cells provide a sense of direction used for navigation. These neurons fire as a function of the animal's HD and are located in multiple, interconnected brain regions in the limbic system. Interestingly, HD cell activity has been observed in regions outside of the canonical limbic HD circuit, including the dorsal striatum (DS) and medial precentral cortex (PrCM). We performed a series of electrophysiological and neuroanatomical studies in rats to examine the functional and anatomical relationships between the limbic HD circuit, DS and PrCM.
We first recorded HD cells in the DS and PrCM. These extralimbic HD cells were nearly identical to limbic HD cells recorded in the anterodorsal thalamic nuclei (ADN) in regards to their basic firing characteristics and responses to environmental manipulations. Angular head velocity (AHV) cells – neurons modulated by head motion – were also recorded in the DS and PrCM. We then recorded DS and PrCM activity in animals that had received ADN lesions to

disrupt the limbic HD circuit. Complete lesions abolished extralimbic HD cell activity, indicating that the HD signal in the DS and PrCM is dependent upon output from the limbic HD circuit. AHV cell activity was spared in lesioned animals, suggesting that it is either generated locally or inherited from an external structure independently of the ADN. Finally, to determine if the DS and PrCM provide self-motion information to the limbic HD circuit (e.g. a motor efference signal or AHV signal), we recorded ADN HD cells in animals with combined DS and PrCM lesions. These lesions did not affect the limbic HD signal, suggesting that self-motion information is not conveyed from the DS and PrCM to the limbic HD circuit.
Next, we performed neuroanatomical tracing experiments to identify pathways that could facilitate communication between the limbic HD circuit, DS and PrCM. Retrograde tracing revealed that the DS receives direct input from multiple regions in the limbic HD circuit, including the lateral mammillary nuclei (LMN), ADN, retrosplenial cortex (RSC) and medial entorhinal cortex (MEC). These projections preferentially target the same DS subregion in which we recorded HD cells and AHV cells. The PrCM receives direct input from the LMN, RSC and MEC. Direct projections from the LMN to the DS and PrCM may convey AHV information independently of the ADN. Anterograde tracing revealed that the DS and PrCM indirectly project to the limbic HD circuit via the entopeduncular nucleus.
Collectively, these foundational studies describe how the DS and PrCM are functionally and anatomically integrated into the HD cell circuitry, expanding our understanding of the neural basis of navigation.

Title: Modulation of GluN2B subunit-containing NMDA receptors expression and spatial long-term memory in medial septal immunolesioned rats

Authors: *G. BESELIA, M. DASHNIANI, M. BURJANADZE, R. SOLOMONIA, L. KRUASHVILI, N. CHKHIKVISHVILI

Abstract: The hippocampus is important in the formation of spatial memory in both humans and animals. The N-methyl-D-aspartate (NMDA) type of glutamate receptors in the hippocampus has been reported to be essential for spatial learning and memory as well as for the induction of

synaptic plasticity. Evidence accumulated from recent studies suggest that GluN2A and GluN2B subunit-containing NMDA-Rs preferentially contribute to the induction of hippocampal LTP and LTD. Using a Morris water maze (MWM) task, the LTP-blocking GluN2A antagonist had no significant effect on any aspect of performance, whereas the LTD-blocking GluN2B antagonist impaired spatial memory consolidation.
The present study was designed to investigate the effect of selective immunolesions of cholinergic and GABA-ergic septohippocampal projection neurons [using 192 IgG-saporin (SAP) or GAT1-1 saporin (GAT), respectively] on spatial memory assessed in MWM and NMDA receptor GluN2B subunit expression in the rat hippocampus. We used MWM training protocol with eight training trials. One day after training, probe test with the platform removed was performed to examine long-term spatial memory retrieval. We found that immunolesions of medial septal cholinergic or GABAergic neurons did not affect spatial learning as exhibited by a decreased latency to find the hidden platform across the eight training trials. Trained control and SAP treated rats spent significantly longer than chance (15 s) performances such as swimming time in test sector (where the hidden platform was located). Moreover, they spent significantly longer in test sector than the opposite sector, confirming the establishment of long-term memory. In contrast, the preference for test sector was abolished in medial septal GAT treated rats. Because GAT treated rats learned the location of the hidden platform during training, the result suggest that GAT level of NR2B subunit of NMDA receptor in the hippocampus was decreased significantly in the GAT treated group compared with the control and SAP treated groups.
In conclusion, our findings suggest that immunolesion of medial septal GABAergic neurons can interrupt hippocampus dependent spatial memory, possible through modulation of NMDA receptor subunit expression in the hippocampus. Moreover, our finding that selective lesions of medial septal GABAergic neurons affect probe-test performance but not spatial learning, suggests that septohippocampal GABAergic projections are involved specifically in the consolidation or retrieval, but not in the acquisition of long-term memory.

Title: Calbindin in distinct populations of hippocampal neurons modulates stress susceptibility and resilience

Authors: *J.-T. LI[1], X.-M. XIE[1], J.-Y. YU[2], Y.-A. SU[1], M. V. SCHMIDT[3], X.-D. WANG[2], T.-M. SI[1]

Abstract: Calbindin critically modulates intracellular Ca2+ dynamics and synaptic plasticity. Reductions of hippocampal calbindin levels have been implicated in cognitive disorders, including those induced by early-life stress. However, it is unclear how early-life stress modulates calbindin expression in distinct hippocampal neurons and the contribution of calbindin in each neuronal population to cognition. Here, we report that calbindin in hippocampal excitatory and inhibitory neurons modulates the susceptibility and resilience to stress-induced spatial memory deficits respectively. Stress exposure during early postnatal period lastingly reduced calbindin levels in all CA1 and DG neurons. Reduced calbindin levels in CA1 or DG excitatory neurons, but not CA1 interneurons, correlated with spatial memory impairments. Accordingly, selective knockdown of calbindin in CA1 or DG excitatory neurons mimicked early-life stress-induced memory deficits in adulthood. By contrast, calbindin knockdown in CA1 interneurons preserved memory both under basal conditions and after an acute stress challenge. Moreover, calbindin expression levels were suppressed by early-life stress through the CRHR1-nectin3 pathway, and in turn reduced inositol monophosphatase levels. Our findings highlight calbindin as a key molecule for the reprogramming effects of early-life stress on cognition, and exemplify how distinct neurons sharing a same molecule confer the susceptibility or resilience to stress.

Title: Targeting DNA methylation to enhance learning and memory

Authors: K. E. ZENGELER, C. P. GETTENS, A. R. GOGLIETTINO, T. S. R. HOTZ, B. G. MALACHOWSKY, *A. J. KENNEDY
Chem., Bates Col., Lewiston, ME

Abstract: The storage and retrieval of memories is driven by a series of biochemical reactions that ultimately alter the expression of plasticity-regulating genes in participating neurons. Epigenetic mechanisms, such as DNA methylation, can regulate levels of gene expression and have been associated with altered plasticity in memory circuits. Specifically, active DNA methylation has been demonstrated to be necessary for the formation and consolidation of long-term memory. Here, we investigated the TET family of dioxygenase enzymes that drive active cytosine DNA demethylation in the CNS as targets for enhancing memory formation and storage. By the selective knock out or ASO-targeted knock down of the different isoforms of the TET family of enzymes, we examined isoform efficacy at altering the methylation and expression of plasticity-related genes in the hippocampus. Next, we determined whether these TET-driven changes were sufficient to enhance spatial and context-dependent long-term memory. Finally, we examined whether targeting TET isoforms is sufficient to treat the cognitive deficits associated with Pitt Hopkins Syndrome (PTHS), a monogenetic autism-spectrum disorder caused by haploinsufficiency of *Tcf4* that is associated with reduced DNA methylation in the hippocampus. Altogether, our results indicate a therapeutic potential for TET enzyme inhibition to improve learning and memory in diseases and disorders of memory.

Abstract: The epigenetic changes by histone modification is important for synaptic plasticity and brain function. Lysine-specific demethylase 1 (LSD1) is a histone demethylase that participates in transcriptional repression or activation. Recent studies reported that LSD1 is involved in learning and memory. Although LSD1 phosphorylation by PKCα was implicated in circadian rhythmicity, the importance of LSD1 phosphorylation by PKCα in learning and memory is unknown. In this study, we examined the roles of LSD1 in synaptic plasticity and memory using *Lsd1*$^{SA/SA}$ knock-in (KI) mice, in which a PKCα phosphorylation site of LSD1 is mutated. Interestingly, short-term and long-term contextual fear memory as well as spatial learning and memory were impaired in *Lsd1* KI mice. Extracellular field recordings showed that short-term synaptic plasticity, such as paired pulse ratio and post-tetanic potentiation was impaired in *Lsd1* KI mice, whereas long-term synaptic plasticity, including long-term potentiation and long-term depression, was normal. Moreover, the frequency of miniature excitatory postsynaptic current was significantly increased, suggesting presynaptic dysfunction in *Lsd1* KI mice. Consistent with this, RNA-seq analysis using the hippocampus of *Lsd1* KI mice showed significant alterations in the expressions of presynaptic function-related genes. Intriguingly, LSD1n-SA mutant showed diminished binding to histone deacetylase 1 (HDAC1) compared to LSD1n-WT in SH-SY5Y cells. These results suggest that LSD1 is involved in the regulation of presynaptic gene expression and subsequently regulates the hippocampus-dependent learning and memory in phosphorylation-dependent manner.

Title: The role of the ventral hippocampus in contextual fear conditioning

Authors: *J. A. GRAHAM[1], B. J. WILTGEN[2]
[1]Neurosci., [2]Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: The hippocampus(HPC) is critical for the storage and retrieval of episodic and spatial memories. It is also necessary for the retrieval of contextual fear memories wherein a previously neutral place becomes associated with danger. However, since the HPC is not the site of storage for the context-shock association, it must communicate with other structures in order to drive memory retrieval. Current evidence strongly implicates the amygdala (AMY) as the site of storage for the CS-US association in fear memories. In the case of contextual fear conditioning, it is thought that the HPC provides the contextual information needed by the AMY to form the CS-US association and support memory retrieval. Projections to the AMY originate within the ventral 2/3 of the HPC and terminate in anterior portions of the BA (basal amygdala). Several studies suggest that this projection is necessary for the retrieval of contextual fear memories. Here, we confirm that VHC-BA neurons are restricted to a particular lamina within the VHC, and that optogenetic manipulation of VHC neurons can disrupt fear memory retrieval. We plan to extend these findings by first quantifying activity during context fear training and retrieval within the VHC-BA projection using a combination of c-fos imaging and the expression of retrograde tracers. We will then utilize the fos-tTA inducible tagging system to identify ensembles activated by contextual fear memory retrieval in VHC-BA projecting neurons and restrict optogenetic manipulations to these same cells. In doing so, we will determine whether context-specific activity in this projection is necessary and/or sufficient to drive fear memory retrieval.

Title: Context fear learning triggers metaplasticity in the hippocampus

Authors: *J. N. KRUEGER[1], A. P. CRESTANI[2], B. J. WILTGEN[1,3]
[1]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [2]Neurosci. Grad. Program, Federal Univ. of Rio Grande do Sul, Rio Grande do Sul, Brazil; [3]Dept. of Psychology, Univ. of California, Davis, Davis, CA

Abstract: It is widely believed that NMDARs are required for learning and memory. However, several studies have shown that prior experience can reduce or eliminate the need for these receptors during subsequent learning. For example, animals trained on a hippocampus-dependent fear conditioning task are able to encode new fear memories in the absence of NMDAR activation. Results like these suggest that prior behavioral training modifies cellular plasticity mechanisms such that NMDARs are no longer required for learning. Current models of memory cannot explain this finding and the mechanisms that give rise to NMDAR-independent learning have yet to be identified. Therefore, the goal of the current experiment is to identify hippocampal plasticity mechanisms that are altered by behavioral experience and determine their contribution to NMDAR-independent learning.
Electrophysiological studies have identified several types of long-term potentiation (LTP) in the hippocampus that do not require NMDARs. These forms of plasticity can be mediated by metabatropic glutamate receptors (mGluR), kainite receptors (KR), or voltage-gated calcium channels (VGCC). The current experiments determined which of these mechanism mediates NMDAR-independent learning. To do this, mice underwent fear conditioning in context A followed by context B. We have shown that the former requires NMDAR while the later does not. During learning in context B, we infused antagonists for mGluRs, KRs or VGCCs into the hippocampus and examined the effects on memory. Our preliminary data indicate that memory for context B is only impaired when mGluR receptors are blocked by the antagonist MCPG prior to training in context B. Antagonists for NMDARs, KRs or VGCCs were ineffective. In addition, MCPG had no effect on learning in context A. Together these data suggest that learning about novel events requires NMDARs while learning about similar events requires mGluRs. Similar results have been found in the barrel cortex after whisker stimulation (Clem & Barth, 2008).

Title: Molecular mechanisms of working memory and possible involvement of TRPC channels

Authors: *A. REBOREDA[1,2], M. J. VALERO-ARACAMA[3,4], F. M. THEISSEN[2], A. ARBOIT[2], A. CORBU[3], M. YOSHIDA[1,2]

Germany; [3]Ruhr Univ. Bochum, Bochum, Germany; [4]Inst. for physiology and pathophysiology, University of Erlangen, Germany

Abstract: Working memory (WM) tasks and temporal association tasks require the subject to hold information for a short period of time. This retention of information is thought to be done by persistent firing which is shown in vivo from areas active during these tasks (i.e.: hippocampal area, prefrontal cortex) during the retention period. However, it still remains unclear what mechanism supports persistent firing in vivo.
In contrast to the classical idea that recurrent synaptic network supports persistent firing, we and others have shown that TRPC channels can support persistent firing in individual neurons in vitro. TRPC channels are modulated by complex intracellular molecular pathways downstream of metabotropic G-protein coupled receptors. However, it was never systematically studied whether these modulations of TRPC channels are in agreement with the modulation of WM. To assess the plausibility of the idea that TRPC channels support WM, in the present work, we review molecular pathways supporting WM and persistent activity in vivo, and then we compare them to the mechanisms supporting persistent activity and TRPC channels in vitro.
We conclude that muscarinic (mainly M1), serotonin $5HT_{2A}$ and moderate activation of noradrenergic α_1 receptors, which are coupled to Gq and lead to PLC pathway activation, show a positive effect on WM and the maintenance of the persistent firing in vivo. While in vitro, the same pathway activates TRPC channels and trigger persistent firing in the areas engaged in WM activities. In addition, receptors coupled to Gi (M2, α_2, β_2, D_2) improve also WM and increase persistent firing in vivo, while in vitro experiments show that the Gi-triggered decrease of cAMP levels can activate TRPC channels and strengthen persistent firing. On the other hand, receptors coupled to Gs (β_1, $5HT_6$, D_1) impair WM and persistent firing in vivo, while the increase of cAMP levels leads to TRPC inhibition and suppression of the persistent firing observed in vitro. After reviewing and comparing the metabotropic pathways involved in WM and those leading to TRPC activation, we conclude that they show a high degree of homology and that makes TRPC channels strong candidates to be activated during the WM and temporal association tasks generating the persistent firing observed in vivo.

Title: Investigating the role of TRPC channels in hippocampal persistent firing

Authors: *A. ARBOIT[1], F. THEISSEN[1], J. SCHWEIHOFF[2], L. BIRNBAUMER[3,4], M. YOSHIDA[1,5]
[1]Cognitive Neurophysiol., German Ctr. For Neurodegenerative Diseases-DZNE, Magdeburg, Germany; [2]Ruhr-Universität Bochum, Bochum, Germany; [3]Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC; [4]Inst. of Biomed. Res. (BIOMED UCA-CONICET), Buenos Aires, Argentina; [5]Leibniz Inst. For Neurobio., Magdeburg, Germany

Abstract: The hippocampus plays an important role in memory tasks requiring an active maintenance of memory for a short period of time. Persistent firing, the ability of a neuron to maintain sustained firing after an input is terminated, is thought to support this phenomenon at the cellular level. In this study, we investigated the roles of transient receptor potential cation (TRPC) channels in supporting persistent activity in the hippocampal CA1 pyramidal cells focusing mainly on the TRPC4 and TRPC5 channels, which are highly expressed in the hippocampus. TRPC channels are one of the main candidates supporting persistent firing. However, their role in this phenomenon in the hippocampus is still not clear. Previous works in the prefrontal cortex using TRPC KO animals didn't show a clear link between persistent firing and these channels. Hence to give a conclusive answer, we choose to tackle the question combining different approaches, using pharmacological tools, antibodies and conditional KO of TRPC5. Our immunohistochemistry confirmed the expression of both TRPC4 and TRPC5 channels in the hippocampus. Using in vitro whole-cell patch clamp recordings in mouse hippocampal slices, we found that bath application of Carbachol (CCh), a cholinergic receptor agonist, induced persistent firing (PF) in about 70% of cells recorded. Frequency of persistent firing was around 9Hz and persistent firing typically lasted for 20 seconds. Then we investigated the role of TRPC channels. We started with a pharmacological approach using two novel TRPC channels blockers: clemizole hydrochloride and ML204. These drugs at high concentrations target both TRPC4 and TRPC5 while at lower concentrations ML204 targets mainly TRPC4 and clemizole hydrochloride targets TRPC5. Both of these blockers affected persisting firing, blocking it or reducing its length and/or frequency. In the second step, we used TRPC antibodies diluted in the intracellular solution to investigate how selectively blocking those channels could affect persistent activity. TRPC4 or TRPC5 antibodies suppressed PF in a similar way to the TRPC blockers. In the last approach we used a conditional TRPC5 KO mouse. Persistent firing in KO mice was greatly reduced compared to wild type mice leaving only a short depolarization. This depolarization plateau was almost completely suppressed by an application of ML204 or relatively high concentration of clemizole hydrochloride, suggesting an involvement of TRPC4. These results suggest that TRPC4 and TRPC5 channels may play a central role in supporting persistent firing in CA1 hippocampal cells.

Abstract: Increasing evidence suggests the involvement of the hippocampus in temporal association tasks and working memory both in human and animals. Persistent firing has long been believed to be the cellular correlate of these tasks to support short-term (up to tens of seconds) retention of memory. However, the molecular mechanisms supporting persistent firing have not been identified. We have recently shown that hippocampal principal neurons support persistent firing driven by cholinergic receptors, and downstream activation of TRPC-like channels in vitro. To investigate the role of TRPC channels in temporal association memory, we tested a conditional gene-knockout (KO) confined to the hippocampus in male TRPC5 floxed mice, in a trace fear conditioning task. Conditional KO was induced by an injection of a viral vector containing Cre recombinase and a GFP reporter. A control group of animals was injected with a viral vector containing only a GFP reporter. Four weeks later, we first conducted in vitro recordings. We found that persistent firing in CA1 pyramidal cells was significantly reduced, indicating the supportive role of TRPC5 in persistent firing. Conditioning of the remaining animals was conducted as follows: After a baseline period, mice were presented with several tone-shock (CS-US, trace period of 30 seconds) pairings on day 1 in Context A, and were probed 24 hours later in Context B, and a further 24 hours later in context A. The two groups differed in their freezing levels throughout the conditioning session on Day 1, with the TRPC5 KO mice freezing significantly less, indicating that they struggled to learn the condition of the task. On Day 2, the KO group also showed significantly less freezing in response to the tone, indicating that they had failed to form the association between the tone and the shock. On Day 3 there was no significant difference between groups, and both groups freezing levels remained very low, indicating that the initial conditioning had led to an association between the CS and the US, instead of an association between the US and the context. Hereby we have shown that TRPC5, a

channel which is fundamental to the generation of sustained activity patterns, contributes to trace fear conditioning performance.

Title: Deficiency of TRPC1 exacerbated the apoptosis and cognitive impairment induced by Aβ

Authors: *M. LI[1], J. WANG[2]
[1]Pathophysiology, Huazhong Univ. of Sci. and Technol., Hubei, China; [2]Pathophysiology, Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Extracellular precipitation of β-amyloid (Aβ) is a pathological characteristic of Alzheimer's disease (AD). Canonical transient receptor potential (TRPC) channels are widely expressed throughout the nervous system while their functions remain largely unclear. Here, we studied the effects of TRPC1 on cognitive deficit induced by Aβ. We found that TRPC1 was dispensable for cognition of mice in physiological conditions. However, mice lacking of TRPC1 had a poorer performance in learning and memory when injected with Aβ in the unilateral ventricle. Treated with Aβ, TRPC1 knockout mice showed an increased level of apoptosis and a significant lossing of neurons in hippocampus. while deficiency of TRPC1 in physiological conditions did not affect the hippocampal apoptosis of mice. To further verify it, we overexpressed TRPC1 in cells and found it protected aganist to the apoptosis induced by Aβ treatment. On the other hand, we found that overexpression of TRPC1 reduced the production of Aβ in 293-APP cells, which overexpressed amyloid protein precursor stablly. These findings indicate that deletion of TRPC1 exacerbated the cognitive impairment induced by Aβ through apoptosis increasing.

Title: Methamphetamine activating hippocampal HCN channels involves in drug-associated context learning

Authors: *R. SONG[1], S.-Z. ZHANG[1], D.-N. CAO[1], L.-J. YANG[2], Z.-Y. WANG[1], N. WU[1], J. LI[1], J.-Q. ZHENG[1]
[1]Beijing Insistitute of Pharmacol. and Toxicology, Beijing, China; [2]Dept. of Anesthesia, Chinese PLA general hospital, Beijing, China

Abstract: Addictive drug-associated context learning plays an important role in the development of drug addiction, and changes in the electrophysiological properties and synaptic plasticity of hippocampal neurons are thought to be the cellular underpinnings of drug-context associative learning and memory. Hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels play a fundamental role in controlling neuronal excitability and synaptic transmission in the hippocampus; however, whether HCN channels participate in context-associated learning remains unclear. In the present study, we found that methamphetamine (1 μM) increased the frequency of action potentials accompanied by a moderate depolarization of membrane potential in CA1 pyramidal neurons in hippocampal slices, which was abolished by blocking HCN channels, suggesting an involvement of HCN channels activation. Methamphetamine (0.1 and 1 μM) augmented the I_h amplitude by enhancing the conductance of HCN channels and shifting the activation curve to more depolarized potentials in hippocampal CA1 pyramidal neurons, thereby increasing the action potentials frequency. Furthermore, we found that the facilitation of HCN channels by methamphetamine was in a dopamine-dependent manner and probably also in a direct fashion. Functionally, the methamphetamine facilitation of HCN channels involved the long-term potentiation induction at Schaffer collateral-Cornu Ammonis1 excitatory synapses and the conditioned place preference acquisition, suggesting an important role of HCN channels in drug-associated context learning. In conclusion, these data supported that methamphetamine activated HCN channels in hippocampal pyramidal neurons and thus enhanced pyramidal membrane excitability and excitatory synaptic plasticity, which contributed to drug-associated context learning. These findings extend our understanding of the neurobiological mechanisms

underlying methamphetamine addiction. **Keywords:** Drug addiction, Hyperpolarization-activated cyclicnucleotide-gated channels, Methamphetamine, Drug-associated context learning, Hippocampal pyramidal neurons, Long-term potentiation

Title: Role of CREST in synaptic plasticity and memory formation

Authors: *T. J. HEMSTEDT, E. A. KRAMÁR, Y. ALAGHBAND, D. P. MATHEOS, J. J. BANIHANI, M. A. WOOD
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Epigenetic mechanisms have the potential to make persistent changes at the cellular level that can lead to long-term behavioral adaptations. Alterations of the epigenome have been shown to impact memory consolidation and to change gene expression profiles during memory consolidation. Chromatin remodeling is a major epigenetic mechanism, but it only recently gained attention in the learning and memory field. Chromatin remodeling complexes are multi-protein complexes that interact with DNA or chromatin structure and possess an ATP-dependent enzyme that induces a shift in the nucleosome positioning and ultimately regulate gene transcription. Recently, the Brg1/hBrm Associated Factor (BAF) complex has been gaining interest as it contains neuron-specific subunits and has been linked to intellectual disability disorders. Here, we investigate the neuron-specific subunit calcium-responsive transactivator (CREST) of the BAF complex. To knockdown the expression of CREST, we injected morpholinos and siRNA against CREST into the CA1 region of the dorsal hippocampus of mice.

Our results indicate that CREST is critical for synaptic plasticity and additionally a decrease in CREST expression leads to deficits in contextual fear memory and object-location memory.

Title: HDAC3-inhibition facilitates long-term memory consolidation of sound-specific information

Authors: *A. SHANG, S. BYLIPUDI, K. M. BIESZCZAD
Behavioral and Systems Neuroscience, Dept. of Psychology, Rutgers Univ., Piscataway, NJ

Abstract: Neuroplasticity and successful long-term memory (LTM) can be modulated by epigenetic mechanisms, such as chromatin modification. Histone deacetylases (HDACs) typically oppose histone acetyltransferases (HATs) and repress gene expression by constricting chromatin. HDAC inhibitors have therefore been shown to open chromatin and facilitate various forms of LTM (e.g. McQuown & Wood, 2011; Malvaez et al., 2013). For example, rats treated with a pharmacological HDAC3-inhibitor (HDAC3i) during consolidation of an auditory associative task have enhanced memory for the behaviorally-salient sound-frequencies in a memory test after training, as well as expanded representation in primary auditory cortex (A1) for the signal-frequencies (determined by electrophysiological “mapping” of A1 tonotopy after all training and testing; Bieszczad et al., 2015). Here, we test the emerging hypothesis that HDAC3 controls the sensory-specificity of LTM (Phan & Bieszczad, 2016). Adult male rats (Sprague-Dawley) were trained on a two-tone frequency-discrimination (2TD) task with immediate post-training injections of an HDAC3i (RFGP966, Abcam Inc.; 10mg/kg, *s.c.*) or vehicle (Veh) for 3 consecutive days. Rats learned to associate one of two spectrally-different pure tones with reward over ~3 weeks (5.0 kHz, CS+; 11.5 kHz, CS-). HDA3i facilitated the rate of 2TD task acquisition: treated rats (N=12) reached performance criterion faster than vehicle controls (N=12). Furthermore, after both groups reached the *same level* of asymptotic performance, a stimulus generalization memory test (SGT) was administered. BP responses

elicited by different sound frequencies (including the CS+ & CS-) were recorded under extinction conditions. Groups differed in the proportion and latency of BPs to SGT test tones, which indicated that HDAC3i-treated rats had formed more *specific* memory for both CS frequencies compared to Veh-treated rats (N=9). A subset of animals also underwent a 2-week delayed SGT (HDAC3i, N=4; Veh, N=4) and were immediately re-tested for 2TD performance. Resilient performance in HDAC3i-treated rats weeks after HDAC3i injections suggest that limited treatment during initial task acquisition has lasting effects on frequency-specific memory. A1 recordings after immediate and 2-week delayed SGTs reveal how tonotopic representation of different associative sound-signals (CS+ and CS- frequencies) interacts in animals that have specific vs. non-specific memories. These data support that HDAC3 is key negative regulator of the sensory specificity of LTM formed.

Title: Histone acetylation controls transcription of the atypical protein kinases in primary neuronal cultures

Authors: *A. BORODINOVA, M. VOLOBUEVA, A. BOLSHAKOV, P. BALABAN
Inst. of Higher Nervous Activity, Moscow, Russian Federation

Abstract: Epigenetic modifications play a crucial role in learning and memory consolidation and storage. Some indirect evidences support the idea that atypical protein kinases (aPKCs), involved in memory consolidation and maintenance, may be the targets of epigenetic modifications. In the current study we are testing whether increased acetylation of histones, which usually occurs during learning, may determine transcriptional activity of aPKCs. Using real-time PCR method we have analyzed the dynamics of aPKCs expression in primary cortical neuron cultures incubated with histone deacetylase inhibitor trichostatin A (TSA). Histone acetylation affects the chromatin structure and usually enhances gene transcription. As it was expected, in the presence of TSA the mRNA levels of protein kinase C iota/lambda (PKCi/l) and protein kinase C zeta (PKCz) has temporarily increased. Surprisingly, the pattern of expression of protein kinase M zeta (PKMz) was characterized by gradual decrease with a minimum at 18-19 hours of

incubation with TSA. Moreover, similar changes in aPKCs expression were observed in cortical cultures, incubated with alternative histone deacetylase inhibitor sodium butyrate for 18-19 hours. It perfectly corresponds to our previous results and excludes the possibility of nonspecific activity of TSA. Application of the transcription inhibitor actinomycin D one hour prior to TSA treatment abolished the TSA-induced rise of PKCi/l and PKCz mRNA levels. Observed changes in PKMz expression during incubation with actinomycin require further investigation. Summarizing, our results suggest that histone acetylation status may directly determine the level of expression of atypical protein kinases in the neurons.

Title: Changes in nuclear geometry are associated with long-term memory formation

Authors: *I. CERA, A. ABENTUNG, C. REDDY, P. FEURLE, G. APOSTOLOVA, G. DECHANT
GE Neurowissenschaften, Innsbruck, Austria

Abstract: Special AT-rich sequence binding protein 2 (*SATB2*) is a risk locus for schizophrenia and encodes a highly conserved DNA-binding protein that regulates higher order chromatin configuration. We recently showed that deletion of Satb2 from adult mouse forebrain impairs long-term memory formation (Jaitner et al., 2016). At molecular level, we found that Satb2 interacts with proteins of the inner nuclear membrane including Lem2, Lem3, Baf and Lap2. Complexes of these lamina-associated proteins are known regulators of both gene transcription and nuclear shape. Therefore we have investigated the role of Satb2 in neuronal activity-dependent plasticity of nuclear morphology of hippocampal neurons. In hippocampal neuronal cultures synaptic activity stimulates the formation of nuclear infoldings (Wittman et al., 2009) and causes an up-regulation of Satb2 protein levels. We found that genetic deletion of Satb2 prevents these changes of nuclear morphology. Overexpression of Satb2 in vitro increased the number of nuclear infoldings in unstimulated cultures. To test whether the interaction between Satb2 and inner nuclear membrane proteins is required for nuclear infoldings, we used an RNAi approach to reduce Lem2 protein level. The experiment confirmed that the interaction between Satb2 and the nuclear envelope trans-membrane protein Lem2 is important for Satb2-induced changes in neuronal nuclei geometry. In vivo the number of nuclear infoldings is greatly reduced in the hippocampal CA1 field of $Satb2^{CamKIICre}$ conditional knock-out mice. Nuclear

dysmorphology is rescued together with long-term memory deficit when *Satb2* is re-expressed in the hippocampus of Satb2 conditional mutants. Based on our results we hypothesize that Satb2 in the neuronal nucleus modulates association of specific chromatin loops with the inner nuclear membrane and consequently regulates genes expression underlying the consolidation of memory.

Title: Multiple acute concurrent stresses and memory: Females are not protected

Authors: *A. K. SHORT[1], Y. CHEN[2], J. MOLET[4], J. C. LAUTERBORN[3], C. M. GALL[5], T. Z. BARAM[1]
[2]Pediatrics, [3]Dept Anat. & Neurobio., [1]Univ. of California Irvine, Irvine, CA; [4]CLINATEC, CEA MINATEC CAMPUS, Grenoble, France; [5]Anat. and Neurobio., Univ. of California, Irvine, CA

Abstract: Rationale: Multiple, concurrent acute stresses involving emotional, physical and social components enduringly impair spatial memory in male mice, which is associated with functional loss of synaptic potentiation and structural disruption of synapse-bearing dendritic spines in the hippocampus. Male and females behave differently in response to emotional and social stressors, and sex differences in spatial memory have long been observed in humans and animals. However, little is known about the underlying synaptic and molecular mechanisms responsible for these differences. Here, we subjected male and female mice to simultaneous multiple stresses lasting 2 h (MAS) and investigated the sex effects of MAS on memory function and their underlying synaptic basis. Methods: Male and female C57 and YFP transgenic mice were subjected to MAS separately and trained/tested in a hippocampus-dependent novel location object task 6 h, 24 h, and 1 week after the stress. Hippocampal slices from stressed mice and controls were used to test the different effects of MAS on the dendritic spines (YFP and Golgi staining on slices) and synapses represented by PSD-95 in field CA1, the location has been implicated to play a key role in place field and memory consolidation. Further experiments are in progress to identify the molecular basis responsible for the differences observed. Results:

Simultaneous acute stresses provoked profound, enduring memory problems in male mice. These resulted from lost ability of hippocampal synapses to sustain a potentiated state. In females, synapse loss was as profound as in males. Memory tests are in progress at the time of this submission.Conclusions: Modern life is rife with concurrent acute stresses. The consequences of these multiple acute stress clearly differ from those of a single acute stress in males. The current studies increase our understanding of sex-specific differences in the effects of multiple, acute, concurrent modern-life like stress on memory.

Title: IQGAP1-ERK signaling regulates histone posttranslational modifications in fear memory

Authors: *C. GAO, X.-Y. LIU, B. YAO, L. JIN, N. SUN, J.-R. HAO
Sch. of Anesthesiol., Xuzhou Med. Univ., Jiangsu, China

Abstract: Epigenetic mechanisms in learning and memory are in particularly interesting in neuroscience recently. We previously found IQGAP1, a scaffolding protein of MAPK, was involved in fear memory via interacting with GluN2A subunits of NMDA receptors and the ERK cascade. But it's unknown whether histone posttranslational modifications is regulated by IQGAP1/ERK signal pathway. To shed light on specific functions of IQGAP1 in memory progresses and the precise mechanisms of this regulation, we performed in vivo studies using *IQGAP1*$^{-/-}$ and *IQGAP1*$^{+/+}$ mice. We found that *IQGAP1*$^{-/-}$ mice exhibited impaired fear memory as previously described. In addition, *IQGAP1*$^{-/-}$ mice showed decrease in ERK1/2 and histone H3S10 phosphorylation, H3K14 acetylation, as well as decreased levels of c-Fos and BDNF compared to their wild-type littermates after fear training. Correspondingly, disruption of the epigenetic regulation induced by ERK signaling with intrahippocampal injection of MEK antagonist U0126 or GluN2A-selective pharmacological antagonist NVP-AAM077 blockaded contextual-dependent memory, while no changes were noted with NR2B-selective antagonist Ro25-6981. SAHA, a HDACs non-specific inhibitor, or knock-down HDAC2 with shHDAC2-AAV in dorsal hippocampus could significantly rescued the impaired fear memory, H3S10 phosphorylation, H3K14 acetylation, as well as decreased levels of c-Fos and BDNF. Thus, we

believe that the GluN2A/IQGAP1/ERK-dependent mechanisms in histone posttranslational modifications could underlie multiple phases of memory processes.

Abstract: Nuclear Receptor Corepressors (NCORs) directly participate in the epigenomic action of various hormones and metabolic intermediates. NCORs are implicated in the pathogenesis of autism, but their role in cognitive function remains unclear. NCOR1 and NCOR2 (also known as SMRT) regulate gene expression by recruiting and activating histone deacetylase 3 (HDAC3) through the Deacetylase Activation Domain (DAD). Here we find that abolishing HDAC3 enzymatic activity with knock-in mutations in DAD (NS-DADm) led to mood alteration, social

avoidance, and cognitive dysfunction in mice. Depletion of NCORs specifically in GABAergic neurons recapitulated the cognitive dysfunction and memory deficit. Electrophysiology, optogenetics, chemogenetics, circuit mapping, functional genomics, ribosome profiling, and immunofluorescence analysis identified molecular and circuitry mechanisms through which NCORs regulate GABA signaling and hippocampal synaptic plasticity. These findings established NCORs as pivotal epigenomic regulators of GABA signaling and cognitive function.

Title: Tat-PTEN1 enhances hippocampal LTP and learning & memory through selective inhibition of calpain-2-mediated PTEN cleavage

Authors: *Y. LIU[1], Y. WANG[1], J. SUN[1], Y. LUO[1], X. BI[2], M. BAUDRY[1]
[1]Western Univ. of Hlth. Sci., Pomona, CA; [2]Western Univ. Hlth. Sci., Pomona, CA

Abstract: Calpain-1 and calpain-2 play opposite roles in learning and memory: Calpain-1 activity is required for certain types of synaptic plasticity and learning and memory, while calpain-2 activation limits the extent of plasticity and learning during the consolidation period. During the consolidation period, calpain-2 cleaves PTEN, which stimulates mTOR-dependent synthesis of the ERK inhibitor, SCOP, thereby limiting the duration of ERK activation. A selective calpain-2 inhibitor (Z-Leu-Abu-CONH-CH2-C6H3(3,5-(OMe)2), enhances learning & memory by preventing calpain-2 mediated PTEN cleavage and prolonging ERK activation in dorsal hippocampus in mice. To further evaluate the role of calpain-2-mediated PTEN cleavage in learning and memory, we first determined the calpain-2 cleavage sites in PTEN. Two PTEN fragments generated by calpain-2 cleavage were analyzed by LC/MS/MS, which resulted in the identification of S364-V365 as one of the putative calpain-2 cleavage sites in PTEN. Five peptides based on PTEN sequence surrounding S364-V365 were synthesized. While none of the peptides inhibited overall calpain-1 or calpain-2 activity, one of them was directly cleaved by calpain-2 and they all partially blocked calpain-2-mediated PTEN cleavage. We selected

SSTSVTPDVSDN and linked it to the tat peptide to make it membrane-permeable, and this construct is referred to as tat-PTEN1. Tat-PTEN1 (10 μM) enhanced theta burst stimulation (TBS)-induced LTP, when applied for 90 min before TBS in hippocampal slices from WT mice. The effects of the tat-PTEN1 on fear conditioning learning and SCOP levels in dorsal hippocampus will be evaluated to confirm the role of calpain-2-mediated PTEN cleavage in L&M. These results further support the notion that calpain-2-mediated truncation of PTEN plays a critical role in the regulation of LTP and learning and memory in hippocampus. They further suggest that tat-PTEN1 could be further develop to enhance learning and memory under conditions associated with learning impairment.

Abstract: The role of perirhinal cortex in visual recognition memory is well established, as is the role of cholinergic activation of perirhinal M1 muscarinic receptors. Neurophysiological data demonstrate that successful visual memory formation is characterized by enhanced multiunit activity in the upper-middle and deep layers of perirhinal cortex. However, the M1 muscarinic dependent intracellular signaling profiles underlying the critical synaptic changes that occur during long term visual memory formation are unclear. Long term memory formation depends upon protein translation and synaptic remodeling, both of which are regulated by the mTOR pathway. Here, we explore the mTOR signaling pathway in laser capture microdissected subregions of medial temporal lobe structures in normal monkeys.
Snap frozen samples of area TE, perirhinal (PRh), entorhinal (ERh), and hippocampal tissue from four Rhesus monkeys were cryosectioned and stained for Nissl substance. Laminar lysates were prepared by laser capture microdissecting specific layers of interest: layers III and V/ VI from PRh and area TE; layers II/III and V/VI from ERh; the stratum pyramidale (*str. pyr.*), the stratum radiatum (*str. rad.*) plus the stratum lacunosum-moleculare (*str. l-m.*) from regions CA1

and CA3, and the stratum granulosum (*str. gr.*) and stratum moleculare (*str. mol.*) of the dentate gyrus. In addition, whole region lysates spanning all cortical layers were prepared. The laminar and whole region lysates were printed onto protein microarrays, which enable a quantitative and multiplexed analysis of protein levels and phosphorylation states. Averaged over four monkeys, ERh displayed the highest mTOR pathway activation in whole region lysates, followed by PRh, area TE and the hippocampus. In laminar lysates, differential mTOR pathway activation patterns were revealed in the various cortical regions. For example, ERh layers II/III exhibit significantly increased phosphorylation levels along the mTOR pathway [e.g. mTOR S2481, p70S6K T412, rpS6 S235/S236, and eIF4E S209] compared to ERh layers V/VI. In contrast, PRh layers V/VI saw increased phosphorylation levels in eIF4E S209 and eIF4G S1108 compared to PRh layer III. In the hippocampus, increased levels of p70S6K S371, rpS6 S235/236, 4EBP1 T37/T46, and eIF4G S1108 were seen in the *str. pyr.* of CA1 and CA3 compared to their respective levels in *str. rad*. and *str. l-m.*; the dentate gyrus trended similarly with increased phosphorylation in *str. gr.* compared to *str. mol.* Using laser capture microdissection, we were able to demonstrate significant differences in mTOR signaling pathway activation in cortical layers implicated in memory formation.

Title: mTORC1-mediated late LTP in somatostatin interneurons regulates hippocampal network plasticity and memory precision

Authors: *J. ARTINIAN[1,2], A. JORDAN[1,2], A. KHLAIFIA[1,2], A. LA FONTAINE[1,2], I. LAPLANTE[1,2], J.-C. LACAILLE[1,2]

Abstract: Long-term synaptic plasticity is a prime candidate cellular substrate for learning and memory which remains largely unexplored in inhibitory interneurons. In the hippocampal CA1

region, excitatory synapses onto somatostatin interneurons (SOM-INs) show cell type-specific long-term potentiation (LTP) that regulates hippocampal network plasticity, can persist 24h and requires translation via Mechanistic Target Of Rapamycin Complex 1 (mTORC1). The present study aimed at investigating the functional role of translation-dependent LTP in SOM-INs in hippocampal networks and memory, by knocking out the expression of Raptor, an essential component of mTORC1, selectively in SOM-INs (SOM-Raptor-KO mice).
We first determined that treatment with mGluR1a agonist failed to increase ribosomal S6 protein phosphorylation, a downstream effector of mTORC1, and to induce persistent LTP in SOM-INs from SOM-Raptor-KO mice. Thus, SOM-INs show impairment in mTORC1 signalling and persistent synaptic plasticity in SOM-Raptor-KO mice. We next investigated the behavioral relevance of mTORC1-mediated persistent LTP. We showed with whole-cell recordings 24h after contextual fear conditioning (CFC) that training induces an increase in spontaneous and minimally evoked excitatory transmission, as well as input-output function at SOM-INs synapses in WT mice. SOM-INs dendritic spine density was also increased following training. These changes were prevented in SOM-INs from SOM-Raptor-KO mice, demonstrating that CFC induces persistent mTORC1-dependent LTP at SOM-INs synapses. At the network level, field recordings revealed upregulation of pyramidal cell Schaffer collateral pathway LTP by late LTP induction in SOM-INs which was prevented in SOM-Raptor-KO mice, indicating impairment in the regulation of CA1 network metaplasticity by SOM-INs LTP in SOM-Raptor-KO mice. At the behavioral level, SOM-Raptor-KO mice showed impaired long-term spatial reference and fear memory, and context generalization in CFC, but intact long-term cued-fear memory. These results indicate impairments in hippocampal-dependent memory in SOM-Raptor-KO mice.
Finally, we used transgenic mice with a knock-down of the upstream repressor of mTORC1, Tuberous Sclerosis Complex 1 (TSC1), selectively in SOM-INs (SOM-$TSC1^{+/-}$ mice) and found increased contextual fear memory but impaired context discrimination in these mice, indicating that increasing mTORC1 function in SOM-INs was sufficient to modulate hippocampal memory consolidation.
Our results suggest that learning-induced persistent mTORC1-LTP in SOM-INs regulates CA1 local network plasticity and hippocampal memory.

Abstract: Neuronal activity regulates the transcription and translation of the immediate early gene Arc/Arg3.1, a key mediator of synaptic strength and plasticity. Ubiquitin-directed proteasomal degradation of Arc tightly limits its temporal expression, yet the significance of this regulation remains unknown. Here we have disrupted the temporal control of Arc removal by creating an Arc knock-in mouse (ArcKR) where the predominant Arc ubiquitination sites are mutated. In ArcKR neurons, induction of Arc with the group I mGluR selective agonist DHPG resulted in persistent accumulation of Arc protein. Consistent with the increased longevity of Arc protein, ArcKR mice have enhanced α-amino-3-hydroxy-5-methyl-4-isoxazolepriopionic acid (AMPA) receptor internalization and metabotropic glutamate receptor-dependent long-term depression (mGluR-LTD). Although ArcKR mice have no obvious motor or hippocampal-dependent spatial memory impairments, they exhibit deficits in selecting the strategy to perform a reversal task. This cognitive inflexibility is coupled to an increase in hippocampal Arc expression immediately following behavioral training and with a reduction in the threshold to induce mGluR-LTD. These findings suggest that the abnormal persistence of Arc protein limits the dynamic range of Arc-mediated AMPA receptor endocytosis during reversal learning, thereby reducing cognitive flexibility. Our work illuminates how the precise temporal control of activity-dependent molecules, such as Arc, regulate synaptic plasticity and is particularly crucial for cognitive flexibility.

Title: Enhancement of synaptic plasticity by NYX-2925: The role of receptor trafficking and intracellular signaling

Authors: *R. A. KROES[1,2], M. E. SCHMIDT[1], S. U. SAHU[1], J. S. BURGDORF[1,2], M. A. KHAN[1], J. R. MOSKAL[1,2]
[1]Aptinyx, Inc., Evanston, IL; [2]Falk Ctr. for Mol. Therapeut., Northwestern Univ., Evanston, IL

Abstract: Aptinyx has developed a novel class of small molecule N-Methyl-D-Aspartate (NMDA) receptor modulators with broad applicability across neurologic and psychiatric disorders. It binds with high affinity to all four NR2 subtypes, rapidly enhances LTP, and improves learning and memory in rats. In addition, NYX-2925 (1 mg/kg, PO) induced significant alterations in structural plasticity, as measured by mature dendritic spine formation 24 hr post-dosing. To evaluate the rapid-acting effects of NYX-2925, an unbiased proteomic strategy was used to elucidate the biochemical processes that underlie its unique mechanism of action.
Rats were treated with either vehicle (0.5% CMC in saline; 1ml/kg) or NYX-2925 (1 mg/kg, PO). Medial prefrontal cortical proteins were isolated from animals sacrificed at 15, 30, 60 min, and 24 hr post-dosing. Both total and phosphopeptides enriched by HILIC fractionation were analyzed using nano-LC MS/MS analysis. The functional roles of the identified proteins were evaluated using Ingenuity Pathway Analyses.
The most robust proteomic changes in both phosphorylated and unmodified proteins, following administration of NYX-2925, were in signaling pathways associated with synaptic plasticity (LTP and LTD) and glutamatergic receptor trafficking (including clathrin-mediated endocytosis signaling, 14-3-3-mediated signaling, ephrin receptor signaling, protein ubiquitination, CDK5 signaling, aryl hydrocarbon receptor signaling, and semaphorin signaling).
To gain mechanistic insight into NYX-2925-mediated synaptic changes, proteomic analyses were performed on PSD95-coimmunoprecipitated proteins from drug-treated rats. Significant increases in cortical PSD95-associated GRIA2 and NMDAR2A at 60 min and 24 hours following drug administration were observed.
These results suggest that the cognitive-enhancing effects of NYX-2925 are driven in part by the modulation of trafficking and insertion of AMPARs and NMDARs into the synaptic PSD complex which, in turn, enhances LTP-associated synaptic plasticity.

Title: Impaired cerebellar plasticity and eye-blink conditioning in calpain-1 knock-out mice

Authors: *M. R. FOY[1], S. HEYSIEATTALAB[2], K.-H. LEE[2], Y. LIU[2], X. BI[2], M. BAUDRY[2]
[1]Dept. of Psychology, Loyola Marymount Univ., Los Angeles, CA; [2]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Our recent studies indicate that calpain-1 activation is required for hippocampal synaptic plasticity, including long-term depression (LTD) and long-term potentiation (LTP) in field CA1, while calpain-2 activation limits the extent of potentiation during the consolidation period. However, little is known regarding the contributions of calpain-1 and calpain-2 to cerebellar synaptic plasticity, and in particular to LTP and various forms of LTD at synapses from the parallel fibers to the Purkinje cells. Low frequency (LFS, 1 Hz, 5 min)-induced LTP at these synapses was markedly impaired in cerebellar slices from calpain-1 knock-out (ko) mice. Application of a selective calpain-2 inhibitor improved LFS-induced LTP in both wild-type (wt) and calpain-1 ko mice, suggesting that, like in hippocampus, calpain-1 and calpain-2 play opposite functions in cerebellar LTP. Three different protocols were used to induce LTD at these synapses: LFS (1 Hz, 15 min), application of K-Glu (5 min) and application of the mGluR1 agonist, DHPG (10 min). All three forms of LTD were impaired in calpain-1 ko mice. DHPG

application was found to stimulate calpain-1 in cerebellar slices and DHPG-induced LTD impairment was reversed by application of a PP2A inhibitor, okadaic acid. To investigate the role of calpain-1 in a well-studied form of behavioral associative learning, we compared calpain-1 ko mice vs. wt mice in cerebellum-dependent delay eyeblink conditioning (EBC). Calpain-1 ko mice exhibited significant learning impairment in EBC during the first 2 days of acquisition training. However, after 5 days of training, the percentage of CRs between ko vs. wt mice was identical. During extinction, both calpain-1 ko and wt mice exhibited typical extinction patterns and there were no significant differences between these two groups. Our results indicate that calpain-1 plays critical roles in a variety of forms of synaptic plasticity and learning and memory in both the hippocampus and cerebellum, and that some of the signaling pathways underlying these forms of plasticity and learning are similar in both structures.

Title: GABAergic modulation of cells within the neurogenic niche of the postnatal spinal cord

Authors: *N. SHAFIN[1,2], J. DEUCHARS[1], S. A. DEUCHARS[1]
[1]Sch. of Biomed. Sci., Univ. of Leeds, Leeds, United Kingdom; [2]Sch. of Med. Sci., Universiti Sains Malaysia, Health Campus Kubang Kerian, Malaysia

Abstract: Modulation of GABA mediated neuronal inhibition is one of the most important approaches for the treatment of CNS diseases. Precise targeting of such treatments depends on identification and characterisation of the different subunit complexes that exist. In the CNS, there are pools of neural stem cells (NSC), which can differentiate to become neurones, astrocytes or oligodendrocytes while progenitor cells have limited lineage. In addition to brain regions, where NSCs are now known to exist, the spinal cord area also has a neurogenic potential. Ependymal cells (ECs) of the brain and spinal cord respond to GABA. One approach to develop pharmacological treatments to modulate stem cell activity is to determine how endogenous proteins and receptors on NSCs can regulate their behaviour. Whole cell patch clamp recordings were made from cells in acute spinal cord slices. Responses to GABA were determined and compounds known to modulate GABA receptors in a subunit selective pattern were tested. Bath and puff application of GABA receptor agonists and antagonists were able to modulate the GABA receptor activation. FGIN-27; 1 μM (an agonist acting at a peripheral benzodiazepine receptor, called translocator protein (TSPO)) significantly enhanced responses to GABA in

ependymal cells. Octadecaneuropeptide (ODN), the endogenous ligand of the central benzodiazepine receptor alone caused both depolarising and hyperpolarising effects on ECs but did not significantly affect responses to GABA. Local ODN application caused fast hyperpolarisations that were mimicked by local application of low (2.5 μM) concentrations of GABA. To further characterise the GABA receptor, agonists and antagonists were used to enhance and block the receptor accordingly. Since TPMPA antagonised responses to ODN and low concentrations of GABA, this suggests that GABA receptors contain subunits from both GABAA and GABAC. Cells that responded to these modulators were recovered and viewed using fluorescence method and diaminobenzadine staining. The cells viewed were confirmed as ECs. If cells within the central canal area responded to GABA, it is possible that following an injury or onset of pathological condition, GABA and endogenous ligands such as ODN could be released in this area to modulate proliferation and differentiation. These experiments will help to confirm the role of GABA receptors in spinal cord cell proliferation.

Title: Blockade of the sigma-1 receptor prevent brain plasticity induced in mice by habituation to a complex environment, the Hamlet test

Authors: *L. CROUZIER, T. MAURICE
INSERM UMR-S1198, Montpellier, France

Abstract: The σ_1 receptor is a membrane-associated protein expressed in neurons and glial cells. It is highly expressed at mitochondria-associated endoplasmic reticulum (ER) membranes (MAMs), complexing the glucose-related protein 78/binding immunoglobulin protein (BiP). Upon cellular stresss, or via agonist stimulation, σ_1 receptor dissociates from BiP and binds inositol 1,4,5-trisphosphate (IP_3) receptor, enhancing calcium entry into mitochondria. It can also translocate to plasma membrane and modulate the activity of numerous ionophores and receptors for neurotransmitters and trophic factors. The σ_1 receptor shapes cellular plasticity also by directly modulating the activity of pleiotropic transcription factors, such as NFKB, CREB or c-fos, involved in the modulation of pro- and anti-inflammatory genes, cell death and survival. The σ_1 receptor-mediated neuromodulation, affecting several cellular pathways has an important role on brain plasticity, response to stress, learning and memory, and neuroprotection. For instance,

its activation potentiates long-term potentiation, neurite outgrowth and hippocampal neurogenesis. We here analyzed its impact on brain plasticity induced by habituation to a complex enriched environment. The Hamlet test is a novel behavioral analysis appliance, fully automatized (ViewPoint, Lissieu, France), that provides a complex environment for testing topographical memory and spatio-temporal disorientation in mice. The apparatus mimics a small village with a central agora and streets expanding from it, leading to functionalized houses (Drink, Eat, Play, Run, Interact). Environmental enrichment is induced by habituating animals in the Hamlet, in groups of 6/8 individuals, during 4 h a day, for several weeks. Memory can be tested by depriving mice from water and testing their ability to locate the Drink house. Several groups were analyzed in parallel (non-habituated; habituated; habituated and repeatedly administered with NE-100, a selective σ_1 antagonist) and the expression and activity of the σ_1 receptor were analyzed after habituation. The antidepressant and anti-amnesic effect of selective σ_1 agonists, the hippocampal neurogenesis and trophic factor levels were analyzed. We report that the pharmacological inactivation of σ_1 receptor following NE-100 treatment prevented topographic memory, resistance to forced swimming and increased neurogenesis induced by habituation. The data showed that σ_1 receptor activity plays a major role in the consequences of enriched environment and therefore suggest that MAM physiology is impacted by enriched environment.

Title: NYX-783: A novel small molecule NMDA receptor modulator with therapeutic potential for the treatment of post-traumatic stress disorder

Authors: *E. M. COLECHIO[1,4], T. BHATTACHARYA[4], J. S. BURGDORF[2], J. DUNNING[4], A. L. GROSS[6], J. M. PRIEBE[5], M. A. KHAN[4], P. K. STANTON[7], X.-L. ZHANG[7], C. CEARLEY[6], J. R. MOSKAL[3]
[1]Dept Neurosci, [2]Falk Ctr. for Mol. Therapeutics, McCormick Sch. of Engin., [3]Northwestern Univ., Evanston, IL; [5]Behavioral Pharmacol., [4]Aptinyx, Inc., Evanston, IL; [6]Aptinyx Inc, Evanston, IL; [7]Cell Biol. & Anat., New York Med. Col., Valhalla, NY

Abstract: Aptinyx has developed a novel class of small molecule N-Methyl-D-aspartic acid receptor (NMDAR) modulators with broad applicability across neurologic and psychiatric disorders. In the present study, NYX-783 was evaluated for efficacy in several animal models of learning and memory and of psychiatric disorders relevant to post-traumatic stress disorder

(PTSD). NYX-783 is an NMDAR modulator able to bind to all 4 NMDAR2 subtypes. NYX-783 was shown to enhance the magnitude of LTP at Schaffer collateral/CA1 synapses from hippocampal slices at 24 hours and 1 week post-dosing in vivo. NYX-783 was found to have high oral bioavailability and brain penetration, and showed no adverse effects in the Rotarod assay. NYX-783 showed an acute and long-lasting antidepressant-like effect in the forced swim assay: NYX-783 significantly decreased floating time vs. vehicle at all doses (1 ng/kg- 1 mg/kg) and this response was maintained up to 1 week post-dosing. To assess the therapeutic potential of NYX-783 for treating PTSD, NYX-783 was evaluated in a contextual fear conditioning assay. Rats were dosed with NYX-783 or vehicle 1 h before the first extinction trial and were assessed for freezing behavior on days 1-7 and 14. Treatment with NYX-783 decreased freezing relative to vehicle on days 2-4 and 14 demonstrating that NYX-783 is effective in facilitating fear extinction as well as enhancing consolidation of extinction learning. NYX-783 facilitated the extinction of contextual fear, suggesting that NYX-783 enhanced a synaptic plasticity-like mechanism associated with learning and memory and has therapeutic potential for the treatment of PTSD.

Title: Amygdala c-Fos expression in rats with tolerance to anxiolytic effect of midazolam

Authors: *D. J. GONZÁLEZ-SÁNCHEZ, SR, G. CASTILLO-ROBERTO, J. C. P. ARRIAGA-RAMÍREZ, S. E. CRUZ-MORALES
Psychopharmacology, UNAM, Tlalnepantla de Baz, Mexico

Abstract: Benzodiazepines (BZD) are prescribed mainly for treatment of anxiety and sleep disorders. Repeated administration of BZD induces the development of associative and pharmacological tolerance. C-Fos gene expression is a marker of neural activity, therefore could be a useful tool in the study of two different types of tolerance. The objective of present study was to assess the anxiolytic effect of midazolam (M), the development of associative and pharmacological tolerance, and the C-Fos expression in amygdala nuclei (CeA, LA, MePD and MePV) in rats administrated acutely or chronically in different contexts and placed on an Elevated Plus Maze (EPM).
Wistar male rats (200 g) were randomly assigned to five independent groups (N=8 rats in each group). A control group received saline; two groups were injected acutely with M in different contexts, colony (aMC) and laboratory (aML); two groups were injected for 20 days with M in different contexts, colony (cMC) and laboratory (cML). The groups received either acute or chronic administrations of 1 mg/kg, ip of M 15 min before the exposure to the EPM, the chronic groups were evaluated in the EPM on day 21 of treatment. The percentage of number of entries and time of permanence in open arms were considered an index of anxiety. Two h after EPM exposure, subjects were sacrificed and the c-Fos protocol was followed.
An anxiolytic effect was detected, and pharmacological and associative tolerance to M. C-Fos expression in CeA and LA was lower in acutely administrated groups and in cMC, conversely, C-Fos expression in cML was similar to that in the control group. There were not significant differences in C-Fos expression in MePD and MePV. Results suggest that CeA and LA are involved in the anxiety process.

Title: Chemotherapy-induced cognitive deficits in an APOE mouse model

Authors: *A. SPEIDELL[1], T. DEMBY[2], Y. LEE[3], O. RODRIGUEZ[4], C. ALBANESE[4], J. MANDELBLATT[5], G. REBECK[1]
[1]Neurosci., [2]Dept. of Tumor Biol., [4]Oncology, [5]Med., [3]Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Cancer-related cognitive impairment is being increasingly reported among breast and other cancer survivors, although risks for this outcome are not fully understood. The apolipoprotein E4 (APOE4) allele, the strongest genetic risk factor for Alzheimer's disease, has been identified as one potential genetic risk factor for cancer-related cognitive impairment. Understanding risks and mechanisms related to diverse therapies is difficult in human populations. While there have been some important animal models of cancer-related cognitive impairment, none have examined gene-treatment interactions. We evaluated whether a battery of rodent behavioral assays could identify cognitive deficits in APOE knock-in C57BL/6 mice after treatment with chemotherapeutic drug. Twenty-four three-month old tumor-naïve mice (APOE3 n=11; APOE4 n=13) were subjected to a series of behavioral tests both before and after a single 10 mg/kg tail vein injection of Doxorubicin, a topoisomerase IV inhibitor used in treatment of breast cancer. Pre- and post-treatment open field and elevated plus tests demonstrated significantly decreased rearing behavior and willingness to explore open environments in both APOE3 and APOE4 mice following chemotherapy. Using the Barnes maze to measure post-treatment spatial learning and memory, there was significantly greater primary latency to the target hole (spatial learning) in the APOE4 mice compared to the APOE3 mice. Treated APOE4 mice showed similar impairment in recall of the target hole location in a 72-hour probe trial of the Barnes Maze (spatial memory). A marble burying assay and a novel object recognition test did not detect significant differences before and after Doxorubicin treatment in either group of APOE mice. These results suggest that chemotherapy has an adverse effect on cognitive behaviors, and that this may be an excellent model to elucidate how APOE genotype interacts with chemotherapy to affect behavior, brain structure, and brain biochemistry.

Title: 6-Gingerol attenuates LPS-induced memory impairment via its anti-inflammatory and antioxidant activity

Authors: F. ZHANG[1], J.-G. ZHANG[1], X.-Q. HOU[1], Y.-M. ZHOU[1], *H. ZHANG[2,1]
[1]Institute of pharmacology, Taishan Med. Univ., Taian, China;[2]Depts Behav Med. & Psych, Pharm, West Virginia Univ. Hlth. Sci. Ctr., Morgantown, WV

Abstract: 6-Gingerol, a major component of gingerols extracted from *Zingiber officinale*, has been shown to exhibit anti-inflammatory and antioxidant bioactivities. Since neuroinflammation plays an important role in neurodegenerative diseases such as Alzheimer's disease, it was of interest to know if 6-gingerol improved memory via its anti-inflammatory and antioxidant properties. This was addressed using lipopolysaccharide (LPS)-induced changes in vitro in C6 cells and in vivo in rats. LPS at 100 µg/ml decreased cell viability, which was blocked by 6-gingerol (20 µM). Similarly, 6-gingerol reversed LPS (20 µg/ml)-induced increases in reactive oxygen species (ROS), nitrite (NO), inducible nitric oxide synthase (NOS2), tumor necrosis factor α (TNF-α), and interleukin-6 (IL-6) in C6 cells. Consistent with the in vitro effects, 6-gingerol (1 and 2 mg/kg) reversed LPS (2 µg, icv)-induced increases in latency to the platform during the acquisition training and decreases in the time spent in the target quadrant in the probe trial in the rat water-maze test, suggesting memory enhancement. These data suggest that 6-gingerol improves memory most likely via its anti-inflammatory and antioxidant effects and could be used for treatment of neurodegenerative disorders such as Alzheimer's disease.

Title: Informative cues and drug reward modulate risky decision-making in a probabilistic foraging task

Authors: *A. P. SMITH[1], J. BECKMANN[2]
[1]Psychology, Univ. of Kentucky Dept. of Psychology, Lexington, KY; [2]Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Many decisions involve uncertainty in regard to their potential outcome, and the ability of an individual to learn from such decisions requires flexible value updating from trial and error feedback. One method for assessing an individual's propensity for trial and error learning is through 'foraging' procedures offering uncertain choices between two rewards that dynamically change in their probability of reward. Using foraging procedures, the ability of an individual to learn about their environment has been successfully parameterized with reinforcement learning models (RLM) utilizing the error between predicted and obtained outcomes (Beierholm & Dayan, 2010; Iigaya et al., 2016; Rutledge et al., 2009). It is still uncertain, however, how cues within the individual's environment and drug rewards may modulate the real-time updating of relative value between uncertain options.
Herein, two groups of rats engaged in a foraging task of dynamically changing reward probabilities. Rats initially chose between two nose pokes that probabilistically delivered a sucrose pellet. For the Unsignaled group, choice of either nosepoke resulted in different lever stimuli that were uninformative as to the outcome. For the Signaled group, one nosepoke also resulted in uninformative stimuli, but the informative option produced a lever stimulus only when reward was to follow, while a white cue light indicated reward omission. Following sufficient training, varying doses of remifentanil, a short acting Mu agonist, replaced one choice in the Unsignaled group and the informative choice for the Signaled group. Results revealed relative preferences were sensitive to both Signaled conditions and remifentanil dose. The informative cue in the Signaled group further modulated risk preferences and showed dissociable patterns of behavior relative to the Unsignaled group. Finally, RLM indices successfully parameterized both remifentanil dose-dependent and stimulus signaling effects on trial-by-trial value updating. These results suggest that learning and risk preferences are modulated by environmental cues and drug rewards, and these modulations can be successfully parameterized

using an RLM framework to describe real-time changes in relative value under uncertain conditions.

Title: Increasing dietary choline attenuates persistent spatial memory deficits in female mice exposed to cyclophosphamide and doxorubicin

Authors: B. E. JOHNS, M. FICKEN, M. E. ENGBERG, *L. WECKER, R. M. PHILPOT
Psychiatry & Neurosci., USF Hlth. Morsani Col. of Med., Tampa, FL

Abstract: Chemotherapy-related cognitive deficits (CRCDs) are a common occurrence for cancer patients. These deficits often persist following treatment and can adversely impact quality of life for decades. To date, the mechanisms mediating the occurrence of CRCDs are unclear and there are no approved treatments for this condition. Given the role of acetylcholine (ACh) in cognitive processes, it is plausible that CRCDs involve a reduction in cholinergic function. Indeed, increasing cholinergic activity with acetylcholinesterase inhibitors attenuates chemotherapy-induced cognitive impairments in mice, but these compounds lead to many adverse effects. Choline (Ch) is a dietary nutrient necessary for the synthesis of ACh, and choline supplementation (+Ch) maintains cholinergic function under conditions of high neuronal demand. Studies have shown that +Ch improves cognitive function in impaired animals and in humans with poor memory, vascular dementia or Alzheimer's disease. Therefore +Ch might be useful for CRCDs. To determine whether +Ch can attenuate spatial memory deficits induced by the chemotherapeutic agents cyclophosphamide (CYP) and doxorubicin (DOX), female BALB/C mice, 64 days of age, were trained in the Morris water maze and baseline performance determined on day 6. Following baseline assessment, mice were placed on a high choline diet (2.0% Ch; Teklad) or remained on standard diet (SD; 0.12% Ch; Teklad). Mice received intravenous injections of CYP (25mg/kg) and DOX (2.5mg/kg) on days 7, 14, 21 and 28 and spatial memory was assessed weekly, from day 13 to 62. On day 6, the % of entries (%E), % of movement (%M) and time (T), in the correct zone exhibited by mice during the probe trial were significantly greater than chance, indicating memory of the platform location. Both groups

exhibited reductions in %E, %M and T on days 13-27 during CYP+DOX exposure. On days 35-62, the performance of +Ch mice was significantly different from SD mice, with +Ch mice exhibiting 8-10% greater %E, 6-20% greater %M and 9-15sec longer T. These data indicate that CYP+DOX administration produces a prolonged impairment in spatial memory and that +Ch can attenuate this deficit when administered during and following chemotherapy. Although it remains to be determined whether this effect extends to other cognitive domains and whether +Ch is prophylactic or therapeutic, these findings suggest that +Ch may be an effective intervention for CRCDs.

Abstract: Avoidance response has been observed in humans and animals. The amygdala, the prefrontal cortex and the dopamine, through the D1 and D2 receptors, are fundamental for modulating this response. There are two population in the avoidance test distinguished by their performance, the good and poor performers (criteria: less than twenty avoidance responses during two consecutive days of training). The objective of our work was to evaluate the role of dopamine as a modulator of this behavior distinction. For that male Wistar rats were used. First, the role of dopaminergic receptors (D1 and D2) was studied in good performers through intraperitoneal injection of saline, D1 antagonist SCH 23390 (0,025 or 0,05 mg/Kg) or D2 sulpiride (20 or 40 mg/Kg). The administration of SCH 23390 reduced the number of avoidance responses ($F_{(4,47)}$=15,10, p&it0.001), concomitantly with a decreased in c-Fos activation only in the amygdala in basolateral (BLA)($F_{(4,18)}$=5,71; p&it0.05) and Medial (Me) nuclei ($F_{(4,20)}$=3,67;

p&it0.05). In the next experiment, good performers received intra-amygdala (basolateral or central nucleus - Ce) administration of D1 SCH23390 antagonist (0,3μg / 0,3μL), D2 sulpiride (0,2 μg / 0,2 μL) or saline; and the poor performers, D1 SKF 38393 agonist (0,4μg / 0,4μL),D2 quinpirole (0,1μg / 0,1μL) or saline. The results showed an increase in avoidance responses after the administration of D2 agonist in BLA ($F_{(2,44)}$=40,46: p<0.001) and Ce nuclei ($F_{(2,94)}$=45,04; p<0.05). The next experiment, evaluated the intrinsic levels of dopamine and its metabolites (DOPAC and HVA). The results showed that good performers had a decreased in DOPAC levels ($F_{(2\ 25)}$=4,35; p&it0.05), and poor performers in HVA lelves ($F_{(2,25)}$=8,18; p&it0.05), both in the right amygdala. The last experiment evaluated the hydroxylase staining comparing good and poor performers considering substantia nigra, ventral tegmental area and locus coeruleus. The results showed an increase in tyrosine hydroxylase positive neurons in good performers considering the substantia nigra ($t_{(1,4)}$ = 4,34; P &it0.05), ventral tegmental area ($t_{1.4)}$ = 10,2, P &it0.001) and locus coeruleus ($t_{(1,3)}$ = 3,55, P &it0.05) as well as a strong correlation between the avoidance behavior equal in substantia nigra (R^2=0.77), ventral tegmental area (R^2= 0.83) and locus coeruleus (R^2=0.89). The main contribution of our work is a better understanding of dopaminergic modulation of avoidance behavior.

Title: Intermittent stimulation of the Nucleus Basalis of Meynert improves performance on the Continuous Performance Task in adult monkeys

Authors: R. LIU[1], J. CRAWFORD[1], P. CALLAHAN[2], A. V. TERRY, JR[3], C. CONSTANTINIDIS[4], *D. T. BLAKE[5]
[1]Brain/Behavior Discovery Inst., [2]Pharmacology/Toxicology, [3]Dept Pharmacol Toxicol, Augusta Univ., Augusta, GA; [4]Wake Forest Univ. Sch. of Med., Winston Salem, NC; [5]Brain and Behavior Discovery Inst., Med. Coll Georgia/Augusta Univ., Augusta, GA

Abstract: Cholinergic transmission has been implicated in working memory and executive function and its loss leads to cognitive impairments. We tested whether cholinergic

pharmacological administration, or electrical activation of the Nucleus Basalis of Meynert, would improve executive function in young adult monkeys during a Continuous Performance Task. In this task, each 500 msec, a square was presented at the center of the screen, with a pseudorandom color chosen from Blue, Red, Yellow, Green and White. The animals were rewarded only if they touched the white square within 500 msec. Stimulation electrodes were implanted in the Nucleus Basalis bilaterally. During stimulation they delivered 60 pulses per second for 20 seconds of each minute. In the pharmacology experiments, we used a cholinesterase inhibitor, donepezil (200ug/kg), a muscarinic cholinergic antagonist, scopolamine (6.25ug/kg) and a nicotinic cholinergic inhibitor, mecamylamine (300ug/kg) to investigate the effects on animals' performance. Deep brain stimulation in Nucleus Basalis improved performance in two animals. Percent correct touches increased from 67.1% to 70.5% (Animal One) and 81.6% to 84.2% (Animal Two, binomial test $p<0.001$ for both monkeys), respectively. Unexpectedly, donepezil application alone, decreased animals performance from 67.1% to 64.4% and 81.6% to 77.8%, respectively ($p<0.001$ for both monkeys). When electrical stimulation and donepezil were combined, percent correct decreased from 74.6% to 71.6% and 88.2% to 84.5%, respectively ($p<0.01$ for both monkeys). To investigate cholinergic receptor subtype impact on performance, we used scopolamine or mecamylamine. Scopolamine decreased the animals' percentage of correct responses (animal 1: 54.8% to 50.1%, $p<0.01$ animal 2: 76.9% to 39.9%, $p<0.001$) while mecamylamine increased it (animal 1: 58% to 65.7%,$p<0.01$, animal 2: 76.9% to 81.2%,$p<0.001$). The results indicate that deep brain stimulation in Nucleus Basalis is superior to donepezil, a frontline medication used to improve cholinergic action, in increasing cognitive performance in a sustained attention task. The improvement is likely the result of complex interactions between projecting cell types from Nucleus Basalis and cholinergic receptor subtypes, as well as interplay between differing roles of acetylcholine in the striatum and in thalamocortical networks.

Title: Medial prefrontal cortex glutamate and canabinoide systems modulating reconsolidation and extinction of contextual fear conditioning memory

Authors: *L. B. RESSTEL[1], D. G. REIS[2], S. F. LISBOA[3]
[1]Schl Med, FMRP-USP, Ribeirao Preto- SP, Brazil; [2]Univ. Sao Paulo, Ribeirao Preto, Brazil; [3]Pharmacol., Univ. of São Paulo - FMRP, Ribeirao Preto, Brazil

Abstract: The ventral portion of medial prefrontal cortex (vMPFC) is involved in the modulation of processes involving the expression and extinction of conditioned emotional response (CER). vMPFC NMDA and CB1 receptors present opposing roles on behavioral (Freezing) and autonomic modulation (mean arterial pressure (MAP), heart rate (HR) and cutaneous temperature (TC), during expression of the CER. However, the role of a possible interaction between these receptors on autonomic and behavior responses associated to reconsolidation and extinction of contextual fear memories has not be fully studied. The aim of the present study was to investigate the effect of antagonism of vMPFC NMDA and CB1 receptors on reconsolidation and extinction processes. Male Wistar rats (250g) had a radio-telemetry probe implanted for recording autonomic activity and guide cannulas in vMPFC for drug administration. Day 1: Preconditioning started 1 wk after guide cannula implantation and consisted of one 10-min-long pre-exposure (habituation) in the footshock box. After four hours, the animals received 4 electrical footshock (0.8 mA, 1 s). Day 2: Two groups were tested, reconsolidation group (5 min session) or extinction group (30 min session) re-exposure without footshock presentation. Each group received two intra vMPFC injections (1st vehicle or CB1 antagonist AM251 30 pmol / 2nd vehicle or NMDA antagonist LY235959 0.4 nmol) 15 or 10 min before reconsolidation or extinction sessions forming 4 groups (Vehicle x Vehicle / Vehicle x LY235959 / AM251 x Vehicle / AM251 x LY235959). Day 3: The test session take place in the next day consisting of a 10-min re-exposure to the footshock box without any shock or injection given. Reconsolidation Day 2: No significant differences were observed between all groups on CER (Freezing: $F_{(3, 19)}$=0.4; P>0.05 ΔMAP: $F_{(3, 85)}$ = 1.386 P<0.05 ΔHR: $F_{(3, 85)}$ = 0.7 P<0.05 ΔCT: $F_{(3, 85)}$=22; P<0.05). Day 3: Group AM251 30 pmol x vehicle presented an elevated expression of CER compared to all other groups (Freezing: $F_{(3,19)}$=8.9; P<0.05 ΔMAP: $F_{3,85}$=13 P<0.05 ΔHR: $F_{3,85}$=42; P<0.05 ΔCT: $F_{3,85}$=22; P<0.05). Extinction Day 2: No significant difference were observed between all groups on CER (Freezing: $F_{(3, 119)}$ = 0.5; P>0.05 ΔMAP: $F_{(3, 102)}$ = 1,1 P>0.05 ΔHR: $F_{(3, 102)}$ = 0.6 P>0.05 ΔCT: $F_{(3, 102)}$ = 0.3 P>0.05. Day 3: Group AM251 30 pmol x vehicle presented an elevated expression of compared to all other groups (Freezing: $F_{(3,19)}$=8.9; P<0.05 ΔMAP: $F_{3,85}$=6.37 P<0.05 ΔHR: $F_{3,85}$=19; P<0.05 ΔCT: $F_{3,85}$=31; P<0.05). The interaction between NMDA and CB1 receptors in vMPFC modulates both reconsolidation and extinction process associated to contextual fear memories

Title: Spontaneous novel object recognition, object location recognition, and temporal order discrimination in rats neonatally treated chronically with MK-801

Authors: *T. HATAKEYAMA[1], H. FURUIE[2,3], K. YAMADA[1], Y. ICHITANI[1]
[1]Lab. of Behavioral Neurosci., Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Ctr. for Med. Sci., Ibaraki Prefectural Univ. of Hlth. Sci., Ami, Japan; [3]Natl. Inst. of Mental Hlth., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: Glutamatergic N-methyl-D-aspartate (NMDA) receptors play a critical role in early brain development. Rats chronically treated with a NMDA antagonist in early developmental stage have been reported to show spontaneous object recognition impairment in adulthood, suggesting the usefulness of neonatal NMDA receptor blockade as a potential model for schizophrenia. Previous studies, however, focused mainly on novel object recognition, and little is known whether the deficits in the spontaneous object location and temporal order recognitions would appear in adulthood. Therefore, here we investigated the effects on the two types of tests as well as novel object recognition in rats neonatally treated chronically with MK-801.
Male Wistar rat pups received injection of 0.4 mg/kg of MK-801 or vehicle (SAL) twice a day on postnatal day 7-20. At the age of 10-13 weeks, three types of spontaneous object recognition tests were conducted. Firstly, the novel object recognition test consisted of a sample phase (5 min) in which rats were exposed to a pair of identical objects (AA) in an arena, a delay of 10 min, and a test phase (5 min) in which one of the two objects was replaced by a novel object (AB) and preference was assessed by comparing the time spent exploring the familiar versus novel object. Secondly, the object location recognition test consisted of a sample phase (10 min) in which two identical objects (CC) were placed, a delay of 10 min, and a test phase (5 min) in which one object was moved to a new position in the arena and novel location preference was assessed. Thirdly, the temporal order recognition test consisted of a sample phase (5 min) in which the first presentation was a pair of identical objects (DD), and then, 125 min later, the second presentation was another pair of objects (EE), a delay of 10 min, and a test phase in which two different objects (DE) were placed and old object preference was assessed by comparing the time spent exploring the old versus recent object.
In the novel object recognition test, there was not a significant difference of discrimination ratio (DR) between MK-801- and SAL-treated groups. However, if the delay was prolonged to 60

min, MK-801 group tended to show a lower DR compared with SAL group. In the object location recognition test, MK-801 group tended to show a lower DR compared with SAL group. In the temporal order recognition test, there was a significant difference between neonatal treatment groups, and the DR of MK-801 rats was significantly lower than that of SAL rats. These results suggest that chronic neonatal NMDA receptor blockade may induce long-lasting effects on the brain regions subserving temporal order discrimination in adulthood.

Title: The chemotherapeutic agent paclitaxel selectively impairs reversal learning while sparing prior learning, new learning and episodic memory

Authors: *D. PANOZ-BROWN, L. M. CAREY, A. E. SMITH, M. GENTRY, C. M. SLUKA, H. E. CORBIN, J.-E. WU, A. G. HOHMANN, J. D. CRYSTAL
Psychology, Indiana Univ. Bloomington, Bloomington, IN

Abstract: Chemotherapy is widely used to treat patients with systemic cancer. The efficacy of cancer therapies is frequently undermined by adverse side effects that have a negative impact on the quality of life of cancer survivors. Cancer patients who receive chemotherapy often experience chemotherapy-induced cognitive impairment across a variety of domains including learning, memory, and attention. In the current study, the impact of paclitaxel, a taxane derived chemotherapeutic agent, on episodic memory, prior learning, new learning, and reversal learning were evaluated in rats. Neurogenesis was quantified post-treatment in the dentate gyrus of the same rats using immunostaining for Bromodeoxyuridine (BrdU) and Ki67. Paclitaxel treatment selectively impaired reversal learning while sparing prior learning, new learning, and episodic memory. Furthermore, paclitaxel-treated rats showed decreases in markers of hippocampal cell

proliferation, as measured by markers of cell proliferation assessed using Ki67 and BrdU immunostaining. This work highlights the importance of using multiple measures of learning and memory to identify the pattern of impaired and spared aspects of chemotherapy-induced cognitive impairment.

Title: Atomoxetine enhances working memory and other behavioral domains in young and aged animals

Authors: *A. V. TERRY, JR[1], P. M. CALLAHAN[1], M. PLAGENHOEF[1], D. BLAKE[2]
[1]Dept Pharmacol Toxicol, [2]Brain Behavior Discovery Inst. & Dept. of Neurol., Augusta Univ., Augusta, GA

Abstract: Atomoxetine is a norepinephrine reuptake inhibitor that is approved for the treatment of attention deficit hyperactivity disorder (ADHD) in children, adolescents, and adults. While it is typically considered a second line therapy for ADHD when compared to stimulants such as methylphenidate and amphetamine, it offers the advantages of reduced abuse liability, decreased risk of motor side effects and it can serve as an alternative medication for patients who are not responsive to stimulants. While there is some evidence that atomoxetine (in addition to its positive effects on attention) may have the potential to improve other domains of cognition such as working memory, this subject has not been systematically studied and, moreover, atomoxetine has not been studied extensively in aged subjects. In the experiments described here, we evaluated atomoxetine in doses ranging from 0.3-5.6 mg/kg (i.p. 30 or 60 minutes before behavioral testing) in adult rats in a variable inter-trial interval (VITI) version of a five choice serial reaction time task (5C-SRTT) and a radial arm maze (RAM) delayed non-match to

position (DNMTP) task. Atomoxetine, doses ranging from 0.03-1.0 mg/kg (i.m., 60 minutes before behavioral testing) was also evaluated in a distractor version of the delayed match to sample task (DMTS-D) in aged (greater than 20 years old) monkeys. In rats, atomoxetine was associated with dose-dependent improvements of inhibitory response control in the 5C-SRTT, as well as with improved performance of the RAM-DNMTP task. In aged monkeys, atomoxetine was associated with dose-dependent decreases in distractibility in the DMTS-D task. Collectively, these studies support the argument that atomoxetine has the potential to decrease distractibility and to improve certain domains of cognition (e.g., working/short memory) and as well as to improve impulse control. Each of these positive findings has relevance to neuropsychiatric disorders such as ADHD and schizophrenia as well as age-related disorders such as Mild Cognitive Impairment (MCI) and Alzheimer's disease.

Abstract: Dopamine D4 receptors (D_4R) are G protein-coupled receptors predominantly expressed in the prefrontal cortex where they play an important role in cognition, attention, and decision making. Previous studies using D_4R ligands of varying efficacies have determined that D_4R signaling alters behavior in animal models of drug addiction and cognition. Developing novel D_4R-selective ligands will allow more detailed investigations into the biological role of D_4R signaling in the brain and assist in medication development for neuropsychiatric disorders, including Alzheimer's disease and substance use disorders (SUD). In order to develop new candidate medications for SUD, we have designed, synthesized, and pharmacologically evaluated novel D_4R antagonist ligands. Starting with the D_4R antagonist 2-(4-(4-(pyrimidin-2-yl)piperazin-1-yl)propyl)benzo [*d*]thiazole as our parent compound, we optimized a next-

generation compound library by using a computational modelling approach. We hypothesized that structural modifications of the parent compound template would produce novel ligands with high D_4R binding affinity, receptor subtype selectivity, and efficacy. In this pursuit, we have produced a library of eighteen compounds with varied substitutions on the pyrimidinylpiperidinyl (PP) ring and/or the benzothiazole moieties. These novel ligands were synthesized and their *in vitro* binding affinities were determined using [^{3}H]*N*-methylspiperone radioligand binding in HEK293 cells expressing dopamine D2-like receptors. By modifying the pyrimidinylpiperidinyl and benzothiazole moieties, we have identified several high-affinity compounds ($K_i \leq 4.85$ nM) with >100-fold selectivity at the D_4R versus D_2 and D_3 receptors. Based on binding profiles, a subset of analogues were evaluated in functional assays measuring β-arrestin recruitment and cAMP production. These new lead compounds will be further evaluated for effects in animal models of cognition and/or drug addiction.

Title: Acetycholinesterase inhibitors prevent, but do not reverse, persistent spatial memory deficits induced in female mice by cyclophosphamide and doxorubicin exposure

Authors: M. FICKEN, B. E. JOHNS, M. E. ENGBERG, L. WECKER, *R. M. PHILPOT
Psychiatry and Behavioral Med., Univ. South Florida, Morsani Col. of Med., Tampa, FL

Abstract: Cancer patients often experience impairments in cognitive function during and following chemotherapy. These chemotherapy-related cognitive deficits (CRCDs) can persist for decades, impairing day-to-day functioning and adversely impacting quality of life. Acetylcholinesterase (AChE) inhibitors improve cognitive function in individuals suffering from Alzheimer's disease and research in mice indicates that the AChE inhibitor donepezil (DON) may be beneficial for the prevention or treatment of CRCDs induced by methotrexate and 5-fluorouracil. To determine if DON can attenuate CRCDs induced by cyclophosphamide (CYP) and doxorubicin (DOX), if these actions are prophylactic or therapeutic, and if the AChE inhibitor galantamine (GAL) produces similar effects, female BALB/C mice, 64 days of age,

were trained in the Morris water maze. Baseline performance was determined on day 6 and mice were assessed weekly from day 13 to 62. Mice received weekly intravenous injections of CYP (25mg/kg) and DOX (2.5mg/kg) on days 7, 14, 21 and 28. For exp 1 and 2, CYP+DOX administration reduced the % of entries (%E), % of movement (%M), and time spent (T) in the correct zone during the probe trial, indicating impaired spatial memory. On day 35, 7 days following the final injection of CYP+DOX, mice began receiving daily injections (s.c.) of DON (3mg/kg), GAL (3mg/kg), or equivalent volumes saline (SAL). DON- and GAL-injected mice did not differ from SAL mice and did not improve on any measure of spatial memory during treatment (days 35-62). For exp 3, mice received daily injections (s.c.) of DON (3mg/kg), GAL (3mg/kg) or SAL during the 4 weeks of CYP+DOX administration, from day 7-34. Relative to day 6, the %E, %M, and T exhibited by mice was reduced by 13-38%, 14-58% and 19-56%, respectively, on days 13-34. On days 41-62, the performance of DON- and GAL-injected mice was significantly greater than SAL-injected mice, with DON- and GAL mice exhibiting 11-25% greater %E, 7-28% greater %M and 11-14sec longer T in the correct zone than SAL mice. The performance of DON and GAL mice did not differ from each other on any measure. The results indicate that AChE inhibitors do not reverse spatial memory deficits induced by exposure to CYP+DOX, but can attenuate deficits if administered during CYP+DOX exposure. These findings suggest that AChE inhibitors may be useful for the prevention of CRCDs if administered concurrent with chemotherapy.

Title: Effects of heat shock protein induction on spatial learning and memory in mice

Authors: *R. TANOUE, Y. MORITA, S. YAMAMOTO, N. HASHIKAWA-HOBARA, N. HASHIKAWA
Okayama Univ. of Sci., Okayama-Shi, Japan

Abstract: Learning and memory functions in organisms are important functions directly connected to life support such as food intake and danger avoidance, and there are many similar mechanisms from lower organisms to higher organisms. Heat shock protein (HSP) is a group of proteins expressed when cells undergo stress such as heat, ultraviolet rays, burns etc, and acts as a molecular chaperone that folds nascent proteins and repairs denatured proteins. HSP expression is closely related to diseases of the central nervous system, but its effect on learning and memory

is not clear. In the present study, to clarify the role of HSP in learning and memory, geranyl-geranyl acetone (GGA) known as HSP inducer was administered orally to C57BL6J mice, and assessed Morris water maze test (spatial memory), Rota-rod test (motor learning memory), Passive avoidance test (fear memory), and Y maze test (working memory). Furthermore, the level of HSP mRNA in the brain was analyzed by real-time PCR. In the Rota-rod test, the Passive avoidance test, and the Y maze test, GGA administered did not show any significant differences when compared to control. However, GGA treatment mice learned the water maze task at a higher rate than control and had better performance scores by the end of the training period and on a probe trial. Our findings demonstrated that GGA treatment lead to ameliorate spatial memory.

Title: An automated test of olfactory working memory in rats: Effects of MK-801

Authors: H. A. KELLIHER[1], S. A. NELSON[2], K. DYER[2], S. ACCATTATO[2], L. RICHARDSON[2], M. MATHEWS[2], *J. GALIZIO[2]

Abstract: Available procedures to study working memory capacity in rodents generally use manual arena or maze tasks. For example, the odor span task uses an incrementing non-match to sample procedure in which digging in cups scented with novel olfactory stimuli results in reinforcement on each trial, while responses to previously presented stimuli are not reinforced. The present study modified this procedure for use in an automated operant chamber using a 15-channel olfactometer. Rats were trained on a go, no-go procedure to make nose-poke responses in a port through which odorants were delivered. A series of odorants was presented several times during a session. Responses to each odorant were reinforced on an FI 5-s schedule the first time it was presented, but once an odor had been presented, responses to that odor were no longer reinforced. Rats rapidly learned to differentiate between novel and familiar odors and responded at high rates to new stimuli and much lower rates to repeated stimuli. Accuracy was disrupted with the insertion of a mid-session distractor task. The effects of NMDA antagonist, MK-801 were assessed in six rats and produced a dose-dependent impairment in accuracy. These

results were similar to findings obtained in the odor span task, and illustrate the value of studying memory for multiple stimuli using an automated procedure.

Title: Nicotinergic alpha7 and alpha4/beta2 sub-receptor agonists differentially enhance reversal learning speed and attentional filtering of distraction in a non-human primate model

Authors: *M. AZIMI[1], M. OEMISCH[1], T. WOMELSDORF[1,2]
[1]Biol., York Univ., Toronto, ON, Canada; [2]Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Nicotinic acetylcholine receptors (nAChR) are believed to modulate attention, memory, and higher executive functioning through the alpha 4-beta 2 and/or the alpha 7 nACh sub-receptors. These suggestions are mainly derived from rodent studies using task paradigms with only an indirect relationship to flexible attention and learning behavior of the primate behavioral repertoire. We therefore set out to identify the specific contributions of two highly selective agonists for alpha7 (α7) and alpha4-beta2 (α4β2) nAChRs in mediating flexible reversal learning and attentional filtering of distractors in a non-human primate model. We used two different doses of each agonist to compare the effects of drug to non-drug conditions while the monkey performed a feature-based reversal learning task. The task allowed dissociating subcomponent processes of attentional filtering, learning efficacy, motivation, impulsivity and perseveration tendencies.
We found for both sub-receptor agonists a dose-dependent enhancement of specific aspects of reversal performance. The optimal dose for α7 increased performance accuracy and sped up learning in reversals of the rewarded feature value. However, we found that this effect was specific to the first 25 minutes after the task started. This duration of behavioral improvement corresponded to the period when the agent was at its peak concentration in blood plasma. In contrast to the α7 effect, the best dose of the α4β2 nAChR agonist increased performance accuracy specifically in those subsets of trials that had an enhanced demand to filter out distracting visual information. However, in contrast to these behaviorally enhancing effects on reversal learning speed (α7) and attentional filtering (α4β2), neither drug modulated motivation, impulsivity, or perseveration rates.

In summary, our results document sub-receptor specific effects on higher order learning and attention functions in a healthy non-human primate. The effectiveness of both agonists was dependent on the inferred, relative concentration of the drug in blood plasma. These findings are an important first step to identify the neuromodulatory mechanisms of attention and learning functions in the primate brain. We speculate that these results could be a first step towards the development of function-specific drugs alleviating cognitive deficits evident in multiple neuro-psychiatric diseases.

Title: Behavioral flexibility is improved by chronic fluoxetine treatment through BDNF/TrkB signaling

Authors: *J. UMEMORI[1], G. DIDIO[1], F. WINKEL[1], H. ANTILA[2], M. L. POU[3], V. VÕIKAR[1], R. GURADO[1], E. CASTREN[2]
[1]Neurosci. center, [2]Neurosci. Ctr., Univ. of Helsinki, Helsinki, Finland; [3]Biomed. Science,, Univ. of Barcelona, Barcelona, Spain

Abstract: Brain-derived neurotrophic factor (BDNF) is a major regulator of neuronal plasticity through the activation of its receptor tyrosine kinase TrkB. We have demonstrated that chronic fluoxetine treatment combined with fear extinction or monocular deprivation, but neither treatment alone, induced an enduring loss of conditioned fear memory or shift of ocular dominance in the visual cortex, respectively, activated by BDNF/TrkB pathway (Vetencourt et al., 2008; Karpova et al., 2011). Thus, chronic antidepressant drug treatment induces a critical period-like plasticity, which allows brain networks to better adapt to the internal and external milieu in the adult brain. However it is not clear whether spatial reversal learning or behavioral flexibility is improved by chronic fluoxetine treatment during learning process via BDNF/TrkB pathway.
Here we used BDNF heterozygous knockout (Bdnf hKO) and heterozygous TrkB knockout specifically in Parvalbumin (PV)-expressing interneurons (hPV-TrkB) mice, and assessed the effects of fluoxetine on plasticity using Intellicage (NewBehavior AG, Zurich, Switzerland), where transponder-implanted female mice were group-housed in a genotype-mixed manner. In IntelliCage water-deprived mice were rewarded by access to water when visiting conditioning

corners in defined sequence during the acquisition phase, and then it was exchanged to the opposite direction in the reversal phase. In wild-type mice, chronic treatment with fluoxetine did not affect acquisition of the spatial memory but improved “reversal” learning. Bdnf hKO mice showed impaired acquisition of spatial memory as previously indicated (Linnarsson et al., 1997), but chronic fluoxetine treatment improved spatial memory in the acquisition and reversal phase to similar level as in the wild-type mice. On the other hand, hPV-TrkB mice did not show deficits in learning or memory in the acquisition or reversal phase, but the treatment with fluoxetine did not improve reversal learning as in the wild-type mice. These results indicate that fluoxetine promotes behavioral flexibility in the reversal learning task by activating TrkB signaling in PV interneurons.

Title: The phosphodiesterase 1 inhibitor Lu AF64386 increases cGMP and cAMP in the brain and exerts procognitive effects in the rat

Authors: *A. MORK, H. S. LINDGREN, V. NIELSEN, C. T. CHRISTOFFERSEN, J. KEHLER, J. NIELSEN
H. Lundbeck A/S, Copenhagen-Valby, Denmark

Abstract: Phosphodiesterase 1 (PDE1) is a dual substrate enzyme hydrolyzing cGMP and cAMP and thus plays a major role in cell signaling. There are 3 PDE1 genes. PDE1A is expressed at high levels in the brain primarily in the output neurons of layers 5/6 of the cortex and in CA1-3 of the hippocampus. PDE1B is also expressed at high levels in the brain with highest expression in the striatum, but also expressed in the cortex, dentate gyrus and other brain regions. PDE1C is expressed at low levels in the brain. Various preclinical studies have suggested an association between activity inhibition of different PDE families and cognition enhancing actions. In the present study we investigated the effect of the PDE1 inhibitor Lu AF64386 (1) on PDE1 in vivo binding and levels of cGMP and cAMP in the brain of awake rats. Furthermore, the effect of Lu AF64386 was studied in preclinical models of cognitive function. PDE1 occupancy was measured by in vivo binding, i.e., displacement of a [^{3}H]-labelled PDE1 inhibitor after pretreating with un-labelled Lu AF64386. Effects on extracellular levels of cGMP and cAMP in

the brain were measured by microdialysis in freely-moving rats and the content of nucleotides in the microdialysis samples was determined by HPLC and tandem mass spectrometry analysis. Effects on executive function and memory were evaluated by using the attentional set shifting task and contextual fear conditioning. Subcutaneous administration of Lu AF64386 at 0.3-30 mg/kg dose-dependently occupied striatal PDE1 (EC50 2.5 mg/kg), reaching full occupancy at the highest dose. Moreover, Lu AF64386 dose-dependently increased cGMP and cAMP in the rat striatum, the prefrontal cortex and the hippocampus. Extracellular levels of cGMP reached > 700% of baseline for rats treated with the highest dose, whilst cAMP levels within those rats reached 150 - 200% of baseline. Similar doses of Lu AF64386 also improved memory function assessed in the contextual fear conditioning task, as well as attenuating the subchronic phencyclidine-induced deficit at the extradimensional shift in the set-shifting task. Since PDE1 is highly expressed in brain areas mediating cognition, Lu AF64386-induced increases in cyclic nucleotides may affect impaired synaptic function and improve cognitive functions in patients with psychiatric disorders. 1. Title: The relationship between blood pressure reduction and working memory performance in spontaneously hypertensive rats (SHR): Understanding the effects of hydralazine and strains differences in rats

Authors: *T. SATO
Social Welfare, Nagano Univ., Ueda, Japan

Abstract: Spontaneously hypertensive rats (SHRs) were originally developed as a model to study hypertension in humans. It is well known that SHRs exhibit certain behavioral characteristics, such as, increased locomotor activity, which decreases with decreasing blood

pressure (BP) induced by the intravenous administration of hypotensive drugs. However, it is unclear if the cognitive functions of SHRs, such as learning and memory, change upon reducing BP. This study aimed to determine the effects of BP reduction on SHR memory function. For this purpose, we used 8 well-trained SHRs, along with 8 Wistar-Kyoto strain (WKY) rats as normotensive control, for a delayed-matching-to-place (DMTP) task, results of which were compared between the two rat-strain groups in terms of the number of correct responses. Upon the completion of pre-training, all rats were repeatedly tested in the DMTP task four times. In each session, rats were intravenously injected with a vasodilator, hydralazine, at one of the four different doses (0, 0.1, 0.3, 0.6 mg/kg) in a randomized order. During the DMTP task, rats were reinforced with food when they made a matching response, i.e., when the rat pressed the retractable lever inserted as the sample at the beginning of the respective trial. In addition, each task session had 100 trials. At the beginning of each trial, one lever was randomly selected as the sample and inserted in the chamber. When the rat pressed the lever, the lever retracted and the food-cup light in the rear wall illuminated. After the rat made a nose poke to the food cup twice, both levers were inserted. Both levers retracted when one of them was pressed. To obtain a retention gradient, the time interval between the first nose-poke and the end of the delay interval, wherein no nose-poke was effective for the presentation of both levers, was varied amongst five different time lengths (0, 2, 5, 10, 20 s) in a randomized order. A three-factor ANOVA and its subsequent analyses indicated that, when the delay time was more than 2 s, the number of correct responses gradually decreased in proportion to the delay time length. Subsequent analysis also revealed that the number of correct responses following the injection of 0.3 and 0.6 mg/kg hydralazine was smaller than that after saline injection; however, the size of the difference between these dosages was relatively small. Additionally, the strain difference between SHR and WKY rats was not statistically significant. In conclusion, these results reveal that the effects of average to high doses of hydralazine on memory performance in the DMTP task are statistically significant, though relatively small, and the strain difference between SHR and WKY rats is not evident.

Title: Modulating the cortico-striatal output gate of working memory

Authors: *J. MILLER[1], A. KIYONAGA[1], R. B. IVRY[1,2], M. D'ESPOSITO[1,2]
[1]Helen Wills Neurosci. Inst., [2]Dept. of Psychology, UC Berkeley, Berkeley, CA

Abstract: Working memory (WM) confers the unique ability to guide behavior based on internal representations, and to therefore plan for the near future. However, some WM representations are irrelevant to current goals. For instance, WM content is often maintained for a future goal, during performance of more immediate tasks. During WM maintenance, WM content can bias perception in favor of similar stimuli. The relevance of the WM content to the immediate task may determine its activation status in either a prioritized or latent state (i.e., 'silent coding'; Stokes, 2015), as well as the extent of its influence on current perception. However, it is unknown whether WM content has an analogous impact on the execution of actions: How and when does active thought content involuntarily influence motor behavior? A 'gating' process has been proposed to describe goal-dependent, flexible control over what information gets entered into WM (i.e., input gating), and when those WM representations are selected to control behavior (i.e., output gating; Chatham & Badre, 2015). Prefrontal-striatal circuitry has been implicated in the control of this gating process, but there is very little empirical evidence for the output gating hypothesis. Here, we sought to (1) behaviorally engage the putative WM output gating mechanism, and (2) causally test the cortico-striatal circuitry of WM output gating through transcranial magnetic stimulation (TMS). We developed a novel behavioral task to test whether WM content can involuntarily influence behavior, similar to how it biases perception: participants maintained a WM sample (either the word "up" "down" "left" or "right") and then performed a motor reaching task to a cued location during the WM delay. WM content could be compatible or incompatible with the goals of the reaching task. Movement initiation was fastest when WM content was compatible and slower when WM content was incompatible with the action goal, suggesting that WM content can influence response initiation for a different task. This compatibility effect was only evident, however, when the movement task goal was indicated with a symbolic cue; there was no compatibility effect when the movement goal was exogenously cued, suggesting the WM content influenced response selection rather than implementation. Further, TMS delivered to lateral prefrontal cortex (PFC)—targeted based on striatal connectivity—modulated the magnitude of the behavioral effect. Our results suggest that active WM content can involuntarily influence actions, and that the selection of representations from within WM to guide behavior (i.e., output gating) is controlled by prefrontal-striatal interactions.

Title: Reactivation and suppression of representations in working memory using frequency specific tms

Authors: *J. RIDDLE[1], D. CELLIER[3], S. DHANANI[3], M. DESPOSITO[2]
[2]Helen Wills Neurosci. Inst., [1]Univ. of California Berkeley, Berkeley, CA; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Working memory (WM) is the ability to maintain and manipulate information after it is no longer present in the environment. A retro-cue during the delay period of a WM task triggers reactivation of a subset of WM representations, providing a useful method for dissociating WM encoding from WM reactivation processes. Magnetoencephalography studies have shown that theta frequency oscillations emerge in areas that maintain WM representations during reactivation with a retro-cue (Wallis et al. 2016), whereas when WM representations are inhibited or suppressed, alpha frequency oscillations emerge (Sauseng et al. 2009).To establish the necessity of neural oscillations in WM, we used rhythmic transcranial magnetic stimulation (TMS) to causally manipulate alpha and theta oscillations during the reactivation and suppression of WM traces. Subjects were presented with 4 colored squares in each visual field. After a 1 second delay, a retro-cue (arrow pointing to one side) instructed subjects to remember the items in one visual field and the items in the other visual field could be forgotten. After another 1 second delay, subjects judged an array of 4 colored squares to be a match or non-match to the memory array. Subjects were screened for their ability to utilize the retro-cue over a non-informative neutral cue. In another session, 14 screened subjects performed the task during fMRI for functional localization of the left middle frontal gyrus (L-MFG) and left inferior intraparietal sulcus (L-IPS). In the 3rd and 4th sessions, subjects received online TMS to either L-MFG or L-IPS immediately after the presentation of the retro-cue. The key manipulation was the TMS frequency: theta (5 Hz), alpha (10 Hz), or arrhythmic control. Our hypothesis was that disruption of theta frequency oscillations would impact the retro-cue benefit of items in the right visual field, which was confirmed as only right retro-cues during theta TMS to L-IPS and L-MFG decreased the retro-cue benefit relative to arrhythmic control. We also hypothesized that entrainment of alpha frequency oscillations would boost suppression of items in the right visual field, improving the left-visual field retro-cue benefit. This effect was not significant but the retro-cue accuracy benefit in the left visual field following alpha TMS was inversely related to the accuracy detriment in the right visual field that was found following theta TMS.These results provide causal evidence for the role of theta frequency oscillations in the reactivation of a WM memory trace. Also, these results suggest an inverse relationship between theta and alpha frequency oscillations in reactivating and suppressing WM representations.

Title: May mental arithmetic performance be enhanced by transcranial direct current stimulation? - Preliminary results

Authors: *S. JANG[1], *S. JANG[1], M. KWON[1], K. KIM[2,3], S. C. JUN[1]
[1]Sch. of Electrical Engin. and Computer Sci. (EECS), Gwangju Inst. of Sci. and Technol. (GIST), Gwangju, Korea, Republic of; [2]Ctr. for Biosignals, Korea Res. Inst. of Standards and Sci. (KRISS), Daejeon, Korea, Republic of; [3]Dept. of Med. Physics, Univ. of Sci. and Technol. (UST), Daejeon, Korea, Republic of

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation to modulate various cognitive functions such as working memory. The role of working memory in mental arithmetic has been studied in various research groups. Posterior parietal cortex (PPC) is known to be involved in arithmetic processing, but some researchers argued that dorsolateral prefrontal cortex (DLPFC) may also be involved in this processing. To verify this argument, we recorded magnetoencephalography (MEG) pre- and post-tDCS to find which area is strongly involved in multiplication problem. In this study, behavior tests were analyzed as a preliminary study.
Fifteen healthy volunteers (9 females, aged 24.5 ± 3.0 years) participated in our experiment. All subjects were given 3 stimulation types (anode, cathode, sham) on 3 other days (interval is at least one week). The current stimulation was delivered using a Starstim device (Neuroelectrics) via a pair of circular electrodes with sponge surface (25 cm^2). A 1.5 mA current intensity was applied for 25 min. The active electrode was placed over the left PPC at P3, and the reference electrode was located at Fp2 on the right DLPFC. Each participant performed mental multiplication problems and 152-channel whole-head MEG (KRISS) at a sampling rate of 1024 Hz was recorded.
Table 1 shows behavior results. A reaction time of solving the multiplication problems in post-tDCS was faster in anodal tDCS than those in cathodal and sham tDCS (anode vs. cathode:

p=0.028, anode vs. sham: p = 0.049), whereas there was no significant difference between cathodal and sham tDCS. Moreover, the reaction time (p = 0.078) and accuracy (p = 0.102) in only anodal tDCS were improved between pre- and post-tDCS. However, there was no significant difference in the reaction time and accuracy on the other stimulations.
The behavior results showed that anodal tDCS on the left angular gyrus associated with verbally mediated processing improves ability to solve the problems. It is known that the mental calculation is involved in phonological working memory related to arithmetic fact retrieval and procedural strategies. Thus, our preliminary results infer that activation in the left PPC may play some role of phonological working memory to solve the multiplication.

Table 1. Behavior analysis : Reaction time and accuracy of problem solving (Mean ± SD)

	Anode	Cathode	sham
Pre-tDCS			
Time (sec)	3.27 ± 1.50	3.29 ± 1.52	3.36 ± 1.56
Accuracy (%)	95.99 ± 2.35	95.33 ± 3.29	94.91 ± 4.28
Post-tDCS			
Time (sec)	3.13 ± 1.45	3.29 ± 1.54	3.31 ± 1.61
Accuracy (%)	97.22 ± 2.13	96.94 ± 2.27	96.94 ± 2.68

Title: Transcranial direct current stimulation during working memory training increases transfer to problem solving and alters connectivity between the dorsal attention network and trained cortex

Authors: *D. CISLER, M. STRENZIOK, A. HARWOOD, R. PARASURAMAN, P. GREENWOOD
George Mason Univ., Fairfax, VA

Abstract: An important goal of cognitive training is far transfer to fluid cognitive ability (Gf). Although working memory (WM) training has shown the strongest evidence to date of far transfer to fluid ability (e.g., Jaeggi et al., 2008), the literature is inconsistent. Previous work using transcranial direct current stimulation (tDCS) has shown benefits on n-back WM performance (meta-analysis of Brunoni & Vanderhasselt, 2014). Based on evidence that successful cognitive training modulated connectivity between nodes of the dorsal attention network (DAN) and trained cortex (Lewis et al., 2009; Strenziok et al., 2014), we hypothesized that cognitive training, in conjunction with anodal tDCS over the DAN, would facilitate far transfer and modulate functional connectivity involving the DAN.
Young adults were pre-tested and pre-scanned before being randomly assigned to adaptive WM training during either 2 mA or .1 mA (sham) tDCS to CP4 (cathode on left arm). The supervised training was 1.5 hours a day (with tDCS or sham for 30 min of that time) for 4 consecutive days on adaptive WM memory tasks, followed by post-testing and post-scanning. Pre- and post-testing included: spatial working memory, visuospatial attention, WAIS Letter-Number Sequencing, WAIS Matrix Reasoning, Wechsler Memory Scale, Logical Memory, and the Everyday Problems Test. Functional connectivity (fcMRI) images were acquired at rest with participants' eyes open in axial plane with a single-shot echo-planar sequence sensitive to change in the BOLD response (TR = 2500 ms, TE = 30 ms, 42 slices, $3mm^3$ resolution, flip angle 70°). A MANOVA on the behavioral data revealed effects of tDCS on transfer tasks (Wilks' lambda, p=.048). Only speed of spatial working memory and Everyday Problems Test (Willis & Marsiske, 1993) benefited from tDCS (p=.037). Analysis of the fcMRI data involved a whole-brain seed-based correlation analysis in the dorsal attention network (superior parietal cortex, SPC), using a 2 mm spherical region (MNI: -14, -69, 48) previously used to show changed fcMRI following sensory training (Lewis et al., 2009; Strenziok et al., 2014). Functional connectivity analyses demonstrated a Group x Time interaction ($p < .05$) in the lateral occipital lobe indicating a decrease in connectivity in the tDCS group and increase in the sham group, from pre-to post training. This extends to young adults and to WM our previous finding of perceptual training-related functional connectivity change in older adults (Strenziok et al., 2014). Effects of tDCS on changes in the fMRI BOLD signal as a function of size of cues around the memory array of a cued spatial WM task will be included.

Title: Prefrontal high gamma contributes differentially to the multi-frequency MEG response to rest and working memory task activation

Authors: F. W. CARVER[1], D. Y. RUBINSTEIN[2], S. I. FRADKIN[1], T. HOLROYD[1], *R. COPPOLA[1]
[1]MEG Core Facility, [2]CTNB, NIMH, Bethesda, MD

Abstract: Human electrophysiological activity contains oscillations at several distinct frequency bands, the relative amplitudes of which can be modulated by factors such as alertness and the performance of tasks. In recent years, task-dependent signal change has been localized to specific brain regions utilizing high density EEG and MEG systems combined with advanced source localization techniques. Largely due to a low signal-to-noise ratio, the high end of the cortical power spectrum (~>60 Hz) has received relatively little experimental attention compared to higher amplitude bands such as theta (~3-8 Hz), alpha (~8-12 Hz), beta (~13-30 Hz), and gamma (~30-60 Hz). Here we employed a large sample of healthy volunteers (*n*=191) to characterize the oscillatory response to an n-back working memory task by contrasting the data to a resting eyes-closed recording using a 275-channel CTF system. Analysis of channel power spectra from 2-back, 0-back, and rest trials revealed signal reduction associated with greater task difficulty in alpha and beta bands, a well-known phenomenon known as event-related desynchronization. Significantly, the spectra also showed task-related increase in power in a broad band of high-frequency activity greater than 60 Hz, which researchers often refer to as high gamma band. Source localization of this activity using synthetic aperture magnetometry revealed a distinct distribution of sources for this high gamma activation compared to the alpha and beta bands. Activity in the band was especially prominent in prefrontal cortex, including Brodmann areas 9, 10, and 32, regions known to be critical for the executive functions such as attention and working memory necessary for the performance of the n-back task. These results indicate that the high gamma band is part of the neurophysiological instantiation of these, and other, cognitive processes. The data were collected as part of a larger study of the genetic contributions to the development of schizophrenia, a patient group known to exhibit abnormalities in prefrontal function. Our findings suggest that elucidating the high gamma band will be important for discovering the origin of these abnormalities, and their contribution to diminished cognitive function.

Title: Novelty modulates human striatal activation and prefrontal-striatal effective connectivity during working memory encoding

Authors: ***L. S. GEIGER**[1], A. SCHAEFER[1], C. MOESSNANG[1], Z. ZANG[1], M. ZANGL[1], H. CAO[1], T. VAN RAALTEN[2], A. MEYER-LINDENBERG[1], H. TOST[1]
[1]Central Inst. of Mental Hlth., University of Heidelberg, Mannheim, Germany; [2]Rudolf Magnus Brain Ctr., University Medical Center Utrecht, Utrecht, Netherlands

Abstract: The gating function of the basal ganglia (BG) in motor responses is well established and growing evidence supports an analogous role of BG during working memory (WM) encoding, a task phase in which gating of relevant materials is essential (e.g. McNab and Klingberg, 2008; Moore et al., 2013; O'Reilly and Frank, 2006). One important, but highly understudied aspect of stimulus relevance is the novelty of WM items. We therefore set out to study the effect of novelty on corticostriatal function and effective connectivity during an established WM task.
We used a modified Sternberg WM task (van Raalten et al., 2008) with different memory phases (encoding vs. retrieval) and degrees of stimulus familiarity (novel vs. previously practiced). FMRI data were acquired at 3T in a sample of 74 healthy participants (43 females, age: 26 ± 7.0 years). Data preprocessing was performed using standard routines of the Statistical Parametric Mapping software (SPM8; http://www.fil.ion.ucl.ac.uk/spm/software/spm8/). First level analyses included the calculation of individual contrast images to assess the effect of memory phase (encoding vs. retrieval) and effect of stimulus type (novel vs. practiced). Individual contrast images were subjected to a second-level random-effects model and one-sample t-tests were calculated for statistical inference at the group level ($P < 0.05$, whole-brain family-wise error corrected). Corticostriatal connectivity analyses were performed in two key regions, the dorsolateral prefrontal cortex (DLPFC) and the striatum using dynamic causal modeling (DCM) implemented in the DCM12 toolbox (SPM12). First, we defined model families based on different modulation patterns (2^4 = 16 families) and compared these families using Bayesian model selection. The models within the winning family (15 models) were subsequently

compared using random effects Bayesian model selection (BMS) to determine the winning model (Stephan et al., 2007).
Activation analyses demonstrated a significant engagement of the striatum and the DLPFC specifically during the encoding of novel WM items. DCM analyses identified a selective positive modulatory influence of novelty encoding on the connection from the DLPFC to the striatum. These data extend prior research by further underscoring the relevance of the BG for human cognitive function and provide a mechanistic account of the DLPFC as a top-down regulatory element of striatal function that may facilitate the gating of novel WM items. Further studies should address this gating mechanism in a longitudinal approach or in clinical populations with working memory dysfunction such as in patients with schizophrenia.

Title: Verbal working memory elicits synchronization between cortex and hippocampus

Authors: *J. SARNTHEIN[1], E. BORAN[1], P. HILFIKER[2], L. STIEGLITZ[1], T. GRUNWALD[2], T. FEDELE[1]
[1]Klinik für Neurochirurgie, Universitätsspital Zürich, Zurich, Switzerland; [2]Swiss Epilepsy Ctr., Zurich, Switzerland

Abstract: Objective: Verbal working memory elicits workload-dependent theta and alpha oscillations in the frontal and parietal surface EEG (Michels, 2008), but the involvement of subcortical nodes is not known.
Methods: Epilepsy patients with electrodes in the hippocampus and on the scalp performed a modified Sternberg task with setsize 4, 6 and 8 letters. We analyzed the time-frequency profile and the phase locking value (PLV) in theta (4-8 Hz) and alpha (8-12 Hz) and high gamma (> 100 Hz) frequency bands while stimuli were encoded and retained in memory.
Results: In 9 of 10 participants, the theta/alpha PLV was elevated between hippocampus and scalp. In 4 participants, the PLV increased with setsize, predominantly towards the end of the

retention period and to frontal and parietal electrodes. Two participants showed strong frontal midline theta and parietal alpha during retention, in agreement with our earlier scalp EEG study. Concurrently, the workload and/or the task conditions modulated the hippocampal theta/alpha and high-gamma power.
Conclusion: While hippocampal activity is known for visuospatial memory tasks, we show here hippocampal involvement also in a cortical network that is activated during verbal working memory and mediated by synchronized theta/alpha EEG oscillations.

Title: Exploring the effect of age, task performance and learning style on prefrontal hemodynamics during a working memory task

Authors: *A. A. ANDERSON[1], K. PARSA[1], S. GEIGER[2], R. ZARAGOZA[1], R. KERMANIAN[1], E. SMITH[1], A. GANDJBAKHCHE[1]
[1]NICHD, NIH, Bethesda, MD; [2]St. Olaf Col., Northfield, MN

Abstract: Existing literature outlines the quality and location of activation in the prefrontal cortex (PFC) during working memory (WM) tasks. However, the effects of individual differences on the underlying neural process of WM tasks are still unclear. In this functional near infrared spectroscopy study, we administered a visual and auditory n-back task to examine activation in the PFC while considering the influences of age, task performance, and preferred learning strategy (VARK score). Results showed that younger subjects had higher activation in the right ventro-medial-PFC compared to older subjects. Aside from age differences, high performance (HP) subjects (task accuracy > 90%) showed lower activation compared to normal performance subjects. After accounting for learning style we found a correlation between aural VARK score and level of activation in the PFC. Subjects with higher aural VARK scores displayed lower activation during auditory stimuli, while exhibiting higher activation during visual stimuli. High performance subjects during auditory task had higher aural and visual VARK scores, indicating an effect of learning style on the task performance and activation. The results of this study show that learning style and task performance can influence PFC activation,

with applications toward neurological implications of learning style and populations with deficits in auditory or visual processing.

Title: Higher working memory capacity is associated with better suppression of internal noise

Authors: *A. RAJAN, S. MEYYAPPAN, H. WALKER, M. DING
J. Crayton Pruitt Family of Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Working memory capacity (WMC) is thought to measure an individual's ability to maintain executive attention to task relevant information in the presence of distraction. Past work testing this idea has mainly focused on external distraction in the form of environmental distractors. To what extent WMC also enables the suppression of internal distraction or noise, such as mind wandering mediated by the default mode network (DMN), is unknown. We addressed this problem by recording fMRI data from 20 subjects performing a cued attention task. Each trial started with an auditory cue, which directed subjects to attend to a spatial location (left or right visual field) or a color (red or green). Following a random time delay, two stimuli in the form of a colored rectangle were displayed in the right and left visual field. The subjects were required to discriminate the orientation (vertical or horizontal) of the rectangle in the cued location or cued color. The WMC of each subject was separately assessed by an automated operation span (OSPAN) task. We found the following results. First, posterior cingulate cortex (PCC) of the DMN was significantly deactivated in response to the cue, and the magnitude of deactivation was inversely correlated with the reaction time (RT) variability, namely, the stronger the PCC deactivation, the smaller the RT variability. Second, the magnitude of PCC deactivation was inversely correlated with WMC, namely, subjects with higher WMC had more deactivation in PCC in response to attentional cues. Third, a beta series connectivity analysis using PCC as the seed region revealed that PCC was positively correlated with the major DMN regions including medial prefrontal cortex, bilateral angular gyrus, bilateral parahippocampal region but anti-correlated with major task control regions including dorsal anterior cingulate, bilateral anterior insula, and bilateral dorsolateral prefrontal cortex. These results support the hypothesis that subjects with higher WMC are better at suppressing internal noise, leading to

reduced attention lapses, and such suppression is possibly implemented by the higher-order task-control networks such as the salience network and the central executive network.

Title: Examination of cerebral cortico-cortical communication for cognitive workload assessment during dual-task walking

Authors: ***E. P. SHAW**[1,2,3], J. C. RIETSCHEL[5], B. D. HENDERSHOT[1,6,7], A. L. PRUZINER[1,6,7], M. W. MILLER[8], B. D. HATFIELD[2,3], R. J. GENTILI[2,3,4]
[1]Rehabil., Walter Reed Natl. Military Med. Ctr., Bethesda, MD; [2]Neurosci. and Cognitive Sci., [3]Kinesiology, [4]Maryland Robotics Ctr., Univ. of Maryland, College Park, MD; [5]Veteran's Hlth. Admin., Baltimore, MD; [6]DOD-VA Extremity Trauma and Amputation Ctr. of Excellence, Bethesda, MD; [7]Rehabil. Med., Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [8]Kinesiology, Auburn Univ., Auburn, AL

Abstract: While some prior work has employed ERPs and EEG spectral content to successfully evaluate cognitive workload during dual-task walking, none have examined changes in cerebral cortico-cortical communications; a critical component of brain dynamics during cognitive-motor performance. Therefore, this study aimed to examine whether changes in the magnitude of cortico-cortical communications could serve as an index of cognitive workload under various levels of cognitive challenge during dual-task walking. EEG was collected from twelve uninjured participants who were seated or walking on a treadmill in a Computer Assisted Rehabilitation Environment while performing a cognitive task of varying difficulty (easy or hard). Due to its common use in brain research, EEG coherence was employed to assess cortical networking. Additionally, the weighted phase lag index (WPLI) was computed as it is more robust to volume conduction. Both metrics were initially computed using a scalp montage centered over the motor planning region (i.e. electrode Fz). Such a montage was employed due to its common use in cognitive-motor studies. Statistical analysis of Repeated Measures ANOVAs revealed some significant contrasts of interest for both the difficulty of the cognitive task (easy/hard) and the condition performed (seat/walk) in EEG fronto-frontal coherence for the lower- to mid- frequency bands. However, these findings were not fully supported by the WPLI. Similar analyses of the mid- to high-frequency bands did not reveal differences in cognitive task

difficulty, but were moderately sensitive to differences in the performance conditions. Overall, the findings did not provide a clear assessment of cognitive workload in contrast to ERP and regional activation analyses employed in similar dual-task walking studies. Although dual-task walking has an important cognitive-motor component, it is possible that the montage considered here may not have been able to fully capture changes in cortical networking of uninjured individuals. This is because walking alone is likely to be more automatic (requires less motor planning) compared to upper-extremity task performance. Consequently, a more exhaustive analysis based on data mining is currently underway to capture more detailed patterns of cortical connectivity underlying various changes in task demands. This work was supported by the DoD Defense Health Program (NF90UG) and the DoD-VA Extremity Trauma & Amputation Center of Excellence. Views expressed are those of the authors and do not reflect the official policy or position of the Departments of the Army, Navy, or Defense, or the U.S. Government.

Title: Methylphenidate manipulation of the neural underpinnings of anxiety and working memory interactions

Authors: *B. FUCHS, T. LAGO, N. BALDERSTON, C. GRILLON, M. ERNST
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Anxiety can impair cognition, and cognitive processes can decrease anxiety. However, the neural mechanisms underlying these effects are unclear. Here, cognition and anxiety were manipulated orthogonally to examine their effects on the neural substrates of working memory (WM). Enhancing executive functioning pharmacologically with a single-dose of methylphenidate-MPH (vs. placebo-PLC) was expected to: (1) facilitate recruitment of the cognitive circuitry, and (2) free resources to attend to threat, i.e increased recruitment of the threat circuitry (vs. safe condition), particularly during high-load WM (vs. low-load).
In a placebo-controlled, double-blind, parallel-group fMRI study, 61 healthy volunteers received MPH (20 mg) or PLC, and performed 90min later an N-back WM task in the scanner (1- and 3-back), under both conditions of threat of shock or safety. Functional images were preprocessed and analyzed in AFNI. WM performance and BOLD activity were assessed using Drug (MPH,

PLC) x Threat (Safe, threat) x Load (1-back, 3-back) repeated measure ANOVAs. Behaviorally, in the MPH group, threat increased accuracy during 3-back and decreased accuracy in 1-back. In the PLC group, threat did not influence behavioral performance. Neurally, whole brain analyses revealed main effects of threat (insula, cingulate, inf parietal) and load (inf frontal, sup parietal, cingulate, med temporal). A threat x load ANOVA in the MPH group revealed an interaction in the superior parietal lobule (SPL), an area vital for WM. Post-hoc analyses in SPSS revealed a drug x threat x load interaction, where in MPH, threat increased SPL BOLD during the 3-back and decreased BOLD during the 1-back. This interaction was not seen in the PLC group.
Results suggest that MPH increased resources towards cognitive circuitry, resulting in improved accuracy, during threat in high load. The opposite effect of MPH on WM-related processing during 1-back suggests that the increased resource spills over to process task-irrelevant threat information, which interferes with the task at hand, resulting in decreased accuracy. However, MPH did not appear to modulate threat-related processing. Future work is necessary to further examine these anxiety and cognition interactions.

Title: The effect of threat of shock on working memory maintenance vs. manipulation during the Sternberg paradigm

Authors: *N. L. BALDERSTON, A. HSIUNG, V. ONYEACHU, M. ERNST, C. GRILLON
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Previous studies show that increasing working memory (WM) load reduces anxiety. One possible explanation for this effect is that anxiety and WM engage similar processing resources, and must compete for these resources when task demands are high. A key region implicated may be the right dorsolateral prefrontal cortex (dlPFC), which has been shown to play a role in both anxiety and WM. One way to test this hypothesis is to manipulate WM load using multiple methods (i.e. maintenance and manipulation), and examine whether these processes differentially engage the dlPFC when subjects are anxious. According to the shared resources hypothesis, anxiety should increase dlPFC activity similarly for maintenance and manipulation

processes.
Subjects performed a Sternberg WM task in an fMRI study. They were presented with a series of letters followed by a brief maintenance period. The task included 3 types of trials based on the number of letters presented and the instructions: maintain 5, maintain 8, and sort 5. On the maintain trials, subjects were instructed to maintain the letters in the order they were presented, while on the sort trials subjects were instructed to rearrange the letters in alphabetical order. These trials took place during blocks of safety and unpredictable shock threat.
BOLD responses were extracted to the trial types using a functional region of interest centered on the right dlPFC. We quantified maintenance activity by subtracting the BOLD responses to the maintain 5 trials from BOLD responses to the maintain 8 trials. We quantified manipulation activity by subtracting BOLD responses to the maintain 5 trials from BOLD responses to the sort 5 trials.
In healthy controls, maintenance-related dlPFC activity was increased by threat, whereas manipulation-related activity was elevated for both safe and threat blocks. Given that increasing WM load through maintenance but not manipulation leads to threat-related dlPFC increases, these results suggest that the shared resources hypothesis alone is not sufficient to explain the effect of WM load on anxiety. Instead, they support the hypothesis that increasing WM maintenance processes engages an active attention control mechanism when subjects are anxious, and that this attention control mechanism is also engaged by WM manipulation. Preliminary results in individuals diagnosed with generalized anxiety disorder suggest reduced dlPFC responses in general, with a similar pattern across the conditions, compared to controls.

Title: The impact of age of language exposure on spatial working memory using fNIRS neuroimaging

Authors: *G. KARTHEISER[1], L.-A. PETITTO[2]
[1]Brain and Language Lab. For Neuroimaging, Washington, DC; [2]Gallaudet Univ., Washington, DC

Abstract: Early-exposed (native) signers of signed languages have been shown to outperform hearing individuals with no signed language on behavioral tests of spatial working memory (e.g. Emmorey et al. 1993), presumably because of the spatial nature of signed languages. This permits a powerful test of hypotheses about the development of the neural circuitry underlying human spatial cognition and its relation to language. Spatial cognition is argued to be a capacity that is *not* vulnerable to sensitive periods in development, yet human language learning is widely understood to be highly impacted by the age of first language and second language exposure; early exposure to two languages produces positive, robust impact on neurocognitive development, even possibly prolonging the sensitive period of human language learning (Jasinska & Petitto, 2013). Using fNIRS to study adult first-time learners of a signed language (both spatial and a language), and varying proficiency in achievement (low and high), we ask whether the age of sign language exposure impacts the neural recruitment underlying spatial working memory and language? Age-effects were predicted to shed new light on sensitive periods for human spatial cognition.
Methods. Hearing signing adults, 3 Groups: Native Signers (N=5); Late adult learners of sign/Low Proficiency (N=5), and Late adult learners of sign/High Proficiency (N=5). Block design, 3 spatial n-back conditions: 0-back, 1-back, 2-back. Time-locked recorded fNIRS neuroimaging.
Results. fNIRS: n-back behavioral accuracy/speed scores were impacted by task difficulty, confirming task validity. As difficulty increased, Native Signers showed significant neural activation in L agranular frontal area ($p<.006$) and inferior frontal gyrus ($p<.006$). High Proficiency late adult sign learners showed significant activation in R agranular frontal area ($p<.006$); Low Proficiency showed significant activation in R frontopolar prefrontal cortex ($p<.023$).
Preliminary findings suggest that spatial working memory is sensitive to *age* of exposure. Human signed languages permit a new way to examine the malleability of other higher cognitive functions—here, spatial cognition—and permit insights into the brain's structural and functional plasticity. The findings also advance scientific debate about the nature of the flexibility and reversibility of sensitive periods in adult learning. This work has potential for high translational significance as it suggests early sign language exposure may be used as a novel tool in building spatial cognition for all individuals, as it has been shown that spatial abilities greatly predict STEM success.

Title: Memory in autism: a preliminary fmri study

Authors: *S. HUEMER
Psychology, Loyola Marymount Univ., Los Angeles, CA

Abstract: Background: The Remember/Know (R/K) procedure (Tulving, 1985, 2002) is used in recognition tasks to study both semantic and episodic memory systems. Zelazo and Frye (2001) have shown that children with ASD have problems with episodic remembering. Episodic recognition involving the recollection of contextual information (R) is mediated by hippocampal processes while familiarity based recognition (K), which is intact in ASD, is mediated by perirhinal processes (Brown & Aggleton, 2001). Morphological abnormalities of the hippocampus are well documented in ASD (Groen et al., 2010; see Nicolson et al., 2006). Objectives: Our study was interested in finding out how adolescents with ASD process their own first name as opposed to other names and compared to neurotypical peers. We predicted that control subjects would activate areas of self-reference and episodic memory, such as the left tempo-parietal cortex, the superior temporal gyrus, and the hippocampus when hearing their own name. Subjects with ASD, on the other hand, were expected to employ compensatory processes including the perirhinal regions when hearing their own name. Methods: In this preliminary functional magnetic resonance imaging (fMRI) investigation, we compared brain activity of 9 adolescents with ASD with those of 9 neurotypical controls to four categories of auditory language stimuli: their own first name, familiar people's names, names of objects of high interest, and numbers. Each participant listened passively to the randomly sequenced names five times during three sessions. We administered a test of verbal receptive ability to test whether our results may align with scores on the test. Results: When hearing their own names, controls and subjects with ASD who scored high on the verbal ability test activated regions in the insula, superior temporal gyrus as well as the hippocampus, brain regions associated with self-referential processing and long term memory, or, R (remembering). In contrast, subject with ASD who scored low on our test of receptive verbal ability lower-scoring subjects showed activity in the prefrontal cortex and the thalamus, regions associated with new learning and K (knowing). Conclusion: Our findings suggest that ASD subjects with lower verbal ability recognize, or, "know" their own name like a newly acquired fact rather than "remember" their name in a self-referential and spatio-temporal context. The results of controls and ASD subjects with higher verbal ability were more like each other than the results of the higher and the lower scoring ASD groups, which indicates that memory function in ASD aligns with verbal ability.

Title: Intervention of memory consolidation by post-trial learning: An fMRI study on figure-word associative memory

Authors: *T. CHOU[1], F.-W. WU[1], K.-C. LIANG[2]
[2]Psychology, [1]Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Memory consolidation is an off-line process in which a memory trace is growing and gradually resisting to interference. It involves changes of neural substrates requiring hippocampal-cortical interaction. Interruption of this process, such as introducing a post-encoding task, reduces memory strength and hence the retrieval performance in a test. To address the issue, this study probed the effect of a post-encoding task on memory consolidation of pair association. By using task-related fMRI, we observed the brain activity during periods of retrieval and consolidation in particular. The experiment contained a learning phase and a retrieval phase that were separated by 24 hrs. Thirty-eight participants were instructed to learn two sets of lists containing 48 pairs of fractal figures with words: a target list and an intervention one. After learning the target list, participants learned the intervention list within an hour. The memory performance was examined both immediately (day 1) and 24 hrs (day 2) after learning by recognition. The results showed that recognition of the figure-word association was accompanied with greater activation in the hippocampus, anterior cingulate cortex, and posterior cingulate cortex for day 1 as compared to day 2. In contrast, recognition of the figure-word association was accompanied with greater activation in the left inferior frontal gyrus and right occipital cortex for day 2 as compared to day 1. Greater inferior frontal activation is thought to reflect increased demands on retrieving verbal information of figure-word associative memory. Moreover, greater occipital activation is associated with analyzing visual information of figure-word associative memory. These findings suggest that a post-encoding task may affect memory formation and hippocampal-cortical connectivity, implying that consolidating figure-word associative memory in humans may require reverberating activity among the hippocampus, inferior frontal gyrus, and right occipital cortex.

Title: Spatiotemporal neural activity dissociates encoding and retrieval states

Authors: *N. M. LONG, M. L. DRASCHER, B. A. KUHL
Univ. of Oregon, Eugene, OR

Abstract: When you reencounter someone whom you've previously met, you may find yourself trying to retrieve past details about them only to realize that you have been ignoring what they are presently saying to you. This dichotomy between encoding and retrieval states has been demonstrated in rodents (Hasselmo et al., 2002) and recently in humans using fMRI (Richter et al., 2016). Here we conducted a human scalp electrophysiological study using multi-variate pattern analysis to test for dissociable representations of encoding and retrieval states. We employed a task in which participants viewed two lists of object pictures, with pairs of similar objects distributed across lists. For example, list 1 might contain a picture of an apple and list 2 would contain a picture of a different apple. Critically, during the second list participants were cued, on each trial, to either ‘retrieve’ (think back to) the item from list 1 (A) or to ‘encode’ the newly presented item (A'). Notably, even when the instruction was to retrieve, participants still had to process the second list item (A') in order to know which first-list item (A) they were to retrieve. Thus, in both conditions, participants were required to process current sensory information. Following several blocks of these paired lists, participants completed a forced-choice recognition post-test. On each trial of the post-test, participants were shown two similar objects (e.g., two apples) and were instructed to select the object they had previously seen. Memory for all list 1 (A) and list 2 (A’) objects was tested, but list 1 and list 2 items were tested on separate trials. For example, the apple from list 1 would be paired with a novel apple and the apple from list 2 would be paired with an additional novel apple. Behaviorally, instructions during list 2 influenced memory on the post-test. ‘Retrieve’ and ‘encode’ instructions were associated with relatively better memory for list 1 and list 2 items, respectively. This behavioral evidence indicates that subjects were able to modulate internal memory states. Pattern classification analyses revealed that encoding and retrieval states were also associated with dissociable patterns of spectral EEG activity. In part, these states were associated with shifts in high frequency activity. Collectively, these findings indicate that memory is influenced by shifts in processing states and that processing states are associated with distinct electrophysiological signals.

Title: Disentangling interactions between context switches and repetition effects

Authors: *L. J. LOHNAS, L. DAVACHI
New York Univ., New York, NY

Abstract: Improved memory for spaced over massed repetitions is a well-established finding (Cepeda, Pashler, Wixted and Rohr, 2006), and more recently it has been shown that a retrieved context model can account for these effects (Lohnas Siegel & Kahana, 2014). Further, encoding contexts have been shown to modulate repetition effects: whereas recall probability is greater for massed items repeated in different contexts, recall probability is greater for spaced items repeated in the same context (e.g., Verkoeijen, Rikers & Schmidt, 2005; Maskarinec & Thompson, 1976). Here we consider the role of context switches, as such switches modulate memory and attentional processes (Ezzyat & Davachi, 2014; DuBrow & Davachi, 2013) yet have not been considered in the aforementioned result. Twenty participants were presented with twelve lists of words while undergoing functional magnetic resonance imaging (fMRI). Participants performed free recall and source recognition for each list. During encoding, each word had an associated task context, and could be presented once, twice massed (lag=0) or twice spaced (lag=5). At each lag, words could be repeated with the same or different encoding contexts. For a massed item presented with different contexts, the second presentation always immediately follows a context switch, but the improved memory for these items has not yet been considered with respect to repetition effects. We thus introduced a matched control to the massed items, such that half of the spaced items repeated in different contexts had the second presentation immediately following a context switch, and half had the second presentation two items after the context switch. Using univariate and multivariate approaches, our results reflect how switches in encoding contexts modulate fMRI activity as well as successful encoding of repeated items.

Title: Conceptual knowledge modulates visual representations through a frontoparietal network

Authors: *K. BRAUNLICH[1], B. C. LOVE[1,2]
[1]Univ. Col. London, London, United Kingdom; [2]The Alan Turing Inst., London, United Kingdom

Abstract: Concepts can emphasize certain aspects or features of stimuli through selective attention. For example, the size of garments is critical when choosing what to purchase whereas weight may be more critical when choosing how to ship them. In an fMRI study, participants learned about two contrasting concepts, consisting of visual stimuli varying along four binary dimensions (position, size, shape, and color), through trial-and-error learning. A cognitive model of categorization was fit to individuals' categorization decisions. These model fits provided an attention weight for each of the four stimulus dimensions for each participant. Focusing on occipitotemporal cortex, we found that the more a stimulus dimension was attended, the better we could decode what value (e.g., red or blue) the dimension displayed on each trial. These results indicate a top-down influence of conceptual knowledge on visual representations of objects with this influence well characterized by a successful cognitive model of human categorization. To better understand the neural bases of these top-down concept-driven attentional effects, we investigated how these multivariate occipitotemporal representations interacted with activity elsewhere in the brain. To do so, we projected the occipitotemporal neuroimaging data onto a lower-dimensional subspace, which was spanned by a set of basis vectors that provided an estimate of both the sign (i.e., the evidence towards one particular dimensional attribute over the other, e.g., red vs. blue) and the strength of the multivariate occipitotemporal representation for each distinct perceptual dimension. We then employed a full-brain connectivity analysis to identify regions that might interact with these estimates of occipitotemporal representation. Activity in the right frontal eye fields, right inferior frontal sulcus (IFS), and bilateral intraparietal sulcus was consistent with a role in reading out information about the individual dimensional attributes. IFS, which is thought to be a part of a domain-general network associated with executive control, also carried general information (not tied to a specific feature value) about which stimulus dimensions were critical to the categorization decision, as well as signaled the overall entropy of the category decision. These results suggest that IFS plays an important role in modulating attention to specific perceptual dimensions by integrating knowledge of category structure, perceptual uncertainty, and overall decisional confidence.

Title: Estimating the functional dimensionality of neural representations

Authors: *C. AHLHEIM[1], B. C. LOVE[2,3]
[1]Exptl. Psychology, [2]Univ. Col. London, London, United Kingdom; [3]The Alan Turing Inst., London, United Kingdom

Abstract: Recent advances in multivariate fMRI analysis make it possible to distinguish fine-scaled differences in evoked brain patterns. Key to interpreting these patterns is estimating the underlying dimensionality of neural representations. Dimensions may correspond to psychological dimensions, such as length and orientation, or involve other coding schemes. Unfortunately, when adopting a naïve analysis approach, the noise structure of fMRI data inflates dimensionality estimates to the extent that data with no underlying dimensionality can display maximal dimensionality. To address these and related issues, we developed a novel approach that identifies brain regions that carry reliable task-modulated signal and estimates the signal's functional dimensionality.
Data takes the form of a voxel x condition (e.g., stimulus, task, etc.) matrix of beta estimates, resulting from a general linear model estimation of the BOLD response. Our approach uses a low-rank approximation technique, singular value decomposition (SVD), coupled with nested cross-validation to find the best low-dimensional projection of a pattern of voxel-responses on a single-subject level. Quality of the low-dimensional projections is measured as Pearson correlation between the projected and a held-out test set. To establish the validity of the technique, we conducted model recovery studies with simulated (i.e., synthetic) fMRI data. These checks indicated that our approach robustly estimates the underlying functional dimensionality across varying noise levels. With the soundness of the method established, we applied it to three published fMRI data sets involving conceptual and visual object recognition tasks. For the first concept learning dataset, functional dimensionality was found in occipital and fronto-parietal areas that heavily overlapped with the bespoke model-based fMRI analysis results reported in the original study, which bolstered the authors' original interpretation of their results. In a second concept learning fMRI dataset, we found that concepts that involved integrating

more stimulus features engendered higher-dimensional representations in a lateral occipito-temporal region of interest, which again elaborated the authors' original aims. Finally, we discuss results from a third study dissociating object shape and category. Together, these results indicate the theoretical value of identifying and characterizing the dimensionality of neural representations. We argue that doing is a necessary precursor to evaluating specific theories of neural function as the presence (or absence) of dimensionality constrains the interpretation of data.

Title: Measures of neural similarity

Authors: *S. BOBADILLA SUAREZ, B. C. LOVE
Exptl. Psychology (UCL), Univ. Col. London, London, United Kingdom

Abstract: One central goal in cognitive neuroscience is to understand how the brain represents information. In short, what makes two brain states similar? For example, when viewing a sparrow, representations in the visual system should be more similar to those of a robin than to those of a truck. When using fMRI to measure brain states, it is commonly assumed that Pearson correlation across voxels is an appropriate measure of neural similarity (i.e., when the voxel representations elicited by two stimuli correlate, then the brain states are similar), but this major theoretical assumption has not been fully evaluated. For example, Pearson correlation assumes that overall levels of (task-related) voxel activity are normalized and that each voxel independently contributes to similarity. Whereas, for instance, Minkowski measures assume similarity involves distances in a metrical space instead of vector directions or angles between vectors. Relatedly, the Mahalanobis measure expands on both measures by assuming the distributional pattern of voxel activity is consequential. Which similarity measure best describes the brain's operation? In this project, we endeavour to answer this question by evaluating a range of possibilities, including Pearson correlation. We address open questions such as whether the nature of neural similarity is common across tasks and brain regions. To that end, we follow the

tradition of grounding similarity in confusability; when two things are similar they are easily confused. Confusability of different brain states can be measured with classification procedures such as linear support vector machines (SVM). For example, a sparrow may be more likely to be misclassified as a robin than a truck. We then consider which similarity measure (from a large set) best characterizes this confusability data for each brain region and task considered. Across two previously published fMRI datasets, we find that similarity measures perform comparably across brain regions within a task, but that the best similarity measure is strongly task-dependent. In particular, a visual categorization task that involves stimuli that readily decomposes into parts is most consistent with Minkowski measures whereas a stimulus set involving natural images is most consistent with the Mahalanobis measure of similarity. We discuss possible causes for these task-specific neural representations and implications for multivariate analyses of neural data.

Title: Detecting content-specific patterns using targeted memory reactivation

Authors: B. WANG[1], J. W. ANTONY[1], S. LURIE[1], K. A. PALLER[2], *K. NORMAN[1]
[1]Princeton Univ., Princeton, NJ; [2]Dept. of Psychology, Northwestern Univ., Evanston, IL

Abstract: The replay of learning-related hippocampal and neocortical activity patterns is thought to drive memory stabilization. In this study, we attempted to decode replay in the electroencephalogram (EEG) in order to predict the consolidation of specific, recently-learned information. Human participants first encoded objects in one of four locations on the left or right part of the screen. Each object was accompanied by an inherently related sound (e.g. “moo” for cow) that we used to target memories during sleep. During encoding, we instructed participants to imagine moving their corresponding hand (i.e., left hand for objects on the left side, right hand for objects on the right side) towards the object for five seconds, after which they were instructed to execute the movement, touching the object picture on a touch-sensitive screen. As expected, participants showed significant lateralized activity for left- and right-hand trials during the imagination period. We then tested participants on the location of each object before they took an afternoon nap. During online indications of slow-wave sleep (SWS), we presented half of the sound cues associated with left- and right-hand movements. Finally, after a 2.5 hr break, participants returned for a final memory test. Behaviorally, participants remembered the correct

hemifield (left vs. right) significantly better for cued than uncued items. Neurally, we found lateralized EEG activity elicited by cues during sleep that discriminated between sounds linked (during wake) with left- vs. right-hand movements, thereby signaling the reactivation of learning-related memory content. Further analyses will determine the extent to which these asymmetries predict subsequent memory.

Title: Effects of contextual reinstatement on retrieval of item-emotion associations

Authors: *R. SAMIDE, K. KURKELA, M. RITCHEY
Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: Reinstating the encoding context during retrieval has been shown to enhance item recognition and recall, whereas switching contexts between encoding and retrieval may hinder memory performance. However, it is unknown whether contextual reinstatement confers memory benefits to non-contextual associations learned in that context, such as the emotional significance of an item. To fill this gap in the literature, we tested the effects of contextual reinstatement on memory for items and item-emotion associations. Participants viewed short blocks of neutral object images overlaid on one of four visual contexts, and for each block they were cued to learn that the objects were either ‘bombs’ or ‘safe.’ The bomb/safe designation was balanced across contexts, such that valence and context were orthogonal to one another. To imbue the ‘bomb’ stimuli with emotional salience, they were accompanied by an unpredictable startle probe (250ms burst of white noise) on 25% of trials. Immediately after encoding, participants completed a retrieval phase that assessed item recognition and emotional association memory. Memory sensitivity for the item-emotion association was assessed using a modified d’ measure (‘emotion discriminability index’). Importantly, during retrieval, items were shown overlaid on either the same context as encoding or a different context, which served as our manipulation of contextual reinstatement. Unexpectedly, emotion discriminability was significantly greater when the retrieval context was different from the context presented at encoding, indicating that under some conditions, contextual reinstatement can actually disrupt memory for non-contextual associations. Future research using fMRI will examine brain activity

related to the retrieval of emotional information in the presence or absence of contextual information.

Title: Testing leads to consolidated-like memories

Authors: *J. ARNAEZ-TELLERIA[1], M. CARREIRAS[1,2], P. M. PAZ-ALONSO[1]
[1]Basque Ctr. On Cognition Brain and Language, Donostia-San Sebastian, Spain;
[2]IKERBASQUE, Basque Fndn. for Sci., Bilbao, Spain

Abstract: Testing during encoding facilitates memory consolidation relative to classical repeated-study. This facilitation is known as the testing effect, which constitutes a robust phenomenon widely replicated. The retention interval (RI) between encoding and the final retrieval test seems to play a key role in this effect, with RIs longer than a day showing stronger results compared to RIs of a few hours. This finding points out the potential critical role of consolidation processes in the testing effect. As critical as it is sleep for memory consolidation, the testing effect has not been studied manipulating sleep periods. The present MRI study was aimed at investigating the functional and structural correlates underlying the effects of sleep in the retrieval of episodic memories encoded via repeated retrieval (RR) or repeated study (RS). To this end, 80 young adults divided in 4 groups participated. Participants encoded 180 Swahili-Spanish word pairs (e.g., *rafiki-amigo*) either under repeated retrieval or repeated study conditions. Participants came back three times and performed cued-recall tasks on 60 studied and 20 new non-studied items at 12 hours, 24 hours and 7 days after the initial encoding. Critically, participants were divided in 4 groups based on the initial encoding procedure (RT, RS) and

having or not an immediate sleep period after the initial encoding (Sleep, Wake): Repeated Retrieval Sleep (RRS), Repeated Retrieval Wake (RRW), Repeated Study Sleep (RSS) and Repeated Study Wake (RSW).
Behavioral results showed the beneficial effect of RR relative to RS across the three RIs, with one exception: the RSS group exhibited a similar performance to the RRS and RRW in the shortest RI (12 hours). However, this beneficial effect of sleep for the RSS group vanished in the longer RIs (24 hours and 7 days). For the RS groups, neuroimaging data revealed stronger hippocampal engagement for sleep (RSS) versus wake (RSW) groups during successful memory retrieval in the shortest RI (12 hours). Interestingly this difference also vanished in the longer RIs, with both RSS and RSW showing similar hippocampal engagement during successful memory retrieval after 24 hours and 7 days RIs. Functional connectivity analyses revealed tighter coupling among distributed hippocampal-PFC regions for successful retrieval of items studied under RR versus RS conditions in all three RIs and independently of the sleep/wake condition. Altogether, behavioral and neuroimaging data suggest that information studied via RR formed consolidated-like memories, while memories created via RS were more susceptible to benefit from regular consolidation processes.

Title: Dynamic changes in directed connectivity during paired associates memory task

Authors: R. YAFFE[1], J. I. CHAPETON[2], S. K. INATI[1], *K. A. ZAGHLOUL[3]
[1]Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD; [2]NINDS, NIH, Bethesda, MD; [3]Surgical Neurol. Br., Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: We investigated functional connections in human intracranial EEG data during paired associates memory encoding and cued recall. Our approach capitalizes on an important feature of functional connections that mediate communication in the human brain. Whether through direct or indirect synaptic connections, changes in local field potential signals coordinated across regions, or even the propagation of electric fields, communication between brain regions must occur through a physical connection of some kind. Importantly, the constraints associated with any physical connection imply that the time required for communication should be well defined and preserved. Every time information is conveyed from one point to another, it should take

approximately the same amount of time to do so. Hence, one plausible requirement for identifying a functional connection between brain regions is that the communication between them occurs with a consistent time delay. At any given moment in time, however, the amount of information being transferred may vary.
Here, we investigate functional connections in iEEG recordings as patients with medically refractory epilepsy participate in a paired-associates verbal memory task. Using the temporal precision afforded by iEEG, we used time-lagged mutual information (MI) to identify functional connections in the human brain that exhibit a consistent and significant increase in MI with a specific time delay. Mutual information (MI) is attractive in that it captures all temporal relations between two brain regions, and is agnostic to the particular neural mechanism underlying how those regions are communicating. We identify connections that have a consistent latency and change their level of communication dynamically in response to the presentation of memory stimuli. Our results suggest that we can identify connections in the brain that increase or decrease their flow of information during memory encoding and retrieval.

Title: Neural signature of successful memory updating

Authors: *L. M. KLUEN[1], G. JOCHAM[2], L. SCHWABE[1]
[1]Cognitive Psychology, Univ. of Hamburg, Hamburg, Germany; [2]Ctr. For Behavioral Brain Sciences, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany

Abstract: In everyday life, we often experience situations in which existing memories turn out to be incorrect, requiring their modification in the light of new information. Although several lines of recent research indicate that memories are highly dynamic entities, how exactly established memories can be updated is largely unknown. In order to unravel the neural processes involved in successful updating of existing memories, we tested 48 participants in a novel memory updating paradigm on three consecutive days. On day 1, participants memorized face-city associations followed by a cued recall test for these associations. On day 2, participants saw the face stimuli again, while fMRI was recorded. Part of the faces were paired with the same city names they had been associated with the day before, while others were now presented with novel city names, requiring participants to update their memories. On day 3, participants

completed a recognition test, to assess whether the updating of their initial memories was successful. Results indicated that participants learned the initial face-city associations very well. Memory performance in the recognition test was generally high but memory updating was successful for only about 35 percent of the stimulus pairs that were altered on day 2. Our neuroimaging data revealed that successful memory updating, a key feature of adaptive memory, was linked to the recruitment of the dorsolateral prefrontal cortex during the presentation of information conflicting with established memories.

Title: Dopamine gene polymorphism, prefrontal cortex activation and neural pattern similarity during episodic memory encoding

Authors: *L. ZHENG, G. XUE
State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China

Abstract: Neural pattern similarity across multiple learning events, which is posited to reflect the fidelity of cortical representation of the studied materials, is an effective indicator of subsequent memory performance. Although the role of dopamine in enhancing the fidelity of cortical representation has been implicated in computational and animal studies, evidence from human subjects is still rare. Using fMRI and a face-name association task, we investigated the relationship between neural pattern similarity and subsequent memory performance in more than 400 subjects. We further examined the neural and genetic factors that contributed to the individual differences in neural pattern similarity. We found that neural pattern similarity in the ventral visual cortex could predict the subsequent associative memory performance across items and individual subjects, even after controlling the activation level in these regions. Meanwhile, the prefrontal cortex activation level was also associated with better memory performance across items and individual subjects. Importantly, we found the prefrontal cortex activation was associated with greater neural pattern similarity in the VVC, which were in turn associated with better memory performance. Furthermore, the prefrontal cortex activation level was associated with individuals' dopamine beta hydroxylase (DBH) gene polymorphisms. Our results suggest a critical role of dopamine neurotransmitters and prefrontal cortex in enhancing neural pattern similarity and episodic memory encoding.

Title: Context-dependent memory effects revealed by reinstated neural oscillations

Authors: ***M. J. WÄLTI**, D. G. WOOLLEY, N. WENDEROTH
Neural Control of Movement Lab., ETH Zurich, Zuerich, Switzerland

Abstract: Many theories of memory rely on a mechanism called context-dependent memory, which refers to the finding that learnt information can be recalled better when the context of the test setting matches the encoding setting. A widespread method for investigating context-dependent memory effects has been the manipulation of simple context features, for example on a computer screen.
Here we performed a series of behavioral experiments to investigate whether context-dependent memory effects differ when encoding occurs in increasingly enriched visual environments. Based on an a-priori power analysis, each experiment included 40 participants who encoded 24 words embedded in different visual contexts. Subsequently, the words were freely recalled while the encoding context was either reinstated or not.
Experiment 1 was a replication experiment of Isarida and Isarida (2007), where we investigated the effect of reinstated background colors on free recall memory performance. We found no significant difference between reinstated versus not reinstated recall ($t(39) = -1.309$, $p = 0.198$).
Experiment 2 investigated the effect of using two distinct landscape images as backgrounds on a computer screen. However, the context again had no significant influence on recall ($t(39) = -1.723$, $p = 0.093$).
Experiment 3 provided two full-surrounding virtual reality environments during encoding. Again, no significant context effect on recall ($t(39) = 0.934$, $p = 0.356$) was observed, even in this highly immersive visual environment.
Finally, in **Experiment 4** we examined whether visual stimuli flickering at different frequencies that can potentially reinstate neural activity via sensory entrainment during encoding and retrieval would influence memory performance. Subjects observed flickering stimuli in the background on a computer screen to induce steady-state visually evoked potentials at 6 or 15 Hz in visual areas of the brain. We found that reinstatement of specific steady-state visually evoked potentials significantly improved recall performance compared to not reinstated conditions ($t(39) = 2.097$, $p = 0.043$).
The presented results indicate that effects of visual contexts on recall memory performance are

rather small, potentially because they are overshadowed by individual mnemonic strategies. We suggest that in Experiment 4, the flickering background and induced oscillations in visual areas are highly salient, i.e. more difficult to be ignored by the participant, and are therefore more likely to have an influence on the memorization/recall process.

Title: Cortical oscillations during a fact-based memory integration task relate to academic success

Authors: *N. L. VARGA, J. R. MANNS
Psychology, Emory Univ., Atlanta, GA

Abstract: The acquisition and flexible extension of knowledge depends on the capacity to integrate across overlapping experiences. Memory integration refers to the process by which separate yet related memories are combined to support the derivation of new information. Recent functional magnetic resonance imaging (fMRI) studies have indicated that interactions between several cortical areas support memory integration in adults. Yet an open question concerns how the millisecond-level dynamical interactions between cortical regions involved in memory integration unfold in real-time. Thus, the goal of the present study was to investigate the rapidly-unfolding processes of memory integration by measuring oscillatory power and synchrony in scalp-based electrophysiological (EEG) recordings. Adults read novel, related facts (e.g., *Apple seeds are call pips; Cyanide is found in pips*) and were tested for self-derivation of novel integration facts (*Apple seeds contain cyanide*) while EEG was recorded. Alpha oscillations were prominent in the EEG and were observed to show marked second-by-second changes during encoding of the original, directly learned facts. Moreover, analyses of alpha coherence between clusters of EEG channels revealed that cortical alpha synchrony was greatest in a left-parietal cluster during encoding of the second, related fact (i.e., the first opportunity for memory integration) as compared to the first fact. This integration-related alpha synchrony was most pronounced in participants who subsequently showed enhanced memory integration performance. Integration-related alpha synchrony also showed marked differences between high and low performing participants when split by measures of scholastic achievement (i.e., college grade point average and SAT scores). Together, the findings inform our understanding of the

dynamical interactions between cortical regions supporting this fundamental learning ability, and have implications for how these processes relate to real-world academic success.

Title: Illusory shape processing during encoding of scrambled items induces subsequent false memory for intact shapes

Authors: *J. M. KARANIAN[1,3], S. D. SLOTNICK[2]
[1]Psychology, [2]Boston Col., Chestnut Hill, MA; [3]Psychology, Wesleyan Univ., Middletown, CT

Abstract: In a recent study, we assessed whether the lateral occipital complex (LOC) – a conscious shape processing region – was associated with false memory for intact shapes (Karanian & Slotnick, under review). In that study, participants viewed intact or scrambled colored abstract shapes during encoding. During retrieval, colored disks were presented and participants indicated whether the corresponding item was previously "intact" or "scrambled". Like true memory for intact shapes, we found that false memory for intact shapes ("intact"/scrambled > "scrambled"/scrambled) activated LOC at retrieval. Such LOC activity likely reflects conscious shape processing during false memory construction. In the present analysis, we employed the identical fMRI dataset to assess whether scrambled items that were subsequently remembered as intact shapes ("intact"/scrambled) were associated with illusory shape processing at encoding. The conjunction of intact shape processing during encoding (intact shapes > scrambled items) and subsequent false memory for intact shapes (subsequent "intact"/scrambled > subsequent "scrambled"/scrambled) produced activity in LOC. By comparison, the conjunction of shape processing during encoding (intact shapes > scrambled items) and subsequent true memory for scrambled items (subsequent "scrambled"/scrambled > subsequent "intact"/scrambled) did not produce activity in LOC. These findings suggest that false memory for intact shapes was induced by illusory shape processing during encoding. Furthermore, we ran a conjunction of subsequent false memory for intact shapes (at encoding) and false memory for intact shapes (at retrieval) to assess whether retrieval-related false memory activity reflected sensory reinstatement of encoding-related activity. This conjunction revealed overlapping activity in LOC. However, this activity only comprised a subset of LOC activity that was observed at retrieval, which indicates that not all retrieval-related activity reflects sensory reinstatement. The present evidence suggests that retrieval-related activity in LOC during false

memory for intact shapes reflects both sensory reinstatement of illusory shape activity associated with encoding and additional conscious shape processing activity associated with retrieval.

Title: Target-lure similarity predicts eye movements during encoding and retrieval in a mnemonic discrimination task

Authors: *D. K. BJORNN[1], C. STRAW[2], E. S. BRIGHTON[2], C. B. KIRWAN[3]
[1]Psychology, [2]Neurosci. Ctr., [3]Psychology and Neurosci. Ctr., Brigham Young Univ., Provo, UT

Abstract: Mnemonic discrimination allows an individual to differentiate very similar memory representations. At encoding, mnemonic discrimination is thought to rely on pattern separation whereby similar memory representations are orthogonalized. At retrieval, false alarms (mistakenly labeling a similar lure as a repeat) are proposed to be due to pattern completion whereby a previously encoded memory representation is reactivated given a noisy or degraded cue. An alternate explanation for false alarms to similar lures is poor encoding of the target stimulus. A recent study by Molitor, Ko, Hussey, and Ally (2014, Hippocampus) used eye tracking as a measure of memory encoding to understand whether discrimination errors come about because of poor encoding or pattern completion. The authors suggested that false alarms to similar lure trials come about because of poor encoding rather than the involvement of pattern completion upon retrieval.
We sought to extend the previous work by using a larger sample size and greater number of trials as well as controlling for lure-pair similarity. Images of everyday objects were displayed one at a time to human participants while eye tracking data were collected. Sixty participants indicated whether each image was an exact repeat, a similar lure, or a novel stimulus. Similarity level for lure trials was controlled so that there was an equal number of high and low similarity lure trials in each block.
Normalized fixation counts were entered into a repeated measures ANOVA with factors for presentation (first, second) and response type (hit, lure correct rejection, lure false alarm). Results supported the finding of Molitor et al. (2014) that lure false alarms had fewer fixations on encoding trials than lure correct rejections, but also diverged from their work by showing the same pattern on retrieval trials. A further analysis was done on lure trials with factors for presentation (first, second), response type (lure correct rejection, lure false alarm), and similarity level (high, low). Low-similarity lure trials showed significantly fewer fixations on encoding

trials for lure false alarms as compared to lure correct rejections. High-similarity lure trials, however, showed significantly fewer fixations on retrieval trials for lure false alarms as compared to lure correct rejections.
These results suggest that inattention at encoding accounts for false alarms to low-similarity lures. However, for high-similarity lures, our data suggest the involvement of pattern completion during retrieval. These results indicate that target-lure similarity is a better predictor of the fixations and response outcome of trials than just poor encoding.

Title: Mnemonic discrimination in context-dependent memory specificity utilizing eye tracking confidence measures

Authors: *T. WINN[1], A. HEDGES-MUNCY[1], B. KIRWAN[2]
[2]Psychology, [1]Brigham Young Univ., Orem, UT

Abstract: The relationship of objects and their contexts is at the core of long-term declarative memory and critically involves hippocampal processing. To further explore the effect of surrounding visual context on memory for objects, we evaluated behavioral performance in a contextual memory task that especially taxes pattern separation processes. Adding a contextual component to memory specificity tasks is believed to increase the level of difficulty of the task by interfering with the ability to successfully perform pattern separation processes. Some researchers propose that when the object matches its context, there will be more efficient discrimination between stimuli and thus more accurate responses. However, some hypothesize that repeat and similar objects presented with the same background will be more accurately remembered than objects presented with different backgrounds due to the increase of interference. We tested these hypotheses by conducting a mnemonic similarity task in which we manipulated object-background congruency during the encoding phase. We recruited 80 participants to perform the two-part memory task. In the study phase, participants were shown images of everyday objects with backgrounds that were congruent (e.g., a shopping cart against a grocery store) or incongruent (e.g., a gorilla against a classroom). In the test phase, participants were shown images containing items either exactly the same as or similar to the previously studied items (repeats and lures, respectively) but with no background. All images were

presented for 2500 ms with an inter-trial interval of 500 ms. During the test phase, participants were instructed to indicate whether the item in the image was a repeat or lure. As a measure of subject confidence and attention, eye movements were recorded during both phases of the experiment in order to determine time spent studying the object vs. time spent studying the background in the study phase, and time spent studying the object during the test phase.Repeated measures ANOVA showed a difference in performance related to whether the background was congruent or incongruent as related to recognition and discrimination. There was also a relationship between sex and performance of pattern separation tasks. In order to identify possible brain subregions associated with these differences, we intend to continue investigation utilizing functional magnetic resonance imaging (fMRI) techniques.

Title: Exploring the resting state neural activity of monolinguals, late and early bilinguals

Authors: *A. L. HOWELL[1], C. E. GOLD[2], C. B. KIRWAN[1,3]
[1]Neurosci., [2]Spanish Pedagogy, [3]Psychology, Brigham Young Univ., Provo, UT

Abstract: Learning a foreign language is one of many lifestyle factors correlated with a delay in the onset of Alzheimer's disease, a costly public health concern. However, much of the research surrounding bilingualism and memory disorders focuses on individuals who acquire their second language before puberty (early bilinguals); it is unknown whether post-pubertal language acquisition (late bilingualism) affords similar preventative possibilities. This study aimed to ascertain potential differences in memory performance and resting state neural activity for early and late bilingual subjects as compared to monolingual controls.
We recruited ninety young adult subjects (ages 18-30) to one of three groups—early bilingual, late bilingual, and English control—for a total of thirty subjects per group. Bilingual subjects grew up speaking English and Spanish; late bilinguals were native English or Spanish speakers who began learning either Spanish or English, respectively, after puberty. We assessed English and Spanish proficiency with an elicited imitation language task, the results of which are highly correlated with ACTFL's proficiency scale. Additionally, we obtained structural MRI and resting state fMRI data for each participant. No tasks were completed in the scanner.
In addition to scanning, participants completed a mnemonic-discrimination task, which has been shown to be sensitive to hippocampal integrity and related to volume of hippocampal subfields. During the study phase, participants viewed a series of images depicting everyday objects, and

subjectively determined whether each item belonged indoor or outdoor; this judgment facilitated encoding. In the subsequent test phase, participants viewed a second series of images containing images from the original list (repeats) as well as images highly similar to the original images (lures) and entirely new images (foils). For each image, we instructed the participant to make an old/similar/new judgment by pressing specified buttons on the keyboard while the image remained on the screen. The images appeared for a total of 3 seconds and progressed automatically.
We observed significantly greater grey matter volume for late bilinguals compared to controls and early bilinguals in several brain regions including the right hippocampus, left parahippocampal gyrus, and right middle temporal gyrus. Behaviorally, late bilinguals performed significantly better than controls for recognition memory, but not for mnemonic discrimination.

Title: Mri data pre-processing steps differentially affect volumetric measures

Authors: *A. HEDGES, N. M. MUNCY, B. KIRWAN
Psychology, Brigham Young Univ., Provo, UT

Abstract: In MRI studies, researchers often clean the data via pre-processing algorithms prior to analyzing registration-based volumes. The various steps in pre-processing algorithms may differentially affect the volumetric output as each pre-processing step adjusts voxel intensities, the mathematical space of the scan, and the overall amount of data available in the scan; such manipulation of the scan may affect the volumetric output. To determine if the pre-processing has a statistical effect on the volume measures, we scanned healthy, young adult participants (n=50) on a Siemen 3T Tim-Trio scanner, with a subset of these participants (n=15) being scanned four subsequent times at the same time each day. All scans were pre-processed following a stepwise pipeline, starting with the scan in original space after a conversion to Neuroimaging Informatics Technology Initiative (NIfTI) format, rotating and cropping the scan, aligning the anterior commissure-posterior commissure (AC-PC) axes, correcting for field inhomogeneity, and finally skull-stripping the scan. After each successive step, we assessed the volumes for the left and right putamen, hippocampus, and middle temporal gyrus (MTG). To test for the effects of pre-processing on volumetric output, we performed a multivariate, repeated

measures analysis on structure volumes following each pre-processing step, correcting for total brain volume. The analysis showed a main effect of pre-processing step and an interaction of step by region-of-interest. Each pre-processing step produced significantly different volumes in the left and right putamen. For the hippocampi, all steps produced significantly different volumes except for the AC-PC alignment and the field inhomogeneity correction. Finally, all steps produced different left and right MTG volumes except for the final skull-stripping step. This indicates that different anatomical regions are differentially affected by the pre-processing steps. We then provide a correction for the pre-processing noise that can be applied in future studies to account for variability introduced by different pre-processing steps.

Title: The fate of memory representations in mnemonic generalization: An FMRI study

Authors: *N. MUNCY[1], B. KIRWAN[2]
[1]Neurosci., [2]Psychology, Brigham Young Univ., Provo, UT

Abstract: Mnemonic discrimination is the ability to form and retrieve distinct memory representations for similar stimuli or episodes. Recent investigations of mnemonic discrimination have focused on the ability to discriminate between similar items and often induce research participants to generalize and falsely endorse similar lures as repeated (i.e., false alarms). The fate of the underlying memory traces following mnemonic generalization is unknown. Further, the underlying neural processes involved in perpetuating or recovering from a mnemonic generalization are unknown. We therefore developed a protocol to investigate the fate of generalized memory representations, and hypothesized that activation in regions of the medial temporal lobe and prefrontal cortex would predict whether the participant recovered from or perpetuated the mnemonic generalization.Thirty-five healthy, young adults participated in a study-test1-test2 design. During the study phase, participants were exposed to visual stimuli while performing an orienting task. In the test1 phase, participants were exposed to either the same (target) or a similar (lure) stimulus as during the study phase and indicated whether the stimulus was the same or different. The decision that a lure was the same as the original study stimulus is termed mnemonic generalization (and the recognition that it is similar but different is mnemonic discrimination). In the test2 phase, both the target and its lure counterpart were presented, and the participant chose which of the two was the original study stimulus. Study, test1, and test2 were performed inside an MRI scanner while high-resolution (1.8mm3), whole-

brain functional data were collected. We found that neural regions which were differentially activated during encoding predicted subsequent discrimination performance, and that neural regions were differentially activated during test1 discrimination versus generalizations. Critically, and in accordance with our hypothesis, we found a number of regions including the bilateral superior frontal, fusiform, and right middle temporal gyrus that were differentially activated during test1 generalizations that predicted subsequent test2 performance, i.e. regions that predicted whether or not the mnemonic generalization would be perpetuated. We conclude that generalizations can result from poor encoding or poor recovery, and that not all generalizations are equal; that failures to discriminate can result in either multiple memory representations or a rewriting of the original trace, and that the recovery from mnemonic generalization is dependent on the processing of certain anatomic regions.

Title: Physical activity is associated with differential BOLDresponses In the hippocampus during pattern separation: an fMRI study

Authors: *C. B. HODGES, N. M. MUNCY, C. B. KIRWAN
Psychology, Brigham Young Univ., Provo, UT

Abstract: There is growing interest in the impact of physical activity on neural and psychological outcomes, especially given the link between physical activity and improved cognitive functioning in adolescents, young adults, and middle-aged adults. Pattern separation is a computational process associated with declarative memory, and involves the formation of distinct neural representations of incoming stimuli. Pattern separation is often associated with orthogonalizing similar or partially overlapping patterns to reduce memory interference. This present study aims to utilize a mnemonic discrimination paradigm that taxes pattern separation processes to investigate differences in neuronal activity among young adults with various levels of physical activity. It is hypothesized that people with higher levels of physical activity will show pattern separation responses in hippocampal subregions. Sixty right-handed subjects (30 men and 30 women), ranging from ages 18-40, were recruited for one of three groups: a sedentary group, a low-physical activity group and a high-physical activity group. Subjects were given exercise logs and an accelerometer to wear for one week. After this week, subjects had structural (T1- and T2-weighted) and functional (whole-brain high-resolution multi-band) MRI scans. Regions of interest selected were CA1, CA3/dentate gyrus, and subiculum subregions of

the hippocampus. During these MRI scans, subjects completed a continuous recognition mnemonic discrimination task that involved viewing photographs of similar objects, and responding whether or not the image had been shown previously. As hypothesized, subjects with lower levels of physical activity showed decreased BOLD responses, in comparison to the high physical activity group, in the bilateral hippocampal regions during correct responses to our pattern separation task. Additionally, these subjects showed decreased BOLD responses, compared to the high physical activity group, in the medial prefrontal and medial temporal regions for correct responses. These effects were also consistent between the low physical activity and high physical activity group.

Title: The neural mechanism of testing effect in episodic memory

Authors: *Z. YE, G. XUE
State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China

Abstract: Retrieval practice, or testing has long been known for its role in benefiting long-term memory performance. Although previous studies have shown that retrieval practice could facilitate the acquisition of new memories and/or the inhibition of competing old memories, the neural mechanisms underlying these effects remain poorly understood. In current study, we applied fMRI and multiple voxel pattern analysis to directly examine the testing effect in memory updating. On day one, subjects were over-trained in words (A)- picture (B) association. On day two, they were introduced the new A-C associations (B and C were of different visual categories) before entering the scanner. In the scanner, the new A-C associations were studied three times under one of the two conditions: restudy vs. testing. Subjects were scanned again on Day Three to test A-C memory performance using a cued recall test. We found that behaviorally, testing could improve A-C recall and reduce the intrusion of A-B memory. MVPA classifier evidence also showed stronger reactivation of target (i.e., C) memory in the medial prefrontal cortex (MPFC) and weaker reactivation of competitor (i.e., B) memories' in the ventral temporal regions. During encoding, the reactivation of target memory increased across repetitions in test condition but decreased in the restudy condition. The left dorsal prefrontal cortex showed greater activation in test condition compared to restudy condition during encoding, which was in turn

associated to better memory updating (target - competitor reactivation) in the MPFC. There were also stronger competitor memory reaction and overall reduced hippocampal activation under the test condition than under the restudy condition. Taken together, our results suggest that testing may facilitate memory updating via a memory reconsolidation mechanisms and the prefrontal cortex plays a critical role in this process.

Title: Using virtual reality environments to assess context boundary effects and temporal memory performance via spatiotemporal exploration

Authors: *K. M. HORECKA[1,2], M. R. DULAS[1,2], N. J. COHEN[1,2]
[1]Univ. of Illinois at Urbana-Champaign Col. of Liberal Arts and Sci., Urbana, IL; [2]Beckman Inst., Urbana, IL

Abstract: Virtual Reality (VR) has been identified as a useful tool in neuropsychological evaluation thanks to its increased control and measurement capabilities over other methods (Schultheis et al, 2002). More recently, evidence shows that along many measures, VR provides similar ecological validity to real environments (Kuliga et al, 2014). One area of research which is particularly amenable to VR paradigms is learning and memory. Previous work has suggested that context-boundaries impact the binding of sequential information, resulting in within-context information being remembered as closer together than across-context information, even when equidistant, i.e. the segmentation effect (DuBrow & Davachi, 2013). Previous work by our group has shown that segmentation effects can be found in the spatial reconstruction of item locations within and across contexts, with within-context items being placed closer together and across-context items being placed further apart. The present study explored segmentation effects in temporal memory; a VR spatiotemporal navigation task with four contexts (colored time periods) and 2 objects per context (one that appears and one that disappears) was constructed to evaluate how memory for item pair temporal locations within a context differ from pairs which cross contexts. During study, participants were instructed to explore the VR environment and learn the spatiotemporal locations of all items. Importantly, participants were given the ability to explore not only space, but also time, via a button press that changed the direction of the flow of time. Measurements of participant position, orientation, and subsequent memory for item

spatiotemporal locations were assessed across four repeated trials. Results showed significant increases in performance (speed, efficiency of movement/orientation, and memory accuracy) across successive training/test trials. Across all trials, participants showed a significant event segmentation effect, with across-context pairs being remembered as further apart in time and within-context pairs closer together, despite these pairs being equidistant. These segmentation effects remained stable despite improvements in overall accuracy suggesting they are tied to the organization of memory, and not simply a type of error. Lastly, temporal exploration during the first study phase correlated with the size of the segmentation effect, suggesting early exploration behavior may influence the organization of memory relative to context. These results show that temporal segmentation effects are present even when participants can freely navigate the axis of time.

Title: Separating memory and attention within the parietal memory network: An fMRI investigation comparing explicit and implicit retrieval processes using overt picture naming and recognition

Authors: *A. W. GILMORE[1], S. E. KALINOWSKI[1], S. C. MILLEVILLE[2], S. J. GOTTS[1], A. MARTIN[3]
[1]Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD; [2]NIMH / LBC, Bethesda, MD; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Differentiating between that which is novel and that which is familiar is a critical aspect of human behavior. This is often accomplished automatically, yet at other times we intentionally reflect upon a specific person or object and attempt to ascertain if we have had any prior experience with them. Prior investigations of such “implicit” and “explicit” retrieval conditions have found their respective neural correlates to be generally distinct.
However, it has been hypothesized that a parietal memory network (PMN) displays broad sensitivity to stimulus novelty or familiarity across numerous task states. PMN regions typically deactivate when orienting to novel, but activate when orienting to familiar, stimuli. To further understand the functional significance of this network, we must be able to separate activity that is related to familiarity *per se* from activity that may be driven by attentional demands which differ

across task states.
We therefore designed a task in which subjects would encounter novel and familiar stimuli in both implicit and explicit retrieval conditions, matching the two as closely as possible. While undergoing fMRI, subjects were presented with images of animals and man-made objects and either named the object aloud or verbally made an old/new recognition judgement. Naming was performed in the context of only novel items (as in typical “encoding” conditions), or was done in a mix of old and new items (as in typical “retrieval” conditions). Recognition was always performed on a mix of old and new items. A slow event-related design helped ensure that speaking-related motion did not corrupt peak response estimates, and a multi-echo BOLD sequence was employed to help identify and remove noise components within each scan run. Task-related differences between novel and repeat items were identified broadly across the cortex, reflecting both increases and decreases across repetitions. Notably, regions within the PMN demonstrated robust old > new effects in both the naming and recognition tasks. This is consistent with the hypothesis that activity within PMN regions is sensitive to familiarity in general. However, we also observed that activity was greater during recognition than during naming for familiar items, suggesting a prominent role for attentional or task demands in determining PMN responses. Collectively, these findings suggest that the basic old > new effects which are so consistently observed in the network cannot be fully understood without consideration of the task states in which they appear.

Title: The stimulus specific representation underlies similar memory discrimination

Authors: *Z. GAO[1,2], L. WANG[1]
[1]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: When some features of our experiences overlap, successful discrimination among similar memories involves in remembering the specific details that can dissociatively characterize prior experience. This ability builds up formation of event-unique memory traces termed as pattern separation that mainly rely on the hippocampus, but are proposed to occur throughout the brain. However, we have little knowledge on neural representation in similar-item memory discrimination. In this study, participants viewed images of objects (each with 3 repetition) while performing a likeness judgement task during fMRI scan; then, in a later recognition test, they judged whether test items (3 categories: target: same as studied item, foil: novel, completely different with studied item; lure: similar but not same with studied items) were 'same' or 'new' relative to the items seen before. Using representational pattern analysis, we identified a set of regions in which neural representation fidelity during encoding can predict memory discrimination correct (lure judged as new) or false (lure judged as same). Especially, we only found that representation fidelity in the MTL are higher for correct than false lure memory. Besides, the MTL showed higher Item specificity (within item similarity minus between item similarity) for correct than false lure memory discrimination. Furthermore, encoding-retrieval similarity analysis revealed that successful memory discrimination was accompanied by greater item level reinstatement in MTL, ITG, precuneus, and frontal orbital cortex.

Title: The influence of prediction error on episodic memory reconsolidation

Authors: *A. H. SINCLAIR, M. D. BARENSE
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: A reminder can temporarily destabilize an established memory trace, creating a window of opportunity during which the memory can be modified, until it is stabilized again through the process of *reconsolidation*. Recent research has suggested that a *prediction error* at

the time of reactivation is necessary to destabilize a memory trace. The present study was the first to use video stimuli to investigate the influence of prediction error on the reconsolidation of complex episodic memories. On Day 1, participants (N=23) viewed 18 target videos, each depicting a salient action-outcome event (e.g., a baseball batter hitting the ball out of the park). On Day 2, we reactivated memories by presenting each target video again either in *match* form, identical to the original viewing, or *mismatch* form, cut off abruptly before the completion of the video (e.g., the baseball batter cut off mid-swing). We hypothesized that mismatch-reactivation would generate a prediction error, most effectively destabilizing memories. Participants also viewed 18 new *interference* videos, each semantically-related to one of the target videos (e.g., a baseball fan in the stands catching a foul ball). Critically, participants in the Experimental condition received the reactivation prior to interference, whereas participants in the Control condition received the interference prior to reactivation. On Day 3, participants completed an interview-style recall test on the target videos. The rate of *intrusions*, details from the interference videos mistakenly attributed to the corresponding target videos, was significantly higher in the Experimental condition, $F(1, 21) = 20.11$, $p < .001$, $\eta^2 = 0.5$. Furthermore, there was a significant interaction between condition and reactivation type, $F(1, 21) = 5.23$, $p = .033$, $\eta^2 = .2$. In the Experimental condition, mismatch reactivation produced a higher rate of intrusions than match reactivation. In contrast, reactivation type did not affect intrusions in the Control condition. Self-reported confidence was rated to be “moderately high” for all participants and did not differ between conditions, suggesting that metamemory judgments do not accurately reflect memory distortions.

Our results provide a compelling demonstration that episodic memories undergo reconsolidation. In particular, the intrusions from the interference videos characterize the reconsolidation process as a dynamic updating mechanism which allows new information to be incorporated into a memory. Moreover, we point to a recently proposed mechanism, implicating prediction error in the destabilization and reconsolidation process.

Title: Sleep selectively enhances associative aspects of emotional memories

Authors: *R. COX[1,3], M. VAN BRONKHORST[2], H. GOMILLION[2], A. C. SCHAPIRO[4], R. STICKGOLD[5]
[1]Dept. of Psychiatry, [2]Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Psychiatry, Harvard Med. Sch., Boston, MA; [4]Psychiatry, Beth Israel Deaconess Med. Ctr. / Harvard Med., Boston, MA; [5]Dept Psychiatry, Ctr. For Sleep and Cognition, Boston, MA

Abstract: Introduction Sleep promotes the retention of episodic memories, but prioritizes memory stabilization depending on items' perceived relevance. Typically, emotional material benefits more from a period of sleep than neutral information. At a more fine-grained level, however, it is unclear which aspects of emotional memory are preferentially consolidated. Here, we test whether selective consolidation effects differ for item recognition and associative memory.
Methods Forty-five healthy volunteers encoded 128 neutral and 128 negative stimuli presented visually to either the left or right visual field, with separate groups encoding in the morning (n=16) and evening (n=29). Immediately after encoding, and after a 12 h interval containing either sleep or wake, individuals were shown items that were presented before as well as new items. Crucially, items were now presented centrally, not lateralized. Subjects judged each item in two distinct ways. First, to measure item recognition, subjects provided an old/new rating. Second, to measure associative memory aspects, they indicated the side where they believed the item was originally presented. We analyzed behavioral data by performing several 2 (GROUP: sleep/wake) x 2 (VALENCE: emotional/neutral) x 2 (TIME: immediate/delayed) mixed ANOVAs. In addition, we recorded high-density EEG in the sleep group throughout the encoding, retrieval, and sleep periods, to search for neural correlates of sleep-dependent memory effects.
Results Source memory for correctly recognized old items was selectively enhanced for emotional items over a period of sleep vs. wake. This was expressed as a significant 3-way interaction between all factors (P=0.004). Follow-up tests demonstrated that while associative memory performance decreased across time for emotional (P=0.015) and neutral items (P=0.10) in the wake group, and for neutral items in the sleep group (P=0.001), source memory improved significantly for emotional items across sleep (P=0.035). In contrast, changes in recognition memory over time did not depend on whether subjects slept or not, either for emotional or neutral items. EEG oscillatory correlates underlying behavioral consolidation effects will be presented.
Conclusion These results of selective strengthening of associative links for emotional items during sleep are consistent with theoretical accounts of sleep's role, recoding labile, hippocampus-dependent, relational memories to a more stable neocortical format.

Title: Strength of initial encoding in the selection of memories for sleep-dependent consolidation

Authors: *D. DENIS[1], R. STICKGOLD[2]
[1]Ctr. for Sleep and Cognition, Boston, MA; [2]Dept Psychiatry, Ctr. For Sleep and Cognition, Boston, MA

Abstract: A large body of research has shown that sleep plays an important role in the consolidation of recently acquired memories. However, the brain does not retain all of the information that it encodes each day. Recent research has started to uncover the mechanisms by which the brain selects which information should be preserved and therefore subsequently consolidated during sleep, and which information is to be forgotten. The aim of this study was to investigate the role that initial encoding strength has on subsequent sleep-dependent consolidation. Previous studies have found mixed results, with some evidence showing that weaker memories are prioritized for consolidation during sleep, with others showing that stronger memories are prioritized. Here we had participants learn unrelated concrete noun word-pairs to 5 different levels of encoding strength. After learning, there was a 5-minute eyes-closed quiet rest period followed by a recall test of all word pairs (test 1). Participants were then divided into 3 groups and were told to return for a re-test (test 2) at either 4 hours (short-wake), 12 hours (long-wake), or 24 hours (sleep) later. Change scores in recall performance was calculated as the difference in the number of pairs recalled at test 1 and test 2. Preliminary results suggest a beneficial effect of sleep on weaker encoded memories, but the absolute weakest level of encoding showed no sleep-dependent benefit. Strongly encoded memories did not benefit from a period of sleep. These results show that the brain prioritizes weaker memories for consolidation during sleep, but a minimum threshold has to be reached in terms of initial encoding strength in determining which memories to select for consolidation. Very weak memories are not selected possibly because the memory trace is too poor for consolidation to be possible. On the other hand, strongly encoded memories are also not selected, possibly because the memory trace is strong enough that further consolidation of the memory is not necessary for long-term retention.

Title: Neural consequences of directing retrospective attention in visual working memory

Authors: *P. M. BAYS, R. TAYLOR
Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: An informative cue that directs attention to one of several items in working memory improves subsequent recall of that item. Here we examine the mechanism of this retro-cue effect using a model of short-term memory based on neural population coding. Our model describes recalled feature values as the output of an optimal decoding of spikes generated by a tuned population of neurons. This neural model is found to provide a better account of human recall data than an influential model (Zhang & Luck, Nature, 2008) that assumes errors can be described as a mixture of normally-distributed noise and random guesses. The retro-cue benefit is revealed to be a consequence of a relative increase in the firing rate of the encoding population, with no change in tuning specificity (Figure 1). Additionally, a retro-cued item is less likely to be swapped with another item in memory, an effect that can also be explained by increased activity of the underlying population. These results provide a parsimonious account of the effects of retrospective attention on recall and demonstrate a powerful method for probing neural representations with behavioural tasks.

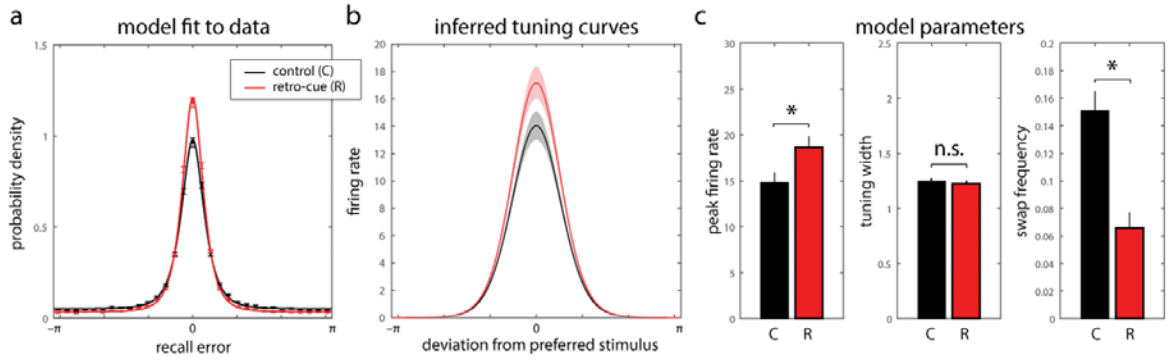

Figure 1. (**a**) Symbols indicate empirical recall errors (mean ± SE) and curves show fit of population coding model, for trials with (red) and without (black) a retro-cue. (**b**) Inferred tuning functions of neurons encoding the visual memoranda. (**c**) Model parameters: peak firing rate and swap frequency were modulated by retro-cueing, with no effect on tuning width.

Title: Maintenance of location information for the unattended memory item during visual working memory

Authors: *Q. YU, B. POSTLE
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Previous studies of information held at different levels of priority in visual working memory have suggested that only information in the current focus of attention is represented in an active state. The “unattended memory item (UMI)”, on the other hand, may be retained in an “activity-silent” state. In the current study, we aimed to investigate how the system keeps a record of a UMI while it is still potentially relevant for behavior. Participants viewed two gratings with different orientations (one in each hemifield) and were asked to remember both of them across an initial delay (Delay 1). In the Retain-One-Item (R1) condition, participants saw a cue indicating which of the two items would be relevant for the remainder of the trial, and were tested on their memory for that item after a second delay (Delay 2), then re-cued and re-tested on that same item after a third delay (Delay 3). In the Retain-Two-Items (R2) condition, participants performed a similar task, except that the first cue did not predict which item would be relevant for the final memory probe. Because the cued and uncued items were separated in space, we could test whether information about the retinotopic location of the UMI might be retained across Delay 2, using multivariate pattern analysis (MVPA). Independently, we could track the representation of orientation with inverted encoding models (IEM). In the R2 condition, consistent with previous work, we observed degraded neural representation of the orientation of the UMI after the first cue. MVPA, however, indicated that the location of the UMI, but not the attended memory item, was robustly retained across Delay 2. The comparable location information could not be decoded for either item in the R1 condition. These patterns held across multiple regions in early visual cortex. These results support the idea that the brain may retain an active representation of episodic information about UMIs so long as they remain potentially relevant for behavior.

Title: The neural representation of stimulus information, of the stimulus location, and of the location-dependence of stimulus information in visual working memory

Authors: *Y. CAI[1], D. A. SHELDON[2], B. R. POSTLE[2]
[1]Beijing Normal Univ., Beijing, China; [2]Univ. Of Wisconsin–Madison, Madison, WI

Abstract: This study applied multivariate inverted encoding modeling (IEM) to fMRI data to track the dynamics of stimulus representation across a visual working memory (VWM) task. Each trial began with the presentation of an oriented bar ("sample") in one of four locations (one in each quadrant), followed by a blank 8-sec delay, followed by a recall dial requiring estimation of the sample orientation. The recall dial appeared in the same location as the sample. Across 11 subjects, mean estimation error our 6.7 deg., and a 2-factor mixture model estimated a mean guess rate of less than 5%. Sample-evoked BOLD signal intensity was elevated in occipital, parietal, and frontal regions; delay-period activity in parietal and frontal. Unilateral ROIs were defined in each of these lobes as the 400 voxels showing the greatest difference in sample-evoked activity for contralateral versus ipsilateral stimuli. When IEMs were trained and tested at each TR, in all three regions, stimulus orientation could be reconstructed with signal evoked by contralaterally presented samples as well as by signal evoked by ipsilaterally presented samples. In the occipital ROIs, the same was true for data from the delay and recall periods. In the parietal ROIs, orientation could be reconstructed during the delay period only when the sample had been presented contralaterally. These stimulus representations were dynamic, because reconstruction failed when sample-trained IEMs were fed data from later portions of the trial. To further investigate the temporal evolution of these memory representations, we also trained IEMs on signal from the occipital ROIs from the delay and the recall periods. Whereas recall-period output of sample-trained IEMs distinguished those that had been trained contralaterally from those that had been trained ipsilaterally, information about sample location was weaker in delay-trained IEMs, and weaker still in probe-trained IEMs, suggesting that the mnemonic representation of orientations became progressively less location-dependent over time. In contrast to this, multivariate pattern analysis (MVPA) of the same ROI indicated that occipital cortex retained a robust representation of sample location through the trial. These findings demonstrated that the neural representation of the location dependence of nonspatial stimulus features can be dissociated from the neural representation of stimulus location, per se.

Title: Neural substrate of objects' material properties held in visual working memory

Authors: *M. FUJIMICHI, H. TSUDA, H. YAMAMOTO, J. SAIKI
Kyoto Univ., Kyoto-Shi, Japan

Abstract: Previous studies on neural mechanisms underlying visual working memory have shown that intraparietal sulcus plays important roles for the memory of color and shapes. In contrast, studies on perception of objects' material properties reported activities in the ventral visual pathway. Which regions are responsible for visual working memory for objects' material properties? In the present study, we conducted an fMRI experiment to explore this question. In the main task, participants performed a delayed discrimination task regarding objects' surface glossiness or roughness in a 3T scanner. In each trial, two sample objects were sequentially presented, followed by a numerical cue about which objects' material property to memorize. When the two samples were different in glossiness (roughness), the participants had to memorize the glossiness (roughness). After an 11s delay, a probe object was presented and the participants indicated which one of the probe object and the memorized one had higher glossiness (lower roughness). The imaging runs of the working memory task were followed by two kinds of imaging: localizer runs to identify brain regions processing objects, color, faces, and scenes, and phase-encoded retinotopy measurements to define retinotopic visual areas. To explore working memory representations for the objects' material properties, we conducted a multi-voxel pattern analysis (MVPA) to predict the memorized material property, glossiness or roughness. The results of MVPA during the delay period showed above-chance accuracies in the ventral object vision pathway and intraparietal sulcus. In contrast, early visual areas could not predict the memorized material property. These results suggest that the ventral object vision pathway and intraparietal sulcus, but not early visual areas, can carry information about objects' material properties even though there are no physical stimulus.

Univ., Beijing, China; [4]Epilepsy Ctr. of Yuquan Hospital, Tsinghua Univ., Beijing, China; [5]CAS Ctr. for Excellence in Brain Sci. and Intelligence Technol., Shanghai, China

Abstract: Working memory (WM) is a buffer storage in mind, consisting of verbal and visual forms. Although the former has had been studied well that we could hold several verbal stimuli as chunks in mind, the study of multi-object visual working memory (VWM) attracted some controversies. The present study used intra-cranial electroencephalography (iEEG), recorded neural activity of neuronal population directly from 30 refractory epileptic patients, to explore how our brain maintains multiple-items simultaneously in mind. On studying of multi-objects maintenance, memory load is a very commonly used manipulation. While in traditional paradigms, memory load is indexed by the number of items in display. This kind of experiments certainly involves a confounding factor, namely perceptual load. Here, we developed a novel visuospatial delayed match to sample task (DMST) to separate these two factors. During sample display, all eight spatially dots (non-colorized and colorized dots) presented simultaneously. But only the number of colorized ones (one, two or four dots), rather than the number of total dots (eight), denoting the memory load. Therefore, the perceptual load (the number of all dots) kept the same when manipulating memory load. Preliminary results of this study indicated that behavior performance deteriorated severely with increasing memory load. And the capacity estimator, Cowan's K value first increased then saturated at load 2 condition, which in consistence with the idea that visual working memory was severely limited. Event related

potentials (ERPs) were analyses to validate the effectiveness of perceptual load control. And no load effect was observed during the first 320 ms perceptual period after sample onset, which contained the evoked response components P1 and N1. For the recorded local field potentials (LFPs), time-frequency decomposition with Morlet wavelet was conducted on each channel. Then ANOVA of load effect was analyzed with cluster correction on these time-frequency representations to find the working memory task related channels. The result manifested that these channels distributed widely across different recorded cortical cortexes, namely frontal, parietal, temporal and occipital region. In addition, the number of significant channels in different cortexes exerted no differences under the Mantel-Haenszel test. Therefore, we concluded that when maintain multi-items simultaneously in mind, different cortex regions work together as a network. And how does these regions communication will be investigated in the later analyses.

Title: Resource allocation and confidence in visual working memory

Authors: *A. H. YOO[1], Z. KLYSZEJKO[1], W. J. MA[1,2], C. E. CURTIS[1,2]
[1]Psychology, [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: To improve the precision of working memory (WM), people flexibly allocate attentional resources across items prioritized by their behavioral relevance (Klyszejko et al., 2014; Emrich et al., 2017). Moreover, people are less confident when they have a noisier WM representation (Rademaker et al., 2012). While past computational models of WM typically account for varying item precision through set size manipulations, they do not account for strategies that distribute WM resources to a fixed number of items according to their priority, nor do they account for memory confidence. Here, we collected psychophysical data from two experiments and extended the variable precision (VP) model of WM (van den Berg et al., 2012) to address two aims: how the allocation of WM resources reduces WM error and whether a VP model could account for the trial-to-trial association between WM error and confidence. In Exp.

1, participants performed a memory-guided saccade task in which we manipulated priority by varying the probability that each of four targets would later be the saccade goal. Behaviorally, errors and response times (RT) decreased monotonically with increasing priority. Through computational modeling, we demonstrate that participants did not allocate resources proportional to priority. Rather, they slightly under-allocated to high and over-allocated resources to low priority targets. In Exp. 2, following the memory-guided saccade, participants indicated their memory confidence by adjusting the size of a disc centered on their saccade landing. A smaller disc led to a higher reward, but only if the target was within the disc. Again, errors and RT decreased with priority. Additionally, disc size decreased with priority and was positively correlated to WM error. We extended the computational models from Exp. 1 to include confidence reports, defined an optimal observer model, and compared which model fit each participant's data best. We replicate the results of Exp. 1; the best fitting model suggests that participants under-allocate to high and over-allocate resources to low priority targets relative to proportional or optimal. The best-fitting model also captures the relationship between WM error and disc size. These results demonstrate that, while not optimally or even proportionally, people allocate resources based on priority to enhance performance. Moreover, people are aware of the fidelity of their WM, which they perhaps use to temper memory-guided responses.

Title: Retroactive spatial prioritization in working memory

Authors: K. MAXOOD, A. TEMUDO, *K. K. SREENIVASAN
New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Working memory (WM) is famously capacity limited. A key feature of WM is that its resources can be deployed flexibly in order to prioritize individual items over others, thus increasing the precision with which these items are maintained and recalled. This has most notably been demonstrated using a retrocuing paradigm, where performance is enhanced by a cue during the memory delay that indicates which memory item will be tested. Other recent demonstrations of the flexible allocation of WM resources come via studies that manipulate attentional priority during encoding, either by varying the bottom-up salience or the top-down behavioral relevance of the different items in the memory display. As a result, higher priority items are maintained with higher precision, while lower priority items are maintained with lower precision. An open question is whether attentional prioritization can occur during WM

maintenance, after encoding is complete.
We sought to address this question by having subjects perform a modified delayed estimation task for spatial WM where spatial priority was indicated by a retrocue. On each trial, subjects saw four dots presented on an invisible annulus and retained the location of these dots over a brief memory delay. In the middle of the memory delay, subjects were presented with a central retrocue that indicated the probability (either 0, 0.1, 0.3, or 0.6) that each of the four locations would be probed at the end of the trial. At the end of the memory delay, the subjects were cued to report the location of one of the items. The critical test was whether the degree of error in subjects' reports was proportional to the probed item's rank ordered probability as indicated by the retrocue. We predicted that the amount of response error would be least for items that indicated a 0.6 probability of being probed, and would increase as the probability of being probed decreased.
In line with our prediction, there was a roughly linear effect of priority on average memory error, with the least error for the item cued with 0.6 probability and the most error for the item cued with 0.1 probability. This graded effect provides evidence that WM representations can be assigned a rank-ordered priority after encoding. In addition to providing evidence that mechanisms of spatial prioritization generalize to WM maintenance, these findings have important implications for models that posit multiple representational states in WM.

Title: Decoding uncertainty in visual spatial short term memory from retinotopic cortex

Authors: *T. C. SPRAGUE, M. RAHMATI, A. YOO, W. MA, C. E. CURTIS
Dept. of Psychology, New York Univ., New York, NY

Abstract: When performing tasks requiring the maintenance of information over a brief delay period, observers can introspect the quality of visual short-term memory (VSTM) representations

to optimally guide behavior (Rademaker et al, 2012; Suchow et al, 2016). According to theories of Bayesian probabilistic population coding, such memory representations are manifest as probability distributions over feature values, and the width of these distributions reflects uncertainty in the represented feature value (Ma et al, 2006). Accordingly, if VSTM representations are maintained using probabilistic population codes, and they can be accurately modeled and sensitively measured, representation accuracy as indexed by neural decoding error and behavioral recall precision should be worse when decoded uncertainty of neural representations is greater. We tested these predictions by assaying neural representations of remembered spatial positions and their uncertainty across visual, parietal, and frontal cortex during a memory-guided saccade task using functional MRI. On each trial, participants precisely maintained the position of a briefly-flashed target stimulus over a 10 s delay interval, then generated a memory-guided saccade to the remembered position. We adapted a recently-developed multivariate decoding method based on a Bayesian generative model (van Bergen et al, 2015), which estimates a probability distribution over feature values given neural activation patterns to recover estimates of represented spatial positions and their uncertainty on each trial. In several topographic visual maps, decoding errors increased with increasing decoded uncertainty, consistent with predictions from probabilistic population coding. Additionally, when decoded uncertainty was high during the memory delay, subsequent memory-guided saccades tended to be less accurate. A parsimonious cortical encoding scheme for spatial VSTM representations could exploit the retinotopic organization across much of human cortex, with the topography of feature-selective activation during spatial VSTM maintenance matching the retinotopic structure of visual maps (Mackey, Winawer & Curtis, 2017). Indeed, during the delay period, position preferences of voxels exhibited strong topographic organization along the cortical surface, and this relationship was especially strong in regions which representations related to behavioral performance. Together, these results demonstrate probabilistic population codes implemented across retinotopic maps as a plausible mechanism for the maintenance of visual spatial positions over a delay, as well as their uncertainty.

Title: Oculomotor capture reveals trial-by-trial neural correlates of attentional guidance by contents of visual working memory

Authors: *V. BECK, T. VICKERY
Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Evidence from attentional and oculomotor capture, contingent capture, and other paradigms suggests that mechanisms supporting human visual working memory (VWM) and visual attention are intertwined. Features held in VWM bias guidance toward matching items even when those features are task irrelevant. However, the neural basis of this interaction is underspecified. Prior examinations using fMRI have primarily relied on blocked designs or coarse comparisons across experimental conditions that produce varying amounts of capture. To examine the neural dynamics of attentional capture on a trial-by-trial basis, we applied an oculomotor paradigm that produced discrete measures of capture. Hollingworth, Matsukura, and Luck (2013) previously demonstrated that VWM-matching items attract attention in an oculomotor response task. On each trial, subjects were shown a memory item, followed by a blank retention interval, then a saccade target that appeared to the left or right. On some trials, an irrelevant distractor appeared above or below fixation. Once the saccade target was fixated, subjects completed a forced-choice memory test. Critically, either the target or distractor could match the feature held in VWM. Although task irrelevant, this manipulation produced differences in behavior: participants were faster to saccade to a VWM-matching target, and more likely to saccade first to an irrelevant VWM-matching distractor - providing a discrete measure of capture. We replicated these findings while recording eye movements and scanning participants' brains using fMRI. To examine the neural basis of oculomotor capture, we separately modeled the retention interval for capture and non-capture trials within the distractor-match condition. We found that a region previously associated with VWM, dorsolateral prefrontal cortex, was more active during the retention interval of capture than non-capture trials, suggesting that active maintenance of target information in VWM differentially predicted the tendency to be inappropriately guided to the VWM-matching distractor. In addition, we modeled eye movement latency within each condition. For target-matching trials, with or without a distractor, longer latency positively predicted left hippocampal activity, compared to target non-match trials. These findings suggest that more efficient long-term storage of the target feature mitigated speeding of eye movements, selectively for target-matching conditions. Our findings demonstrate the power of trial-by-trial analyses of oculomotor capture as a means to examine the underlying relationships between VWM and attentional guidance systems.

Title: Trans-saccadic integration and visual working memory

Authors: *A. L. FROST[1], M. NIEMEIER[2]
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Univ. Toronto, Scarborough, ON, Canada

Abstract: The eyes make about three fast movements per second, and across these “saccades” the brain needs to update the spatial locations of objects to maintain a stable representation of the world. This is achieved through trans-saccadic integration, involving processes of spatial remapping together with memory buffers. To understand how these processes relate to other cognitive mechanisms, in the current study we measured people’s trans-saccadic and other types of working memory performance. In the trans-saccadic task participants briefly viewed arrays of objects, followed by a saccade and then used a mouse cursor to click on one of the remembered object locations. In addition, they performed an n-back and a change detection task, two well-established spatial visual working memory paradigms. We found that both classic measures were unrelated to systematic errors during the trans-saccadic task. However, unsystematic errors were predicted by n-back performance. Surprisingly, working memory capacity as quantified with change detection showed no correlations. Follow-up studies altered the change detection task in several ways to identify the features that would make it more similar to the other tasks. We ruled out features such as interference and remapping locations across visual fields. In contrast, forcing participants to detect changes based on egocentric rather than allocentric information did produce significant correlations. Our results suggest that trans-saccadic integration involves separate mechanisms for trans-saccadic remapping of spatial information and trans-saccadic memory. Moreover, trans-saccadic memory relies on similar buffers as other forms of working memory depending on the spatial coordinate system, with separate buffers for egocentric and allocentric representations of space.

Title: Frontal visual field maps mediate noise resilience of working memory

Authors: *W. MACKEY[1], C. E. CURTIS[2]
[1]New York Univ., New York, NY; [2]Psych & CNS, NYU, New York, NY

Abstract: Working memory (WM) extends the temporal period within which neural representations can be integrated and transformed, enabling a vast array of cognitive abilities. Conversely, WM has severe capacity limitations, and varies widely between individuals and across the lifespan (Anders, Fozard, & Lillyquist, 1972). Psychophysical studies and computational models indicate that random noise corrupts the quality of WM representations (Bays, 2015). Recently, we reported that the size of visual field maps in frontoparietal and early visual cortex predicted individual differences in WM precision (Curtis, et al., SFN 2016). Moreover, we simulated the fidelity of WM in various sizes of neural networks and found that smaller simulated populations were noisier. These findings suggest that WM resource limitations may have a structural basis. However, these relationships were correlational in nature, and could not address whether this relationship was unique to either encoding or maintenance processes. To address these limitations, we combined computational neuroimaging and repetitive transcranial magnetic stimulation (TMS) during a classic spatial WM task to investigate the causal relationship between individual differences in structural properties of visual field maps in frontal cortex and WM precision. First, we used population receptive-field mapping (Mackey, Winawer, & Curtis, 2017) to identify a visual field map that lies in the superior branch of the precentral sulcus (sPCS), a frontal area necessary for WM (Mackey et al., 2016). This served as our stimulation target in each subject. Second, we measured the effect on memory accuracy of a short burst of TMS applied during the delay period of a memory-guided saccade task. We assumed that TMS would introduce random noise, perturbing the population activity in sPCS (Mackey & Curtis, 2017). We predicted that sPCS map size would mediate the effects of TMS on WM performance. Indeed, we found a relationship between individual differences in map size and the TMS induced decrement in WM precision. Specifically, TMS applied during the retention interval caused a greater reduction in WM accuracy in subjects with smaller sPCS maps. Interestingly, subjects with large maps were resilient and were hardly affected by TMS. Together, these results indicate that 1) the sPCS is necessary for maintaining spatial WM, 2)

sPCS size may place a hard constraint on WM resources, and 3) individual differences in sPCS size may predict one's resilience or the degree to which WM representations are corrupted by noise.

Title: Efficient coding in visual working memory accounts for stimulus-specific variations in recall

Authors: *R. TAYLOR, P. M. BAYS
Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Human recall errors in visual working memory (VWM) show systematic variation within feature dimensions. For example, recall of color appears biased toward certain color prototypes, and recall of orientation is more precise for cardinal than oblique directions. While a number of existing models can approximate the average distribution of recall error across target stimuli, attempts to capture the way in which error varies with the choice of target have been ad hoc. Here we build on an existing account of the neural architecture of VWM, in which stimuli are encoded in the normalized spiking activity of a population of tuned neurons (Bays, 2014), to provide a principled account of these stimulus-specific effects. While the original model assumed homogeneous tuning curves (Figure 1A), here we allow each neuron's tuning function to vary according to the principle of efficient coding (Figure 1B; Barlow, 1961; Ganguli & Simoncelli, 2014; Wei & Stocker, 2015). This principle states that neural responses should be optimized with respect to the natural frequency of stimuli in the environment. For orientation this means incorporating a prior that favors cardinal over oblique orientations. While continuing to capture changes to the mean distribution of errors with set size, the resulting model also reproduced stimulus-specific variations in precision (Figure 1C). Additionally, the efficient coding model predicted a repulsive bias away from the cardinal orientations: such a bias was observed in human response data. The model provides a general framework for describing stimulus-specific variations in VWM recall that can be readily extended to other feature dimensions.

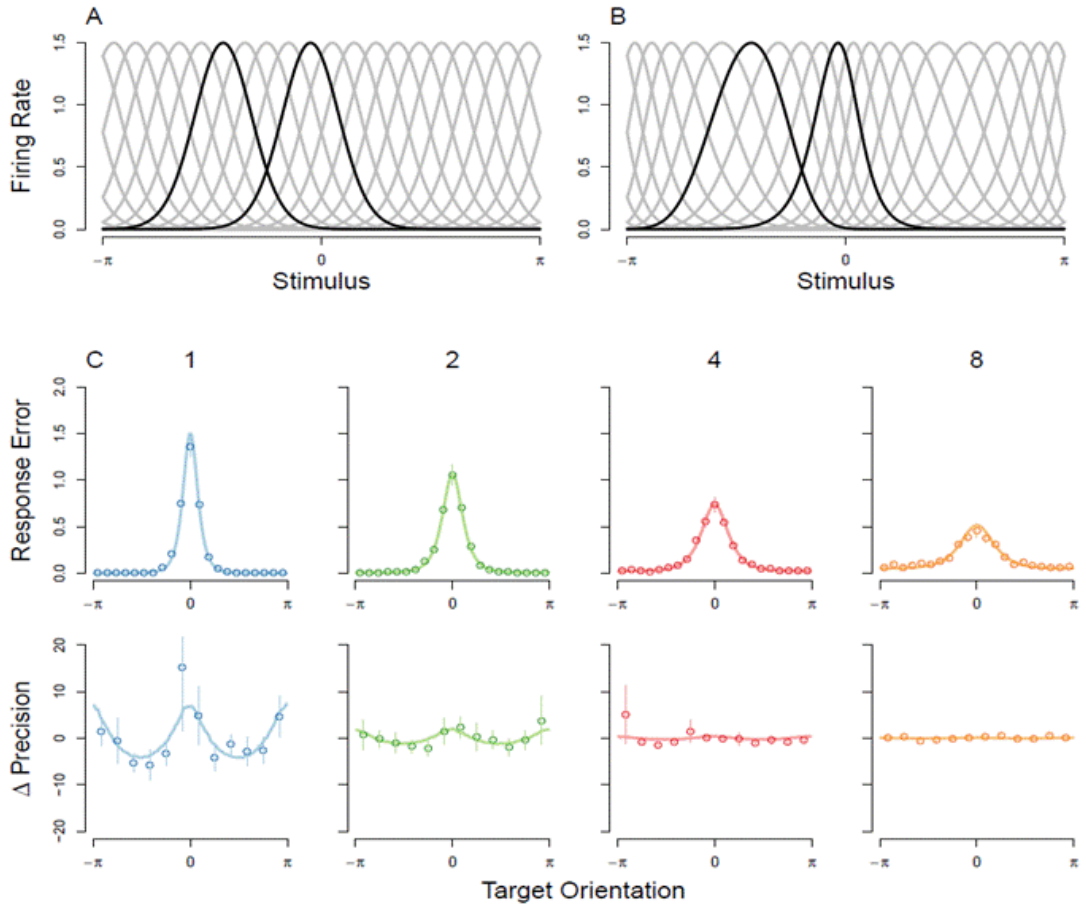

Figure 1. A) A homogenous population of Von Mises tuning curves. **B)** Under the principle of efficient coding, tuning functions become narrower, and more densely concentrated, around cardinal orientations (0, π). **C)** Distribution of recall errors for array sizes one to eight and precision across orientation space. Observers exhibit increased precision for cardinal orientations. Model fits shown as lines. Error bars represent 1± SE.

Title: What about grades in school?: the role of the working memory and fluid intelligence

Authors: *J. SIBAJA-MOLINA[1], O. A. RODRÍGUEZ-VILLAGRA[2,3]
[1]Neurosci. Res. Ctr., Univ. of Costa Rica, San Jose, Costa Rica; [2]Inst. for Psychological Res., [3]Neurosci. Res. Ctr., Univ. of Costa Rica, San José, Costa Rica

Abstract: Working Memory (WM) and Fluid Intelligence (FI) are described as two abilities associated with better adaptation in educational contexts and academic achievement. WM is a cognitive system related to temporary storage and manipulation of information for goal-directed processing. FI is defined as the ability to solve complex and novel problems, and formation of concepts, independent of learning and experience. In this behavioral study, we examined whether individual differences in WM and FI in preschoolers, predict the average grades in basic subjects (e.g., Math, Spanish, Science, Social Studies) at the first school year (i.e., academic achievement).We assessed WM and FI abilities of 132 students from public preschools located in San José, Costa Rica (~5.9 years; 67 girls; Spanish speakers).Two years after their preschool evaluation, grades were requested to the institutions where the children were enrolled in their first grade. Structural equation models were conducted to analyze the data. Tests of factorial invariance showed that all parameters of the measurement model were equivalent across girls and boys, thereby allowing the comparison of the mean structures across sex. Our main finding was that WM, but not FI, predicts the academic achievement factor. In the latter factor, a significant correlation between Spanish and Mathematics improved the fit of the model to the data suggesting further common aspects between these subjects. These results provide evidence of cognitive elements that underlie school grades. This information is relevant for educational curricula development and it shows the key role of WM in complex cognitive processes, which develop incrementally across early school stages. Understanding of WM is a hot topic in neuroscience research, and it is also important in fields like Education because it offers knowledge about the brain function that underlies some aspects of learning. Based on the behavioral results of this study, the current research in our laboratory is aimed at finding encephalographic correlates of WM (e.g. frontal midline theta rhythms) in early scholar ages, with the purpose to provide early measures that allow us to detect futures learning problems.

Title: Pre-allocation of memory resources improves working memory performance in a sequential memory task

Authors: *H. LEE[1], Y. PARK[1], S.-B. PAIK[1,2]
[1]Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Since working memory capacity is limited to a small number of items (Christophel et al., 2017), efficient use of memory resources is an important issue. Pre-allocation, the process of determining where memory will be stored before information comes in, is used in various memory systems, including computers, to utilize storage space. However, it is not clear whether pre-allocation of working memory exists in the brain. In this study, we propose that pre-allocation of working memory may exist, and it may be possible to improve memory performance based on human psychophysical experiments. We suggest a possible neural mechanism of pre-allocation using a neural network model.

First, to examine the effect of pre-allocation, we designed an experiment in which subjects memorized sequentially presented visual patterns under the conditions whether the subjects were (1) not informed or (2) correctly informed of the number of stimuli. For further analysis, (3) the subjects were informed of an incorrect number of stimuli to investigate how false information affects memory performance. Our results showed that performance for the early-presented items in the sequence was higher in the correctly informed case than in the other two cases. This suggests that memories for the early-presented items were less overwritten by recently-presented items when subjects were correctly informed, which indicates the presence of memory pre-allocation.

Next, to explain the systematic basis of experimental results, the concept of ‘neuronal ensemble’ (Josselyn et al., 2015) was applied. We designed a neural network model which learns input patterns and generates consistent output for trained patterns (Park et al., 2016). A group of neurons that selectively responded to learned inputs were defined as a ‘neuronal ensemble,’ and we could freely control the probability that a neuron would be recruited into the ensemble (pre-allocated) by modulating neuronal excitability (Silva et al., 2009). Using this model, we showed that the pre-allocation prevents old memories from being overwritten by new memories because it reduces the overlap between multiple ensembles. On the other hand, without pre-allocation, old memories were easily overwritten by new memories due to the large overlap between ensembles. These results are comparable with those obtained for the ‘correctly informed’ and ‘uninformed’ cases, respectively.

Overall, our results suggest that memory pre-allocation is in effect; thus, working memory performance is improved in the sequential presentation. The overlap of neuronal ensembles is one possible way to describe the effects of pre-allocation on memory performance.

Title: Neither cholinergic nor dopaminergic enhancement improves spatial working memory precision in humans

Authors: A. N. HAREWOOD SMITH[1], J. ADITYA CHALLA[2,3], *M. A. SILVER[4,1,3]
[1]Vision Sci. Grad. Group, [2]Dept. of Electrical Engin. and Computer Sci., [3]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [4]Sch. Of Optometry, Univ. Of California, Berkeley, Berkeley, CA

Abstract: Acetylcholine and dopamine are neurotransmitters that play multiple important roles in perception and cognition. Pharmacological cholinergic enhancement reduces excitatory receptive field size of neurons in marmoset primary visual cortex, increases learning and performance of a spatial navigation task in rats, and sharpens the spatial tuning of visual perception in humans. Moreover, previous studies have shown that manipulation of dopaminergic signaling alters the spatial tuning of macaque prefrontal cortical neurons during the delay period of a spatial working memory task and can improve spatial working memory performance in human subjects. Here, we investigated the effects of systemic cholinergic and dopaminergic enhancement on a behavioral measure of the precision of spatial working memory in human subjects. Cholinergic transmission was increased by administration of 5 mg of the cholinesterase inhibitor donepezil, and dopaminergic signaling was enhanced with 100 mg L-dopa/10 mg carbidopa. Each neurotransmitter system was separately studied in double-blind placebo-controlled experiments. On each trial of the spatial working memory task, a square was presented for 150 ms at a random location along an invisible circle with a radius of 12 degrees of visual angle, followed by a 900 ms delay period with no stimulus shown on the screen. Then, the square was presented at a new location, displaced in either a clockwise or counterclockwise direction along the circle from the original location. Subjects compared their memory of the location of the original square to the location of the subsequent presentation and reported the direction of displacement. We defined spatial working memory precision as the amount of displacement corresponding to 75% correct performance. We observed no significant effect on spatial working memory precision for either donepezil or L-dopa/carbidopa. There was also no significant effect on performance on the spatial working memory task (percent correct across a wide range of displacements) for either donepezil or L-dopa/carbidopa. Thus, despite evidence that acetylcholine and dopamine can regulate spatial tuning of individual neurons,

pharmacological enhancement of signaling of these neurotransmitters does not substantially affect a behavioral measure of the precision of spatial working memory in humans.

Title: Electroencephalographic features during the performance of a test demanding working memory in early postmenopausal women

Authors: ***M. SOLIS-ORTIZ**[1], E. G. GONZALEZ-PEREZ[2], M. L. GUTIERREZ-MUÑOZ[3]
[1]Inst. Invest Med, Univ. Guanajuato, Leon, Mexico; [2]Med. Sci., Univ. de Guanajuato, Leon, Mexico; [3]Psicologia, Univ. Autonoma de Nuevo Leon, Monterrey, Mexico

Abstract: Studies examining the influence of the menopause on cognitive function have been contradictory. Working memory is key to successful cognitive processing, however how it co-varies with electroencephalographic (EEG) activity in early postmenopausal women is not well known. This study was aimed to explore the EEG features during the performance of a test demanding working memory based in a multivariate analysis. Twenty-five early postmenopausal healthy women between 48 and 60 years participated in the study. EEG was recorded during performance of a test demanding working memory. Absolute power of delta, theta, alpha1, alpha2, beta1, beta2 bands, the number of categories completed, correct responses (trials) as well as perseverative errors and errors of test were obtained and submitted to a principal components analysis. Four eigenvectors that accounted the 79.12 % of the total variance were identified. Theta, alpha1 and alpha2 bands were grouped together in an independent eigenvector (component 1), which explained 45.87 % of the total variance. The component 2 grouped beta2 band, and the component 3 grouped delta band, which explained 16.54 % and 11.49 % of the total variance, respectively. The component 4 grouped alpha2 band and the perseverative errors and errors of test in the occipital derivations, which explained 5.22 % of the total variance. The execution of the test was relatively poor. The number of categories achieved was less three out of a total number of six, and there were many errors. These findings show that during working memory processing theta and alpha bands, involved in activation of the working memory, executive performance and sustained attention, did not co-vary with beta2 and delta bands, which have been involved in alertness, focused arousal and inhibition of internal attention. The

errors committed covaried together with alplha2 band and they were independent of the other variables EEG.

Title: Intersubject correlation analysis of brain activity when viewing videotaped teacher's explanation

Authors: *Y. HIRAKO[1], T. ITO[2], S. SHIMADA[3]
[1]Meiji Univ. Grad. Sch., Kawasaki-Shi, Japan; [2]Sch. of Arts and Letters, Meiji Univ., Ochanomizu, Japan; [3]Sch. of Sci. and technology, Meiji Univ., Kawasaki-Shi, Japan

Abstract: In recent years, educational methods using videotaped lessons have attracted attention. Previous studies showed that brain activities during viewing video movies have been studied using intersubject correlation (ISC) analysis. This study investigated the mechanism of comprehending videotaped teacher's explanation by utilizing ISC analysis of students' brain activity by using functional near-infrared spectroscopy (fNIRS). Twenty-four right handed subjects participated in the experiment (one female, aged 21.3 ± 0.17 years, mean ± SD). Half of the subjects (N=12) watched the explanation of a teacher about basic probability statistics in the recorded video. Another half watched a video clip of the equivalent explanation performed by another teacher. The hemodynamic responses in the bilateral cortical areas (9 x 9 square cm area each) were recorded by using 48-ch fNIRS. The sampling frequency was 10 Hz. The measured brain activity was analyzed by ISC analysis between two subjects who watched the same teacher (valid pairs) or different teachers (invalid pairs). ISC is calculated by utilizing general linear model (GLM) with one subject's brain activity as a model to see how similar the other subject's brain activity was. We also calculated dynamic ISC using 150 sample moving window (15.0s), on the channel that showed the significant difference in ISC between the groups. The ISC analysis showed a significant difference in ISCs between the valid pairs and the invalid pairs in the right DLPFC (ch-38: $t(24) = 1.78$, $p < 0.05$). We investigated the time series change of the ISC in ch-38 and found that they were consecutively significant ($z > 1.66$, $p < 0.05$) in the scenes that the teacher was explaining "variance" (teacher A : 120.0s - 136.4s, teacher B : 156.3s - 177.4s) and "standard deviation" (A : 176.0s - 207.0s, B : 202.5s - 226.6s), where the

explanation is relatively easy to understand for subjects as the teacher read aloud sentences written in the slide. These results suggest that rDLPFC is involved in comprehending videotaped teacher's explanation, possibly by playing a role as working memory to translate verbal information into abstract numerical representation.

Title: Decoding the limits of simultaneous storage in working memory

Authors: *K. C. ADAM, E. AWH, E. K. VOGEL
Psychology, Univ. of Chicago, Chicago, IL

Abstract: Recent work has shown that the topography of power in the alpha-band (8-12 Hz) of the human EEG signal tracks the location of a single item held in visual working memory (Foster et al., 2016). A critical question in working memory (WM) research is the existence and nature of capacity limits. Most models of visual WM endorse a capacity limit of 3 simple items, but others have suggested that active representation may be limited to a single prioritized item. To best address capacity debates, we need methods for simultaneously decoding the identity of all items purportedly stored in WM. Here, we made advances toward this aim by presenting and decoding the identity of up to 3 simultaneously-presented items. One weakness of prior research in this area is the confound of increasing visual stimulation with an increasing number of items; this confound could lead to inadequate decoding for higher set-sizes because of increased noise at encoding. To control for visual stimulation between the different load conditions, we used a selective encoding working memory task. On every trial, three colored squares appeared in three of eight possible location bins equidistant from fixation. To manipulate memory load, participants were pre-cued to 1, 2, or 3 of the relevant locations with centrally presented spatial cues (small lines pointing toward the location or locations). We found reliable decoding of all 3 load conditions using alpha-band activity. The selectivity of decoding was highest for set-size 1 trials, and then declined for set-sizes 2 and 3. Our findings are consistent with previous work demonstrating a decrement in behavioral precision for increased memory loads, and demonstrate the feasibility of extending alpha-based decoding to test the limits of capacity.

Title: Alpha-band activity reveals concurrent storage of independent locations in spatial working memory

Authors: ***J. J. FOSTER**, D. W. SUTTERER, K. C. ADAM, E. K. VOGEL, E. AWH
Univ. of Chicago, Chicago, IL

Abstract: Past work has shown that the scalp distribution of oscillatory alpha-band (8-12 Hz) activity - measured with electroencephalography (EEG) - precisely tracks locations held in working memory (WM). Thus, spatially selective tuning profiles (called channel-tuning functions or CTFs) can be reconstructed from the spatial distribution of alpha power using an encoding model of spatial selectivity (Foster et al., 2016). Recent work using functional magnetic resonance imaging (fMRI) has shown that feature-selective patterns of BOLD activity degrade as the number of items to be stored increases (e.g., Sprague et al., 2014). Here, we examined whether increased storage loads elicit a similar decline in the spatial selectivity of alpha-band activity. On each trial, subjects encoded and maintained the location of one or two colored dots while we recorded EEG. After a 1s delay period, subjects were cued to report the location of one of the dots. The set size 2 condition revealed concurrent alpha-band CTFs that tracked the position of each item throughout the delay period, but with reduced spatial selectivity relative to the set size 1 condition. In addition, set size 2 data was robustly decoded using a set size 1 training set, showing that subjects did not rely on a configural code to accomplish simultaneous storage of the items in the set size 2 condition. Likewise, simulations revealed that CTF selectivity in the set size 2 condition was high enough to rule out trial-by-trial switching of attention between the items in the set size 2 condition, bolstering evidence for concurrent storage of independent feature values in working memory. Thus, oscillatory activity in the alpha band enables time-resolved tracking of concurrent representations in visual WM and dovetails with past observations that mnemonic quality declines as storage load increases.

Title: Evidence for concurrent activation of sequentially encoded spatial locations

Authors: *D. W. SUTTERER[1,2], E. AWH[2]
[2]Psychology, [1]Univ. of Chicago, Chicago, IL

Abstract: A robust body of work has demonstrated speeded reaction times to the last item encoded in a Sternberg task (Vergauwe et al., 2016, Oztekin, Davachi, & McElree 2010). A key debate is whether this RT benefit reflects a narrow focus of attention on the most recently presented item, in line with suggestions that working memory capacity may be limited to a single item or encoding episode. Here, we tested this hypothesis by using alpha band activity to track the time course and content of representations maintained in spatial working memory (Foster et al., 2016). This method allowed us to observe whether or not sequentially encoded items are concurrently represented during the delay period of a working memory task. On each trial, observers memorized the location of two sequentially presented colored dots while EEG was recorded. After a 1s delay period, participants were cued to report the location of one of the dots. We trained an inverted encoding model (IEM) to assess alpha selectivity for each item and found robust representations of both to-be-remembered items during the 1s delay interval consistent with the interpretation that both items are simultaneously maintained in an active state. These findings disconfirm the hypothesis that only the final item in a sequence is actively represented during the delay period. Thus, although faster RT for the final item in a sequence may reflect a higher priority or familiarity for the most recently encoded item, multiple items in a sequence can be simultaneously stored in visual working memory.

Title: Restoration of fMRI decoding quality does not imply latent working memory states: A neural field model of retro-cue effects

Authors: *S. SCHNEEGANS, P. M. BAYS
Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The prevailing view of working memory is that memory representations are maintained through sustained spiking activity in neural populations. This view has recently been challenged by studies using machine learning methods to decode memory content from human fMRI and EEG data (Sprague et al., 2016; Rose et al., 2016; Wolff et al., 2017). These studies found that previously diminished decoding fidelity of an item was restored following an informative cue or non-specific stimulation. This was interpreted as evidence for an activity silent working memory state (realized e.g. through synaptic changes), which can itself not be decoded from neural activity, but which can be restored into an active state or modulate activity patterns in response to external stimulation. Here, we test the validity of this conclusion by formulating a neural network model that employs sustained neural activity as its sole memory mechanism, and represents feature combinations through conjunctive coding. We apply this model to a spatial recall task with retrospective color cueing as used in a recent fMRI study, and demonstrate that it can reproduce both behavioral and fMRI decoding results. In particular, an informative color cue in the model strengthens the spatial representation of the cued item and suppresses memory representations of non-cued items within the conjunctive space-color map. This produces an increase of decoding quality following the color cue (Figure 1), replicating the key effect of the fMRI study that was claimed as evidence for latent working memory. These results demonstrate that activity-silent memory states are not necessary to explain restoration of decoding quality, and highlight how sustained activity in a neural system can interact in complex ways with new inputs.

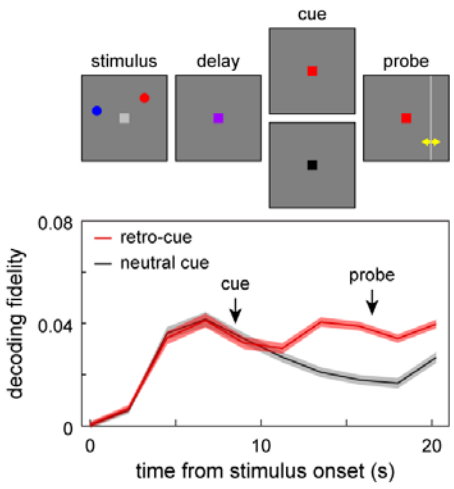

Figure 1: Psychophysical task and decoding fidelity for the target location in the neural network model. Fidelity is computed from simulated BOLD signals based on the activity in the neural network, emulating the reconstruction approach of a recent fMRI study (Sprague et al., 2016). In the task, subjects were presented with two colored disks, and after a delay had to report one location cued by the corresponding color. In the absence of an informative cue, decoding fidelity decays over the course of the delay period. But following a color retro-cue that indicates which item will be tested, decoding fidelity for the target location recovers significantly. An analogous finding in the fMRI data has been interpreted as evidence for a latent working memory state, but in the neural model it is produced by interactions between sustained memory activity and the color cue.

Title: Associations between MEG-measured prefrontal activity during working memory and dopamine D_1 receptor availability measured with PET

Authors: *D. Y. RUBINSTEIN[1], D. P. EISENBERG[1], A. M. IANNI[1], F. W. CARVER[2], D. R. WEINBERGER[3], R. COPPOLA[2], K. F. BERMAN[1]
[1]Section on Integrative Neuroimaging Clin. & Translational Neurosci. Br., [2]MEG Core Facility, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: A relationship between working memory-related dorsolateral prefrontal cortical (DLPFC) activity and dopamine D_1 receptor signaling within the prefrontal cortex has been well studied in non-human primates, but it has been difficult for human studies to achieve similar specificity in the measurement of the electrophysiological and neurochemical components underlying this relationship. To better elucidate the association between DLPFC activity and D_1 receptor biology in healthy volunteers, we used magnetoencephalography (MEG) to measure neuronal activity and PET to measure DLPFC-specific D_1 receptor function and tested the relation between the two parameters. In a large sample of healthy volunteers (N=342), neuromagnetic activity was recorded with a 275 channel whole head MEG during performance of 2-back working memory and 0-back sensorimotor control conditions. Source localization was achieved with an adaptive beamformer, which was used to estimate the 2-back to 0-back power ratio at 5mm-spaced points throughout the brain in 400ms windows time-locked to correct responses, in theta, alpha, beta, and gamma frequency bands. In a subsample of this cohort (n=40), [^{11}C]NNC112 PET scanning was also performed, beginning with an 8-minute transmission scan to correct for attenuation, followed by a 90-minute emission scan. Receptor availability was assessed by calculating the non-displaceable binding potential (BP_{ND}) at each voxel in a subject's brain, using PMOD to implement a simplified reference tissue model with a cerebellar reference region. An a priori, cytoarchitectonically-based mask of the DLPFC from the literature was used to extract MEG and PET values for correlative analysis. While all frequency bands exhibited various robust working memory-related power modulations across the brain, only beta band revealed a fronto-parietal activation pattern similar to that observed with other modalities. In the context of this activation pattern, we found robust working memory-related beta band DLPFC desynchronization (activation) in the time window centered on 200ms before correct responses ($p < .001$). Within the subsample who also had PET, individuals with greater DLPFC activation also exhibited higher D_1 receptor availability in the same region ($r = .42$, $p < .01$), after adjusting for effects of age. These results are consistent with primate studies

demonstrating an important role for D_1 receptors in the modulation of prefrontal WM-related activity, and are among the most direct evidence of such a relationship in humans. Future research in patients will help determine dopaminergic mechanisms underlying their prefrontal, WM-related deficits.

Title: A self-organizing memory network

Authors: *C. FEDERER[1], J. ZYLBERBERG[2]
[2]Physiol. and Biophysics, [1]Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Working memory relies on us being able to retain information about stimuli even after they go away. Stimulus information is encoded in the activities of neurons, which change over timescales of milliseconds[1]. Information in working memory can be retained for tens of seconds, leaving the question of how time-varying neural activities keep representing the same information. Prior work shows that, if the neural dynamics are in the “null space” of the representation - so that changes to neural activity do not affect the downstream read-out of stimulus information - then information can be retained for periods much longer than the time-scale of individual-neuronal activities[2]. The prior work, however, has a fine-tuning problem: precisely constructed synaptic connectivity matrices are needed for information to be retained, and it is unclear how biological circuits would obtain that level of precision. To identify mechanisms through which biological networks can self-organize to support memory function, we derived biologically plausible synaptic plasticity rules that dynamically organize the connectivity matrix to enable retention of stimulus information. Networks implementing this plasticity rule can successfully information about stimulus even if only 10% of the synapses are plastic; they are robust to synaptic noise and can store information about multiple stimuli. Networks can also maintain information about stimulus even if only 10% of the network is connected. Networks that have been pre-trained on stimuli can continue to store new stimuli without being able to update the synapses. The derived synaptic updates require a global error

signal across the network. We propose two possible sources of this signal: calculations via segregated dendrites or from neuromodulators[3]. Our results suggest a biologically plausible model of stimulus retention with time varying neural activity and connectivity. **References** [1] Brody *et al*. (2003). *Cereb. Title: Network competition and reconfiguration during working memory processing

Authors: *A. KIYONAGA, D. J. LURIE, M. D'ESPOSITO
Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: A core function of working memory (WM) is to temporarily maintain information in the face of disruptions and more immediate attention-demanding tasks. It is unclear, however, why simultaneous processing demands can have widely variable degrees of impact on WM performance, and how the brain manages the competition between demands to maximize performance. Prefrontal and parietal brain regions have long been implicated in WM maintenance and dual-task performance, but we lack a firm grasp of their specific contributions to these processes. Here, we examine interactions between these brain regions, and their roles in large scale brain network organization—during several types of WM disruption—to achieve a clearer picture of the neural circuitry of WM dual-task processing. During fMRI scanning, participants completed a visual WM delayed match-to-sample task with an intervening visual search demand embedded in the delay. Delay-spanning processing demands were factorially manipulated on two levels: 1) interference from perceptually dissimilar or similar visual search stimuli and 2) attentional demand from an easier or harder visual search task. Behavior was impacted by both interference and attentional demand, as well as an interaction between factors. WM recognition performance was worst when demands were high on both factors. This interaction was also reflected in univariate BOLD activity in prefrontal and parietal regions that are typically engaged when task demands are high. Specifically, when dual-task demands were greatest, activity peaked in the rostral portions of prefrontal cortex that have been implicated in the coordination of multiple simultaneous demands. Moreover, separate “cognitive localizer” tasks identified distinct but overlapping networks that were engaged by WM vs. attentional

orienting demands, and a greater extent of overlap between these networks related to impaired dual-task performance across individuals, suggesting that better segregation between functional networks can facilitate efficient dual-task processing. These data illustrate how competition emerges between task demands at the whole brain network level, and shed light on how task-based functional network configuration can protect WM content from disruption.

Title: Disentangling sensory specialization from task specialization in lateral frontal cortex

Authors: *A. L. NOYCE[1], N. CESTERO[2], S. W. MICHALKA[3], B. G. SHINN-CUNNINGHAM[2], D. C. SOMERS[1]

Abstract: Prior work has suggested that much of human lateral frontal cortex (LFC) is part of a 'multiple demand' network, supporting a wide range of cognitive tasks and processes (e.g. Duncan 2010; Fedorenko et al. 2013). In contrast to this multiple-demand view, several groups have recently reported that portions of LFC show a preference for processes associated with a particular sensory modality (Michalka et al. 2015; Braga et al. 2016; Mayer et al. 2016). Michalka et al. demonstrated that selective spatial attention to visual or auditory stimuli recruits specific structures within LFC. Two bilateral regions are biased for visual attention, superior and inferior precentral sulcus (sPCS and iPCS), and two bilateral regions are biased for auditory attention, transverse gyrus intersecting precentral sulcus (tgPCS) and caudal inferior frontal sulcus (cIFS). Here, we used fMRI to replicate this finding in a substantially different task paradigm and to examine the 'multiple demand' responsiveness of these regions. We observed that visual and auditory 2-back working memory tasks recruited interleaved visual- and auditory-biased structures that correspond to those reported by Michalka et al. These structures were mapped in each individual subject (n = 15). Within-subject reliability (n = 7) was high across the

two tasks. We then tested the degree to which these sensory-biased structures demonstrated multiple demand behavior. First, we measured BOLD recruitment in the non-preferred memory task; visual-biased sPCS and iPCS showed significantly more recruitment during auditory WM than did tgPCS and cIFS during visual WM. Second, for each vertex within these structures we projected the activation in the two tasks into a 2D vector space; the multiple demand index derived from these values was significant for visual-biased but not for auditory-biased LFC structures. Finally, MVPA stimulus classification tested the degree to which the structures carried information about two classes of visual and two classes of auditory stimuli; visual-biased sPCS and iPCS carried high amounts of information about both stimuli sets, but auditory-biased tgPCS and cIFS carried significantly less information about visual than about auditory stimuli. All three metrics indicate that the visual-biased LFC structures exhibit stronger multiple-demand responsiveness than do the auditory-biased structures, suggesting that the auditory processing network may be more specialized in its cognitive role. These results reconcile two competing theories of LFC's contribution to human cognition by demonstrating the coexistence of sensory specialization and multiple demand behavior.

Title: Spatially specific delay period activity in the human superior colliculus

Authors: *K. DESIMONE[1,4], M. RAHMATI[2], G. T. SABER[3], K. K. SREENIVASAN[4], C. E. CURTIS[5]
[1]Dept. of Psychology, [2]New York Univ., New York, NY; [3]New York Univ., Charleston, NY; [4]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates; [5]Psych & CNS, NYU, New York, NY

Abstract: The superior colliculus (SC) is a key node in a distributed oculomotor network and mediates orienting behaviors such as saccadic eye-movements and gaze shifts. The SC is a laminar structure sitting atop the brainstem and contains two tightly registered retinotopic maps: a visual map in the superficial layer, and a motor map in the intermediate and deep layers representing the angle and amplitude of saccades (Wurtz & Albano, 1980; Sparks, 1986). However, this classical view of the response properties of the SC has been challenged by

pharmacological inactivation of the deep layers of the SC in the macaque, which induces a form of visual neglect akin to extinction not accounted for by paresis or anopsia (McPeek & Keller, 2004; Lovejoy & Krauzlis, 2010). We sought to examine the extent to which the human SC is able to maintain representations of behavioral goals beyond simpler visual and/or motor responses. We hypothesized that the SC acts as a topographic map of spatial priority (Fecteau & Munoz, 2006), and predicted that we should find spatially specific representations of behavioral goals in human SC during a delay period between visual stimulation and motor execution. To test this, we used fMRI to measure SC activity while participants performed memory-guided pro- and anti-saccades. The anti-saccade trials provide the key test of our hypothesis, as these trials dislocate visual and motor responses in space. We examined the trial-wise time series of the population activity in the SC during the anti-saccade task. In addition, we used an inverted encoding model (Sprague & Serences, 2013) to characterize the topographic organization of SC activity during the task. The activity of each SC voxel was modeled as the weighted sum of a set of spatial basis functions spanning the locations of visual stimuli and saccade targets. These channel weights were then combined across voxels to generate reconstructions that recast the SC population activity during pro- and anti-saccade trials into visuotopic coordinates. First, we found robust and spatially specific univariate persistent activity during the delay period following presentation of the visual cue and but prior to execution of the saccade. This suggests that populations of neurons in the human SC are able to maintain task-relevant information throughout a long delay. Second, we also found that the early delay period activity of the SC reflected the location of the visual stimulus. However, as the delay period progressed, the locus of activity shifted from the visual stimulus to the location of the saccade endpoint. Thus, the dynamics of the human SC tracked the spatial and temporal aspects of the behavioral goal.

Title: Association of hippocampal D_1/D_2 receptor availability and neural activity during implicit encoding

Authors: *S. E. GROGANS[1], R. RASETTI[2], M. GREGORY[1], B. KOLACHANA[1], M. WINSTON[1], C. HEGARTY[1], A. IANNI[1], P. KOHN[1], J. H. CALLICOTT, III[3], D. R. WEINBERGER[4], K. F. BERMAN[5]

[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]CBDB, NIMH, NIH, Bethesda, MD; [3]DIRP, NIMH, NIH, Clin. and Translational Neurosci. Br., Bethesda, MD; [4]Lieber Inst. For Brain Develop., Baltimore, MD; [5]Section on Integrative Neuroimaging, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Hippocampal dysfunction is implicated in several neuropsychiatric conditions, including Alzheimer's disease and schizophrenia. The hippocampus (HIP) receives important dopaminergic input from the VTA and contains populations of both D_1 and D_2 receptors, which may be relevant to this structure's function in a way that could inform disease models. Prior research has suggested mnemonic functions may be reliant on HIP recruitment and HIP availability of dopamine receptors; additionally, activation of D_1 receptors alter excitability in the HIP and therefore influence memory encoding. However, work in other regions of the cortex propose that D_1/D_2 ratios determine signal-to-noise during cognitive processing. Based on these previous data, we hypothesized that increased HIP D_1/D_2 availability ratio would be positively correlated with increased HIP activation during episodic memory in a sample of healthy volunteers.

Fifty-four healthy volunteers (mean age=33.8±9.4; 24 women) underwent both PET and fMRI investigations. PET imaging measured DA receptor availability with [^{11}C]-NNC 112 (D_1 receptors) and [^{18}F]-fallypride (D_2 receptors), using time activity curves from the cerebellum and bilateral HIP as reference and of-interest regions, respectively, and non-invasive simplified reference tissue modeling. FMRI measured BOLD activation during the neutral image encoding condition of a simple implicit memory task well known to engage the HIP. We tested for voxelwise correlations between BOLD activation and the ratio of HIP binding potentials (BP_{ND}; D_1/D_2 ratio) for [^{11}C]-NNC 112 and [^{18}F]-fallypride. Results were considered significant at $p<0.05$, FWE-corrected within the HIP region-of-interest. Whole-brain analyses and retrieval performance effects were also examined.

HIP D_1/D_2 ratio (but not D_1 nor D_2 availability individually) positively correlated with activation in the left HIP ($p_{FWE\text{-}corrected\text{-}within\text{-}ROI}=0.009$). In the whole-brain analysis, hippocampal D_1/D_2 ratio was positively correlated with activation in dorsal anterior cingulate ($p_{FWE\text{-}corrected\text{-}whole\text{-}brain}=0.015$). Neither of these results changed when age and gender were used as covariates of no interest. Additionally, HIP D_1/D_2 ratio was not associated with performance.

Our results suggest that relative D_1/D_2 receptor availability in HIP may have importance in the neurophysiology of novel stimuli visual encoding. These findings provide insight into the role of DA receptors in episodic memory, suggesting that relatively increased D_1 with respect to D_2 may be advantageously associated with increased HIP engagement.

Inst., Univ. of California Berkeley, Berkeley, CA; [6]Dept. of Neurolog. Surgery and Physiology,, Univ. of California, San Francisco, CA

Abstract: Cognitive control requires working memory (WM) to maintain relevant information that provides a context for behavior. Efficient use of WM resources requires selectively encoding new representations (input gating) and selecting stored information to exert a contextual influence (output gating). In EEG, MEG, and LFP studies, several power-spectral features have been identified as mechanistic markers for exertion of cognitive control in frontal cortex. Specifically, intra-cortical beta events, frontal theta-synchrony, and PFC beta-gamma and theta-gamma interactions have been implicated with WM related functions. These functions are likely implemented by timing-dependent mechanisms in the frontal cortex. Within hierarchical cognitive control, the ordering of contextual information may influence these neural mechanisms for the purpose of facilitating WM input and output gating. Prior work suggests that a largely overlapping corticostriatal network facilitates both gating mechanisms. However, the relationship of these gating mechanisms and oscillatory markers of cognitive control function remains unknown. In order to discover the neurodynamic functions that underlie the input/output gating of WM, we recorded from intracranial electrodes while human patients performed a WM gating task. In each trial, subjects were presented with either a *context-item-item* sequence, permitting input gating, or an *item-item-context* sequence, necessitating output gating, and were asked to recall which presented *item* corresponded to the presented *context*. We analyzed the power-spectral profiles of each event and found (1) differential theta activity during output gating, (2) beta burst activity for items informed by a input-gated context, and (3) temporally-specific interactions between regions and frequency bands across the frontal cortex. Together,

these results inform a neurodynamic model for input gating and output gating mechanisms within frontal cognitive control networks.

Title: Load-related theta decrease in DLPFC during information maintenance in working memory predicts subsequent performance

Authors: *A. BRZEZICKA[1,3], J. KAMINSKI[1,4], A. MAMELAK[1], U. RUTISHAUSER[1,4,2]
[2]Dept. of Neurol., [1]Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]SWPS Univ. of Social Sci. and Humanities, Warsaw, Poland; [4]Caltech, Pasadena, CA

Abstract: Theta (3-8 Hz) oscillatory activity is thought to be crucial for maintaining information in working memory (WM). Whereas in animal work, the focus is on hippocampal theta, human WM studies are focused on cortical frontal-midline theta (Mitchell et al., 2008). Results from both lines of work show theta power increase with memory load. Here, we focused on the relationship between load-related theta power changes in dorsolateral prefrontal cortex (DLPFC). DLPFC is thought to be critical for the maintenance of information in working memory as shown by many monkey single unit and human fMRI studies. We performed human intracranial recordings in 12 neurosurgical, epileptic patients. We recorded local field potential (LFP) signals from depth electrodes implanted in DLPFC during a modified Sternberg task with three levels of memory load and pictures as a study material. We localized the most lateral DLPFC contacts for each patient (total of 48 DLPFC electrodes). We found a surprising pattern of theta power changes: it increased in the beginning of the task compared to baseline (t_{48}=2.38, p=0.021; M_{bas} = 0.021 [SEM=0.008]; M_{task} = 1.64, [SEM=0.056]) but showed a substantial load-depended decrease during the maintenance period of the task ($F_{2,46}$=27.34; p<0.0001, eta^2=0.54, linear trend $F_{1,47}$=53.81, p<0.0001, eta^2=0.53). This load-dependent decrease in theta predicted

individual differences in performance of the Sternberg task. Such that the bigger the theta change the faster (r=-0.393, p=0.006) and more accurate (r=-0.289, p=0.046) was the subject. In contrast, in the hippocampus (24 electrodes in total) theta power increases as a function of memory load $_{F2,22}$ = 4,01, p=0.033, eta^2=0.267. Those striking differences suggest that cortical theta in the DLPFC reflects neuronal processes distinct from those reflected by hippocampal theta. Lisman and Jensen (2013) postulated that a signature of excited (or engaged in task) cortex is a reduction in the power of theta (similar to alpha band), so we hypothesize that decreases in power are related to more effortful task completion. Such thinking is also supported by previously shown negative relationships between cortical theta power and fMRI BOLD changes. In addition, recent work shows that the extent of theta power decreases in cortical areas, including the DLPFC, predicts how well information will later be remembered in long-term memory tasks (Greenberg et al., 2015). Our observations extend this phenomenon to DLPFC theta during maintenance of information in working memory.

Title: The limits of unconscious working memory

Authors: ***M. PAYTON**[1], I. UL-HAQ[2], V. BABUSHKIN[4], K. K. SREENIVASAN[3]
[1]Psychology, New York Univ., New York, NY; [2]Div. of Sci. and Mathematics, [3]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates; [4]Div. of Sci. and Mathematics, New York Univ. - Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Working Memory (WM) is canonically defined as a conscious and effortful process that allows for the retention and manipulation of information over brief periods of time. Recent work has suggested that short-term maintenance can be achieved in the absence of subjective awareness of the memory item, challenging the long-held notion that WM is by definition a conscious process. In light of this work, an important goal is to understand which aspects of WM require conscious awareness.
The present study sought to test key properties of unconscious WM. Specifically, we were

interested in (i) whether unconscious WM representations can be manipulated; (ii) the degree to which features of an object can be bound together in unconscious WM; and (iii) the capacity limitations of unconscious WM. To address these questions, we had observers perform a delayed estimation task for spatial location. On each trial, observers were presented with a dot that appeared at a random location around an invisible annulus. The observers' task was to maintain the spatial location of this dot over a brief delay, and then report the remembered location with a mouse click. We manipulated conscious awareness of the dot stimulus using backward masking. At the end of each trial, observers rated their awareness of the dot stimulus on a standard 4-point perceptual awareness scale, a score of 4 indicating 'a very clear image' and a score of 1 indicating 'no information' (Sandberg et al., 2009). Analysis of unconscious data was limited to masked trials scored as 1 by the observer. To test whether unconscious WM representations could be manipulated, Experiment 1 required observers to mirror the remembered location over a randomly oriented line and subsequently rotate the mirrored location around the circle by 90 degrees. Subjects reported the end result of these two transformations. To test feature-binding and capacity limitations, Experiment 2 required observers to remember the locations of multiple colored dots and bind the dots' location and color.
Contrary to earlier studies on unconscious serial processing (Sackur & Dehaene 2009), Experiment 1 demonstrated that observers could perform serial spatial manipulations on unconscious WM representations. In Experiment 2, we found that observers could successfully perform feature binding at a set size of 2, although results were more variable as set size increased. Together, these results show that unconscious WM shares critical features with conscious working memory but with potentially stricter resource limitations.

Title: Ear morphometrics correlate with schizotypal inventory scores and SAT performance in sex- and side-specific manners

Authors: *J. CANNON[1], P. T. ORR[2]
[1]Dept. of Psychology, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Our lab has been studying the relationships among facial features and a number of cognitive (e.g., SAT) and personality (e.g., schizotypal) characteristics (Cannon et al., 2015). Embryological development of the face and anterior brain occur in synchrony, are often

influenced by common genes, and have the potential to be dramatically and characteristically altered by genetic abnormalities or environmental insults. Adhikari et al. (2014) performed a genome-wide association study that identified multiple loci associated with variations in human ear morphology. They found moderate and significant heritability in all ear characteristics measured. Here we examined relationships among Adhikari et al.'s ear morphology features and our behavioral measurements.

Left and right digital profile photographs were taken of undergraduates (N = 110; 74.5% female). Scoring with the same 0-2 ranking system utilized by Adhikari et al., paired blind observers evaluated 9 of 10 ear characteristics examined by Adhikari et al. The 10th feature, Protrusion, was not interpretable in our profile images. Inter-rater correlations were high ($r > .84$) and averages of the paired observers were used for statistical analyses. Pearson correlations were performed among ear measurements and overall/subscale scores of the Schizotypal Personality Questionnaire (SPQ) and Math/Verbal SAT scores.

Significant for Averaged Ears in Males: Tragus Size (TS) with Verbal-SAT (-.564). Significant for Averaged Ears in Females: Crus Helix Expression (CH) with Cognitive/Perceptual SPQ factor (C/P) (-.268), CH with Ideas of Reference (IR) (-.308), Lobe Attachment (LA) with Odd/Eccentric Behavior (O/E) (-.251), Lobe Size (LS) with O/E (.309), and Helix Rolling (HR) with Constricted Affect (CA) (.372).

Significant for Left Ears in Females: Superior Crus of Antihelix Expression (SCA) with C/P (-.267), CH with IR (-.330), SCA with No Close Friends (NCF) (.393), HR with CA (.362), and Folding of the Antihelix (FA) with CA (.374). Significant for Left Ears in Males: FA with C/P (.492).

Significant for Right Ears in Females: Darwin's Tubercle (DT) with Verbal-SAT (.362), LS with Disorganized SPQ Factor (D) (.259), CH with Odd Beliefs/Magical Thinking (OB/MT) (-.262), CH with NCF (.234), FA with OB/MT (.305), SCA with NCF (.247). Significant for Right Ears in Males: HR with CA (.259).

These data suggest that ear morphology may be a valuable complement to facial features when assessing human cognitive and personality variables. Accumulating genetic literature relating to the development of facial and ear morphologies could provide clues to the etiology of normal and abnormal behavioral states.

Title: Hippocampal subfield analysis in schizophrenia psychosis

Authors: *J. M. PEREZ, K. GLEASON, S. GHOSE, T. KIM, C. A. TAMMINGA
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Schizophrenia (SZ) is one of the thirty most incapacitating conditions and affects over 67 million people worldwide; suicide occurs in 10% of those diagnosed with schizophrenia. Symptoms are persistent and often severe. They include hallucinations, delusions, thought disorder, and deficits in executive function and memory. Treatments available are not curative. 20-40% of people with SZ are entirely resistant to treatment and less than 20% completely recover. The complex symptom manifestations of SZ lack a molecular pathology. Consequently, advances in novel treatment directions are limited. We have examined postmortem human hippocampal tissue, directed by human in vivo imaging data, for molecular causes and correlates of the illness. We conceptualize psychosis as a disorder of learning and memory that critically involves dentate gyrus (DG) and CA3. We have shown considerable and consistent evidence for deficits in DG and CA3 hyperactivity with molecular and cellular changes implicating homeostatic plasticity changes within CA3. Specifically, we show increased perfusion in CA3 in schizophrenia, a correlate of neuronal activity, as well as an increase in spine density and increased protein levels of synaptic plasticity markers like GluN2B and PSD-95 in CA3 and decreased GluN1 in DG in schizophrenia. We suggest that reduced glutamatergic neurotransmission from DG may generate an increase in CA3 basal activity through homeostatic changes, possibly leading to illogical memory formation with psychotic content.
In a hypothesis generating approach, we have analyzed the transcriptome from all three hippocampal subfields from control (n=13) and schizophrenia cases (n=7 “off-drug”; n=6 “on-drug”), in a global and unbiased manner, using whole transcriptome sequencing to identify additional molecular changes, which have not been hypothesized. We have conducted differential gene expression analysis in DG, CA3, and CA1 to identify individual genes that are significantly differentially expressed between schizophrenia and control cases. We have also used the weighted gene coexpression network analysis (WGCNA) package to perform differential coexpression analysis to identify networks of genes that may differ functionally between the schizophrenia and control cases. We expect to show a network of abnormalities in the individual hippocampal subfields, which support the psychosis molecular blue print we have shown with our previous hippocampal subfield analyses.

Title: Altered gene and protein expression of proinflammatory cytokines in the postmortem brain of schizophrenia patients

Authors: *H. ZHANG, H. RIZAVI, X. REN, G. PANDEY
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Abnormalities of the immune function have been observed to be associated with the pathophysiology of schizophrenia (SZ). This is primarily based on the observation that the levels of proinflammatory cytokines, which are released from the immune cells as a result of inflammation or stress, are abnormal in the serum of patients with SZ compared with normal control (NC) subjects. However, it is not known if similar cytokines abnormalities are also present in the brain of SZ patients. In an earlier study, we reported abnormal gene expression of proinflammatory cytokines in the brain of depressed suicide victims. To further examine the involvement of inflammatory cytokines in the brain of SZ patients, we determined the protein and mRNA levels of TNF-α, IL-1β, IL-6, IL-8, IL-10, IL-13, LTA and IL-1RA in the prefrontal cortex (PFC, Brodmann area 9) of SZ patients. The study was performed in the PFC (Brodmann area 9 [BA9]) of 31 SZ patients (16 SZ suicide victims and 15 non-suicide SZ patients) and 24 NC subjects. Subject diagnosis was based on the Structured Clinical Interview for DSM-IV. The postmortem brain tissues were obtained from the Maryland Brain Collection. Protein levels of cytokines were determined by ELISA, and western blot and mRNA levels of cytokines were determined by the qPCR method. We found that the protein and mRNA expression levels of the cytokines TNF-α and IL-6 are significantly increased and those of IL-10 are significantly decreased in the PFC of SZ patients. No difference in the protein and mRNA levels of IL-1β, IL-13, and IL-1RA was observed between SZ patients and NC subjects. The protein expression levels of IL-8 were significantly decreased and those of LTA were significantly increased in SZ patients, but no significant difference in the mRNA levels of IL-8 and LTA was observed between SZ patients and NC subjects. These results suggest abnormalities of specific pro- and anti-inflammatory cytokines in the postmortem brain of SZ patients. These observations may have important implications in understanding the role of inflammatory cytokines in the pathophysiology of SZ.

Title: Effect of single nucleotide polymorphisms in fibroblast growth factor 14

Authors: *J. DI RE[1], P. A. WADSWORTH[2,3], F. LAEZZA[3,4,5]

Abstract: Schizophrenia (SZ) is a complex syndrome comprising of positive, negative and cognitive symptoms with still limited medications. One barrier to medication development is the lack in knowledge of the causative links to disease heterogeneity. As the first step in understanding this complex biology, searching for functional effects of rare, naturally occurring single nucleotide polymorphisms (SNPs) in genes associated with known endophenotypes of SZ might provide new insights in disease classification and targeted therapeutic development. Recent studies have provided breakthrough results demonstrating a novel link between SZ and Fibroblast Growth Factor 14 (FGF14), a molecular component of the neuronal voltage-gated Na+ (Nav) channel complex and a regulator of synaptic plasticity. Previous studies from our group found that *Fgf14-/-* mice present with endophenotypes of SZ associated with cognitive impairment, results there were further supported by decreased expression of *FGF14* and known markers of SZ (such as *PVALB*, *GAD67* and *VGAT*) in patient-derived post-mortem tissue. We have also shown that FGF14 monomer can form homodimers that are structurally and functionally distinct from the FGF14:Nav channel complex. Building on these results, we performed a SNP analysis of FGF14 in publically available human genomic data banks and identified 83 SNPs that are predicted to change the protein coding from wild type to missense mutations or truncated products. Out of these SNPs, we are currently interrogating 9 mutations based on protein:protein interaction sites of FGF14, including sites important to its homodimer as well as the FGF14:Na_V complex. Initial screening assays of these 9 SNPs revealed that 2 SNPs, $FGF14^{F25L}$ and $FGF14^{S231N}$ exhibited decreased ability to dimerize, while other 2 SNPs $FGF14^{Y158N}$ and $FGF14^{G243D}$ exhibited opposite phenotypes ($p<.001$). In addition, all SNPs except for $FGF14^{F25L}$ have an opposite effect on complex formation between mutated FGF14 and Na_V compared to dimerization ($p<.01$). These mutations are expected to have important effects on the balance of FGF14 in its monomer and dimer form, which may in turn affect neuronal excitability and synaptic plasticity. These results may lead to a better understanding of the genetic cause of the disease, as well as new biomarker discovery and disease classification for targeted therapeutic discovery.

Title: Resting-state connectivity in healthy adults is associated with polygenic risk for schizophrenia in dorsal frontal cortex

Authors: *M. O'BRIEN[1], M. D. GREGORY[2], M. L. ELLIOTT[2], J. P. MIKHAIEL[2], B. S. KOLACHANA[2], J. B. CZARAPATA[3], D. P. EISENBERG[4], K. F. BERMAN[5]

Abstract: Schizophrenia is a severe psychiatric disorder characterized by delusions, hallucinations, and thought disorder, as well as negative symptoms, such as impaired cognition and blunted affect. Though schizophrenia heritability is estimated to be approximately 80%, individual single nucleotide polymorphisms (SNPs) only account for a small proportion of this heritability, suggesting the involvement of complex polygenic mechanisms. Conversely, polygenic risk scores (PRS) can be used to explain 10-20% of schizophrenia heritability. In the present study, we performed a connectome-wide association study (CWAS) of resting-state fMRI data in healthy adults to identify brain regions where schizophrenia-based polygenic risk is associated with functional connectivity. Eighty-three healthy adults (36.7+/-11.6yrs, 46 women) underwent 3T resting-state fMRI scanning and genotyping with Illumina genome-wide SNP chips. After imputation, schizophrenia PRSs were calculated for each participant using SNPs with $p<0.0001$ in the PGC-SCZ2 results using PLINK. These scores were used in a CWAS to identify regions where whole-brain connectivity was related to schizophrenia-based genetic risk. Results were thresholded at $p<0.05$, FWE-corrected. Data from significant clusters were used in post-hoc, seed-based analyses to delineate the connectivity patterns driving the association. To corroborate our results, we used data from 101 healthy young adults from the publicly available PNC dataset (19.4+/-1.1yrs, 41 women) to perform seed-based connectivity analyses of the same regions of interest. In the discovery dataset, an area of left dorsal frontal cortex (BA10) was the only region where schizophrenia polygenic risk was associated with whole-brain connectivity. A post-hoc seed-based analysis demonstrated that connectivity of BA10 to bilateral insula and inferior parietal lobules (BA39/40) drove this association. In the PNC dataset, connectivity of BA10 to the same left BA39/40 region was related to schizophrenia polygenic risk ($p<0.05$, uncorrected), though we did not replicate findings in other regions. Here, we show that

functional connectivity of BA10 with insula and BA39/40 is associated with schizophrenia polygenic risk in healthy adults. These results are consistent with prior work identifying these regions as hubs of dysfunction in schizophrenia. Our study elucidates the relationship between network functioning and continuums of polygenic risk, and suggests that these continuums exist even in healthy populations. Future work will further characterize these associations by performing similar evaluations in patients with schizophrenia.

Title: Polymorphism of the IL-6 SNP rs1800795 increases IL-6 production and is associated with symptom severity in chronically ill schizophrenia patients

Authors: *D. BOERRIGTER[1], T. W. WEICKERT[1,2,3], R. LENROOT[1,2], M. O'DONNELL[2], C. GALLETLY[4,5,6], D. LIU[4,5], C. SHANNON WEICKERT[1,2,3]

Care (SA) Mental Hlth., Adelaide, Australia

Abstract: Background: Recent studies have shown a significant role of cortical and peripheral cytokines in schizophrenia, specifically interleukin-6 (IL-6). Polymorphism of rs1800795 in the IL-6 gene has been associated with IL-6 production, where carriers of the mutant C allele are found to have lower IL-6 production. Blood IL-6 levels have been associated with symptom severity in (acute paranoid) schizophrenia. In this study, we tested if the rs1800795 polymorphism would be associated with blood IL-6 levels and symptom severity in a population of chronic schizophrenia patients. We hypothesized carriers of the C allele would have lower levels of IL-6 overall and may have lower symptom severity in people with schizophrenia.
Methods: Whole blood, serum and plasma from 78 controls and 95 schizophrenia or

schizoaffective patients (males and females) with mild-to-moderate symptom severity was collected, genomic DNA and messenger RNA was extracted, followed by first strand synthesis. The rs1800795 Single Nucleotide Polymorphism (SNP) was assayed and peripheral IL-6 mRNA expression levels were measured by RT-qPCR. Plasma concentrations of IL-6 were measured with the MAGPIX system. The Positive and Negative Syndrome Scale (PANSS) was administered by trained psychologists or psychometricians to obtain measures of positive, negative, total symptom severity and general psychopathology. Student t-tests were conducted for carrier vs. non-carrier analyses and ANOVA's for genotype analyses.
Results: Overall, we found that 62% of the healthy controls and 63% of the people with schizophrenia were either CG or CC (C carriers) at rs1800795 polymorphism (p=0.88). In contrast to our hypothesis, we found that C allele carriers have increased peripheral IL-6 expression (p=0.03) and increased IL-6 in plasma (p=0.04). In schizophrenia, C allele carriers had lower negative symptom scores (p=0.03) than non-carriers, no significant changes were found for positive, general or total symptom scores.
Conclusions: Our results show rs1800795 polymorphism relates to increased IL-6 production in blood in our cohort, as opposed to some previous studies. Our findings support the regulatory effect of this SNP, but we suggest that the impact of this genetic change may be context dependent. We did not find an increased incidence of the C allele carriers in schizophrenia. C allele carriers had lower negative symptom scores than non-carriers, suggesting that higher IL-6 production may work to supress negative symptoms in schizophrenia. While this finding supports our initial hypothesis of lower symptoms in C allele carriers it suggests the mechanism may be distinct than originally thought.

Australia, Sydney, Australia; [3]Psychiatry, McGill, Montreal, QC, Canada; [4]Biomed. Sci., Cooper Med. Sch. of Rowan Univ., Camden, NJ

Abstract: Schizophrenia (SZ) is a neurodevelopmental, partially inherited, chronic psychotic disorder affecting 0.5 - 1.0% of the population. While current antipsychotic medications can treat the positive symptoms of SZ, including hallucinations and delusions, there is no FDA-approved therapy for the negative symptoms of SZ, including apathy, avolition and poverty of thought. Despite evidence that the heritability of SZ is ~64%, the identification of common alleles, via leukocyte DNA, with even a moderate increase in the risk for SZ has proven difficult. Therefore, alternative approaches to identifying genetic variants associated with SZ are needed. We examined the role of neuronal somatic mutation in increasing the risk for developing SZ. While somatic DNA variation wouldn't explain the heritability of SZ, it would explain the "environmental" risk of SZ. We focused on the study of somatic neuronal DNA variation mediated by long interspersed nuclear element 1 (LINE1 or L1) retrotransposons, a type of mobile DNA element, with the potential of disrupting genes, which may increase the risk for SZ. DNA was isolated from NeuN+ dorsolateral prefrontal cortex neuronal nuclei from 48 SZ persons and 48 age, sex and ethnicity matched controls. L1 specific DNA was amplified using PCR, and L1 amplicons were subject to next generation sequencing. Sequence data will then be aligned to the human reference genome to identify neuronally expressed genes with de novo L1 insertions, and bioinformatics will be used to determine the relevant biological pathways.

Title: Dysbindin regulates mitochondrial fission in hippocampal excitatory neurons

Authors: *J. ZHAO[1], Z. LI[2]
[1]NIMH/NIH, Bethesda, MD; [2]NIMH, Bethesda, MD

Abstract: Background: Mitochondria have several functions, such as the production of energy and reactive oxygen species (ROS) and calcium buffering, which are essential for neuronal activity and connectivity. Mitochondria form networks in the cell. The mitochondrial network is

dynamically regulated by mitochondrial fission and fusion, which are required for the biogenesis and quality control of mitochondria. Mitochondria dynamics is controlled by mitochondrial fission and fusion proteins, such as MFN-1, DLP1, FIS-1 and so on. Earlier reports have implicated a possible linkage between mitochondrial dysfunction and schizophrenia. However, how schizophrenia risk genes regulate mitochondrial functions and mitochondrial network have not been investigated. Result: In our study, we investigated the role of the human schizophrenia susceptibility gene DTNBP1, encoding dysbindin protein, in mitochondria dynamics. We found that a lack of dysbindin in excitatory neurons results in longer mitochondria and less mitochondrialin postsynapses. These impariments were rescued by dysbindin-1c.Dysbindin significantly changed the subcellular oligomeration of DLP1 and acvitity-induced mitochondrial fission. Conclusion: Our results indicate that dysbindin regulates mitochondrial dynamics and function through DLP1, and therefore dysbindin deficiency may contribute to impaired neural network activity in schizophrenia by causing mitochondrial defects.

Title: Chromatin immunoprecipitation followed by deep sequencing reveals differential repressive chromatin sites in schizophrenia post mortem brain

Authors: B. M. FEINER[1], J. K. MELBOURNE[2], C. ROSEN[3], *R. P. SHARMA[4]
[1]Psychiatry, UIC Psychiatry, Chicago, IL; [2]Psychiatry, [3]Univ. of Illinois At Chicago, Chicago, IL; [4]Dept Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Aberrant chromatin modification levels have repeatedly been shown in the brains and immune cells of patients with schizophrenia. However, the majority of these studies measured total levels of histone modifications from populations of cells, which only allows for quantification of a total increase or decrease without revealing the genomic locations of the modified chromatin. Chromatin immunoprecipitation followed by deep sequencing (ChIP-Seq) allows us to generate a map of the genome that includes differential sites of a chromatin modification of interest. By targeting di-methylated lysine 9 of histone 3 (H3K9me2), a modification that has never been done before in this way in human post-mortem brain, we have discovered over one hundred highly significant differential sites in schizophrenia prefrontal cortex (N=15) when compared to controls (N=15). Bioinformatics and pathway analysis revealed

significant enrichments of genes previously determined to be involved in biological areas important to schizophrenia, such as the synapse or formation of the cortex. To determine functional significance, genes with promoters that had significantly increased or decreased H3K9me2 levels were selected and qPCR was performed. mRNA expression analysis revealed that expression levels correlated well with chromatin modification levels, i.e. genes with H3K9me2-enriched promoters had less mRNA expression and vice versa. Utilization of this method has already provided a number of candidate genes for potential future studies (e.g. CRISPR-directed promoter methylation in cells), and it could be a useful tool in understanding a complex and heterogeneous disorder such as schizophrenia.

Rigshospitalet, Copenhagen, Denmark; [4]Fac. of Hlth. and Med. Sci., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Genetic and environmental factors interact to influence an individual's risk for schizophrenia. Immediate early gene transcription factors (IEG-TFs) are rapidly activated by environmental events such as stress and, in turn, dictate the molecular response of the brain to these events. Dysfunction of IEG-TFs may provide a mechanism to explain the dual genetic and environmental contributions to risk for mental illness. Indeed, the IEG-TF *early growth response 3* (*Egr3*) has been associated with schizophrenia in multiple populations. *Egr3* expression is decreased in the postmortem brains of patients with schizophrenia. We have previously

demonstrated a link between *Egr3* and the schizophrenia candidate gene, *Htr2a*, which encodes the serotonin 2A receptor (5-HT_{2A}R). *Egr3-/-* mice display behavioral abnormalities characteristic of a schizophrenia-like phenotype and have reduced cortical 5-HT_{2A}R levels. Likewise, patients with schizophrenia also display a decrease in cortical 5-HT_{2A}Rs. Our prior work has shown that sleep deprivation (SD), a mild stressor known to activate *Egr3*, increases *Htr2a* expression in the cortex of WT, but not *Egr3-/-*, mice, detected by quantitative real-time polymerase chain reaction (qRT-PCR). In the current study, we examined the cortical regions in which SD activates *Htr2a* expression, and whether this induction requires *Egr3*, using *in situ* hybridization (ISH). In addition, we examined whether this increased expression in response to SD resulted in an increase in level of cortical 5-HT_{2A}R protein detected by 3H-MDL100907 binding. Our results from both ISH and radioligand binding indicate that SD increases 5-HT_{2A}R expression in regions of the frontal cortex of WT mice, but this induction is absent in mice lacking *Egr3*. These findings provide insight into stress-induced cortical abnormalities that are also observed in patients with schizophrenia.

Title: Exploring polygenic risk in cognitive trajectory subgroups of schizophrenia: Unexpected differences in correlations with cognition

Authors: *S. R. ZAIDMAN[1], E. GIANGRANDE[2], D. R. WEINBERGER[3], K. F. BERMAN[4], D. DICKINSON[5]
[1]Clin. and Translational Neurosci. Br., NIMH, Bethesda, MD; [2]Psychology, Univ. of Virginia, Charlottesville, VA; [3]Lieber Inst. For Brain Develop., Baltimore, MD; [4]Section on Integrative Neuroimaging, Natl. Inst. of Mental Hlth., Bethesda, MD; [5]Clin. and Translational Neurosci. Br., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Background:
The purpose of this study was to evaluate associations between cognition and risk profile scores (RPS) for schizophrenia patients divided into three subgroups determined by premorbid and fluid intelligence.
Methods:
550 people with schizophrenia, 432 of their unaffected siblings, and 1127 community controls provided demographic and clinical information, completed cognitive and symptom assessments

and provided blood for genetics analyses, as part of the NIMH Study of Schizophrenia Genetics. We performed cluster analyses (SPSS) in the schizophrenia cases to identify cognitive subgroups, using only “premorbid” (WRAT) and “current” (WAIS) IQ as clustering indicators, with the hypothesis that different patterns of performance identify subgroups with distinct trajectories of cognitive development. Schizophrenia RPS for all individuals were calculated at 10 thresholds based on illness-associated genetic variants identified by the multi-national Psychiatric Genetics Consortium. Across RPS thresholds, we used planned hierarchical regression to test the association of RPS with general cognitive ability (“g”) in the derived cognitive subgroups, controlling for age, sex, and population stratification.

Results:

Based on 1000 runs, three cluster solutions were the most frequent result, suggesting one subgroup with high scores on both WRAT and IQ (Cognitively Stable), one with low scores on both WRAT and IQ (Pre-Adolescent Impairment), and one with high scores on the WRAT and low IQ (Adolescent Decline). The Cognitively Stable subgroup showed significant associations between RPS and “g” at six of 10 RPS thresholds (e.g., at RPS_0.05 p=.002; R^2=0.047). The Pre-Adolescent Impairment subgroup showed a pattern of similar but non-significant associations. However, the Adolescent Decline subgroup showed no evidence of association of schizophrenia RPS with “g” at any threshold.

Conclusions:

Cognitive impairment is recognized as a core feature of schizophrenia. These analyses suggest that for some individuals with schizophrenia, common genetic risk for the condition is also predictive of cognitive impairment. However, for another subgroup, polygenic risk for schizophrenia is entirely “decoupled” from cognition. Differences in cognitive profile and in the association of cognitive performance with common genetic risk for schizophrenia may point to important distinctions in etiology. Ongoing analyses aim to further characterize differences between these subgroups, particularly in terms of environmental factors that could impact development and cognition.

Abstract: Schizophrenia (SCH) is a serious neuropsychiatric disorder with a severe impact on patients' lives. Based on the experimental models it was concluded that altered (decreased) activity of N-methyl-D-aspartate receptor (NMDAR) induces behavior resembling the clinical manifestations of schizophrenia. Therefore, we aimed to determine gene variants of the glutamate receptor regulatory elements and their contribution to the emergence and development of schizophrenia. We were focused on an in-depth analysis of genes encoding NMDARs in selected subgroup of SCH patients showing strong and unique disease phenotype linked to early onset of psychosis. Since promoter regions of gene is the key element that regulates the production of new receptors and thus may be directly responsible for lower gene expression we analyzed distribution and frequency of SNPs in the extended promoter regions of NMDARs. Using NimbleGene SeqCap EZ system we have observed and subsequently analyzed more than 170 SNPs in promoter regions of six NMDAR genes. We found two times higher frequency of SNPs in promoter regions of GluN2B and 3B subunits compared to the other ionotropic glutamate receptors we analyzed. This indicates a greater probability of a change in the activity of these promoters which could also cause a decrease in the overall expression of these subunits. We also found several SNPs in GluN3A promoter region with different distribution between our group of SCH patients and control healthy volunteers. Moreover, one fourth of SCH patient samples carried specific combinations of SNPs in promoter region that we did not observed in control samples. In summary, our data confirmed previous observations that the genetic information of regulatory elements of NMDARs is impacted in SCH. We assume that our data could contribute to the identification of the set of genetic markers indicating higher susceptibility to emergence and development of schizophrenia.

Title: Using random forest machine learning to identify multi-genetic influences on neural activity underlying motivation

Authors: *Q. CHEN[1], R. W. LEFCO[1], R. E. STRAUB[1], K. K. NICODEMUS[2], D. R. WEINBERGER[1], C. F. ZINK[1]
[1]Lieber Inst. For Brain Develop., Baltimore, MD; [2]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Determining genetic influences on human neural activity patterns is likely highly relevant to clinical advances in the treatment of heritable mental illnesses, such as schizophrenia. Traditional techniques in "imaging genetics" - the correlation of genetic variation with neuroimaging signals to speak to cellular/molecular influences - are limited by testing only the effects of one or a few variants at a time without accounting for multi-genetic effects/epistasis, and the variations selected may have limited involvement. We overcome these challenges using an innovative imaging genetics approach that utilizes Random Forest (RF) machine learning to perform a multiple regression. RF is a high-dimensional, non-parametric predictive model composed of a collection of regression (or classification) trees. RF has the potential to uncover interactions among multiple genes that may exhibit only weak main effects, thus providing the percent of variance explained in a signal by multi-genetic effects. It has the advantage of being able to handle large numbers of genetic variants. It also provides an importance score for each variable, rendering RF capable of identifying genetic variations that are most predictive of a given neural activity, which can narrow the focus of future investigations on particular promising genes. Here, we focus on motivation neural activity because lack of motivation is a debilitating symptom of schizophrenia that is generally unimproved by current anti-psychotic medications. Using fMRI, we precisely isolate motivation-related striatal activity in 86 healthy Caucasian adults. Genetic variations of interest were limited to known, common (MAF > 0.15), functional (significant eQTLs) single nucleotide polymorphisms (SNPs) in dopaminergic, glutamatergic, GABAergic, and cholinergic signaling genes because of their well-characterized roles in the striatum. Separate RF regressions were conducted on "gene-sets" categorized by neurotransmitter system. We report the gene-sets that predict a significant amount of variance in the imaging signal and the genes/genetic variations ranked as most influential. We find a significant multi-genetic effect of SNPs in GABA signaling genes on motivation-related striatal activity, with SNPs in GAD2 and subunits of the GABA-A receptor being most important. Our findings implicate the GABA signaling pathway as particularly important for motivation-evoked activity

in the striatum and provide evidence for the utility of the usage of RF multiple regression in imaging genetics to determine multi-genetic/epistatic influences on human neural activity.

Title: Maternal immune activation impacts schizophrenia-related microRNA related to neuroinflammation

Authors: *S. K. AMOAH[1], B. A. RODRIGUEZ[1], C. N. LOGOTHETIS[1], T. R. YELLOWHAIR[2], J. P. WEICK[1], L. L. JANTZIE[1,2], N. MELLIIOS[1]

Abstract: Schizophrenia and bipolar disorder are heterogeneous psychiatric conditions with elusive pathogenesis. Given that protein-coding genes inhabit less than half of the human brain transcriptome it has been speculated that actively transcribed non-coding RNAs (ncRNAs) could contribute significantly to the pathophysiology of psychiatric disease. microRNAs (miRNAs) are a subtype of small evolutionarily conserved ncRNAs that have been shown to regulate several aspects of brain development and synaptic plasticity. Maternal immune activation (MIA) during pregnancy can increase the prevalence of neurodevelopmental disorders, such as schizophrenia, in offspring. We hypothesized that inflammation-related miRNAs (inflammiRs) are altered in the brains of psychiatric patients, and that this could be related to prenatal inflammation. We also tested that MIA in rats would yield similar changes. Employing methods that selectively detect the mature miRNA transcript, we screened and validated numerous differentially expressed inflammiRs altered in postmortem brains from the orbitofrontal cortex (OFC) of schizophrenia and bipolar disorder patients. Results indicate that miR-223 was the most robustly increased inflammiR transcript in schizophrenia brains ($p < .001$). Subsequently, we observed reductions in several of its validated neuronal targets, such as N-methyl D-aspartate receptor subtype 2B (NR2B) and Glutamate receptor 2 (GRIA2). Interestingly, levels of miR-223 were positively correlated with the expression of inflammatory genes, such as Alpha 1-antichymotrypsin (AACT or Serpina3) ($p < .01$) and interleukin 6 (IL-6), and yet showed significant negative associations with its validated targets NR2B ($p < .05$) and GRIA2 expression ($p < .01$). Notably, miR-223 levels were upregulated in embryonic day 17 (E17) brains following intraperitoneal (i.p.) administration of lipopolysaccharide (LPS, 100μg/kg, once daily) on E15 and E16, corroborating our clinical data ($p < .001$). Together, our data show that altered expression of inflammiRs in

schizophrenia can influence NMDA and glutamate receptor levels in human orbitofrontal cortex and could be associated with maternal immune activation. Experiments using human stem cell-derived neuronal cultures and additional rodent models of MIA are underway to evaluate effects of knockdown of miR-223 on microglia and synaptic plasticity.

Title: Study of the functional importance of DISC1 Serine 713/710 phosphorylation in brain development and cognitive behavior in human subjects and in novel mouse models

Authors: *H. JAARO-PELED[1], N. GAMO[1], Y. HORIUCHI[1], S. ISHII[4], K. ISHII[1], K. NISHIHARA[4], Z. HO[2], S. KULASON[3], S. MORI[2], D. SCHRETLEN[1], H. OKANO[4], T. RATNANATHER[3], M. MILLER[3], K. ISHIZUKA[1], A. SAWA[1]

Abstract: DISC1 is involved in many aspects of brain development and function, however, the regulation of its function is poorly understood. We previously identified phosphorylation of mouse Disc1 Serine 710 (S710) as a critical switch from neural progenitor proliferation to migration in the developing cortex using *in utero* electroporation. This study's objectives are (1) to test the significance of this finding in humans using a multifaceted approach and (2) to use newly generated mouse models in which Disc1 S710 has been mutated to test the causality of this phosphorylation in brain development and behavior.
For the human part of the study we collected olfactory cells and fibroblasts from psychotic subjects and from healthy controls, and performed neurocognitive assessments and structural MRI. Using olfactory neurons we found that psychotic subjects had lower phosphorylation levels of DISC1 at S713 (homologous to mouse S710) than controls. Using induced pluripotent stem cells derived from the subjects whose olfactory neurons showed low phosphorylation of DISC1 at S713, we detected delayed neuronal maturation. We also demonstrated a positive correlation between the phosphorylation level in olfactory neurons and the thickness of the anterior cingulate cortex and working memory/attention.
For the mouse part of the study we generated point mutants at S710 using CRISPR technology.

We generated a phospho dead mutant, S710Alanine and a phospho-mimetic mutant, S710Glutamate. The mice are viable and grossly normal even as homozygotes. We performed *ex-vivo* MRI to test the effect of S710A on brain anatomy at P28 (juvenile) and P70 (young adulthood). We found several abnormalities including smaller frontal association cortex, which we are following on with immunohistochemistry. We are also performing neuronal proliferation and migration assays and behavioral testing focusing on cognitive function.
In conclusion, phosphorylation of DISC1 at Serine 713/710 is critical for maturation of neural progenitors, and correlates with human brain development and behavior relevant to psychosis and cognitive deficits. Using our novel mouse models we aim to show causality of this phosphorylation towards these phenotypes.

Title: Medial septum differentially regulates spontaneous dopamine neuron activity in the ventral tegmental area and substantia nigra pars compacta via distinct neurochemical pathways

Authors: *D. M. BORTZ, A. A. GRACE
Dept. of Neuroscience, Psychiatry, and Psychology, Ctr. for Neurosci., Univ. of Pittsburgh, pittsburgh, PA

Abstract: Disruptions in dopamine (DA) signaling are central to the pathophysiology of several major psychiatric disorders. Thus, the discovery of novel therapeutic approaches that normalize DA signaling is a major focus of research. One pathway that is critical for DA regulation originates from the ventral subiculum (Vsub) of the hippocampus and controls ventral tegmental area (VTA) DA neuron activity. A relatively unstudied regulator of hippocampal function is the medial septum (MS); a sub-region of the cholinergic basal forebrain that innervates the hippocampus, including the Vsub, via cholinergic and GABAergic projections, drives hippocampal theta rhythms, and affects goal-directed behavior. Despite this, it has never been

determined if the MS is an afferent regulator of the midbrain DA system, and therefore may be a novel therapeutic treatment target. This question was addressed by infusing NMDA (0.75 µg/0.2 µL) into the medial septum of anesthetized male Sprague-Dawley rats and recording dopamine neuron activity in the VTA and substantia nigra pars compacta (SNc), an adjacent DA region also implicated in psychopathology. MS activation produced a prolonged 71% increase in the number of spontaneously active DA cells in the VTA, and an opposing 40% decrease in the number of active DA cells in the SNc, compared to vehicle infusions. Effects in both the VTA and SNc were dependent on the Vsub as infusion of TTX (1 µM /0.5 µL) into the Vsub reversed population activity changes in both regions. Interestingly, effects in the VTA and SNc were precipitated by different neurotransmitter projections from the MS, with infusion of muscarinic antagonist scopolamine (8 µg/1.0 µL) into the Vsub preventing MS activation-induced DA population activity changes in the VTA, but not the SNc; whereas Vsub infusions of GABAergic antagonist bicuculline (12.5 ng/0.5 µL) prevented population activity changes in the SNc, but not the VTA. Furthermore, the ventral pallidum (VP) was necessary for effects in both the VTA and SNc; however, bicuculline (1 ng/0.2 µL) infusion into the rostral VP selectively prevented population activity increases in the VTA, while bicuculline infusion into the caudal VP selectively prevented population activity decreases in the SNc. These findings demonstrate that distinct septohippocampal pathways play a key modulatory role in the regulation of meso-striatal DA transmission originating from both the VTA and SNc, indicating this pathway may present novel therapeutic approaches for several psychological disorders.

Title: Molecular mapping of the human thalamus. Relationship with thalamocortical wiring and role in schizophrenia

Authors: *R. CALZAVARA[1], H. AKIL[1], J. D. BARCHAS[2], W. E. BUNNEY[3], F. S. LEE[2], R. M. MYERS[4], A. F. SCHATZBERG[5], S. J. WATSON[1]

Abstract: The thalamus is a key structure for relaying and integrating multi-functional information for perception, action and cognition within the cortex. Anatomical and functional data indicate that thalamo-cortical connectivity is impaired in schizophrenia. In particular, dysfunctional connectivity with frontal lobe areas, such as the dorsolateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC), may represent a potential neural substrate for cognitive dysfunction. As a first step toward a cell type specific model of cortico-thalamic fine wiring in schizophrenia, we investigated the basic neurochemical and molecular mapping of the thalamus in control subjects. In particular, we focused on the nuclei connected to frontal cortex, such as the medial dorsal (MD) nucleus. We identified molecular markers of thalamic neurons and we used in situ hybridization to investigate the relative cell expression and distribution of these markers in the thalamus. Preliminary results indicate a complex neurochemical map in which some markers have complementary or similar distributions. In particular, some marker distributions seem to overlap in specific thalamic nuclei, such as observed for the cell clusters in the MD nucleus. This may indicate that thalamic cells can be identified by a unique set of molecular markers. The relative expression of these markers and their distributions in the thalamic relay nuclei is thought to be associated with cell development and neurotransmitter function, and therefore can be related to specific thalamo-cortical circuits. The major goal of our study is to test whether these thalamo-cortical circuits, and potential selective cell types, are particularly affected in schizophrenia. Thus, this gene-expression map of the human thalamus would guide our next steps in the investigation of thalamic gene-expression patterns in schizophrenia.

Title: Immune activation across the visuospatial working memory circuit in schizophrenia

Authors: *A. R. LOCKER[1,2], E. SIPPLE[2], P. LIDSTONE[2], D. VOLK[2]
[1]Psychiatry, UPMC, Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cognitive impairments, including deficits in visuospatial working memory, are debilitating features of schizophrenia. Immune activation, indicated by higher transcript levels for cytokines and interferon-induced transmembrane proteins (IFITMs), have been reported in the prefrontal cortex (area 9) in schizophrenia. The transcription factor nuclear factor-κB (NF-κB) regulates the expression of these IFITM variants as well as the same cytokines that are overexpressed in schizophrenia. We recently found higher mRNA levels for multiple NF-κB family members (NF-κB1, NF-κB2, RelA, cRel) and initiation receptors (IL-1R, TNFR) in the canonical NF-κB activation pathway in area 9 of schizophrenia subjects. Consequently, we examined whether levels of these NF-κB-related markers are higher throughout cortical regions in the visuospatial working memory circuit, including dorsolateral prefrontal (area 46), posterior parietal (area 7), and visual (areas 18 and 17) cortices, in 20 schizophrenia subjects relative to 20 unaffected comparison subjects using quantitative PCR. Overall, schizophrenia subjects had significantly higher mRNA levels for all measured NF-κB-related markers relative to unaffected comparison subjects. Statistically significant regional differences were also seen for many measured NF-κB family members. Region × diagnosis interactions were significant (or nearly significant) for all NF-κB family members. Post-hoc tests revealed that in schizophrenia subjects, most NF-κB-related markers were significantly (or nearly significantly) elevated in each cortical region relative to unaffected comparison subjects. However, post-hoc tests also revealed that in most cases, schizophrenia subjects, but not unaffected comparison subjects, displayed higher levels of NF-κB-related markers in primary and secondary visual cortex relative to posterior parietal and prefrontal cortex. These findings suggest that 1) levels of NF-κB-related markers are elevated across the entire visuospatial working memory circuit in schizophrenia subjects, and 2) these increases may be most prominent in visual cortex. The presence of immune activation across cortical regions may disrupt cortical circuitry function in schizophrenia. Determinations of

disturbances in the precise pathways that underlie cognitive dysfunction in schizophrenia may ultimately aid in the discovery of therapeutic treatments of this disorder.

Title: Relationship of auditory event related potentials with magnetic resonance spectroscopy metabolites in early stage psychosis

Authors: L. BARTOLOMEO[1], A. M. WRIGHT[2], R. MA[2], T. A. HUMMER[3], M. M. FRANCIS[3], A. C. VISCO[3], N. MEHDIYOUN[3], A. R. BOLBECKER[1], W. P. HETRICK[1], U. DYDAK[2], *B. F. O'DONNELL[4], A. BREIER[3]

Abstract: Event-related potential (ERP) deficits in the mismatch negativity (MMN) elicited by deviant tones in a series and the auditory steady state response (ASSR) to 40 Hz stimulation are usually found in schizophrenia (SZ), but the neural basis of these disturbances are not well characterized. *In vivo* magnetic resonance spectroscopy (MRS) have shown alterations in several metabolites, including increased glutamatergic levels (Merritt et al, 2016) and reduced N-acetylaspartate (NAA) levels in SZ (Brugger et al, 2010). The relationship of electrophysiological responses to brain metabolites could provide insights into the neurochemical basis of scalp recorded ERP abnormalities early in the course of psychosis. In the present study, the correlation of MMN and the 40 Hz ASSR to glutamine, N-acetylaspartate, and other metabolites measured with magnetic resonance spectroscopy (MRS) were examined in patients with early stage psychosis. Thirty one individuals within 3 years of the onset of a non-affective

psychotic disorder were tested. MMN amplitude was measured from ERPs to duration deviant tones and ASSR power to 40 Hz click trains (500 ms duration) at midline electrode sites. The MRS volume of interest (VOI) was placed medially in the frontal cortex (size = 2x2x2 cm^3; TE = 30ms; TA = 4min) using a Siemens 3T TIM Trio whole-body scanner with a 32-channel head coil. N-acetylaspartate (NAA), glutamine (Glx), creatine (Cre), myo-inositol (MI) and choline (Cho) were measured. Pearson correlation coefficients were computed between ERP measures and metabolite levels with two-tailed *p* values for significance testing. MMN was correlated with Cre (r = .44, p = .01), Glx (r = .40, p = .03), NAA (r = .49, p < .01) and Cho (r = .44, p = .01) indicating that higher metabolite levels were associated with smaller (less negative) MMN responses. ASSR showed trends (r < .10) for correlations with Glx (r = .30), suggesting that higher levels of Glx was associated with greater 40 Hz ASSR power. In these early stage patients with psychosis, higher metabolic signals were strongly related to reduced MMN amplitude. Notably, elevations of Glu have been reported in schizophrenia (Merritt et al, 2016) and increased concentrations of Cre in the frontal lobe of children with schizophrenia (O'Neill et al, 2004).

Title: Facial emotion processing in schizophrenia using newly created facial stimuli by japanese actors; fMRI study

Authors: *N. ORIBE[1,2], H. KUGA[2], H. TAKAO[2], S. FUKUSHIMA[2], Y. HIRANO[1], T. ONITSUKA[1], T. UENO[2]
[1]Kyushu Univ., Fukuoka, Japan; [2]Hizen Psychiatric Ctr., Yoshinogari, Japan

Abstract: Background: Patients with schizophrenia have been associated with deficits in many aspects of social cognition. Especially, perception of face and/or facial expression is impaired through the course of the illness and that might result in the severe social dysfunction. Functional MRI has been used to detect the key region of this deficit. However, the results from previous studies have not been always consistent partly because of the differences in cultural background. It is commonly more difficult to distinguish the facial emotion in unfamiliar ethnic people then

in the familiar. In the current study, we adopted the facial emotion stimuli, which are played by Japanese actor/actress and evaluated as showing the intended emotions, during the measurement of fMRI.
Methods: Six schizophrenia patients and 7 healthy controls participated in two tasks; Discrimination Task and Emotion Task In the Discrimination task, forty pairs of pictures (Car, Fish or neutral Face) were shown and the subjects were required to push the button if the two pictures were same. In the Emotion task, thirty-two pairs of pictures (Happy, Angry, Sad or Disgust) were shown and the subjects were required to push the button if the two pictures expressed same emotion. The tasks were counterbalanced across the subjects. SPM12 was used to analyze BOLD fMRI data.
Results: In the Discrimination task, there were no group differences. In the Emotion task, patients with schizophrenia showed reduced BOLD signals in the inferior frontal gyrus only to the disgust faces.
Conclusions: These results suggest that schizophrenia patients have inferior frontal gyrus dysfunction in processing disgust faces. This dysfunction might underlie the paranoid notions in patients with schizophrenia.

Title: Tolcapone modulates cortical information processing underlying cognitive control mechanisms in patients with schizophrenia and healthy controls

Authors: *Y. TONG[1], J. A. APUD[2], R. RASETTI[3], J. H. CALLICOTT, III[3], B. KOLACHANA[3], B. K. DAS[3], T. VARGAS[3], B. ZOLTICK[3], D. DICKINSON[3], D. R. WEINBERGER[4], V. S. MATTAY[4], K. F. BERMAN[3]
[1]NIH/NIMH, Bethesda, MD; [2]Office of the Clin. Director, NIH, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Natl. Inst. of Mental Hlth., Bethesda, MD; [4]Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Among the multiple cognitive control deficits in schizophrenia, abnormal response inhibition and interference suppression have been frequently reported, and these have been associated with altered dopaminergic signaling in the prefrontal cortex. Converging evidence from animal and human studies suggests a unique role of catechol-O-methyltransferase (COMT) in regulating dopamine in cortical areas, with low activity of the COMT enzyme leading to

improved prefrontal efficiency. In this study we use a modified Flanker paradigm to investigate the potential effect of the COMT inhibitor tolcapone on modulating prefrontal cortical activity related to response inhibition and interference suppression in patients with schizophrenia (SCZs) and healthy controls (NCs).
In this double-blinded, placebo-controlled study, tolcapone was administered orally three times a day for seven days. Participants underwent BOLD fMRI on the seventh day on a GE Signa scanner. The event-related scan session included four conditions with a total of 145 pseudorandomized trials. The participants were asked to indicate the direction of the central arrow on the screen that pointed left or right, while ignoring the flanking stimuli on the side. In the Congruent and Incongruent conditions the flankers were arrows that could be oriented in the same ('congruent') direction or the opposite ('incongruent') direction to the central arrow. The contrast between the Incongruent and Congruent conditions enables us to explore neural processes underlying interference monitoring and suppression. The NoGo condition, which required subjects to withhold their motor response when two pairs of X's flanking the central arrow, served to evaluate response inhibition.
Images were preprocessed in SPM12. Totally 29 SCZs and 62 NCs had good quality fMRI data during both placebo and tolcapone conditions. Both SCZs and NCs showed decreased right IFG activation while on tolcapone when compared to the placebo condition during NoGo trials (pFWE-corr =0.006, right IFG ROI), suggesting improved efficiency in prefrontal cortical information processing during response inhibition. In addition, a significantly greater posterior cingulate cortex (PCC) deactivation was observed during interference monitoring and suppression (incongruent vs. congruent contrast) on tolcapone (pFWE-corr < 0.05, whole brain) in SCZs and NCs. While this finding requires further study, it raises the intriguing possibility that tolcapone in addition to improving efficiency of cortical information processing also improves top down modulation of default mode regions such as PCC during interference detection and suppression.

Title: Ventral hippocampal fMRI hypoactivity and social memory impairment in a 22q11.2 deletion mouse model of schizophrenia

Authors: *J. B. KAHN[1], S. L. WEHRLI[3], S. A. ANDERSON[2,4], D. A. COULTER[1,5,6]
[1]Neurosci., [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Radiology, [4]Psychiatry, [5]Neurol., [6]Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: One in four patients born with the 22q11.2 deletion develops schizophrenia, making this heterozygous deletion the most significant genetic risk factor for the disorder. Both functional magnetic resonance imaging (fMRI) studies in humans and in vivo tetrode recordings in mouse models of the deletion syndrome (DS) have shown abnormal activity patterns in multiple brain regions, including the prefrontal cortex and the hippocampus. To examine neuronal circuits contributing to 22q11.2 phenotypes, we performed gadolinium-enhanced resting state (rs) fMRI in a mouse model of 22q11.2DS (Df(h22q11)/+). While there was no significant difference in blood oxygenation level-dependent (BOLD) signals between the 22q11.2DS mice and controls in the dorsal cortex or caudate putamen, there was a significant decrease in BOLD signals in the ventral hippocampus, consistent with hypofunction. This circuit deficit proved interesting as previous work has found that both patients with 22q11.2DS and those with schizophrenia experience social cognitive deficits, and recent work from the Tonegawa lab has shown that the ventral CA1 is critical for social memory in mice. Based on this potential circuit-dependent/phenotype link, we performed a social memory test on the same fMRI mouse cohort. In the discrimination task, a novel mouse and a familiar mouse are placed in small chambers at opposite ends of an arena. The subject mouse can freely explore the arena, and the amount of time the subject mouse investigates each chamber is quantified. While control animals preferentially explored the novel mouse, the 22q11.2DS mice failed to discriminate between the novel mouse and the familiar mouse, exploring both mice equally. The neural circuit concordance between the rs fMRI and social memory task deficits implicates ventral CA1 as a primary locus for future investigation. Immediate planned steps include bidirectionally manipulating activity in the ventral CA1 via DREADDs (designer receptors exclusively activated by designer drugs) to mimic and/or reverse 22q11.2 phenotypes in control and DS mice, respectively, providing evidence for a causal link between ventral CA1 circuit phenotypes and behavioral deficits in this mouse model of schizophrenia.

Title: Schizophrenia exhibits bi-directional alterations in cortico-striato-cerebellar circuits

Authors: *J. JI[1], C. DIEHL[1], C. SCHLEIFER[1], G. YANG[1], G. CREATURA[1], G. REPOVS[2], J. D. MURRAY[1], A. WINKLER[3], A. ANTICEVIC[1]

Abstract: A key challenge in clinical neuroscience is the identification of robust biomarkers reflecting disease-related alterations in large-scale neural systems. Distributed neural dysconnectivity is considered a hallmark feature of schizophrenia, yet a tension exists between studies pinpointing focal disruptions versus those implicating brain-wide disturbances. Leading theoretical models of schizophrenia have proposed that distributed disruptions in local microcircuits and imbalanced neuronal E-I signaling might underlie pervasive alterations across neural systems, which in turn manifest in specific behaviors. The cerebellum and the striatum communicate reciprocally with the thalamus and cerebral cortex through monosynaptic and polysynaptic connections, forming cortico-striatal-thalamic-cerebellar (CSTC) functional pathways that may be sensitive to brain-wide dysconnectivity in schizophrenia. It remains unknown if the same brain-wide pattern of alterations persists across CSTC systems, or if specific alterations exist along key functional elements of these networks. We characterized whole-brain cerebellar and striatal connectivity using resting-state functional magnetic resonance imaging in 159 chronic schizophrenia patients and 162 matched controls, along each major cerebellar and striatal functional subdivision. Both cerebellar and striatal associative subdivisions revealed consistent brain-wide bi-directional alterations in patients relative to controls, marked by hyper-connectivity with bilateral sensory-motor cortices and hypo-connectivity with association cortex. Furthermore, consistent with previous findings of thalamic dysconnectivity in schizophrenia, these alterations were more pronounced along the executive subdivisions of these systems, suggesting that higher-order functional neural circuits are preferentially disrupted. We additionally validated these results with independent *k*-means clustering of voxelwise striatal and cerebellar between-group connectivity differences. These results implicate a consistent motif of brain-wide alterations in cortico-striato-cerebellar systems in schizophrenia, calling into question accounts of exclusively focal functional connectivity disturbances.

Title: Role of antipsychotics in disruptions of face detection in schizophrenia

Authors: *P. E. MARINHO[1], N. L. ALMEIDA[2], W. E. M. COMFORT[2], T. M. P. FERNANDES[2], T. L. GOMES[3], N. A. SANTOS[2]

Abstract: Several studies have reported the effects of antipsychotic medication on visual processing, but there is a lack of studies investigating the relationship between medication use and facial detection. Individuals suffering from schizophrenia often display impairment in their ability to detect emotional facial expressions. Impaired processing of visual information may be one of the key causes of deficits in face detection and can be related to an early detection phase of facial processing. The main purpose of this study was to measure the performance of schizophrenic patients in a face detection task, comparing the effects of typical and atypical antipsychotic drugs. Data were recorded from 33 participants, a group of healthy subjects (n = 11), a group of schizophrenic patients using typical antipsychotics (n = 11) and a group of schizophrenic patients using atypical antipsychotics (n = 11); age range 20-45 years. Patients were recruited from the Psychosocial Support Center in Paraiba, Brazil, diagnosed with schizophrenia according to the Diagnostic and Statistical Manual of Mental Disorders - DSM-V. All subjects were free from any cardiovascular and neurological disorder, identifiable ocular disease and had normal acuity. No abnormalities were detected in the fundoscopic examination and in the optical coherence tomography exam. The stimuli used in the experiment were drawn from the FEI face database. Twelve male and twelve female faces were selected. Detection task aim was to detect the location of a face when presented with a face/non-face pair, using 2-AFC discrimination design. Detection task had a limit of 96 trials. The detection task involved selecting right or left side responses when presented with masked images of face/non-face pairs. The order of test image presentation was determined using Bayesian entropy estimation. The presentation time for each trial was selected to yield the maximum of expected information for prediction of the expected mean threshold. The ocular distance to the screen was set to 80 cm. Performance differed between groups. Schizophrenic patients presented significant deficits in face detection compared to healthy subjects. However, post-hoc analyses suggest that schizophrenic patients using typical antipsychotic presented higher disruption of face detection. These results suggest that not only schizophrenia condition but also the type of antipsychotic

used affected face detection. This highlights the importance of understanding diffuse effects of antipsychotics on visual spatial processing.

Title: Metacognition dysfunction and disruptions of global balance between brain networks in schizophrenia

Authors: *W. JIA[1], H. ZHU[2], Y. NI[1], J. SU[1], H. JIA[2], X. WAN[1]
[1]State Key Lab. of Cognitive Neurosci. & Learning, Beijing, China; [2]mental illness diagnosis and treatment Beijing Key Lab., Beijing Anding Hosp., Beijing, China

Abstract: Metacognition is referred to as cognition about cognition, a high-level cognitive control process of the forgone cognitive processes. It automatically occur when something goes wrong, and an uncertainty-based “feeling state” is manifest. Metacognition can be separated into two components, the uncertainty monitoring process and the consequent decision revising or controlling process when uncertainty had been detected. Recent studies suggest that metacognition is impaired and it is a core cognitive dysfunction in patients with schizophrenia, but the neural mechanism of the metacognition dysfunction is little understood. Employing a novel metacognition task paradigm - “decision (cognition)-redecision (metacognition)” and functional magnetic resonance imaging (fMRI) technique, we investigated the neural basis of metacognition dysfunction in patients with schizophrenia in the present study. Thirty-eight Schizophrenia (SC) patients and Twenty-one healthy control (HC) subjects were recruited. The participants made two consecutive decisions on the same situation in a perceptual decision-making task (random dot motion, RDM) and judged their confidence levels after decision-making. We found that SC exhibited impairments both in metacognition monitoring and revising processes. Then, we divided SC patients into two groups according to the uncertainty monitoring (UM) ability. The fMRI results showed that the activation in the core nodes of the metacognition

network was significantly reduced in SC, including dorsal anterior cingulate cortex (dACC), which was involved in metacognitive uncertainty monitoring, and the lateral frontopolar cortex (lFPC), which was involved in metacognitive controlling. Furthermore, the anti-correlation between the metacognition network (MCN) and the default mode network (DMN) was alerted in SC. The strength of correlation between the two networks in SC was weaker during uncertainty monitoring, but became stronger in the least-demand task condition, in comparison to those in HC. It appeared that SC failed to properly coordinate the two networks. The group with high UM ability in SC had relatively less DMN suppression, whereas the group with low UM ability in SC had relatively excessive DMN suppression. Most importantly, the SC clinical symptoms were associated with the global balance of the two networks. In conclusion, our current study showed that SC had metacognition dysfunction both in metacognitive monitoring and controlling processes, and this was associated with the disruption of metacognition network, especially the global balance between the metacognition network and the default mode network.

Title: Global NMDAR hypofunction increases activity of top-down projections during sensory processing

Authors: ***A. RANSON**, E. BROOM, A. POWELL, J. HALL
Cardiff Univ., Cardiff, United Kingdom

Abstract: Converging evidence implicates NMDAR disruption in the pathogenesis of schizophrenia, a condition in which perceptual disturbances are prominent. Theoretical studies have proposed that perceptual symptoms in schizophrenia might be caused by an increased influence of top-down processing on sensory perception. To explore the cortical circuit changes through which NMDAR hypofunction might cause perceptual symptoms we investigated top-down and bottom-up drive to cortical sensory circuits in awake behaving mice during pharmacologically induced NMDAR hypofunction. Following NMDAR antagonist administration we observed increased activation of anterior cingulate axons providing top-down

input to visual cortex which was coupled with a simultaneous reduction in the primary visual cortex of activity of both PV+ interneurons and putative excitatory neurons and alteration of stimulus encoding. These findings suggest that NMDAR hypofunction may lead to altered perception by modifying the balance of top-down and bottom-up influence on sensory processing.

Title: Neurobiology of reality monitoring: Implications for treatment development in schizophrenia

Authors: *K. SUBRAMANIAM[1], L. B. HINKLEY[1], D. MIZUIRI[1], H. KOTHARE[1], S. VINOGRADOV[2], J. F. HOUDE[1], S. NAGARAJAN[1]
[1]UCSF, San Francisco, CA; [2]Univ. of Minnesota, San Francisco, MN

Abstract: Reality monitoring (RM) is the ability to distinguish the source of internal experiences (self-generated information) from outside reality (externally-derived information). Normally, the healthy brain functions as a continuous comparator prediction engine in which perceiving the world efficiently is fundamentally tied to successfully recognizing one's own self-generated actions - such that intact RM must rely on intact predictive encoding operations. In other words, internal predictions about one's own actions provide reliable self-agency cues; however, if an internal prediction is weak, then external cues from environmental feedback are weighted more so that the action is attributed as being externally-derived. Here, we examine prediction encoding on a low-level vocalization task, as well as how encoding relates to subsequent memory retrieval on a higher-order RM task.
During vocalization, an internal prediction about what one hears when one speaks is compared with the actual auditory feedback of listening to one's speech. Normally, feedback matches prediction encoding, and is registered as self-produced. However, if incoming auditory feedback is perturbed to mismatch predictions (i.e., when participants listen to a perturbed pitch shift while vocalizing), prediction errors are generated. We found that participants respond to the pitch shift by reducing the mismatch between predicted and actual outcome (i.e., by compensating against the pitch shift direction). Interestingly, the more that healthy control participants (HC) compensated against the pitch shift, the less likely they were to identify that information was

self-generated on our RM task. We also found that HC recruit medial prefrontal cortex (mPFC) specifically during encoding of self-generated information, which is also activated during accurate retrieval of self-generated information. By contrast, schizophrenia patients (SZ) have specific self-agency impairments and do not show mPFC activation during self-generated retrieval. These findings indicate that SZ may rely more on environmental externally-derived information, rather than on internal self-generated predictions, to guide RM.
These findings have important therapeutic implications in SZ, suggesting that the more participants rely on environmental feedback, the more they compensate in their pitch, and the less likely they are to correctly identify themselves as the source of self-generated information. In conclusion, pitch compensation may be a useful measure of internal prediction encoding operations that may be used to prime better reality-monitoring (i.e., better self-generated identification) in SZ.

Title: Dynamical clustering of mismatch negativity EEG data in large cohorts of schizophrenia patients and healthy participants reveals functionally distinct subgroups

Authors: *R. KIM[1,4], C. LAINSCSEK[4,5], M. L. THOMAS[2], T. COGS INVESTIGATORS[3], T. J. SEJNOWSKI[4,5], G. A. LIGHT[2]

[1]Neurosci., [2]Psychiatry, [3]UCSD, La Jolla, CA; [4]Computat. Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA; [5]Inst. for Neural Computation, La Jolla, CA

Abstract: Background
Schizophrenia (SZ), a complex neuropsychiatric disorder, is often referred to as a heterogeneous disorder due to its wide array of clinical symptoms along with many underlying etiologies, most of which are not yet known. It has been suggested that multiple coupled dynamical systems are involved in auditory sensory processing, and the degree to which each component of the coupled systems is affected may contribute to auditory dysfunction present in schizophrenia. By characterizing general dynamical components of brain signals (electroencephalogram; EEG) obtained from patients diagnosed with schizophrenia, important details about the systems-level states associated with auditory information processing deficits can be found.
Methods
A novel clustering algorithm based on delay differential analysis (DDA) was developed to partition EEG signals based on nonlinear dynamical states. The algorithm was then applied to the Consortium on the Genetics of Schizophrenia (COGS-2) EEG recordings. The multi-center COGS-2 dataset, the largest of its kind, contains mismatch negativity EEG recordings from schizophrenia patients (SZ; *n* =877) and non-psychiatric control subjects (NCS; *n* =753).
Results
Our dynamical clustering revealed functionally distinct subgroups (as indicated by P3a and MMN characteristics) within SZ and NCS group. More specifically, we found that (1) a dynamics spectrum exists not only within the SZ group, but also within the NCS group and that (2) a dynamics spectrum might be closely related to a functional/clinical spectrum. These findings suggest that each subgroup identified in NCS and SZ groups displays distinct auditory ERP features (amplitude and latency of MMN and P3a) which might then translate to subgroup-specific psychosocial functioning. Scores from various cognitive test batteries (California Verbal Learning Test-Second Edition, Wechsler Memory Scale, and Penn's Computerized Neurocognitive Battery) will be used to assess cognitive function of each subgroup.
Conclusions
Investigating EEG nonlinear system features associated with impaired auditory information processing in schizophrenia can reveal disorder-specific biomarkers that might help identify individuals at risk, make early diagnosis, and monitor intervention/treatment responses.

Title: Coincidental disruption of gamma rhythms in first episode schizophrenia

Authors: *Y. HIRANO[1,2], N. ORIBE[1], T. ONITSUKA[1], S. KANBA[1], R. MCCARLEY[3], K. SPENCER[2]
[1]Kyushu Univ., Fukuoka, Japan; [2]VA Boston, Harvard Med. Sch., Boston, MA; [3]VA Boston, Harvard Med. Sch., Brockton, MA

Abstract: BACKGROUND: Deficits in the auditory gamma-band oscillation and volumetric reductions in auditory cortex have been detected shortly after the onset of schizophrenia (SZ), and may be associated with core symptoms such as auditory hallucinations. Disruption of auditory gamma-band oscillation have received considerable interest in this effort, as the basic mechanisms underlying these oscillations are understood and are conserved across species. Evoked gamma oscillation such as the 40-Hz auditory steady-state response (ASSR) are reduced in SZ compared to healthy controls (HC) that could be related to deficits in GABAergic interneuron. Animal models based on NMDA receptor hypofunction demonstrate this deficit as well as an increase in spontaneous gamma power, which has been reported in chronic SZ (Hirano et al.,2015), yet characteristics of these deficits still remain unclear in first-episode schizophrenia (FESZ). Here we examined whether evoked gamma-band ASSR is decreased and spontaneous gamma power is increased in FESZ. **METHODS:** Subjects were 24 FESZ and 38 matched HC. Dipole source localization of dense electrode EEG data was used to examine oscillatory activity in auditory cortices during auditory steady-state stimulation (20/30/40-Hz rates). ICA was used to remove artifacts. Phase locking factor (PLF) and induced power (not phase-locked) were calculated from artifact-free single trial source estimates. Clinical symptoms were assessed by SAPS and SANS. **RESULTS:** Whereas evoked gamma (40-Hz PLF synchrony gamma) was decreased ($p < 0.01$), auditory spontaneous gamma (broadband induced gamma) was increased ($p < 0.01$) during continuous auditory stimuli in FESZ. These two apparently distinctive circuit abnormalities already occurred in the very early stage of the disease. **CONCLUSIONS:** We found coincide disruptions of gamma rhythms, which showed increase in spontaneous gamma (cortical excitability) and decrease in evoked gamma (cortical synchrony failure) during continuous auditory stimuli in FESZ. We propose that assessing ASSR-PLF and spontaneous

gamma in FESZ may provide a sensitive biomarker for the integrity of neural networks that are fundamentally altered in the very early stage of SZ.

Title: Effects of glutamatergic and dopaminergic drugs on auditory steady state response in common marmosets

Authors: Y. IWAMURA, K. MATSUMOTO, T. NAKAKO, H. IMAI, A. KIYOSHI, T. ENOMOTO, A. MATSUMOTO, M. IKEJIRI, T. NAKAYAMA, Y. OGI, *T. ISHIYAMA, K. IKEDA
Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan

Abstract: Introduction
Periodic auditory stimulation can elicit the auditory steady state response (ASSR) in the electroencephalogram (EEG) which rapidly entrains to the frequency and phase of the stimulus. ASSRs to 30 and 40 Hz stimulation are reduced in evoked power or phase locking factor (PLF) in patients with schizophrenia (SZ). These deficits have been hypothesized to be associated with N-methyl-D-aspartate receptor (NMDAR) and parvalbumin-positive GABA interneuron abnormalities in SZ. ASSR is expected to be a translational technique to evaluate the drug candidate for SZ. Here we aimed to establish the method of ASSR recording and to investigate the effects of various glutamatergic and dopaminergic drugs on ASSR in common marmosets.
Materials and methods
EEG electrodes were surgically implanted into the skull in six adult marmosets and EEG was recorded from auditory cortex. EEG signals were transmitted wirelessly at a sampling rate of 512 Hz. Auditory clicks at a variable rate (20, 30, 40 and 80 cycles/s; 0.5 s train duration) were generated by Signal software and routed through an auditory processor to a magnetic speaker. Evoked power, induced power and PLF were calculated by wavelet analysis. All drugs were systemically administered before ASSR recording, and the studies were performed in a cross-over manner. All experimental procedures involving animals use were reviewed and approved by the Institutional Animal Care and Use Committee of Sumitomo Dainippon Pharma, Co., Ltd.
Results
We could detect ASSRs (20, 30, 40 and 80 Hz) from common marmoset. NMDAR antagonist (MK-801) induced ASSR deficits with significant reduction of 30 and 40 Hz PLF and evoked

power, which were similarly seen in SZ patients. mGlu2/3 agonist (LY-379268) reduced induced power and increased PLF. D1 agonist (SKF-81297) increased PLF and evoked power. On the other hand, D1 receptor antagonist (SCH-39166) decreased PLF and evoked power. D2 agonist (quinpirole) did not change PLF, but increased evoked and induced power. D2 antagonist (raclopride) decreased PLF and evoked power. Antipsychotic (risperidone) did not increase PLF.

Conclusion

We could successfully measure ASSR from marmosets and demonstrated that NMDAR antagonist induced SZ-like ASSR deficits such as reduction of PLF and evoked power. Moreover, we showed that increase of both ASSR parameters are induced by D1 agonist, which is reported to enhance cognitive function in marmoset, but not by the other drugs tested. Thus, ASSR in marmoset is considered to be a translational biomarker of glutamatergic and dopaminergic neurotransmission, which may be involved at least in part in cognitive function.

Title: Abnormal hippocampal-mPFC synchrony in the KCNH2-3.1 transgenic mouse model

Authors: ***M. REN**[1], J. ZHU[1], Y. LI[1,2], S. ZHU[1,2], K. MEZEIVTCH[1], Z. HU[1], S. QIN[1], X. LI[3], Q. TIAN[1], D. PARADES[1], Q. CHEN[1], K. H. WANG[3], D. R. WEINBERGER[1], F. YANG[1]
[1]The Lieber Inst. for Brain Develop., Baltimore, MD; [2]Chongqing Med. Univ., Chongqing, China; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The KCNH2-1A potassium channel conducts delayed-rectifier potassium currents that have a rapid activation and relatively slow inactivation in deactivation kinetics. Our previous work has identified a novel primate isoform of KCNH2-1A channel, the KCNH2-3.1 potassium channel, in human brain associated with schizophrenia. And our studies also showed that KCNH2-3.1 transgenic mice exhibit alterations in neuronal structure and microcircuit function in the hippocampus and prefrontal cortex, areas affected in schizophrenia. Neuronal oscillations have been hypothesized to play an important role in cognition and its ensuing behavior, but evidence that links a specific neuronal oscillation to a discrete cognitive event is largely unknown. It has been proposed that failure of functional integration and flow of information

between hippocampus and mPFC results in cognitive deficits in schizophrenia patients. The possibility of functional impairments between hippocampus and mPFC as key pathophysiological mechanisms associated with schizophrenic phenotypes in KCNH2-3.1 mice has not been explored before. In this study, to investigate functional connectivity in these mice, we measured the synchronization of neural activity between the hippocampus and the prefrontal cortex during the performance of a delayed nonmatch-to-place (DNMP) T maze task, which is analogous to a cognitive function disrupted in the schizophrenia. KCNH2-3.1 mice, which display significantly impaired learning compared to control mice in the DNMP T maze task, showed robustly reduced synchrony measured by coherence of local field potentials in ventral hippocampus and mPFC, particularly in beta and gamma oscillations. Interestingly, higher beta and gamma oscillation power is observed in KCNH2-3.1 transgenic mice. These findings provide further insights into the precise alterations in hippocampal-mPFC connectivity observed in this schizophrenia-associated animal model, and could ultimately help elucidate the molecular and cellular basis underlying schizophrenia pathogenesis.

Abstract: Aberrant regulation of dopamine system function is thought to contribute to psychosis in schizophrenia patients; however, the brain regions associated with this dysregulation have not been conclusively demonstrated. We have recently demonstrated that medium spiny neurons in the nucleus accumbens (NAc) receive convergent input from the ventral hippocampus (vHipp) and paraventricular nucleus of the thalamus (PVT). Furthermore, inactivation of either the vHipp or PVT is sufficient to reverse aberrant dopamine system function in rodent models of

schizophrenia. Using, chemogenetic experiments we now provide conclusive evidence that the thalamic input to the NAc plays a role in the regulation of dopamine neuron activity. These data demonstrate that the vHipp and thalamus (specifically the PVT) work in concert to regulate VTA dopamine neuron population activity. Such data are important as they provide evidence that thalamic abnormalities may contribute to the aberrant dopamine system function observed in schizophrenia and suggest that the PVT may be a novel site for intervention in psychosis. To examine this, we explored the orexin system, which is known to provide a dense innervation of the PVT. Indeed, we now show that orexin receptors are expressed on PVT neurons projecting to the NAc and may serve as a substrate for pharmacological manipulation of this pathway. Here, we provide evidence that both systemic and intracranial (PVT) administration of the orexin receptor antagonist, TCS1102, can normalize aberrant dopamine system function in a rodent model of schizophrenia. Collectively, these data suggest that targeting orexin signaling in the thalamus may represent a novel site of intervention for psychosis associated with schizophrenia.

Title: Intra-nucleus accumbens infusion of quinpirole recovers mesolimbic hyperdopaminergia induced by systemic administration of sulpiride

Authors: *S. B. DE SOUZA[1], E. MCKIMM[3], S. M. TRABOSH[3], C. D. BLAHA[2], C. DA CUNHA[4]
[1]Neural Engin. Labs., [2]Dept. of Neurologic Surgery, Mayo Clin., Rochester, MN; [3]Dept. of Psychology, Univ. of Memphis, Memphis, TN; [4]Univ. Federal do Parana, Curitiba, Brazil

Abstract: Dysfunctional hyperdopaminergic signaling, caused by increased release of dopamine from presynaptic terminals, in the mesolimbic system is associated with psychotic symptoms in schizophrenic patients. Dopamine D2 receptors (D2R) antagonists are clinically used to control the manifestation of such symptoms, however, chronic administration has shown to induce supersensitivity of postsynaptic D2 receptors. Yet, both pre and postsynaptic D2R can be occupied by D2R antagonists which contributes to the complexity of the treatment. The goal of the present study was to elucidate the effects of low (presynaptic) and high (pre- and

postsynaptic) doses of the D2R antagonist sulpiride in the evoked dopamine release controlled by D2 autoreceptors in the nucleus accumbens (NAc). We used fixed potential amperometry with the application of low frequency electrical conditioning stimuli (CS = 5, 10, 20 and 40 prepulses at 15Hz, 0.5ms/phase, 0.8mA) to the medial forebrain bundle of DBA/2J mice to evaluate D2 autoreceptors blockade. By increasing the number of CS, we observed the inhibition of dopamine release evoked by a test electrical stimulation (10 pulses at 50Hz, 0.5ms, 0.8mA) applied 0.3s after offset of the CS when compared to a control stimulus of the same magnitude. Intraperitoneal injection of high dose sulpiride blocked both the inhibition of dopamine release controlled by D2 autoreceptors and the dopamine uptake, mediated by the dopamine transporter (DAT). However, a low dose of sulpiride only blocked the inhibition of dopamine release when a small amount of extracellular dopamine was previously released by 5 prepulses CS. Next, intra-NAc infusion of the D2/D3 agonist quinpirole reversed the inhibition blockade effect of both doses of sulpiride and amplified the dopamine uptake previously disrupted by the high dose of sulpiride. Our data shows that mesolimbic hyperdopaminergia is induced by administration of high doses of D2R antagonists through a mechanism mediated by the blockade of D2 autoreceptors and DAT. In addition, we show that balanced activation of D2/D3 receptors is important to maintain physiological mesolimbic dopamine levels. These results further suggest that choosing a pharmacological agent capable of regulating dopaminergic levels in the brain can be a better approach to treat psychotic symptoms experienced by schizophrenic patients.

Title: Focal cortico-striatal tract deymelination in juvenile mice promotes neuro-functional changes related to social and motor-stereotypical behaviours

Authors: *G. MENDEZ-VICTORIANO[1], R. E. REYNA-GUTIERREZ[1], J. M. VEGA-RIQUER[2,1], N. MOY-LOPEZ[1], J. GUZMAN-MUNIZ[1], O. GONZALEZ-PEREZ[1]

[1]Sch. of Psychology/Neurosciences Lab., Univ. of Colima, Colima, Mexico; [2]Med. Sci. PhD Program, Sch. of Medicine/University of Colima, Colima, Mexico

Abstract: Introduction: Recent evidence suggest that schizophrenia's pathogenesis involves white matter dysregulations, cortical hypofunction, striatal hyper-function, and neuroanatomical alterations in brain areas related to social and motor-stereotypical behaviors. During adolescence, white matter alterations that affect neuronal activity have been related to the symptomatic appearance of this disorder. Schizophrenia-like animal models that involve demyelination have been standardized to elucidate the possible relationship between myelin affection with behavioral/anatomical brain alterations. However, these models produce a diffuse white matter affection and cannot establish a possible anatomical and functional relationship. **Purpose:** to evaluate the effects of focal cortico-striatal tract demyelination on neuronal activity, social and motor-stereotypical behavior. **Method:** 20 Six-week-old CD1 mice were injected bilaterally with 0.1% Lysolecithin (experimental) or 0.9% saline solution (control) at +2.3 mm, +/- 1.0 mm, -1.5 mm coordinates related to Bregma. Six days after surgery, to evaluate social and motor-stereotypical behaviors, we used two behavioral tests: the three-chamber sociability test and the marble burying test. Neuronal activity was determined by counting the number of c-Fos+ cells in prefrontal cortex and caudoputamen. **Results:** The demyelinated group showed a decrease in the number of marbles buried and in social motivation and social novelty as compared to the control group. We found an increase in the number of c-Fos+ cells in caudoputamen and a decrease in prefrontal cortex of the demyelinated group when compared to the control group. **Conclusions:** Focal cortico-striatal tract demyelination promotes neuroanatomical changes related to social and motor-stereotypical behaviors. These findings suggest that lysolecithin injection is a suitable model to evaluate the relationship between brain regions demyelination and behavior in some neurodevelopmental disorders.

Title: A study of auditory cortical cross-frequency coupling in schizophrenia

Authors: *N. RAMAKRISHNAN, N. R. MURPHY, C. P. WALKER, N. R. POLIZZOTTO, D. P. WOMACK, R. Y. CHO
Psychiatry, Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: Background: Abnormal neural oscillatory dynamics in schizophrenia patients are thought to give rise to cognitive deficits in the illness. These include gamma oscillatory disturbances as well as possible disturbances in cross-frequency coupling (CFC), the modulation of high-frequency oscillations by lower frequency oscillations. The aim of this study was to investigate phase-amplitude CFC in the auditory cortex during 40 Hz steady-state stimulation and their potential disturbance in schizophrenia patients. **Methods:** Schizophrenia patients (n=10) and healthy controls (n = 9) were presented with a 40 Hz auditory click train stimuli (1000 ms) during high-density (305 channel) Magnetoencephalography (MEG) recording. The MNE Python toolbox was used to process the raw MEG signals and MATLAB scripts were used to compute sensor-level spectral and CFC analysis of the 40 Hz auditory steady state response (ASSR). We defined a functional region of interest (ROI) using 40hz frequency power response over the course of the entrainment period (0 to 1000ms), and averaged over sensors selected within the top quartile. The co-modulogram for CFC was examined for phases of lower frequency oscillations ranging 2 to 16 Hz amplitudes of higher frequency oscillations ranging 20-60 Hz using the mutual information as a measure of interaction between frequency bands. CFC during the entrainment period was normalized by subtracting CFC during the baseline period. **Results:** Steady state gamma power was not significantly reduced in patients relative to controls. Estimates of CFC, however, demonstrated disparities in delta-gamma CFC, with healthy controls exhibiting higher coupling compared to schizophrenia patients. **Conclusions:** This is the first MEG study to investigate cross-frequency neuronal interactions during the auditory steady state responses in schizophrenia patients. Despite comparable gamma oscillatory power, CFC appears to be impaired in patients. Thus, while there may exist relative preservation of the ability to entrain activity to high frequency stimuli, the modulation of such activity by lower frequency activity may be diminished in the illness.

Title: Quantification of immunohistochemistry on adjacent sections comparing fluorescent and DAB markers

Authors: *B. TIPTON, J. BAUN, T. YORK, C. ZURHELLEN, R. C. SWITZER, III
Lab., Neurosci. Associates, Knoxville, TN

Abstract: The location of antibody binding sites in brain tissue sections is commonly detected with fluorescent markers or with colored reaction products such as diaminobenzidine. We sought to answer the question: Do both types of detection schemes reveal the antibody binding sites to the same extent as judged by density of staining?
Adjacent sections of tissue were stained with several antibodies, including GFAP for astrocytes and Iba1 for microglia from rat brains that were unilaterally rendered ischemic by middle cerebral artery occlusion. Sets of adjacent sections were immunohistochemically stained free-floating using standard IHC methods. For one set, the antibody binding site was detected using a secondary antibody conjugated with a fluorescent molecule. The second set was stained using the sequence of a secondary antibody conjugated with a biotin molecule, followed by an avidin-HRP complex and then reacting with diaminobenzidine and H_2O_2.
Two areas of interest were digitally captured for each detection scheme/stain: An ischemic area in one hemisphere and an unaffected area in the other hemisphere. The same region of interest for each stain was analyzed on adjacent sections to rule out any random differences in brain areas. Images of both the DAB and fluorescent stains were converted to 8-bit grayscale. The 8-bit grayscale images of fluorescent-stained tissue were inverted to mimic the 8-bit grayscale images of the DAB images. All 8-bit grayscale images were converted to a binary image for densitometric analysis. Densitometry (measured as the percent area occupied by signal) was performed to determine any differences between the DAB and fluorescent images. The percent area in both the ischemic and normal areas of interest were analyzed in both DAB and fluorescent images for each stain.
There were dramatic differences observed between the two staining methods. In both the GFAP and Iba1 stains there were obvious variations in staining intensity in both the affected and normal brain regions. This is not surprising as there is considerably greater amplification of the antibody presence using the DAB multiple stage sequence vs. the “single” stage fluorophore-secondary antibody sequence. Nonetheless, the degree of hypertrophied astrocytes and microglia seen with the fluorescent method is meager compared to the images using the DAB sequence.

Title: Improved application of the electrophoretic tissue clearing technology, CLARITY, to intact solid organs

Authors: *S. PARK[1], H. LEE[2]
[1]Predictive Model Res. Ctr., Korea Inst. of Toxicology, Daejeon, Korea, Republic of; [2]Keimyung Univ. Sch. of Med., Dalseo-Gu, Korea, Republic of

Abstract: Mapping of tissue structure at the cellular, circuit, and organ-wide scale is important for understanding physiological and biological functions. A bio-electrochemical technique known as CLARITY used for three-dimensional anatomical and phenotypical mapping within transparent intact tissues has been recently developed. This method provided a major advance in understanding the structure-function relationships in circuits of the nervous system and organs by using whole-body clearing. Thus, in the present study, we aimed to improve the original CLARITY procedure and developed specific CLARITY protocols for various intact organs. We determined the optimal conditions for reducing bubble formation, discoloration, and depositing of black particles on the surface of tissue, which allowed production of clearer organ images. We also determined the appropriate replacement cycles of clearing solution for each type of organ, and convincingly demonstrated that 250–280 mA is the ideal range of electrical current for tissue clearing. We then acquired each type of cleared organs including brain, pancreas, liver, lung, kidney, and intestine. Additionally, we determined the images of axon fibers of hippocampal region, the Purkinje layer of cerebellum, and vessels and cellular nuclei of pancreas. CLARITY is an innovative biochemical technology for the structural and molecular analysis of various types of tissue. We developed improved CLARITY methods for clearing of the brain, pancreas, lung, intestine, liver, and kidney, and identified the appropriate experimental conditions for clearing of each specific tissue type. These optimized methods will be useful for the application of CLARITY to various types of organs.

Title: Fluorescent biomarkers as reporters of poor quality transcardial perfusion-fixation in frozen brain sections: A much needed tool for experimental neuroscience

Authors: *A. DEHGHANI[1], *A. DEHGHANI[1], H. KARATAS KURSUN[1], A. CAN[2], M. YEMISCI OZKAN[1,3], E. EREN KOCAK[1,4], T. DALKARA[1,3]

Abstract: Fixation via transcardial perfusion is performed for preserving the tissue uniformly in a life-like state without allowing any hypoxia/hypoperfusion-induced alterations during sacrificing animals. Since frozen sections are commonly used in studies with fluorescent-tagged antibodies, co-localization imaging and transgenic animals expressing fluorescent proteins, we need tools to detect poor perfusion in frozen sections to ensure that observed changes are genuine but not induced by non-optimal tissue fixation. Adult naive Swiss albino mice were anesthetized with 1 mg/g chloral hydrate (i.p.). Transcardial perfusion parameters were varied by changing the flow rate of heparinized saline and 4% paraformaldehyde (PFA) as well as perfusion duration. Brains were extracted and prepared for Nissl, Hematoxylin/Eosin (H&E), Hoechst-33258, YOYO-1, TO-PRO3 staining or NeuN and HMGB1 immunolabeling. Images were taken with fluorescent, phase-contrast, differential interference contrast (DIC), laser scanning confocal and scanning electron microscopy (SEM). The images taken from cortical and subcortical regions of 8 well-perfused brains and 10 poor-perfused brains were quantified at 20x. The nuclear diameter was measured in Nissl at 40x. All fluorescent stainings of frozen sections including Hoechst, YOYO-1, TO-PRO3, NeuN and HMGB1 exhibited a significant number of dysmorphic neuronal nuclei resembling donats (nuclei with unstained core) in poor-perfused brains. In Nissl or H&E-stained sections, these neurons displayed nuclear swelling associated with perineuronal astrocyte endfeet swelling, classical histopathologic hallmarks of early hypoxic/ischemic injury. The average ratio of donat-shaped neurons to Hoechst-labeled nuclei was less than 5% in well-fixed PFA-perfused mice. In addition to studies co-localizing Nissl and fluorescent staining performed with phase-contrast and DIC confocal microscopy, SEM images also clearly showed loss of tissue integrity in poor-perfused brains. Translocation of HMGB1 from nucleus to cytoplasm in these dysmorphic neurons also confirmed that they were exposed to hypoxic/ischemic stress during perfusion-fixation. These findings suggest that dysmorphic 'donat-shaped' neuronal nuclei in Hoechst, TO-PRO3, YOYO-1 stainings as well as NeuN and HMGB1 immunolabeling can be regarded as histological biomarkers reporting poor quality of transcardial perfusion-fixation in frozen sections. Hoechst staining, which is an easily applicable and widely used nuclear marker can be employed for assessing the quality of perfusion-fixation by taking into account the 5% threshold.

Title: Ultra-luminous labels for imaging of individual molecular targets in brain cells

Authors: *V. V. DIDENKO
Neurosurg., Baylor Col. of Med., Houston, TX

Abstract: We describe new highly luminous fluorescent labels developed for biomedical imaging of individual, low abundance molecular targets in brain cells. The new ultra-luminous fluorescent tags are the rod-shaped nanoparticles assembled from organic polymers and nanotubes. They can be individually observed under the fluorescence microscope. These composition fluorophores are significantly lighter and less dense as compared to Q-dots. Such properties ensure their low pull forces in repetitive washing. When conjugated to antibodies these ultra-bright labels make possible the routine detection and observation of individual loosely attached or fragile molecular targets. They can be advantageous for *in situ* labeling of exosomes, microvesicles and individual DNA breaks in brain cells. The ultra-thin profile of the new florescent labels is also beneficial in multiplex labeling of tissue sections by reducing steric hindrance during detection of the closely located molecular targets.

Title: Split-miniSOG for imaging intracellular protein-protein interactions by correlated light and electron microscopy

Authors: *D. BOASSA[1], S. R. ADAMS[2], S. PALIDA[2], V. LEV-RAM[2], J. HU[1], Q. XIONG[2], S. PHAN[1], M. ELLISMAN[1], J. T. NGO[3]
[1]CRBS, NCMIR, [2]Pharmacol., Univ. of California San Diego, La Jolla, CA; [3]Biomed. Engin., Boston Univ., Boston, MA

Abstract: We have engineered a protein fragment complementation probe for imaging intracellular protein-protein interactions by electron microscopy (EM). The probe was constructed by bisection of miniSOG, a fluorescent flavoprotein derived from the LOV2 domain of *Arabidopsis* phototropin. When brought together by interacting proteins, miniSOG fragments reconstitute a functional reporter, permitting labeled complexes to be visualized by fluorescence detection as well as by EM imaging through miniSOG-mediated photooxidation of 3-3'-diaminobenzidine (DAB). The protein fragments are relatively small (10.96 and 5.15 kDa), and interact with one another reversibly, which should minimize perturbation of the native dynamics of the tagged interacting partners. We describe the use of split-miniSOG to the visualization of protein aggregates associated with neurodegenerative diseases, including the homomeric aggregation of alpha-synuclein (AS). In neurons, AS is expressed as both a soluble and membrane-associated protein and is the main component of Lewy bodies, the cellular aggregates seen in the brains of patients with PD and other neurodegenerative conditions. Use of split-miniSOG to detect AS-aggregates provides distinct advantages, such as the ability to distinguish between soluble and aggregated forms of the disease-associated molecule. We have exploited this advantage and generated AS chimeras tagged with complementary miniSOG fragments. Labeled protein aggregates were detected as darkly stained inclusions in the cell bodies and dendrites of transfected neurons, formations consistent with "Lewy bodies" and "Lewy dendrites." Using this technology we are able to locate both fibrillar and oligomeric forms of AS within neuronal cells with unprecedented resolution, precision, and sensitivity.

Title: Direct observation of local protein synthesis in single cells *In vivo*

Authors: *I. KAYS[1], B. E. CHEN[2]
[1]McGill Univ. Hlth. Ctr., Montreal, QC, Canada; [2]Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Proteins are the end products of gene expression and the executors of cell function. Detecting when and how much a protein molecule is synthesized is important for understanding cell function, but current methods have poor cellular or temporal resolution or are destructive to cells. Here, we developed a technique to detect and quantify subcellular protein synthesis events at millisecond resolution *in vivo*. This Protein Translation Reporting (PTR) technique uses a genetic tag that produces a stoichiometric ratio of a small peptide portion of a split fluorescent protein and the protein of interest during protein synthesis. We show that the split fluorescent protein peptide can generate fluorescence within milliseconds upon binding the larger portion of the fluorescent protein, and that the fluorescence intensity is directly proportional to the number of molecules of the protein of interest synthesized. We split a green and red fluorescent protein to allow for detection of synthesis of each parental allele of a gene in two channels to examine the allele-specific distribution of protein synthesis. We also split a photoswitchable fluorescent protein to photoconvert the reconstituted fluorescent protein to a different color, to continually and arbitrarily reset the time of detection of synthesis events. Using PTR, we directly observed and quantified protein synthesis events subcellularly over time *in vivo*.

Title: Nucleomic substrates for social behavior in GnRH1 neurons in an African cichlid fish

Authors: *S. ALVARADO, R. A. FERNALD
Biol., Stanford Univ., Palo Alto, CA

Abstract: Changing behavior to adapt to novel situations is critical for surviving dynamic environments. In this respect, genes are important constituents of behavior but are static and cannot explain the plasticity observed in behavioral phenotypes. Epigenetic mechanisms, such as histone modifications or DNA methylation, lend plasticity to genes that determine behavior with reversible modification. While molecular tools exist that can shed light on epigenetic modifications to whole tissues, few approaches offer insight to individual nuclei. The development of array tomography provides the power to resolve microstructures such as the synapse and nuclei within neurons to 50-200 nm resolution through resin embedding and serial sectioning. We use a fish model system, Astatotilapia burtoni, which has dramatic behavioral polyphenism between dominant and non-dominant males that produce concomitant morphological, neuroanatomical, and molecular changes. Social status in these animals is accompanied with a repertoire of molecular changes that are localized within specific cell populations in the brain. Specifically, dominant males show enlarged soma within their GnRH1 neurons compared to their subordinate counterparts. In this study, we employed the use of a suite of chromatin immunoprecipitation-validated antibodies to trace the 3D organization of chromatin with array tomography in single GnRH1 neurons. In addition to immunostaining histone modifications, we paired our approach with fluorescent in situ hybridization of tiled array generated probes to label genes within active and inactive chromatin marks. As epigenetic mechanisms are emerging as novel mediators of molecular pathologies in general, this approach can be of critical importance for neurosciences and molecular approaches in many other fields.

Title: Study on antioxidant measurement in human brain using MRS

Authors: *T. MURASE, M. UMEDA, T. HIGUCHI
Meiji Univ. of Integrative Med., Kyoto, Japan

Abstract: [Introduction] Glutathione (GSH) and ascorbic acid (Asc, vitamin C) are the most concentrated chemical antioxidants in the central nervous system. Measuring GSH and Asc concentrations non-invasively in vivo is very important in investigating the role of this antioxidant in normal and diseased brain functions. Proton MR spectroscopy (1H-MRS), which can be measured using clinically popular MRI scanner, can detect non-invasively comprehensive metabolites of the human brain. However, it is impossible to reliably quantify the full range of 1H-MRS detectable metabolites in vivo, due to the spectral overlap of resonances from different compounds observed at low magnetic field strength. Since GSH and Asc are metabolites with perfect spectral overlap with other metabolites, "spectrum editing" method is essential. Therefore, in this study, we investigated whether phantom and human brain can measure GSH and Asc by clinical 3 TMRI using spectrum editing method.
[Methods] GSH phantom (10mM GSH and 10mM NAA) and Asc phantom (10mM Asc and 10mM NAA) were acquired at physiological pH. Five healty volunteers gave informed consent for this study. The experimental equipment consisted of a 3T MRI device (SIEMENS company, Trio A Tim system) and a 32-channel head coil. Single voxel MRS (MEGA-PRESS) was used to measure GSH levels for phantom and human brain with the following parameters: TR/TE = 3,000/68 ms, NEX = 128 (*2), VOI = 20mm *30mm *20mm, choice excitation pulse = 4.56 ppm (editing on) / 7.5ppm (editing off). MEGA-PRESS was used to measure Asc levels for phantom and human with the following parameters:The measurement parameters of Asc editing single voxel MRS (MEGA-PRESS) is TR/TE = 3,000/160 ms, NEX = 128 (*2), VOI = 20mm *30mm *20mm, choice excitation pulse =4.01 ppm (editing on) / 5.39ppm (editing off). The spectral signals of GSH and Asc are obtained by the difference between editing off and editing on data. MRS data analysis used 1D FT-NMR (ISBN: 9784782705971).
[Results & Discussion] As a result of phantom experiment, it was confirmed that GSH and Asc can measure 3T MRI scanner using MEGA-PRESS. On the other hand, GSH signals were observed in human brain experiments, but Asc signals could not be observed. The previous studies using a high magnetic field MRI apparatus have reported that GSH and Asc are present in the human brain at a concentration of about 1 mM. Asc was not observed in the human brain, because it seems that optimization of measurement conditions is insufficient, we will investigate in the future.

Abstract: Detailed analyses of neuronal cell morphology in the brain often requires methods (such as Golgi stain) to sparsely and completely label the neuronal cell body as well as their dendritic and axonal processes. To achieve genetically-directed sparse neuronal labeling, our laboratory has provided proof-of-concept that D1 dopamine receptor BAC driven unstable repeat can undergo frameshift to sparsely and stochastically switch on reporter gene expression in a subset of D1-expressing neurons (Lu, 2016). To demonstrate the general utility of this method (called MORF) for labeling many other neuronal (and non-neuronal) cell types, and to achieve more complete labeling of the neuronal processes, we developed here Cre-dependent MORF reporter knockin mouse lines. By crossing one of the lines to a ubiquitous Cre or neuronal cell-type-specific Cre lines, we achieved Cre-dependent, sparse and stochastic labeling of distinct cell populations (e.g. D2 medium spiny neurons or cerebellar Purkinje cells) in the mouse brain. We will describe the distinct reporters used in our knockin MORF lines, their labeling frequencies upon Cre induction, and their utility in brainwide analyses of genetically-defined single neuronal morphology. Future application of such Cre-dependent MORF mice may facilitate the study, at single neuron resolution, the development, function, dysfunction and degeneration of mammalian neurons in vivo.

Title: Quantification of allele-specific protein expression over time in single cells *In vivo*

Authors: *C.-A. LO[1], B. E. CHEN[2]
[1]Ctr. for Res. In Neurosci., Montreal, QC, Canada; [2]Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Protein production is a dynamic and regulated process in cells. However, little is known about the dynamics of protein synthesis in single cells in an animal. Here, we use a fluorescence based non-invasive protein quantification technique to tack protein production dynamics over time in single cells in animals. Specifically, we used a genetic tag, called a protein quantitation reporter (PQR), connecting a gene of interest to a fluorescent reporter gene. Protein quantification is based on the equimolar production of the protein of interest and the fluorescent reporter from the same genomic locus, but the fluorescent reporter is separated from the protein of interest during protein synthesis. Therefore, the fluorescent output of a cell (i.e., its brightness) is linearly proportional to the number of molecules of the protein of interest produced. To monitor endogenous protein production in living animals in real-time, we use CRISPR-Cas9 genome-edited animals that have a PQR inserted into the gene encoding the Ribosomal protein L13a to track and measure protein expression dynamics in single cells *in vivo*. By imaging these animals *in vivo* and tracking protein expression over time in hundreds of single cells, we have found that protein synthesis events occur on timescales of tens of minutes but with large variability across single cells. Interestingly, we have found that cells that are closer together and from the same tissue have similar dynamics of protein production. Since we also created two different genome-edited animals that have different colors of the quantitative reporter, by crossing these two animals we can track protein synthesis from each parent-of-origin allele simply by using color. We have found that nearly all cells express both the mother's and father's copy of the *Rpl13a* gene, but not always equally. Protein synthesis from both parent-of-origin alleles occur with similar dynamics of frequency and duration. Clusters of cells can have a bias for one parental allele which varies across tissues and can change over timescales of hours. Our results indicate that protein expression dynamics across cells and between the parent-of-origin alleles are stochastic, but initially determined by progenitor cells.

Title: Simultaneous mapping and quantitation of neurotransmitters directly in tissue sections using mass spectrometry imaging

Authors: *P. E. ANDREN[1], M. SHARIATGORJI[1], A. NILSSON[1], E. FRIDJONSDOTTIR[1], L. KATAN[1], J. SAVMARKER[1], P. SVENNINGSSON[2], L. ODELL[1]

Abstract: We here introduce a novel approach to image a large number of different neurotransmitters, their precursors and metabolites simultaneously from brain tissue sections. Without modification, most neurotransmitters are not directly detectable by matrix-assisted laser desorption ionization (MALDI)-mass spectrometry imaging (MSI) due to their poor ionization efficiency and the overlapping signals of isobaric compounds. To address the limited ionization and desorption of neurotransmitters, we developed a method for their *in situ* chemical derivatization and charge-tagging. Once modified, the small molecule target compounds are readily ionized and detected, enabling their identification and the quantitative mapping of their distributions by molecular-specific MALDI-MSI. Using the derivatization approach we were able to map numerous neurotransmitter systems, such as dopamine and serotonin, their precursors and most of their metabolites directly in brain tissue sections. For example, the precursor to dopamine, L-DOPA, was imaged for the first time simultaneously with dopamine, and twelve known dopamine metabolites were imaged, as well as three different L-DOPA metabolites. To further demonstrate the potential of the MALDI-MSI methodology we applied the strategy to Parkinson's disease experimental models. In summary, our methodology enables *in situ* mapping of connectivity patterns within and between neurotransmitter systems. Quantitation of functional neurotransmitter balances may be a useful approach in studies of neurodegenerative disorders but also in drug development as a biomarker-based rationale for targeted modulation of neurotransmitter networks.

Abstract: *In vivo* imaging of specific molecular processes across whole brains could lead to earlier diagnosis of neurological diseases, more effective drug evaluation, and advances in basic neurobiology, but molecular imaging techniques are constrained by limitations of the available probes. Magnetic resonance imaging (MRI) offers deeper tissue penetration than optical modalities and higher spatial resolution than nuclear imaging techniques, but molecular imaging agents for MRI can only be applied at levels to high for measurement of many species in the brain. Recently we demonstrated a new and highly sensitive approach for molecular-level imaging which entirely bypasses the need for conventional imaging contrast agents by perturbing the substantial reservoir of endogenous multimodal contrast afforded by the vasculature. We showed that imaging agents derived from calcitonin gene-related peptide (CGRP) can artificially induce vasodilation in rat brain and induce contrast changes, measured by optical imaging and MRI, at nanomolar concentrations in in the brain. Here we demonstrate that such agents can be used as building blocks for switchable analyte-dependent and genetically encoded reporters suitable for molecular imaging of proteases and neuropeptides at physiologically relevant concentrations. These tools offer new capability for monitoring dynamic aspects of brain biology, with potential applications in both science and medicine.

Title: An axon-targeted GCaMP sensor for *In vivo* imaging of distal and local axons in mammalian cortex

Authors: *G. J. BROUSSARD, JR[1], Y. LIANG[2], M. FRIDMAN[3], E. K. UNGER[1], G. MENG[2], L. T. PETREANU[3], N. JI[2], L. TIAN[1]

Abstract: Understanding brain function demands linking neural activity from identified cell types in different brain areas with the animal's behavior. Optical recordings from distant axons terminated in the imaging area provide direct interrogation of output signals carried by specific afferents projected from distant neuronal populations. Untargeted Genetically-encoded- Ca^{2+}-indicators (GECIs) diffuse poorly to small presynaptic compartment in distal axons, resulting in dim, noisy signals. To facilitate optical recording in axons, we developed preSyn-GCaMP6, an axonally-targeted GECI employing a genetic strategy for active targeting to distal and local axons. We characterized the photochemical properties, targeting efficiency and sensitivity of preSyn-GCaMP6s in vitro and in vivo in mammalian neurons. PreSyn-GCaMP6s showed about 6-fold increased enrichment, 2-fold enhanced signal to noise ratio (SNR) and increased density of active boutons in thalamic axons in response to oriented gratings in mouse primary visual cortex (V1), compared to cytosolic GCaMP6s. The increased probe concentration resulted in larger baseline fluorescence in distal axons, facilitating recordings in vivo and image registration. In addition, we were able to image boutons at a depth of 600μm, approximately 50% deeper than anything previously reported with cytosolic GCaMP6s. We then utilize preSyn-GCaMP6s to record layer specific local circuit outputs while excluding postsynaptic signals. Using optical recording with preSyn-GCaMP6s, we discovered a previously unknown difference in tuning responses across cortical layers in axons projected from cells of layer 4 in V1.

Title: An AAV toolbox for enhanced transduction efficiency with regional and/or cell-type specificity in the CNS and PNS after systemic delivery

Authors: *K. CHAN, S. R. KUMAR, M. J. JANG, Y. LUO, R. C. HURT, N. C. FLYTZANIS, N. GOEDEN, B. E. DEVERMAN, V. GRADINARU

Abstract: Recombinant adeno-associated viruses (rAAVs) are extensively used for *in vivo* gene transfer. Capsids and rAAV genomes that enable widespread and efficient gene expression following noninvasive administration with potential for expression that is restricted to target elements (cell types and/or defined nuclei) are needed. We therefore applied the capsid selection method CREATE (Cre-recombination-based AAV targeted evolution; Deverman et al., Nat. Biotechnol., 2016) to evolve and select for novel capsids that more efficiently or more selectively transduce specific cell populations. Here we report several novel capsids with neural tropisms. First, AAV-PHP.eB, an enhanced version of the previously reported AAV-PHP.B vector, is able to transduce 69% of $DAPI^+$ cortical cells after intravenous delivery of 1 x 10^{11} vg per adult mouse. Second, AAV-PHP.S, transduces neurons throughout the PNS. At a dose of 1 x 10^{12} vg per adult mouse, intravenous administration of AAV-PHP.S transduces 82% of $PGP95^+$ dorsal root ganglion neurons. In addition, because of the efficiency of AAV-PHP.S following systemic delivery, it is able to efficiently transduce difficult-to-access sensory neurons, such as those in the cardiac ganglia, or peripheral sensory networks that are widespread, such as the enteric nervous system. Third, we have identified an AAV-PHP.B variant, AAV-PHP.N, which shows strong selectivity for CNS neurons, and reduced liver transduction. To achieve targeted gene expression in nontransgenic animals, we are also presenting on the use of rAAV vectors with both cell type-specific promoters and with miRNA binding sites in the 3' UTR to reduce expression in specific neural cell types. By pairing previously described cell type specific promoters such as serotonergic (FEV), human synapsin 1 (hSyn1), interneuron (Dlx5/6), tyrosine hydroxylase (TH) and Purkinje Cell (PCP), with the AAV-PHP vectors, we can achieve both high efficiency and specificity of gene expression in the CNS and PNS. Finally, we have developed a two-component viral vector system to control the density of labeling when systemically delivering genes with AAV-PHP viruses. We demonstrate the utility of such a system by separately encoding spectrally distinct fluorescent proteins under various gene regulatory elements for single-cell morphology studies. Collectively, the versatility and efficiency of these viral capsids and viral vectors provides an expansion to the current AAV toolbox with potential for efficient and versatile gene manipulation studies.

Title: Deep brain optical imaging reveals motivational salience encoding by dorsal raphe dopamine neurons

Authors: *J. CHO[1], J. E. ROBINSON[2], J. B. TREWEEK[2], D. A. WAGENAAR[2], V. GRADINARU[2]
[1]Computation and Neural Systems, [2]Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Although reward and punishment have opposite valence and promote approach and avoidance respectively, both stimuli can enhance arousal and capture attention to guide appropriate behavioral responses. We have previously demonstrated that dopamine (DA) neurons in the dorsal raphe nucleus (DRN), which project densely to the extended amygdala, are wake-active over sleep states, promote arousal, and show robust activation to salient stimuli, irrespective of their hedonic valence [1]. We further examined whether DRN-DA neurons encode motivational salience [2] (n = 6 TH-Cre mice) with fiber photometry [3]. GCaMP6f-expressing mice were subjected to fear memory acquisition and extinction, where sensory cues of originally neutral context gain and lose motivational salience. Before conditioning, DRN-DA neurons showed small activation to the novel sensory cues (conditioned stimuli, CS; house-light and 65 dB 5 kHz tone) and no significant change across repetitive exposures (Pearson's $r = -0.12$, $p = 0.75$). Throughout learning and repeated pairings (10 trials, random ITIs within [70, 110] seconds) of CS and electric footshock (unconditioned stimuli, US; 0.6 mA for 1 sec), DRN-DA neurons gradually developed phasic response to the CS (Pearson's $r = 0.78$, $p < 0.01$). As previously shown [1], US induced robust activation of DRN-DA neurons, which however

decreased across repeated exposures (Pearson's $r = -0.90$, $p < 0.001$). In contrast to the learning phase, evoked response to the CS diminished across extinction trials, where sensory cues lost motivational salience (Pearson's $r = -0.83$, $p < 0.0001$). These findings suggest that phasic activation of DRN-DA groups encodes motivational salience and that they are modulated by expectations at the population level. To discriminate between projection-specific functions at the single-cell level, we built a two-photon microscope for deep brain imaging of projection-identified DRN-DA cell bodies during appetitive and aversive conditioning tasks. Taken together, these data deepen our understanding of the functional properties of DRN-DA neurons.

Title: Machine learning to predict expression, membrane localization, and functional properties of diverse Channelrhodopsin variants

Authors: *C. BEDBROOK[1], K. K. YANG[2], A. J. RICE[2], X. DING[1], F. H. ARNOLD[2], V. GRADINARU[1]
[1]Biol. and Biol. Engin., [2]Chem. and Chem. Engin., CALTECH, Pasadena, CA

Abstract: To facilitate neuronal circuit interrogation, we aim to advance the repertoire of current optogenetic tools, focusing on diversifying spectral properties, kinetics, and increasing current strength of the light-gated channel, Channelrhodopsin (ChR). To engineer integral membrane ChRs we must introduce mutations that improve desired functional properties while retaining expression and membrane localization. This is a major challenge because the sequence and structural determinants of ChR expression and localization are highly constrained and largely unknown. To address this challenge we trained data-driven models to predict ChR sequences that will express, localize, and function. To train these models we used a data set of expression, localization and functional properties of >200 ChR sequences of our own design [1] combined with data from previously published ChR variants [2,3]. For our designs we used structure-guided SCHEMA recombination [4] to create a large ($2x10^3$) set of functionally diverse chimeras from three sequence-diverse ChRs (CsChrimsonR, C1C2, and CheRiff). From this recombination library we chose 218 ChR chimeras and assayed them for expression and plasma membrane localization in mammalian cells. The majority of the ChR chimeras express and a significant fraction also localize to the membrane. The majority of these localizing chimeras are also functional light-gated channels. Many chimeras have stronger light-activated inward currents than the three parents, and some have unique off-kinetics and spectral properties relative to the parents. Combining these data with the published data on different ChR variants we were able to build models that reliably predict ChR properties. We use these models to identify sequence diverse ChRs capable of efficient localization and function. We applied these models to convert naturally occurring ChR incapable of mammalian localization into ones that localizes well and have novel functional properties. We can interpret these models to elucidate sequence and structure elements important for ChR expression, membrane localization, and functional properties to inform further engineering efforts.

Title: Engineering prokaryotic repressors for optical sensing of neurotransmitters

Authors: *X. DING, C. N. BEDBROOK, N. HUTCHINS, V. GRADINARU
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: As chemical transmission plays a critical role in neural communication, there is a growing need for tools that can report on the dynamics of neurotransmitters *in vivo*. Here we explored the use of prokaryotic transcriptional repressors, specifically TetR family repressors, for sensing melatonin and N-acetylserotonin (NAS). The TetR family of repressors is a highly diverse family of genetic regulators that share the same general fold but sense a large variety of bio-active small molecules. We first screened a number of these natural TetR proteins and identified one TetR family repressor that showed promiscuous sensitivity to melatonin in millimolar (mM) concentrations. Using directed evolution, we improved the repressor's sensitivity and specificity to sense melatonin in micromolar (μM) concentrations, which is within the physiological levels in mammalian pineal glands. In each round of evolution, libraries comprising 1000 – 20,000 variants generated with error-prone PCR or site saturation mutagenesis were transformed into *E.coli* and screened with a high-throughput fluorescence-based assay. Hits with greatest improvement in both sensitivity and specificity were selected, validated, and further evolved. In addition to melatonin-responsive repressors, we also identified NAS-responsive repressors, that could enable multiplexed monitoring of both melatonin and NAS. Interestingly, some repressor variants show reversed ON-OFF activity, which leads to the potential of engineering reverse melatonin-controlled transactivators. Both the repressors and the directed evolution method presented here provide a promising platform for development of genetically encoded neurotransmitter sensors and targeted expression of other neural modulators.

Title: Elucidating the circuit architecture and function of NAc inputs to the VTA

Authors: H. YANG, J. W. DE JONG, Y. TAK, J. R. PECK, H. BATEUP, *S. LAMMEL
Mol. and Cell Biol., UC Berkeley, Berkeley, CA

Abstract: The nucleus accumbens (NAc) is a crucial brain structure implicated in reward processing and neuropsychiatric disorders. In contrast to ventral tegmental area (VTA) dopamine (DA) neurons projecting to NAc, which have been intensively studied over the last decades, much less is known about the circuit architecture and functional role of NAc inputs to the VTA. Recently, anatomical tracing and electrophysiological studies generated considerable debate regarding the synaptic connectivity of inhibitory NAc inputs with DA and non-DA VTA neurons. Importantly, a major limitation of previous work is that the both NAc and VTA have been considered to be largely homogeneous brain structures. Using a multidisciplinary approach combining retrograde tracing, *ex vivo* electrophysiology and optogenetics, we investigated whether distinct subdivisions of the NAc (medial shell [NAcMed] versus lateral shell [NAcLat]) target different DA and non-DA subpopulations in the VTA. Our data demonstrate that D1-expressing medium spiny neurons in NAcMed and NAcLat target different VTA subregions. NAcMed terminals are located preferentially in the medial VTA, while NAcLat terminals can be found in the lateral VTA and substantia nigra. Next, we elucidated the circuit architecture of NAcMed and NAcLat inputs to the VTA. We found that NAcMed inputs predominantly exert direct inhibitory, GABA-A receptor-dependent control over VTA DA neurons projecting to NAcMed. In contrast, NAcLat inputs preferentially inhibit VTA GABA neurons, which presumably results in a disinhibition of DA neurons projecting to NAcLat, as optogenetic stimulation of NAcLat terminals in the VTA increases neural firing of DA neurons projecting to NAcLat. Consistent with a potential mechanism for disinhibition is the finding that *in vivo* optogenetic stimulation of NAcLat terminals in the VTA could strongly drive instrumental behavior as well as real-time place preference. Collectively, these observations strongly suggest that the mesolimbic DA system is comprised of discrete circuits, which may serve distinct biological functions in the regulation of motivated behaviors.

Title: Causal link between neocortical single-cell ensemble activity and specific behaviors

Authors: ***J. H. JENNINGS**[1], C. K. KIM[1], J. MARSHEL[1], M. RAFFIEE[1], L. YE[1], S. QUIRIN[1], S. PAK[1], C. RAMAKRISHNAN[1], K. DEISSEROTH[1,2,3]
[1]Bioengineering, Stanford Univ., Palo Alto, CA; [2]Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA; [3]Howard Hughes Med. Inst., Stanford, CA

Abstract: Neurons in orbitofrontal cortex (OFC) individually respond differentially to distinct rewarding experiences such as caloric- or social-related stimuli, but it is unknown if these activity-specific ensembles play causal roles in discrete behaviors, or in circuit dynamics. To dissect individual contributions of activity-specific OFC neuronal populations to behavior and circuit physiology, we coupled genetically encoded Ca^{2+} imaging with engineered microbial opsin-based control, to optically both monitor and manipulate activity of OFC neurons at the single cell level with two-photon microscopy. Employing this all-optical approach in head-fixed mice during caloric consumption or social interaction, we identified a spatially-biased clustered population within OFC (caloric-encoding cells mean distance=97.66μm ±3.09 SEM, random cells mean distance=110.40μm ±2.30 SEM, P=0.005) that selectively responded to caloric rewards and displayed minimal overlap with social-specific cells ($F_{2,30}$=20.79, P<0.0001, mean=25% caloric-only, 11% social-only, and 6% overlapping (both) cells, n=11 mice). Next, two-photon optogenetic stimulation of individual caloric-responsive neurons was found to play a causal role in behavior, significantly increasing consumption compared to non-stim sessions ($F_{2,30}$=145.7, P<0.0001, mean=20 stim cells, n=6 mice) and to control mice lacking an opsin ($F_{2,30}$=127.9, P<0.0001, mean=20 stim cells, n=6 mice per group); conversely, single cell activation of social-specific neurons did not alter caloric intake ($F_{2,30}$=0.444, P=0.9918, mean=20 stim cells, n=6 mice). We next sought to determine local network activity dynamics arising from

specific single cell-resolution stimulation. The number of neurons that were optogenetic stimulus-excited but not directly-targeted increased monotonically with the number of successfully-targeted cells (Spearman's rho=0.82, P=0.02); surprisingly, this relationship was not seen for neurons that were optogenetic stimulus-inhibited but not directly-targeted (Spearman's rho=-0.14, P=0.78) (*n*=10 light targets per mouse, *n*=9 mice). Of interest, the excited but non-directly-targeted cells exhibited detectable spatial clustering within OFC (excited cells mean distance=80.34 ±6.57 SEM, random cells mean distance=113.53 ±5.26 SEM, P=0.008). Taken together, using all-optical methods for cellular-resolution behaviorally-relevant ensemble control and imaging, we have identified an activity-specific ensemble that is functionally and spatially distinct within OFC that locally modulates other spatially-distinct clusters and selectively controls the behavior it encodes.

Title: Cell-type specific reward dynamics of habenular neurons

Authors: *E. L. SYLWESTRAK[1], S. VESUNA[2], A. CROW[1], C. RAMAKRISHNAN[2], K. DEISSEROTH[3]
[1]Bioengineering, [2]Stanford Univ., Stanford, CA; [3]Bioengin & Psych, Stanford Univ. Dept. of Psychology, Stanford, CA

Abstract: The processing of appetitive and aversive stimuli is essential to guide motivated behavior and is represented in many structures across the mammalian brain. The habenular complex is comprised of a transcriptionally diverse group of cells in the dorsal thalamus, divided into two anatomically distinct regions. The medial subdivision receives input from the limbic system and send projections to the midbrain, and has been shown to play a role in behaviors related to processing of aversive and appetitive stimuli, including stress, nicotine withdrawal, and voluntary exercise. This region is smaller and less studied than its lateral counterpart, but it displays a strong degree of transcriptional heterogeneity, with cells expressing a wide variety of neuromodulatory receptors, neurotransmitters, and neuropeptides. Using multiplexed

transcriptional analysis, viral projection mapping and tissue clearing, we analyzed the distribution of Th-, ChAT- and Substance P- expressing neurons in the habenula and their axonal termination patterns in the midbrain. Using Cre-mediated viral delivery in subpopulations of medial habenula neurons and fiber-based calcium imaging during an operant task, we find that habenular subpopulations exhibit cell-type specific reward dynamics: tyrosine hydroxylase expressing neurons only respond to reward-predictive cues (n=4 mice, p=0.02), cholinergic neurons are not significantly modulated by reward (n=3 mice, p=.33), and tackykinin neurons respond to both reward and reward prediction error (n=6 mice, p=0.01), but with distinct temporal dynamics. These data suggest that medial habenula neurons encode multiple aspects of reward responses and could serve as a mechanism to modulate motivated behavior in different emotional states.

Title: All-optical closed-loop feedback control of targeted neuronal populations in awake animals

Authors: *N. YOUNG, C. K. KIM, M. INOUE, Y. S. KIM, K. DEISSEROTH
Stanford Univ., Stanford, CA

Abstract: Stimulation of targeted neural cells and tissues can be achieved with varying degrees of temporal precision and cell type specificity. Most stimulus strategies used today are “open-loop” in that they ignore ongoing activity and other features of the momentary brain state. For many applications, however, it is desirable to make real-time adjustments to stimulus intensity and waveform based on ongoing activity in the same or other brain areas[1], though this has proven difficult to achieve with electrical methods due to large stimulation artifacts and a lack of cellular specificity. Here we present an all-optical setup for applying stimulation to defined subsets of neurons in closed-loop, leveraging the advantages of genetically-targeted population recording/control. We co-expressed spectrally-separated opsin and fluorescent Ca^{2+} indicator in

genetically-defined subpopulations of neurons in behaving mice. Ca^{2+} responses (serving as a proxy for cellular activity) were recorded using the Frame-Projected Independent-Fiber Photometry (FIP) method described previously[2]. Opsin excitation was achieved by laser through the same optics used for activity recording. This system exhibited a stimulation artifact below 3% of total signal. Surprisingly, we found that simple PID control was sufficient to bring activity within 20% dF/F of a predetermined setpoint. These results demonstrate the utility of approximating population neural activity (as a single time-varying scalar) in behaving animals with a linear plant model.

Title: Molecular and circuit-dynamical identification of top-down neural mechanisms for restraint of reward-seeking

Authors: *C. K. KIM, L. YE, J. H. JENNINGS, N. PICHAMOORTHY, D. D. TANG, C. RAMAKRISHNAN, A.-C. WANG, K. DEISSEROTH
Stanford Univ., Stanford, CA

Abstract: Reward-seeking behavior is fundamental to survival, but suppressed acquisition of even highly-valued rewards can be essential as well; such suppression is adaptive in diverse naturally-occurring situations and is thought to be disrupted in individuals suffering from addiction and other major neuropsychiatric diseases. In humans and rodents, the medial prefrontal cortex (mPFC) has been implicated in suppressing both natural and compulsive reward-seeking; however, despite vital significance in health and disease, the neural circuit pathways through which mPFC regulates reward-seeking remain to be found. Here we show that a specific subset of superficial mPFC projections to a subfield of nucleus accumbens (NAc)

neurons naturally encodes the decision to initiate or suppress reward-seeking when faced with harmful consequences (81.05±1.30% prediction accuracy, bootstrapping with 1,000 shuffles, $p<0.05$, $n=5$ mice). Surprisingly, mPFC projections to the ventral tegmental area- source of the best understood and most potent reward circuitry in the vertebrate brain- did not encode (and could not causally elicit) suppression of reward-seeking; moreover, while optogenetic stimulation of mPFC→NAc neurons as a population could elicit aversion of a neutral environment (Paired t-test, $t_7=2.67$, $p=0.032$, $n=8$ mice), suppression of reward-seeking by this mPFC→NAc population was not found, strikingly even when reward value was mitigated by association with a harmful stimulus (Tukey-Kramer test on 1-way ANOVA, $p=0.69$, $n=8$ mice). Only a highly-resolved subpopulation of top-down projecting neurons, identified by 2-photon Ca^{2+} imaging and novel activity-dependent labeling strategies to recruit the relevant subset of neurons, was capable of suppressing reward-seeking (2-way ANOVA interaction, $F_{1,10}=6.79$, $p=0.026$, $n=6$ mice). This natural activity-resolved mPFC projection to NAc displayed unique molecular-genetic and microcircuit-level features concordant with a broad role in the conserved behavior of reward-seeking regulation, providing cellular and anatomical identifiers of behavioral and possible therapeutic significance.

Abstract: Simultaneous optical modulation and readout of neuronal circuit activities is a promising neurotechnology, which could help us decipher how the brain's electrical signals relate to perceptual, cognitive, emotional and motor functions. During recent years, the use of genetically encoded (optogenetic) actuators such as channelrhodopsin, became overwhelmingly successful. On the other hand, genetically encoded voltage indicators (GEVIs) have not yet been

satisfactorily optimized and their combination with optogenetic modulation has been difficult to achieve in practice. One major obstacle is the overlap of the spectral bands of light used to activate opsin-based actuators and at the same time excite and image available GEVIs. We propose to use novel bacteriophytochrome-based fluorescent proteins (FPs) to generate a new class of GEVIs that are excited and emit fluorescence in the near-infrared (NIR) spectrum (e.g. 720 nm). For this, we have engineered and characterized a set of spectrally diverse monomeric NIR FPs, termed miRFPs, and produced an effective FRET pair consisting of miRFP670 and miRFP720 proteins. Using this FRET pair we then designed several ratiometric FRET-based NIR GEVI constructs. We have also engineered several intensiometric NIR GEVI variants based on single NIR FPs, either miRFP703 or miRFP720. Both types of the NIR GEVI constructs demonstrated good plasma membrane localization and exhibited up to 3% ΔF/F in a response to a 100 mV depolarizing step in membrane voltage in patch-clamped HEK293 cells. To further optimize these NIR GEVI constructs, we apply an all-optical screening platform consisting of imaging hardware and mammalian cells stably expressing optogenetic actuators.

Title: Neural circuit mechanisms underlying drug-induced changes in motivated behaviors

Authors: *J. W. DE JONG[1], S. A. AFJEI[1], J. R. PECK[1], V. HAN[1], C. K. KIM[2], K. DEISSEROTH[3], S. LAMMEL[1]

Abstract: The mesocorticolimbic dopamine (DA) system, which is comprised of DA neurons in the ventral tegmental area (VTA) and their projections to different forebrain regions, has been fundamental in the formulation of most models of drug use, abuse, and addiction. Recently, we demonstrated that different afferent inputs to the VTA mediate reward- and aversion-related behaviors in profoundly different ways. Because drugs of abuse (e.g., cocaine, morphine) modify

the function of excitatory inputs to the VTA, we hypothesized that drug-evoked synaptic adaptations in specific VTA afferent pathways may underlie some of the maladaptive behaviors of individuals with substance use disorder (SUD). The lateral hypothalamus (LH) represents a major afferent pathway of the VTA, which has been previously implicated in both positive and negative motivational states. Using a multidisciplinary approach combing *in vivo* optogenetics, fiber photometry, synaptic electrophysiology, rabies virus-based tracing and *in situ hybridization*, we studied a) function, b) circuit architecture and c) drug-evoked synaptic plasticity of the LH→VTA pathway. We first established a critical role of the glutamatergic component of the LH→VTA pathway for mediating aversion-related behaviors by performing optogenetic stimulation and silencing experiments as well as fiber photometry in freely moving mice. Next, we elucidated the complete circuit architecture of the LH→VTA pathway by combining anatomical and functional neural circuit mapping. We found that, qualitatively, LH neurons target all VTA DA and non-DA subpopulations. Quantitatively, however, we discovered a highly-biased input scheme, which reveals that DA neurons projecting to nucleus accumbens (NAc) medial shell represent a dominant downstream effector of glutamatergic LH neurons. Remarkably, 24 hours after a single injection of cocaine (15 mg/kg, intraperitoneal), the synaptic strength of excitatory LH inputs onto VTA DA neurons projecting to NAc medial shell was significantly reduced compared to saline-treated animals. In contrast, a single injection of cocaine had no effect on the synaptic strength of excitatory LH inputs onto VTA DA neurons projecting to NAc lateral shell. Taken together, our results suggest that cocaine exposure induces synaptic depression in a brain pathway that encodes aversion-related behaviors, which may explain some of the maladaptive behaviors of individuals with SUD in which they continue drug-seeking/drug-taking behavior in the face of negative consequences.

Title: Amygdalonigral salience signals shape action-outcome associations

Authors: *E. E. STEINBERG[1], F. GORE[1], B. D. HEIFETS[1], K. T. BEIER[1], C. FÖLDY[2], T. N. LERNER[3], M. D. TAYLOR[1], L. LUO[1], K. DEISSEROTH[1], R. C. MALENKA[1]

Abstract: The central amygdala (CeA) is known to orchestrate learned fear responses in many species. In addition to its well-described role in fear, the CeA also influences other cognitive processes including reward learning. However, the specific neural circuits that mediate CeA-dependent reward processes and their relationship to fear-promoting circuits remain poorly defined. Midbrain dopamine neurons perform essential computations that are required for many aspects of reward learning. Accordingly, we hypothesized that the robust projection from the CeA to the substantia nigra pars lateralis - a heterogeneous region containing dopamine, GABA and glutamate neurons - was well-positioned to link CeA signals with downstream effectors of reward learning. Consistent with our hypothesis, gain-of-function experiments revealed that optogenetic activation of amygdalonigral projections could potently drive instrumental (action-outcome), though not Pavlovian (cue-outcome), associations, pointing to a selective role for amygdalonigral neurons in reinforcement learning. However, single-cell gene expression analyses demonstrated that amygdalonigral neurons overlap with genetically defined cell types previously implicated in fear learning. Using fiber photometry to monitor population activity during natural behavior, we found that amygdalonigral neurons were activated by both appetitive and aversive stimuli during action-outcome and cue-outcome learning, indicating that as a population, amygdalonigral neurons signal salience as opposed to valence. Ongoing experiments seek to establish synaptic and circuit mechanisms that enable amygdalonigral signals to influence future behavior. Taken together, our data suggest that amygdalonigral neurons encode a salience signal that engages strong motivational drives capable of profoundly shaping action selection, revealing a previously unappreciated mechanism for linking emotion, motivation and action that provides new insight into the complex neural interactions that endogenously regulate motivated behaviors.

Abstract: Internal brain states fluctuate during behavior, impacting perception, cognition, and action. Internal states are governed in part by neuromodulation, but the set of neuromodulatory cell types involved are not fully known. Here we screened for neuromodulatory neuron activity in larval zebrafish during a behavioral task that reports fluctuations in the internal state of alertness. We developed a method to classify cell types from brain-wide neural activity imaging through post hoc immunohistochemistry and volume registration, allowing us to record from neurons in 22 neuromodulatory nuclei during behavior. In addition to noradrenergic neurons in the locus coeruleus, we identified several unexpected cell types encoding alertness, including cocaine- and amphetamine-regulated transcript and cholinergic neurons in the tegmentum, as well as dopaminergic, serotonergic, and neuropeptide-Y-expressing cells in the hypothalamus. We also found somatostatin-expressing neurons in the hypothalamus correlated with reduced alertness. Alertness-encoding cell types were preferentially correlated with one another, and their cooperative activity permitted improved prediction of behavioral performance. We then used this dataset to guide targeted investigation of homologous neuromodulatory nuclei in mice. Deep brain in vivo calcium imaging revealed striking conservation of function between zebrafish and mice, across all seven identified neuromodulatory cell types tested. We found that optogenetic activation of any cell type correlated with alertness was sufficient to enhance alertness - detected by decreased reaction time. However, inactivation of any individual cell type did not change reaction time, suggesting partial redundancy in this behavioral context. Interestingly, we found that optogenetic inactivation of these same cell types in the absence of a motivated behavioral task could decrease physiological measures of alertness and behavioral indices of anxiety, suggesting that the overlap in cell type significance is dynamically conditional upon behavioral context and organismal need. These results reveal an evolutionarily conserved network of multiple neuromodulatory systems that cooperatively regulate a fundamental internal state.

Abstract: Prior experiences affect how future actions are evaluated and selected. This effect is central to reinforcement learning systems and is critical for generating adaptive behavior. Behavioral challenge assays use inescapable stressors to probe how the repeated failure of escape behaviors effect action selection; these assays cause animals to transition to a passive coping state in which minimal effort to escape is made. Several brain regions, including the raphe nucleus, habenula, and periaqueductal gray, are known to be important in regulating passive behavior, but it remains unclear where or how evidence from the ongoing behavioral challenge experience is accumulated to cause the transition from active to passive coping. Here, we develop a behavioral challenge protocol that induces passive coping in late-stage larval zebrafish and use this protocol to perform an unbiased brain-wide search for regions where neural activity

is correlated with the extent of behavioral challenge. We found that during behavioral challenge, individual habenular neurons exhibited staggered recruitment into an activated ensemble. This recruitment caused a steady rise in average neural activity that is confined to the habenula (35% Δf/f change by end of the 36 minute protocol; n=8 fish) and that could be bi-directionally modulated. Prior treatment with the fast-acting anti-depressant ketamine prevented this rise (2% Δf/f change; n=4), while repeat-exposure to behavioral challenge enhanced it (80% Δf/f change; n=12). The magnitude of this habenular signal was correlated with size of the behavior change ($r = -0.56$; $p = 0.003$). Outside the habenula, the raphe nucleus and the dorsal thalamus both exhibited significant reduction in activity which plateaued 22 minutes into the protocol (-19% and -20% Δf/f change, respectively; n=8). Optogenetic stimulation of the habenula combined with brain-wide imaging revealed that habenula activation was sufficient to reduce mobility in an aversive experience-dependent fashion, (-0.45 mm/s; n=8) as well as selectively reduce activity in the downstream raphe nucleus. Taken together, our results suggest that a unique pattern of staggered progressive population recruitment within the habenula encodes aversive experience and underlies behavioral pattern selection in the face of adverse conditions. The development of the larval zebrafish as a vertebrate system for studying active to passive behavioral state transitions creates new possibilities, both for genetic and pharmaceutical screens, and for understanding how the diverse brain areas involved in stress-coping interact-- both in normal and pathological states.

Title: A novel red-shifted excitatory channelrhodopsin with multiple properties enabling markedly improved integration of Ca^{2+} imaging with optogenetic control

Authors: *Y. KIM[1], M. INOUE[1], C. RAMAKRISHNAN[1], H. KATO[1], S. YOSHIZAWA[2], K. DEISSEROTH[1]
[1]Stanford Univ., Stanford, CA; [2]Univ. of Tokyo, Tokyo, Japan

Abstract: Abstract
A rapidly-evolving goal of modern neuroscience is to combine the power of optogenetic activity-control with the information on specific activity patterns that is accessible via genetically encoded fluorescent activity-sensors. This goal has been challenging to fully achieve, due in part to the overlapping spectra of actuators and sensors. Here, we report a novel excitatory channelrhodopsin (ChR) nicknamed here 'MO20' that was discovered through sequence analysis and biophysical characterization of rhodopsin-like proteins from over 600 microbial organisms. MO20 showed robust excitation by redshifted light in the range of $\lambda \sim 585$-650nm, suitable for compatibility with GFP-based activity sensors with minimal optical cross-talk. Peak photocurrent values under orange ($\lambda \sim 585$nm) and red ($\lambda \sim 650$nm) light were 4.5±0.6 and 1.0±0.16 nA, respectively; these values were significantly higher than for previously characterized red-shifted ChRs under the same illumination conditions when tested in parallel. Speed was also suitable; MO20 exhibited more than 80% spiking fidelity in trains at frequencies up to 40Hz (orange light); and action potentials could be readily induced in neurons with orange light with irradiance values down to 0.005mW/mm^2. In a neuronal culture imaging setting with the Ca^{2+} sensor GCaMP6m, MO20 showed 10-fold faster rise-and-decay Ca^{2+} signal kinetics and significantly higher fluorescent signal amplitude than the leading red-shifted ChRs. This striking difference likely relates to reduced spectral overlap between opsin and sensor, faster channel kinetics, larger photocurrent, and pH independence. These unprecedented biophysical properties define a tool for more powerful and precise probing of neuronal function via integration activity sensors and actuators.

Title: Wide field-of-view three dimensional all-optical neurophysiology with millisecond-resolution *In vivo*

Authors: *J. H. MARSHEL, S. QUIRIN, E. L. SYLWESTRAK, A. CHIBUKHCHYAN, A. CROW, C. RAMAKRISHNAN, K. DEISSEROTH
Stanford Univ., Stanford, CA

Abstract: Of presumptive importance for neural coding and processing, cellular activity patterns are sparse in space and time within dense populations of neurons; neighbors often encode different information, have different inputs and postsynaptic partners, and are active at distinct points on the millisecond-timescale. To help identify and understand causal roles, on circuit dynamics and behavior, of precise activity patterns within functionally characterized subsets of neurons, we developed an all-optical microscopy system capable of optogenetic stimulation (e.g., using excitatory opsin $C1V1_{T/T}$) of dozens or more single neurons every 30 ms, addressing sequences of subpopulations with millisecond (~1-3 ms) precision in three dimensions while recording Ca^{2+} activity (GCaMP) of the same neurons and surrounding populations of at least hundreds of neurons in parallel. This novel system combines 3D two-photon imaging with 3D spatial light modulator (SLM) two-photon holographic stimulation, and among other features, improves power efficiency across the volume to quadruple the simultaneously addressable population of neurons (450x450μm x 100μm axial), when applied with standard pixel count SLMs (512x512) and high NA objectives (25x 1.05 NA). We further demonstrate how to at-least double the ensemble excitation pattern-refresh rate of SLM systems, which until now have been theoretically limited to 10-100s Hz based on available SLMs and stimulation parameters. Finally, to yet further expand the addressable population, we commissioned and directed the development of high-speed, high-pixel-count SLMs for precise, large-scale 3D two photon optogenetics (supported under our DARPA Neuro-FAST program from Dec. 2013 onward). Applying our custom SLMs, along with low magnification objectives (e.g., 10x 0.6NA), we discovered that we can simultaneously photo-stimulate neurons across >1mm of cortex, an unprecedented range with substantial implications. We demonstrate and validate these technologies in awake mouse cortex, wherein the same neurons are imaged and stimulated across weeks. Neurons that were imaged and stimulated *in vivo* were later found in registered CLARITY-processed tissue, thus integrating anatomical characterization (of major significance for cell type specific labeling). Together, these novel approaches enable all-optical cellular-resolution read/write, activity-guided, and potentially closed-loop control of precisely emulated activity patterns (coupled with molecular and anatomical information from the same volume), which will be of critical significance for understanding how behavior arises from circuit activity patterns.

Title: Two-photon calcium imaging in behaving rhesus macaque and its feasibility for all-optical brain-machine interfaces

Authors: *X. SUN, E. TRAUTMANN, D. O' SHEA, J. MARSHEL, W. ALLEN, I. KAUVAR, C. RAMAKRISHNAN, S. RYU, K. DEISSEROTH, K. SHENOY
Stanford Univ., Stanford, CA

Abstract: Optical techniques such as two-photon (2p) calcium imaging have the potential to transform the way we interrogate neural circuits, both in the realm of basic neuroscience and in the development of brain-machine interfaces (BMIs) by overcoming some of the limitations of electrophysiological methods. We have developed a platform for performing long-term, stable 2p imaging in behaving rhesus monkeys during a motor task.

There are many challenges to translating 2p imaging from rodents to monkeys. To screen for GCaMP constructs that express at appropriate levels in monkeys, we injected three constructs of different volumes at 6 separate sites in PMd and M1. We monitored GCaMP expression after virus injection with wide-field and 2p imaging. To maintain the optical clarity of the imaging chamber, we developed a chamber that incorporates a transparent replaceable silicone window sealed from the external environment to minimize risks of infection. We minimized the chamber size to support bone health and surgical feasibility, without compromising accessible imaging area using large multiphoton lenses with short working distances. Finally, we developed a novel rigid three-point head restraint system that prevents the task itself from generating motion artifact and a brain stabilization system that applies gentle pressure to restrict total motion throughout multi-hour behavioral experiments. Using an image of surface vasculature acquired by wide-field imaging as a map, it is possible to reliably navigate to specific cortical locations using blood vessels as landmarks. As a result, we are able to visit each injection site repeatedly in a targeted way across imaging sessions.

While systems for 2p imaging in behaving monkeys are progressing, assessing their potential for all-optical BMIs is of interest. A quantitative comparison between imaging and electrode data ideally from the same animal, as well as their BMI decoding performance, has yet to be performed. As a first step, we compared these modalities by decoding hand trajectories using Kalman-filter based decoders from synthetic 2p calcium imaging signals generated from Utah array recordings. We evaluated how realistic, but simulated, imaging signals from hundreds of neurons encode kinematic information in comparison with the measured action potentials. We found that it was possible to decode hand position and velocity from synthetic imaging signals, where decode quality varied considerably as a function of SNR and the imaging frame rate. This simulation provides insights into the value of applying optical techniques to NHP studies, and should help establish the feasibility and design space for all-optical BMIs.

Title: Precise spatiotemporal control of neural activity

Authors: ***A. R. MARDINLY**[1], I. OLDENBURG[2], N. PEGARD[2], S. SRIDHARAN[2], E. LYALL[2], K. CHESNOV[2], S. BROHAWN[2], L. WALLER[2], H. ADESNIK[2]

Abstract: Neural circuits encode information in the rate, timing, and number of action potentials and in the identity of active neurons. A technological approach that could drive precise spatiotemporal trains of neural activity with cellular resolution and millisecond temporal precision in full 3D could unlock a new class of experiments to probe the coding logic of neural circuits. Recently developed all-optical multiphoton approaches combine spiral scanning on C1V1-expressing neurons with 2P calcium imaging to probe the function of neural circuits. While these approaches effectively active specific groups of neurons with high spatial resolution, they do not possess the requisite temporal precision to drive complex, naturalistic sequences of spatiotemporal neural activity. To overcome this challenge, we developed new opsins for scanless 2P stimulation and combined them with a novel form of 3D scanless temporal focusing called 3D-SHOT. We introduce ChroME, a new ultra-fast opsin that is 3.5-fold more powerful than Chronos. Brief (<5 ms) 3D-SHOT stimulation of ChroME-expressing L2/3 pyramidal neurons generates reliable action potentials with sub-millisecond jitter. Using *in vivo* cell attached patch recordings, we demonstrate high fidelity replay of complex, naturalistic sequences of spatiotemporal neural activity in pyramidal neurons using ChroME and in PV, SOM, and VIP interneurons using Chronos. We combine 3D holographic stimulation with volumetric calcium imaging to probe the network response to introducing varying numbers of action potentials into the cortex while holding stimulation rate constant. Finally, we validate that spatial resolution is maintained while volumetrically stimulating up to 50 spots simultaneously, and all-optically activate groups of neurons with millisecond precision. By combining new ultra-fast, powerful

opsins with novel scanless 3D stimulation paradigms, we gained temporal control of multi-photon all-optical experiments, paving the way to systematically activate functionally defined neurons with parameterzed stimulus patterns during simultaneous calcium imaging in the awake, behaving brain.

Title: Automated fine-scale three-dimensional paw tracking and posture classification system in mice

Authors: *M. BALBI, A. LUO, L. BOLANOS, F. BOLANOS, J. LEDUE, T. H. MURPHY
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Forelimb movements represent a refined feature of the mammalian motor system. Goal-directed limb movements integrate relevant sensory inputs and motor commands. The resulting movement trajectory and kinematics lie in a high dimensional space, which is intractable for manual rating. We developed an integrated hardware and software system that uses low-cost, single-board computers, machine vision, and supervised learning to automate paw tracking and posture classification. Head-fixed mice were trained to pull a lever for a water reward upon hearing an auditory ¨go¨ cue while being recorded by a two-camera stereovision system. Previous implementations of machine vision for paw movement analysis only track the centroid of the paw, as the high deformability of the paw imposes a great challenge on automatically discriminating posture. To extract posture information from videos, we developed machine vision techniques to track a fluorescently dyed (Nile Blu 1mg/ml, emission: RG9 -IR-) mouse paw from the videos, extract its geometric and kinematic features, and reconstruct the 3D movement trajectory during contact, grasping and release of the lever. Based on preliminary data, the range of mouse paw postures was clustered into 9 different types, characterized by their static (relaxed-on, contracted-on and off lever) and dynamic features (along the 3 spatial dimensions). We trained nonlinear classifiers (random forests and neural networks) using these features and 3D trajectories to estimate paw posture parameterized with openness, digit extent, and contact with the lever. In our study, we validated the robustness and precision of our system against a physical readout of lever position. Our approach allows for longitudinal automated assessment and comparison of fine-scale paw movements in health and disease.

Title: Correlating mesoscopic cortical calcium activity with single unit activity or body movements in mice

Authors: ***M. P. VANNI**[1], D. XIAO[1], C. MITELUT[1], A. W. CHAN[1], J. LEDUE[1], J. BOYD[1], M. BALBI[1], F. BOLANOS[1], Y. SEKINO[1], G. SILASI[1], N. V. SWINDALE[2], T. H. MURPHY[1]

Abstract: Resting state brain spontaneous activity is commonly used to map the brain at mesoscale in a large number of species. With the recent development of mice expressing new genetically encoded calcium indicators (GCaMP6), cortical activity can be measured at high sensitivity in awake behaving animal at low cost in contrast to most other approaches. A new challenge is now the possibility to combine it with multiple parallel measurements ranging different spatial and temporal scales from single neuron electrophysiology to behavior. Here, we explored the arrangement of mesoscale spontaneous calcium activity in cortex firstly with single cell activity and secondly, with behavior. Mice expressing the calcium indicator GCaMP6 were implanted with bilateral chronic window covering most of the dorsal cortex including motor, somatosensory and visual cortex as well as medial region such as retrosplenial and cingulate cortex. Green fluorescence under blue LED illumination was recorded in awake mice with a CCD camera. To remove the contribution of blood artefact, green or blue reflectance was also recorded in parallel to estimate changes in cerebral blood volume (CBV). Single unit electrophysiology was recorded using chronically implanted tetrodes or laminar 64channels electrodes in different cortical and subcortical regions of the brain. Behavior measurement was performed using video analysis of the paws, whiskers or pupil movement. The cortical sequences of activity associated with each individual neuron was mapped by averaging the fluorescence fluctuation preceding and following each individual spike. We observed that, in contrast to cortex, subcortical neurons exhibit more complex cortical motifs of activity with the presence of strong suppression. By analyzing the cortical dynamic in different cortical regions, motif

classification could be performed. Similarly to spike triggered averaging, mapping could also be performed by using correlation between firing rate and calcium activity. Time jittering of these signals provides information about the temporal dynamics of each signal. Based on this strategy other modalities were combined with mesoscopic imaging such as motor action. By quantifying the density of movement of forepaw or whiskers, behavior triggered averaging or multimodal correlation showed a precise mapping involving forelimb or barrel somatosensorimotor cortex respectively. This multimodal, multiscale approach could be used to explore functional remapping in multiple models of disease such as ischemia. In future, this could be extended to other modalities such as peripheral nerve recordings or mouse vocalization.

Title: Automated optogenetic and mesoscopic brain imaging system for the mouse home-cage with web-based monitoring for up to 10 mice

Authors: *F. BOLANOS, J. M. LEDUE, J. D. BOYD, T. H. MURPHY
Psychiatry, UBC, Vancouver, BC, Canada

Abstract: Over the last several years experiments that rely on awake and behaving mice have become a new standard. These experiments can require the mouse to be head-fixed to obtain high quality optical data and are usually done chronically following many mice over the course of several weeks which can induce stress. Additionally these mice have to be trained to tolerate long sessions of head restraint, and since this is done for each mouse it can become a time consuming task for the experimenter. Here we describe a home-cage based system that automatically identifies, head-fixes, rewards and weighs each mouse. The system is similar to the automated imaging system that we published before (Murphy et al. 2016), but differs in its head-fixing mechanism and in the addition of a movable laser to stimulate different areas of the cortex while the mouse is head-fixed and involves to 2 linked cages increasing mouse number to

potentially 10. We followed 7 mice for 2+ months, 6 of the 7 mice learned to auto head-fix within a week. We obtain an average of 20 minutes of head-fixed imaging data per day, per mouse yielding a total of 2 hours of imaging data per day/cage. Additionally, we obtain ~10 weight data points per day per mouse. The system can support up to ten mice that are automatically imaged, stimulated and weighed. We also describe a training protocol where the RFID identified mice learn to self-initiate brain imaging trials in order to obtain water rewards while their movement becomes progressively more restricted until they are fully head-fixed. The system utilizes the Raspberry Pi single board computer in order to minimize cost and thus maximize the potential to scale up the system (see rendering).

Title: Sub-cortical or peripheral nerve spike-triggered cortical mesoscale activity associated with specific actions in awake chronic mice

Authors: *D. XIAO[1,2], J. M. LEDUE[1,2], J. GREWAL[3], T. H. MURPHY[1,2]

Abstract: Flexible control of voluntary movement relies on hierarchical cortical and subcortical neuronal circuits to mediate sensorimotor and memory information integration. How information processing in the motor pathways eventually drive a specific action still largely unknown. The difficulty comes from recording large scale neural activity in awake mice and at the same time as accurately monitoring the motor output. Here we provide a new design of chronic recording system which integrates with wide-field GCaMP imaging, multi-site sub-cortical/cortical cellular electrophysiology and peripheral nerve recording in head-fixed free running mice. Facial motor nerve impulse was measured by paired fine wire (15 μm) recording directly from the nerve dominating the whisker. Multiple tetrodes were implanted in region of interests to record extracellular activity in motor pathway (can be thalamus, striatum or brainstem). A mesoscale nerve spike-triggered averaging procedure allowed the identification of motifs that are preferentially related to motor output by employing genetically targeted indicators of neuronal activity. Preliminary results indicated self-initiated vibrissa movement not only driven by primary sensorimotor areas (barrel cortex, motor cortex) but also involved in association cortical regions (retrosplenial cortex, secondary motor cortex) and striatum. Motor feedback in the cortex can also be investigated by microstimulation in the motor nerve through the same recording electrode. Our chronic recordings remained stable for weeks, demonstrating that this method can be employed to investigate the dynamic and distributed neuronal ensemble interactions that underlie processes of motor control and sensorimotor learning in behaving mice.

Title: Movement initiation in gcamp6 mice is preceded by stereotyped, multi-second wide-scale dorsal cortex dynamics

Authors: *C. MITELUT[1], A. X. LUO[1], G. SILASI[2], Y. SEKINO[3], J. BOYD[1], F. BOLANOS[1], N. V. SWINDALE[1], T. H. MURPHY[1]

Abstract: Modern experimental neuroscience has sought to identify the neural correlates of free, or voluntary, behaviour largely focusing on instructed task paradigms in humans using fMRI or EEG (Haggard 2008).
Using GCaMP6 transgenic mice (Ai93 and Ai94) we sought to identify neuronal dynamics preceding the initiation of voluntary behaviours (i.e. lever pulling, grooming and licking) by recording calcium activity in dorsal cortex along with simultaneous recordings of a lever deflection angle in a pulling task (11/11 mice) and behavioral videos (5/11 mice). To automate detection of grooming and licking behaviours using video annotation, we segmented the foreground from each frame, projected it to PCA space and used binary Random Forest classifiers to detect behaviour initiation. During each ~20 minute recording session (30-50 sessions/mouse) we identified quiescent periods (i.e. animal was motionless for > 3s) preceding lever pulling (~20-100/session), grooming (10-40/session) and licking (10-30/session) and evaluated calcium activity (dF/F0) in three cortical ROIs: motor, limb and retrosplenial (RS). We found that lever pulling was preceded by limb cortex calcium activation of up to 2% as early as 7 seconds (or more) prior to movement initiation - consistent with findings of early prediction of cognitive performance in humans (Soon 2008). In contrast, grooming was preceded by ~1s of cortical activation and licking by 2-3s. Interestingly, rather than arising from a ~0% dF/F0 baseline and following monotonic activation of limb and motor cortex - all behaviours were initiated during the second activation phase of an activation-depression-activation cycle in limb cortex. This suggests that spontaneous behaviours arise from ongoing large-scale oscillations.
We additionally found that during lever pulling cortical activation peaked at different times in different ROIs: RS activation peaked 1sec before behaviour initiation, whereas motor cortex activation peaked on behaviour initiation (i.e. t=0s) and limb cortex 1s after initiation. This suggests that the distinct roles cortical regions play in complex behaviour preparation and execution can be studied at the mesoscale level using GCaMP6 signals.
These results are consistent with research in humans that behaviour preparation begins substantially earlier than is available to higher order faculties (e.g. awareness in humans). The findings further validate the use of widefield imaging in GCaMP6 mice to study learning and behaviours during task acquisition paradigms and the further investigation of spontaneous behaviour in non-human animals using task-free, non-reporting paradigms.

Title: An active nanophotonic multi-beam probe for optogenetic stimulation *In vivo*

Authors: *A. KEPECS[1], Q. LI[1], A. MOHANTY[2], A. M. TAYADON[2], M. LIPSON[2]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Columbia Univ., New York, NY

Abstract: The ability to optically turn on or off the activity of specific neural populations has revolutionized the investigation of neural circuits. Most applications, however, employ a single optical fiber to flood a large area of the brain with light, limiting the ability to selectively activate neurons with high spatial resolution in vivo. Using silicon photonics technology it is possible to miniaturize complex optical circuits on a silicon chip, resulting in a quantum leap in optical control, matching the scale and resolution currently achieved by electrical silicon probes for electrical recordings.Here we developed and tested the first visible light multipoint-emitting nanophotonic switches for in vivo optogenetics. To enable selective activation of neurons using multiple, independently controllable optical beams, we used micro-switches that could route light toward different diffraction gratings. Fast and independent control over each beam was achieved via external micro-controllers. We demonstrated that the same technology previously used for switching light in the near infrared spectral range could be used for switching light in the visible, using the thermo-optic effect of silicon nitride, a material that is transparent to the visible spectral range.To characterize the probe performance in mammalian brain in vivo, anaesthetized mice expressing ChR2 in PV+ inhibitory interneurons (PV-Cre x Ai32 mice) is used. The demonstrated probe employs a 1x8 multipoint-emitting nanophotonic switch (emitter size: 20 x 20 µm, 250 µm interbeam distance) coupled to a tungsten electrode array. The probe could be readily inserted and lowered into cortex. By applying two external microcontrollers to arbitrarily direct 472nm blue light to 4 output grating light emitters we could independently activate single ChR2-expressing PV interneurons throughout layers 2-6 of visual cortex in vivo. The activated PV interneurons showed robust spike firing with short first spike latency (1.475 +/- 0.063 ms, mean +/- sem) and low jitter (0.031 +/- 0.003 ms, mean +/- sem). In conclusion we successfully show our ability to use external microcontrollers to arbitrarily direct light to multiple densely spaced illumination points along the shank. Scaling it up to a larger number of beams (e.g.128) is expected to be straightforward since these devices are defined lithographically, enabling high-resolution optical stimulation in deep brain regions.

Title: Transgenic sparse expression of genetically

Authors: ***S. D. ANTIC**[1], C. SONG[2], M. COLAVITA[2], T. KNOPFEL[2]
[1]Neurosci, UConn Hlth., Farmington, CT; [2]Med., Imperial Col. London, London, United Kingdom

Abstract: One of the major goals of the BRAIN Initiative is development of the tools for recording electrical activity in many neurons simultaneously. Genetically encoded optical indicators, particularly genetically encoded voltage indicators (GEVIs), enable longitudinally monitoring neuronal circuit dynamics of identified cell populations, and advanced transgenic approaches achieve high levels of indicator expression in vivo. GEVI's membrane delimited signals arise largely from the neuropil where dendritic and axonal membranes of many cells intermingle, hence targeting non-sparse cell populations leads to dense expression patterns such that optical signals from neuronal processes cannot be allocated to individual neurons. Here we show that sparse but strong expression of genetically encoded optical indicators, using a titratable recombination-activated transgene transcription, achieves a Golgi staining-type indicator expression in vivo, and such expression pattern is capable of further resolving morphologies of individual cells including dendritic spines and axonal boutons. Using different transgenic strategies, we also illustrate that co-expression of genetically encoded voltage and calcium indicators can be achieved in the same animal for studying neuronal circuit input-output relationships. These transgenic strategies serve as ideal approaches for GEVI-based optical voltage monitoring of neural circuits at the level of groups of neurons or at the level of single neurons in intact mammalian tissues. Equally important, the sparse GEVI technology allows monitoring voltage transients of specified cell types such as pyramidal neurons in a specific cortical layer, thus further refining the experimental tools for dissection of brain circuits.
