Conversely, hormone replacement therapy in aged rodents and non-human primates restores synapse density in the hippocampus (Gould et al 1990; Hao et al 2003) and pre-frontal cortex (Chisolm & Juraksa, 2012; Hao et al, 2006), and improves cognitive function (Gibbs, 2000; Hara et al, 2016). Importantly, short-term E2 administration promotes rapid synaptogenesis, and these newly-formed synapses are stabilized after a chemical LTP protocol (Srivastava et al, 2008). To ask if E2 treatment can be used to promote recovery of sensory function in the aged brain, we use a rodent model in which severe amblyopia is induced by chronic monocular deprivation (cMD). cMD induces a significant decrease in the visual acuity of the deprived eye, a reduction in excitatory synapses density in primary visual cortex (V1), and is highly resistant to reversal in adults (Montey & Quinlan, 2011). Because the presence of E2 receptors in rodent V1 has been controversial, we first demonstrated robust expression of both classical receptor subtypes (ERα and ERβ) in adult male and female binocular control (BC) LE rats. Using a marker for excitatory synapses (PSD95), we demonstrate that cMD induces a decrease in synapse number (BC: 282.55±15.43 (n=4); cMD: 244.30±24.96 (n = 6)) and synapse size (K-S test, $p = 1.03E10^{-8}$). However, treatment of adults with a single physiologically-relevant dose of E2 (17- α E2, 15 μg/kg) induces a significant increase in synapse number (cMD: 244.30±24.96 (n=6), +E2: 305.50±15.40 (n=12); t-test, p=0.03) and size (K-S test, $p =1.99E10^{-6}$) in the deprived V1 (contralateral to the eye deprived from P14 - P190). Using a marker for recently-active synapses (antibody against phosphorylated Serine-831 of the GluR1 subunit of the AMPA receptor), we show that E2 significantly increases the number (cMD: 180.67±25.12 (n=6), +E2: 305.5±15.4 (n=12); t-test, p=0.02) and size of pS831 puncta in deprived V1 (K-S test, p =0.05). Importantly, E2 followed by visual stimulation (100 cycles of 0.05 cycles/degree, 100% contrast full-field gratings reversing @1 Hz) further increases the size of PSD95 (K-S test, p =0.04) and pS831 puncta (K-S test, $p =5.17E10^{-5}$), suggesting that salient stimulation incorporates newly formed synapses into functional circuits. We are currently examining the how repetitive performance in a visual discrimination task impacts the new synapses induced by E2 treatment.

**Title:** Understanding of how retinal inactivation induces recovery from amblyopia

**Authors: *H. J. DE JESÚS-CORTÉS**[1], M.-F. FONG[2], R. W. KOMOROWSKI[2], M. F. BEAR[2]
[1]Picower Inst. for Learning and Memory, [2]Picower Inst. for Learning and Memory, Brain and Cognitive Sci., MIT, Boston, MA

**Abstract:** Our lab recently discovered that experimental amblyopia induced in mice by temporary monocular deprivation is reversed completely when binocular visual experience follows a brief period of bilateral retinal inactivation using tetrodotoxin (TTX). In the present study, we aimed to understand how retinal inactivation is able to induce this rapid recovery. We hypothesized that retinal inactivation promotes recovery by lowering the threshold for experience-dependent synaptic strengthening via metaplasticity. To test this hypothesis, we first recorded multi-unit activity and local field potentials in layer 4 of mouse visual cortex before, during, and after the period of TTX-driven inactivation. We found that retinal inactivation induces an overall reduction of visually-evoked and spontaneous activity within the first several hours after intravitreal TTX injection. As the drug effect wore off, we observed a striking potentiation of visually-evoked activity, evident 24 hours after treatment and persisting for several days. This rebound effect observed after TTX treatment could be accounted for by a decrease in the synaptic modification threshold that allows the same sensory input to elicit heightened sensitivity in visual cortex. We therefore examined common molecular correlates of metaplasticity in visual cortex. We first examined the subunit composition of NMDA-type glutamate receptors, which has been closely linked to shifting the propensity for LTP in cultures and in vivo. Here, we use immunoblotting to show that retinal inactivation rapidly increases expression of NR2B, resulting in a significant reduction in the NR2A/B ratio. Further, we show that retinal inactivation increases phosphoryation of the *grin2b* transcription factor CREB, an effect that is still observed at 24 hours. We are now conducting experiments to determine if the NR2A/B ratio shift is necessary for recovery after TTX-induced retinal silencing. This knowledge will not only provide crucial information about how the visual cortex compensates for loss of sensory input, but also could suggest novel non-invasive clinical interventions for the treatment of amblyopia.

**Title:** Sensory deprivation promotes cross-modal plasticity at thalamocortical (TC) synapses in the adult mouse brain

**Authors: *G. RODRIGUEZ**[1], H.-K. LEE[2]
[1]Zanvyl Krieger Mind Brain Institute/ Biol. CMDB, [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Sensory loss leads to extensive compensatory adaptations in the brain that impact both deprived and spared sensory areas. In the spared sensory cortices, we previously reported strengthening of thalamocortical (TC) synapses as a result of cross-modal sensory deprivation in adult mice (Petrus, et al. 2014). This was unexpected in light of previous studies demonstrating that TC plasticity is lost after the second postnatal week of development in mice. Here we test the hypothesis that cross-modal sensory deprivation is able to recover synaptic plasticity mechanisms at TC synapses in adults. By combining slice electrophysiology of primary visual cortex (V1) with optogenetic stimulation, we demonstrate that deafening adult mice results in the reemergence of NMDA receptor-dependent long-term potentiation (LTP) at TC synapses in V1. In addition, we show *in vivo* functional changes in V1 as a result of deafening by measuring optical intrinsic signals during presentation of visual stimuli before and after monocular deprivation. We observe a rapid ocular dominance shift after monocular deprivation for 3 days in adult deafened mice that is absent from age-matched normal reared controls. Moreover, we show that this shift is due to accelerated potentiation of the non-deprived eye inputs to V1 in deafened animals. These data suggest that deafening accelerates ocular dominance plasticity in V1 of adult mice by promoting LTP of TC synapses. Furthermore, based on our findings, we propose cross-modal sensory deprivation as a potential method to regain sensory cortical plasticity in adults.

**Title:** Binocular vision restores glutamatergic and GABAergic proteins for regulating experience-dependent plasticity mechanisms to normal level

**Authors: *J. L. BALSOR**[1], B. BESTON[3], D. G. JONES[4], K. M. MURPHY[2]
[1]McMaster Integrative Neurosci. Discovery and Study, [2]Dept Psychol Neurosci & Behaviour, McMaster Univ., Hamilton, ON, Canada; [3]Univ. of Toronto, Missisauga, ON, Canada; [4]Pairwise Affinity Inc., Dundas, ON, Canada

**Abstract:** Abnormal visual experience during the critical period (CP) affects visual acuity, ocular dominance and the molecular mechanisms that regulate experience-dependent plasticity. Previously, we found that early monocular deprivation (MD) disrupts the synaptic environment by shifting some plasticity markers towards immature levels (GluN2A:GluN2B), while others shift to mature levels (GluN1:GluA2 and $GABA_A\alpha1$:$GABA_A\alpha3$) (Beston et al., 2010). This abnormal synaptic environment is thought to reduce plasticity and underly why recovery after MD is often poor, especially when reverse occlusion (RO) is used. Recent studies have suggested that binocular vision (BV) or perhaps even some forms of binocular deprivation (BD) promote better recovery after early MD. Here we asked which treatment paradigm, RO, BD, or BV after early MD leads to the best recovery of glutamatergic and GABAergic synaptic proteins that regulate experience-dependent plasticity.

To address this question we reared animals with early MD to the peak of the CP, and then did either RO, BD or BV. The BV was done for 1hr, 6hrs, 1d, 2d or 4d so that dynamic changes in synaptic proteins could be followed. The expression of glutamatergic (GluN1, GluN2A, GluN2B, GluA2) and GABAergic ($GABA_A\alpha1$, $GABA_A\alpha3$) proteins were quantified using Western blot analysis of synaptosomes. We also analyzed the effect of deprivation and recovery on different regions of the visual cortex representing central (CVF), peripheral (PVF) and monocular (MVF) visual fields because previous studies have shown that deprivation causes the largest changes in the CVF representation.

MD causes reduced expression of GluN1 and increased $GABA_A\alpha1$ in the CVF and PVF, and reduced GluN2A and $GABA_A\alpha3$ expression across all of the visual cortex. Treatment with either RO or BD failed to restore expression of those receptor subunits to normal levels. In contrast, treatment with BV restored expression of some proteins to normal levels. After 4 days of BV the levels of GluN2A in CVF, and GluN1 in CVF and PVF had been restored to normal. Only 6 hours to 1 day of BV restored $GABA_A\alpha1$ expression to normal levels. BV also promoted recovery of the GluN2A:GluN2B and $GABA_A\alpha1$:$GABA_A\alpha3$ balance in all three regions of visual cortex. These findings provide further support for the benefits of BV as a treatment for early abnormal vision by showing that it promotes recovery of synaptic mechanisms that regulate experience-dependent plasticity.

**Title:** Early establishment and stability of cortical network synchronization during development

**Authors: *M. T. COLONNESE**
Pharmacol. and Physiol., The George Washington Univ. Sch. of Med., Washington, DC

**Abstract:** During development neural networks must grow from a state of zero connectivity to the interconnected circuits that underlie complex dynamics in adults. Synchronization of the developing elements is hypothesized to be a critical component of circuit formation. Understanding the nature of this synchronization will constrain models of activity-dependent development. Two broad hypotheses about early synchronous activity exist. In the first, exuberant connectivity and weak inhibition render early networks hyper-synchronous, allowing for rough 'first-draft' connectivity. In this model, maturation of synaptic properties and the integration of new cell classes (eg. inhibitory interneurons) causes activity to become progressively more precise and less-synchronous allowing for synaptic refinement. A contrary hypothesis is that immature activity provides a model of mature function allowing for formation of correct local connectivity from the outset. In this model synaptic maturation and inhibitory neuron integration occurs not to transform network properties, but rather maintain them in the face of increasing connectivity.
To distinguish between these hypotheses I examined early cortical networks for evidence of hyper-synchronization using single-units isolated from multi-electrode arrays in the visual cortex of awake mice from P(ost-natal) day five, through the acquisition of mature activity patterns (P24). Network synchronization was quantified by evaluating the number of co-active neurons active, as well as by pair-wise firing rate co-modulation (Renart et al. 2010. *Science* 327), the distribution of firing vectors (Okun et al. 2012. *J Neurosci* 32) and population coupling (Okun et al. 2015. *Nature* 521). While firing patterns in infant animals during the period of cholinergic retinal waves (P5-9) superficially appear hyper-synchronous because they spend more time in down-states (network silence), when analysis is restricted to active periods synchronization is lower than expected by chance. Adult-like patterns for all measures were established by P10, before eye-opening and during the period of glutamatergic retinal waves. Thus the cortical circuit is exhibiting properties of an asynchronous network before the development of balanced inhibition and before visual experience.
Together the data show that while early thalamocortex produces unique patterns of rhythmic activation and elongated silences, the network properties determining synchronization maybe more similar to the mature brain than expected. Our data provide no support for the hypothesis that early cortical circuits are hyper-connected or hyper-synchronous.

**Title:** Neuromodulator induced bidirectional changes in ocular dominance in the mouse primary visual cortex

**Authors: *S. Z. HONG**[1], S. HUANG[2], A. KIRKWOOD[1]
[1]Mind Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Hussman Inst. for Autism, Baltimore, MD

**Abstract:** Neuromodulatory signals mediated by G protein-coupled receptors are essential for the induction of experience-dependent cortical plasticity. Neuromodulators can exert a push-pull control of Hebbian plasticity, with receptors coupled to Gs and Gq11, promoting the induction of LTP and LTD, respectively, *in vitro*. Importantly, β-adrenergic receptors (coupled to Gs) and 5-HT2c serotonergic receptors (coupled to Gq11) can provide a cellular substrate for reinforced learning, as these receptors can transform the so-called “eligibility traces” into lasting LTP and LTD. Therefore, we tested whether the activation of these receptors *in vivo* can promote lasting bidirectional changes in visual responses. Using optical imaging of intrinsic cortical signals, we found that pharmacological activation of 5-HT2c receptors, in conjunction with brief visual conditioning of one eye, induces LTD-like changes of the responses evoked by the conditioned eye, thus shifting the natural ocular dominance balance. The same visual stimulation, paired instead with the activation of β-adrenergic receptors, results in LTP-like changes and ocular dominance shift in the opposite direction. In addition, blocking β-adrenergic receptors during short monocular deprivation in juvenile mice, which is not expected to change visual responses, resulted in a paradoxical depression of the open eye. These results suggest that the push-pull regulation of Hebbian plasticity underlies the neuromodulation of experience dependent ocular dominance plasticity.

**Title:** An unexpected period of neurochemical imbalance during postnatal development of the rat visual cortex

**Authors: *H. ZHANG**, L. MU, D. WANG, Q. LIU, M. T. WONG-RILEY
Med. Col. of Wisconsin, Milwaukee, WI

**Abstract:** Last year we reported on a surprising period of synaptic imbalance, with suppressed excitation and enhanced inhibition, in the rat's visual cortex from postnatal day (P) 28 to P33. This period falls within the peak of the critical period of development reported by others in rats and mice. We hypothesized that synaptic changes observable at the electrophysiological level had a neurochemical counterpart. The goal of the present study was to analyze the developmental trends of 5 neurochemicals in the visual cortex of normal Sprague-Dawley rat pups *daily*, from the time of eye opening (P14) to P36, when neurons presumably have reached maturity. The 5 neurochemicals were: cytochrome oxidase (a metabolic marker of neuronal activity), NMDAR1 (the obligatory subunit 1 of the glutamatergic NMDA receptors), $GABA_AR\alpha1$ (the α1 subunit of the $GABA_A$ receptors), BDNF (brain-derived neurotrophic factor), and TrkB (tropomyosin receptor kinase or tyrosine protein kinase B, a high-affinity receptor of BDNF). We found that, against a gradual increase in the expressions of all 5 neurochemicals with age, there was a sudden and significant fall in cytochrome oxidase, NMDAR1, BDNF, and TrkB at P28 and sustained until P33/34, before returning to P27 levels at P34/35. On the other hand, the expression of $GABA_AR\alpha1$ continued to increase with age, with a sharper rise within layers II, III, and VI neurons between P27 and P31, before leveling off at P32. Similar patterns of labeling existed in neurons from layers II to VI for each of the neurochemicals. These results are consistent with our hypothesis that the synaptic imbalance demonstrable electrophysiologically has a neurochemical correlate, with reduced excitatory and metabolic neurochemicals and increased inhibitory neurochemical all occurring from the end of the $4^{th}$ toward the end of the $5^{th}$ postnatal week. Moreover, we found that enhanced GABAergic receptor expression during the period of synaptic imbalance is correlated with a decrease, not an increase, in BDNF and TrkB. This negative relationship is unexpected, as the relationship was thought to be positive during the critical period of visual cortical development in rodents. **Title:** Activation of somatostatin inhibitory neurons by Lypd6-nAChRα2 system restores juvenile-like plasticity in adult visual cortex

**Authors:** ***M. SADAHIRO**[1], M. P. DEMARS[1], P. N. BURMAN[1], P. E. YEVOO[1], M. R. SMITH[1], A. ZIMMER[2], H. MORISHITA[1]
[1]Psychiatry, Neuroscience, Opthalmology, Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Inst. of Mol. Psychiatry, Univ. of Bonn, Bonn, Germany

**Abstract:** Globally heightened cortical plasticity during juvenile critical periods declines into adulthood, posing a major challenge for functional recovery following brain injury or disease in later life. The inhibitory cortical network has been long appreciated as a crucial regulator of cortical plasticity, yet contributions of specific interneurons other than Parvalbumin (PV) interneurons in restoring juvenile-like global plasticity in the adult brain have been underexplored. Cortical Somatostatin (SST) interneurons, which represent nearly a third of the cortical GABAergic neurons, are situated as versatile “hubs” due to their ability to integrate multiple inputs, including bottom-up sensory signals and neuromodulation induced by locomotion or top-down regulation. Moreover, SST interneurons highly innervate local PV interneurons, which places them in a potentially ideal position to drive the rapid inhibition known to be instructive to global plasticity. Still, SST interneuron-specific molecular and circuit mechanisms for re-initiating global cortical plasticity in adulthood remain unknown. Here we identified Lypd6, an endogenous SST interneuron-specific positive modulator of nicotinic acetylcholine receptors (nAChRs), as a molecular target for re-initiating cortical plasticity in adulthood. Lypd6 expression in visual cortex decreases into adulthood in concert with declining plasticity. Overexpression of Lypd6 specifically in SST interneurons during adulthood rapidly increases their activity in an experience-dependent manner through the action of α2 subunit-containing nAChRs to in turn inhibit PV interneuron activity and ultimately re-initiate visual cortex plasticity. Importantly, the activity of SST interneurons alone was also found to be an effective target, as transient chemogenetic activation of SST interneurons was able to re-initiate

visual cortex plasticity in adulthood. Identification of the Lypd6-nAChRα2 system and the SST->PV disinhibitory microcircuit as the first SST interneuron-specific plasticity regulator provides potential therapeutic targets for treating disorders with limited recovery due to diminished plasticity such as amblyopia as well as psychiatric disorders with deficits in SST- interneurons.

**Title:** Integrative bioinformatics approach identifies that postnatal lead exposure disrupts critical period plasticity in visual cortex

**Authors: *P. E. YEVOO**[1], M. SMITH[2], M. SADAHIRO[2], J. DUDLEY[2], H. MORISHITA[3]
[2]Friedman Brain Institute, Icahn Sch. of Med., Mount Sinai, New York, NY, [3]Psychiatry, Neuroscience, Ophthalmology, Mount Sinai Sch. of Med., New York, NY, [1]Icahn Sch. of Medicine, Mount Sinai, New York, NY

**Abstract:** Given that thousands of industrial and synthetic chemicals released into the environment have an unknown, but potentially significant capacity to harm neurodevelopment, there is an urgent need for high-throughput systematic approaches to identify chemicals impacting neurodevelopment. Neurodevelopment is marked by periods of plasticity wherein neural circuitry is optimized by the environment. If environmental chemicals perturb these critical periods, development of normal function can be permanently disrupted, and may confer

risk for neurodevelopmental disorder such as autism. To identify chemicals that may disrupt critical periods of neuroplasticity, we applied a high-throughput informatics approach to match a critical period transcriptional signature from primary visual cortex (V1) of juvenile mice at the peak of the critical period for ocular dominance plasticity to approximately 120 known neurotoxic chemical gene sets, derived from the Comparative Toxicogenomics Database. We identified lead (Pb) as the top-ranked chemical whose gene set shows an opposite expression profile to critical period gene expression in V1 (Hypergeometric Test, OR = 4.8, FDR = $3.1x10^{-06}$). Though epidemiological studies have established Pb as a potent developmental neurotoxicant, the functional impact of childhood Pb exposure on critical period plasticity has not been tested. From our analysis indicating that Pb would suppress the critical period gene signature, we hypothesized that juvenile Pb exposure would also suppress experience-dependent plasticity during the critical period. To test this, we administered 50PPM Pb acetate in drinking water to dams and their pups starting at P8, to mimic a childhood exposure to Pb. At the peak of ocular dominance plasticity, we performed monocular deprivation and then assessed plasticity at P28. In mice administered normal water, we observed the expected shift in cortical responsivity. In contrast, Pb treatment suppressed the shift in cortical responsivity, demonstrating that Pb suppressed functional plasticity in vivo.Together, this work indicates that a highthroughput, in silico approach can effectively identify neurotoxicants of critical period plasticity. Given the recent water quality crises in Flint and elsewhere, where elevated levels of Pb were detected, such systematic analyses are critical to identify dangers to childhood neurodevelopment. Future work should identify the mechanisms subserving Pb disruption of developmental plasticity to facilitate therapeutic target discovery to rescue disruption of plasticity and neurodevelopment. **Title:** Integrative bioinformatics approach to systematically identify environmental chemicals that disrupt critical periods of plasticity

**Authors: *M. R. SMITH**[1], P. YEVOO[2], M. PENG[3], M. SADAHIRO[1], B. KIDD[3], J. T. DUDLEY[3], H. MORISHITA[4]
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Icahn Sch. of Medicine, Mount Sinai, New York, NY; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Psychiatry, Neuroscience, Ophthalmology, Mount Sinai Sch. of Med., New York, NY

**Abstract: Background:** Given the thousands of chemicals released into the environment there is an urgent need for high-throughput approaches to identify chemicals impacting neurodevelopment. Central to childhood neurodevelopment are critical periods of plasticity wherein neural circuitry is optimized by the environment. If chemicals perturb these periods, development of normal function can be permanently disrupted.
**Methods:** To identify anti-plasticity chemicals, we computationally matched transcriptional signatures of critical period plasticity (Smith MR et al 2016) to 1742 chemical gene sets from the Comparative Toxicogenomics Database. To gain insight into biology, we applied Chemogenomics Enrichment Analysis (CGEA) to the chemicals across 5191 Gene Ontology (GO) Biological Processes and 96 Library of Integrated Network-based Cellular Signatures (LINCS) ligands. We tested CGEA convergent pathways using qPCR and immunohistochemistry.
**Results:** We identified 50 anti-plasticity chemicals, including antimicrobials, metals, and pesticides. CGEA identified 33 GO Biological Processes and multiple cytokines (FDR < 0.05) enriched among the 50 chemicals, which converged on pathways related to response to pathogen, immune cell chemotaxis, and inflammation via IL1 and TNFa. These pathways mimic a host inflammatory response to infection, including microglia activation. Using the LPS model of inflammation, we found that LPS at a dose that disrupts critical period plasticity (Smith MR et al 2016) activates cortical microglia (>Iba1, $p = 0.02$; >CD68, $p = 0.03$) and decreases the P2y12 purinergic receptor required for critical period plasticity ($p = 0.01$).
**Conclusions:** Anti-plasticity chemicals may induce an inflammatory response, activating microglia to disrupt critical period plasticity. Next steps include directly testing the capacity of anti-plasticity chemicals to induce an inflammatory response to disrupt plasticity.

**Title:** Experience-dependent survival of newly formed spine is gated by Lynx1

**Authors: *M. SAJO**[1], G. ELLIS-DAVIES[2], H. MORISHITA[3]
[1]Psychiatry, [2]Neurosci., [3]Psychiatry, Neuroscience, Ophthalmology, Icahn Sch. of Med. at Mount Sinai, New York, NY

**Abstract:** Newly formed spines usually retract within days without transforming into stable spines. However, to what extent genetic and environmental factors regulate this key process is totally unknown. Identification of mechanisms that gate the conversion of new spines into stable spines could provide conceptually novel strategies for restoring function. Here we examined to what extent exposure to new experience impacts the survival of newly formed spines and whether Lynx1, a nicotinic brake for functional plasticity, modulate this key process. To identify newly formed spines, we chronically imaged the apical dendrites of layer 2/3 and 5 pyramidal neurons in binocular region of primary visual cortex of adult Thy1-GFPM-line wild type (WT) and Lynx1 knockout (KO) mice. “Newly formed spines” were defined as ones to first appear in the second imaging session 4 days after the initial imaging session. We then examined the impact of visual experience on the survival of these newly formed spines by performing monocular deprivation (MD) immediately after the 2nd imaging session and then conducting a 3rd imaging session after 4 days of MD. We found that while the survival rate of newly formed spines in adult WT mice is comparable between the non-deprived (no MD) and MD groups in both L2/3 and L5 neurons, the rate is higher in the adult Lynx1KO mice following 4-day MD compared to no MD condition. A previous study in adult WT mice reported that more spines form during MD, selectively in L5 neurons, but these spines do not show experience-dependent change in survival rate over 16 days (Hofer et al 2009). In adult Lynx1KO mice, we found that survival rate of spines formed during MD is also comparable to no MD condition, suggesting that experience-dependent survival is specific to new spines formed immediately before deprivation, but not to those formed during deprivation. Finally, older spines that have existed longer than 4 days show no change in survival rate between no MD and MD group in both WT and Lynx1KO mice. Collectively, our study suggests that experience-dependent spine survival is selective to

new spines formed immediately before MD. Our study reveals new spines just formed before exposure to new experience as key substrates for circuit plasticity, and Lynx1 as the first modulator of experience-dependent survival of newly formed spines.

**Abstract:** The experience-dependent plasticity of brain circuits is high during early postnatal development, but tapers off as the brain matures. The development of proper excitation/inhibition balance, as well as a steady increase in the expression of myelin-associated axonal growth inhibitors, is thought to direct circuit maturation and restrict cortical plasticity. However, the molecular factors controlling circuit plasticity at the level of synapses remain unknown. Synapse-organizing adhesion molecules are potential modulators of circuit plasticity and here we studied their role in visual plasticity. Our analysis has demonstrated a specific activity-dependent regulation of SynCAM/CADM-family adhesion molecules in the visual cortex of mice following monocular deprivation during the cortical critical period. We performed electrophysiological recordings from live, awake mice deficient in SynCAM-mediated synaptic adhesion after monocular deprivation. This revealed that synaptic SynCAM adhesion limits cortical plasticity and that mice lacking SynCAM-adhesion have heightened adult plasticity. SynCAM-deficient mice additionally exhibited impaired development of oscillatory brain activity. Using Cre-dependent recombination and viral-mediated knockdown, we finally demonstrated that synaptic adhesion mediated by SynCAMs limits the plasticity of the mature brain and that cell-type specific knock-down re-opens plasticity. Our work reveals a missing molecular link between the known pathways that control the extent of cortical plasticity and the organization of excitatory synapses. These findings underscore the emerging role of transsynaptic interactions in the wiring and remodeling of functional circuits.

**Abstract:** Visual cortical networks have a substantial plasticity and ability to reorganize after a visual deficit. For example, there is considerable spontaneous vision recovery following traumatic optic neuropathy in both rats and humans, but little is known about how the cortical network reorganization takes place during this time. In this study, we monitored the residual visual function and plasticity of the cortical networks following a monocular partial Optic Nerve Crush (ONC) across time. To this end, neuronal responses to a monocular flash illumination in each eye were measured in different areas of the visual cortical pathways of awake mice (Thy1-GCaMP6s) using *in vivo* bilateral wide-field calcium imaging, before and 1 hour, 1, 3, 5, 7, 14, 23 and 30 days after the ONC. Moreover, visual acuity of the mice was measured unilaterally in both sides using the optokinetic reflex before and 1, 3, 8, 15, 22 and 29 days after monocular vision loss. The visually-induced cortical response was decreased in V1 and in the secondary visual areas (V2) following the partial optic nerve crush. A recovery of the cortical activity was noted between 3 and 5 days post-crush which remained stable for at least one month after the injury. Despite this recovery, the number of surviving retinal ganglion cells one month after the optic nerve injury was still very low suggesting that the residual function observed by calcium imaging arises from cortical plasticity mechanisms. ONC led to a loss of visual acuity of the injured side which was not followed by recovery to pre-crush levels. However, we observed an increase of the visual acuity of the non-injured eye, indicating compensatory mechanisms and cortical plasticity. In conclusion, our results show a reorganization of the connectivity between

visual and associative cortical areas following optic nerve injury which is indicative of visual cortical plasticity. These results open an interesting avenue to help understand and manipulate recovery or restoration of vision after visual system damage.

**Abstract:** Purpose: Congenital absence of the optic chiasm is a rare disorder preventing normal crossing of the nasal retinal axons to the contralateral hemisphere. Consequently, in achiasmia retinal afferents project entirely to the ipsilateral primary visual cortex resulting in overlaid representations of the left and right visual hemi-fields with bilateral population receptive fields. Here, we report an unusual malformation of visual pathways in an achiasmatic patient who deviated from the known misrouting pattern of achiasma.
Methods: Ultra-high resolution (0.65 $mm^3$, isotropic) functional and structural data were acquired using a 7T Siemens scanner in an achiasmatic participant. Visual stimulation with checkerboard pattern reversal (7.35° vertically and 12.89° horizontally) was performed in a block design for two conditions: (i) bilateral stimulation alternating between the eyes and (ii) left and right hemi-field stimulation of the dominant right eye.
Results: Superimposed hemi-field representations from the ipsilateral eye were found on each hemisphere as typical for achiasma. Using signal detection theory, we also found in a region of calcarine sulcus two neuronal populations responding to either left or right hemi-fields in the

ipsilateral hemisphere across lamina. However, in addition to this pattern we observed for anterior V1 extra input from the contralateral eye indicating that a small portion of nasal fibers decussate at the optic chiasm.
Discussion: The misrouting pattern observed in this participant does not comprise the exclusive hallmark typical for achiasma. The additional representation of the ipsilateral eye can be accommodated by reassigning the ocular dominance columns to hemi-field columns as shown by Olman et al. (2016). However, the process through which the visual cortex incorporates the extra input from the contralateral eye remains a question for further research. Remarkably, similar to other visual pathway abnormalities, relatively normal visual function is preserved by reorganisation of intra-cortical wiring.

**Abstract:** Retinitis Pigmentosa (RP) is a family of inherited disorders caused by the progressive loss of retinal photoreceptors. There is no cure for RP, but research aimed at preventing further photoreceptor loss, or substituting new light-responsive elements of biological or artificial nature, is generating hope for these patients. These strategies require that the visual system downstream of the photoreceptors is capable of elaborating visual signals. Anatomical and functional studies have shown that retinal and thalamic structure are well preserved with RP, but the effect of photoreceptor degeneration on the visual cortex is still unknown. Here, we studied how visual cortical processing changed during the course of progression of RP, and whether the visual cortex retained the capability of plastic remodelling. Binocularity is a key property of primary visual cortex (V1) neurons that is widely used to study synaptic integration in the brain and plastic mechanisms following an altered visual experience. We used visual evoked potential to test whether cortical processing of visual inputs is altered in RP. We found a robust shift in

eye preference in RP animals, due to a selective increase of ipsilateral eye-driven responses. The disruption of the binocular properties of neurons in the primary visual cortex was associated with behavioural deficits in depth perception. We also performed in vitro electrophysiological recordings of field excitatory post-synaptic potentials in V1. Basic synaptic transmission, as assessed by response vs stimulus amplitude, showed a significant shallower response in RP mice. Biochemical analysis suggests that this synaptic deficit could be related to the alteration of absolute levels of inhibition and excitation in the visual corte. These results suggest that cortical changes occur in the visual cortex that might further compromise vision by downregulating or suppressing visual processing, as the retinal input progressively deteriorates.

**Title:** Phosphorylation of CREB at serine 142/143 is required for visual cortex plasticity

**Authors: N. S. PULIMOOD**[1], M. CONTRERAS[2], T. BLANPIED[2], *A. E. MEDINA[3]
[1]Pediatrics, [2]Physiol., [3]Dept of Pediatrics, Univ. of Maryland Baltimore, Baltimore, MD

**Abstract:** cAMP Response Element Binding protein (CREB) is a transcription factor that has strongly been implicated in long term potentiation, activity-dependent neuronal plasticity, as well as learning and memory. Recent work from our lab showed that phosphorylation of CREB at serine 133 (Ser133) is required for both the depression and potentiation components of ocular dominance plasticity (dc-ODP and pc-ODP) in the visual cortex *in vivo.* While phosphorylation at Ser133 is well known to be critical for activation of CREB function and expression of its downstream targets, this single phosphorylation event is often not sufficient for the expression of many CREB-dependent genes. This implies that there needs to be some secondary event(s) in addition to Ser133 phosphorylation to activate transcription of specific sets of genes. Serine 142 and 143 (Ser142/143) are two amino acids on CREB whose phosphorylation is driven by increased synaptic activity *in vitro,* but their involvement in plasticity has never been explored. Therefore we tested the role of these two phosphorylation sites in the ODP model of activity-dependent neuronal plasticity *in vivo*. We hypothesized that phosphorylation of CREB at Ser133

alone is not sufficient for ODP - additional phosphorylation at Ser142/143 is required. We infected animals with a Herpes Simplex viral (HSV) vector expressing a dominant negative form of CREB that cannot be phosphorylated at Ser142 and 143 (CREBdn-S142A/S143A). Then we chronically implanted electrodes in the binocular zone of the mouse visual cortex, and recorded Visually Evoked Potentials (VEPs) in awake mice before and after 7 days of monocular deprivation (MD). Our data showed that blocking phosphorylation at Ser142/143 blocked both dc-ODP and pc-ODP *in vivo*. We also found that cortical cultures infected with CREBdn-S142A/S143A showed decreased activity-dependent expression of the early gene Arc, which is required for ODP. These results reveal a novel mechanism of CREB action in activity-dependent neuronal plasticity, which could confer some specificity on the wide array of plasticity-related genes regulated by this essential transcription factor.

**Abstract:** During critical periods of development, experience shapes cortical circuits resulting in the acquisition of functions used throughout life. The classic example of critical period plasticity is ocular dominance (OD) plasticity which optimizes binocular vision but can reduce responsiveness of the primary visual cortex (V1) to an eye providing low-grade visual input. The onset of its critical period is thought to involve maturation of inhibitory synapses within V1, specifically those containing the GABAA receptor alpha1 subunit. Surprisingly, we find that removing alpha1 from mouse thalamus, but not from cortex, disrupts OD plasticity in V1.

Furthermore, we show that thalamic relay neurons in the dorsolateral geniculate nucleus undergo OD plasticity, which requires thalamic inhibition. Our findings demonstrate that in critical period regulation, thalamic inhibitory circuits are central. This has far-reaching consequences for the interpretation of studies investigating the molecular and cellular mechanisms regulating critical periods of brain development.

**Title:** Exercise affects human ocular dominance plasticity

**Authors: *R. F. HESS**[1], H. GREEN[2], E. FINN[1], A. S. BALDWIN[1], N. GANT[2]
[1]McGill, Montreal, QC, Canada; [2]The Univ. of Auckland, Auckland, New Zealand

**Abstract:** Short-term patching of one eye leads to an increase in the strength of that eye's contribution in psychophysical measurements. Previous studies examining the modulatory effect of exercise on this ocular dominance plasticity in normal adults have reported contradictory results. Lunghi *et al.* (doi: 10.1016/j.cub.2015.10.026), using a binocular rivalry paradigm, found that plasticity was enhanced by exercise. Zhou *et al.* (doi: 10.1155/2017/4780876), using a binocular fusion task, found no exercise effect. This study approaches that same question using the dichoptic surround suppression effect, previously shown to exhibit ocular dominance plasticity (Serrano-Pedraza *et al.*, doi: 10.1167/15.12.379). Our goal was to see if the plasticity measured by this task was modulated by exercise.
Twelve healthy adults were tested. Their dichoptic surround suppression was measured to obtain a baseline. They then underwent one of two, 2 hour treatments, combining either the wearing of an eyepatch with exercise, or the wearing of an eyepatch with rest. Measurements of dichoptic suppression were made at 5 time points after treatment (0, 15, 30, 45 min). All subjects performed both conditions on separate days. Exercise consisted of cycling for 30 minutes at 60% of baseline $VO_2$ max and a 1.5 hr rest period.
In the baseline measurements, dichoptic surrounds elevated contrast detection thresholds by a

factor of 3.5×. This elevation factor was modulated by our treatments. Without exercise, the patching reduced the threshold elevation for detecting a target in the patched eye by a factor of 1.5×. With exercise, this increased to a factor of 1.7×. Exercise made the patching effect stronger. In the unpatched eye we also saw a reduction in dichoptic surround masking. Threshold elevation from the mask in the patched eye was reduced 1.2× without exercise and 1.4× with exercise. These results do suggest an exercise effect for ocular dominance plasticity involving dichoptic inhibitory interactions.

**Title:** Development of orientation selectivity without Mexican hat input correlations

**Authors: F. FUMAROLA**, *K. D. MILLER
Cntr Theoretical Neurosci, Columbia Univ., New York, NY

**Abstract:** Miller (1994) proposed a model for development of orientation (ORI) selectivity via activity-dependent competition between ON- and OFF-center inputs. The main ideas were (1) Hebbian plasticity leads individual cortical cells to develop a "maximally correlated" set of inputs; (2) Assume LGN inputs have a "Mexican hat" correlation structure: two inputs of the same center type (ON/ON or OFF/OFF) are more positively correlated than two opposite-type inputs (ON/OFF) at short retinotopic separations, but less positively correlated at larger retinotopic separations (note: ORI selectivity initially develops normally without vision, so this models correlations in spontaneous activity); (3) Then Hebbian plasticity yields a set of inputs to a cell that alternates between inputs of one center type and the other, with a period corresponding to the period of the "Mexican hat" alternation in correlations; (4) This can yield development of ORI-selective simple cells; (5) Local excitatory connections between cortical cells lead nearby cells to develop similar preferred ORI. Point (5) yields a "low-pass" map, but the model did not explain why ORI maps are periodic. Recent results from Lee et al., 2016 and Kremkow et al., 2016 find local spatial phase organization closely resembling predictions of the Miller (1994) model.
Ohshiro and Weliky (2006) measured correlations in LGN of developing ferret, and did not find a Mexican hat structure: same-type pairs were always more strongly correlated than opposite-

type pairs at retinotopic separations with nonzero correlations. How can ORI selectivity develop with such correlations?
We have now explored parameter regimes not studied in Miller (1994) and discovered that ORI selectivity can develop with correlations like those observed by Ohshiro and Weliky, provided that (1) intracortical connections and/or LGN correlations are sufficiently widespread and (2) there is a constraint that each LGN ON-cell and OFF-cell must maintain its total synaptic strength to cortex. We have analytically solved the model to determine conditions for such development, which correctly describes simulation results. We are now exploring whether modifications of the model can also explain the periodicity of orientation maps.

**Title:** Development of synaptic mechanisms in human extra-striate cortex

**Authors: *C. SIU**[1], J. L. BALSOR[2], D. G. JONES[4], K. M. MURPHY[3]
[1]MiNDS, [2]McMaster Integrative Neurosci. Discovery and Study, [3]Dept Psychol Neurosci & Behaviour, McMaster Univ., Hamilton, ON, Canada; [4]Pairwise Affinity Inc., Dundas, ON, Canada

**Abstract:** Development of human cortex is thought to proceed from primary visual cortex (V1) to extrastriate. Three findings support that idea: 1) synapse counts peak first in V1 and later in higher-order areas, 2) neuroimaging finds sensory areas mature first, 3) low-level vision develops before higher-level vision. For example, visual acuity matures in childhood (~8 years) but face perception develops into adulthood (~40 years). One theory to account for this proposes a common trajectory with slightly delayed peaks at successive higher order areas. We tested this by comparing the development of pre- and post-synaptic proteins in human extra striate areas (V3 and V4a) to their development in V1. Is there a consistent delay in the development of synaptic proteins involved in experience-dependent plasticity that contributes to hierarchical development of visual function? We studied V3 and V4a of 14 postmortem human cases (7 female, 7 male) ages 8 to 80 years. We used Western blotting to quantify a set of pre- (Synapsin; Synaptophysin) and post-synaptic proteins (PSD-95; Gephyrin; $GABA_A$ receptor subunits α1,

α2, α3; AMPA receptor subunit GluA2; NMDA receptor subunits GluN1, GluN2A (2A), GluN2B (2B)). We calculated the balances between pairs of functionally related proteins: pre-synaptic index (Synapsin:Synaptophysin), post-synaptic index (PSD-95:Gephyrin), $GABA_A$ receptor indices (α1:α2, α1:α3), AMPA-NMDA receptor index (GluA2:GluN1), and 2A:2B balance, and the sum of Synapsin, Synaptophysin, PSD-95 and Gephyrin expression to compare with the analysis done for V1 (Pinto et al 2015). We found 3 patterns of development in V3 and V4 compared with V1. 1) Similar development to V1 for total expression of Synapsin, Synaptophysin, PSD-95 and Gephyrin suggesting that fundamental synaptic mechanisms develop on a similar trajectory. 2) Delayed development for the α1:α2, α1:α3, and GluA2:GluN1 balances. α1:α2 development was delayed ~10 years in V3 and V4, driven by late development of α1. α1:α3 development was delayed by ~20 years in V4 and ~30 years in V3, driven by late losses of α3. GluA2:GluN1 development was delayed by ~25 years in V4 and ~35 years in V3, driven by delayed development of GluN1. 3) A different pattern of development for the 2A:2B balance. In V1, the balance shifts from 2B to 2A, but in V3 and V4 the change was opposite: in children, there was more 2A, that shifted to more 2B in adults, and back to more 2A in aging. This suggests cortical development is not a simple wave of maturation that starts in primary areas and progresses across the cortex. Different cortical areas have unique developmental signatures that engage plasticity mechanisms at successive stages of the lifespan.

**Title:** Probing visual field integrity using an anatomical measure of the stria of Gennari at ultra-high field MRI

**Authors: *A. FRACASSO**[1], C. ROELOFZEN[2], G. PORRO[3], D. BERGSMA[4], M. VAN GENDEREN[5], S. O. DUMOULIN[2]
[1]Spinoza Ctr. for Neuroimaging, Amsterdam Zuidoost, Netherlands; [2]Spinoza Ctr. for

Neuroimaging, Amsterdam, Netherlands; [3]Univ. Med. Ctr., Utrecht, Netherlands; [4]Donders Inst., Nijmegen, Netherlands; [5]Bartiméus Diagnos. Ctr. for rare visual disorders, Zeist, Netherlands

**Abstract:** Introduction: The visual input from the retina reaches primary visual cortex at the level of the highly myelinated stria of Gennari. Myelin content and the highly myelinated stria of Gennari represent a marker of input activity from the retina to the primary visual cortex in the calcarine fissure. Using ultra-high field MRI (7Tesla) it is possible to visualize myelin distribution at a sub-millimeter resolution, and visualize the stria of Gennari in-vivo in humans. Many conditions as brain's stroke or tumors along the visual pathways, may cause visual field defects or scotomas. In all of these conditions visual input does not reach primary visual cortex. Here we hypothesize that myelin content co-varies with loss of visual input. We will map myelin in participants with visual field defects or absolute visual scotomas and evaluate whether the clinical symptoms are reflected in cortex myelination in the occipital cortex, providing a proof of concept for an anatomical measure of visual field sensitivity.
Method: Anatomical T1-w images: TD/TI: 6000/1200ms, adiabatic inversion, TR/TE: 8/3ms, flip angle: 8 degrees, voxel size = 500x500x500 $\mu m^3$, FOV: 250x250x180 $mm^3$, 360 sagittal slices, bandwidth 201Hz/px, number of excitations per inversion: 300, linear readout, acceleration using SENSE: 2.5 (anterior-posterior) x 2.5(right-left). Scan duration was 7.5 min (4 to 5 repetitions were acquired for each participant). Proton density scan parameters: 3D turbo-field echo, TR/TE: 6/3 ms, FOV: 250x250x180 mm, voxel size: 1x1x1 $mm^{3.}$ Selction criteria for the participants: diagnosis of unilateral hemianopia or quadrantanopia, with spared (or partially spared) occipital lobe. The event causing the visual field lesion must have happened at least three years prior scanning. These visual deficits give the unique possibility to test within-participants comparisons.
Results: Results are suggestive of a similar myelination content between the affected and non-affected hemisphere, confirming previous results obtained from a between-participant test with congenitally blind participants and normally sighted controls.
Conclusions: Stria of Gennari appears to persist independently of receiving visual input. These results suggest that hard-wired developmental mechanisms forming the stria of Gennari are completed after development, and are not modulated by a sudden change in the functional response of the visual system.

**Abstract:** Autism Spectrum Disorder (ASD) is characterized by altered engagement with the social world and is apparent at early stages of the disorder. A theory in ASD etiology is that neonatal visual function is reflexive, but undergoes an important shift towards voluntary reward-based functioning involving affective neurocircuits. Disruptions in this transition are believed to be involved in ASD pathogenesis (Klin, Shultz & Jones, 2015). Given the critical nature of this transition, illuminating its neurobehavioral underpinnings through a nonhuman primate model will be essential to understanding the pathophysiology of ASD. Twenty-seven mother-reared infant male rhesus macaques living in social groups were eye-tracked longitudinally from birth to 6 months while viewing semi-naturalistic videos of macaque social interactions and full-faced videos of unfamiliar adult and juvenile males and females. Novel stimuli were presented each session with a subset repeated in following sessions to control for novelty across the longitudinal design. Using procedures similar to human studies, 14 sessions were conducted for each infant across the 6 months. The figure demonstrates that monkeys' fixation to the eye region shows an inflection in developmental trajectory, increasing from birth to 8 weeks, decreasing slowly to a trough between 14-18 weeks, before increasing again. Different developmental patterns were observed in fixation on the mouth and body. The results indicate a critical period for social skills refinement around 4-8 weeks of age that parallels the developmental trajectory of eye looking in human infants (Jones & Klin, 2013), and suggest ethologically relevant species differences in the development of mouth and body looking. Importantly, the data suggest the presence of a switch in critical networks supporting these developing social skills. Further analyses of neuroimaging data collected on these animals during this developmental period will allow us to identify neural networks mediating this shift in behavior and will be aid in our understanding of ASD pathophysiology.

**Abstract:** Reading others' facial cues (i.e. trustworthiness) in social interactions is crucial to understand their intentions and emotions, and is impaired in individuals with Autism Spectrum Disorder (ASD). Characterizing the emergence and development of this skill and supporting brain regions may further broaden our understanding of impaired socioemotional development observed in children with ASD. Rhesus macaques, a highly translational nonhuman primate model of early socioemotional development allow for densely sampled longitudinal neuroimaging studies not feasible in human infants. Therefore, this study aims to characterize early development of social and facial feature perception and the underlying brain regions in rhesus infants.

We conducted preliminary analyses of eye tracking and MRI data collected longitudinally in 6 male macaques (1 week - 6 months) living with their mothers in complex social groups. Each session included trials of 2 human faces representing extreme levels of trustworthiness. Looking behavior, including fixation to eye and mouth regions was characterized for trustworthy and untrustworthy faces. Structural MRI scans (T1 MPRAGE sequences (TR/TE = 2600/3.46msec, voxel size: 0.5x0.5x0.5mm)) acquired using a 3T scanner were used to characterize volumetric changes of the amygdala (AMY) and cortical grey matter of the insula, superior temporal sulcus, prefrontal cortex (BA46 & BA9) and inferotemporal area (TE), all areas involved in visual processing of "trust" in faces, and associations with looking behavior were assessed.

At 2 weeks of age, monkeys did not distinguish between the faces, looking equally to them ($p=0.07$), although greater looking to the trustworthy face correlated with smaller right AMY volumes ($r^2=-0.98$, $p=.01$). The ability to distinguish the faces emerged by 8 weeks, when infants looked more at trustworthy faces ($p=0.04$), explained by greater looking to trustworthy than untrustworthy eyes, and greater looking to eyes than mouth of trustworthy faces ($p=0.05$). At this age, there was a trend for an association between looking to trustworthy mouths and increased TE volume (left TE: $r^2=0.79$, $p=.059$; right TE: $r^2=0.79$, $p=.061$). This behavioral pattern was observed at 6 months, with no significant behavior-volume correlations.

Our results show a protracted development in the ability to distinguish between facial features that is predicted by different brain regions across age (AMY and potentially TE). They parallel the developmental trajectories of social visual engagement in human infants (Jones & Klin, 2013), and further validate rhesus monkeys as a translational model of early socioemotional development.

**Abstract:** The ability to attribute intentions and emotions in social interactions based on facial features (i.e. trustworthiness) is impaired in children with Autism Spectrum Disorder (ASD). Understanding the early developmental trajectories of this skill and the underlying brain circuits may further clarify the impaired socioemotional development in children with ASD. Due to limitations of repeated experiments of human infants, we are using a highly translational nonhuman primate model to characterize the early development of social and facial feature perception in parallel with the maturation of the underlying brain networks.
Eye-tracking (ET) data was collected longitudinally (14 times) from 1 week to 6 months in 16 male rhesus infants; here we are only presenting preliminary findings on those with MRI scans (n=6). In each session, monkeys were shown pairs of human faces, one with trustworthy (TW)

and one with untrustworthy (UTW) facial features. Fixations to eyes, mouth and whole face were compared across TW or UTW faces. Structural and resting-state fMRI (rsfMRI) scans were acquired 7 times using a 3T MRI scanner. We mapped developmental changes in functional connectivity (FC) between insula (INS), amygdala (AMY), dorso-lateral prefrontal cortex, superior temporal sulcus and inferotemporal cortex (TE). Associations between ET and rsfMRI data were assessed via Pearson's correlations.
At 2 weeks, there were no significant differences between fixations to TW and UTW regions; however greater looking to the TW faces was correlated with weaker FC between left INS and TE ($r^2$=-0.99, p=.005). The ability to distinguish TW and UTW emerged by 8 weeks, when infants looked more to TW than UTW faces (p=0.04), effect driven by more fixation time to the TW than either UTW eyes (p=0.05) or TW mouth (p=0.05). Greater looking to the TW faces correlated with stronger FC between INS and AMY in the left hemisphere ($r^2$=0.85, p=.003), whereas greater looking to the UTW faces correlated with stronger FC between these regions in the right hemisphere ($r^2$=0.82, p=.047). This pattern was stable through 6 months of age, although at that age greater looking to UTW eyes was associated with weaker FC between right TE and INS ($r^2$=-0.97, p=.002).
Our results suggest a protracted development in social and facial feature perception in infant rhesus macaques and underlying neural networks. These changes parallel typical development of preferential looking abilities in human infants (Jones & Klin, 2013). Results also showed a high conservation of brain regions responsible for facial feature perception in humans and macaques, further validating this model of early socioemotional development.

**Title:** Plasticity for stimulus selectivity in the visual cortex of adult mice induced by patterned optogenetic stimulation

**Authors: *T. TSUBOTA**, E. FRANDI, A. BENUCCI
Brain Sci. Inst., RIKEN, Wako, Japan

**Abstract:** Plasticity in the functional connectivity of cortical neurons is needed for a large variety of adaptive behaviors that allow animals to thrive in a changeable environment. Spike-timing dependent plasticity (STDP) is considered a key biological process governing cortical synaptic plasticity. Although its properties have been extensively characterized in brain slices, it is still largely unknown whether it can change the functional architecture of in-vivo cortical networks of adult animals. In this study we first established an *in vivo* technique for simultaneous imaging and spatially-patterned optogenetic stimulation at the single-cell resolution based on a digital-micromirror-device (DMD). Using adult mice expressing G-CaMP8 and ChrimsonR in the primary visual cortex (V1, n = 6 animals), we paired DMD stimulation of an individual neuron (the “driver”) to a delayed stimulation (10 ms) of tens of surrounding neurons to induce driver-surround STDP (n = 9 experiments). We found that a significant fraction of neurons (268/457 neurons, 59%, $p$ = 4e-05) increased their response amplitude to the orientation orthogonal to the driver’s preferred orientation (166 ± 25% increase in amplitude, mean ± s.e., n = 457 neurons. $p$ = 2e-06), leading accordingly to an overall fractional increase of neurons with an orthogonal preferred orientation relative to the driver (from 26 ± 4% to 41 ± 5%, mean ± s.e., n = 9 experiments, $p$ = 0.02). This effect was not observed in control experiments where the driver and surround stimulation was not paired or where the order of pairing was reversed. Neurons shifting preferred orientation were characterized by weak responsiveness to visual stimulation. Further analysis with a decoding model based on demixed principal component analysis (dPCA) and linear support vector machine (SVM) classifiers revealed that, despite these plastic changes, the network as a whole retained its ability to process stimulus orientations thanks to a core group of unchanged and strongly visually-responsive neurons (average percentage change in correct decoding confidence across orientations: strong neurons, 10.0 ± 5.6%; weak neurons, 26.8 ± 21.2%, mean ± s.d.). In summary, our results show that plastic changes in recurrent connectivity centered solely on the activity of one or a few neurons can dramatically alter the stimulus selectivity of the whole network in a functionally predictable way via processes akin to STDP.

**Title:** Increased use of peripheral vision is associated with increased functional connectivity between peripheral V1 and functionally specialized visual areas

**Authors: *L. L. FLEMING**[1], W. K. BURGE[3], M. DEFENDERFER[1], D. K. DECARLO[2], K. M. VISSCHER[1]

**Abstract:** Visual acuity in central vision is vital for everyday tasks such as recognizing faces and reading words. However, with central vision loss, such as in macular degeneration, individuals must rely more heavily on peripheral vision to perform everyday tasks. Previous work from our lab demonstrates that increased reliance on peripheral vision is associated with increased cortical thickness in areas of primary visual cortex (V1) that process peripheral vision. However, the impact of increased use of peripheral vision on the functional connectivity of V1 remains yet to be fully elucidated. Because macular degeneration patients rely heavily on peripheral vision, we hypothesized that areas of V1 involved in peripheral vision would possess enhanced functional connectivity to visual areas that are important for tasks that are typically performed with central vision. For example, Fusiform Face Area (FFA) and Visual Word Form Area (VWFA) are specialized for the processing of faces and written language, respectively, and would both likely possess altered connectivity to peripheral V1 with increased use of peripheral vision. To test our hypothesis, we used fMRI in 10 macular degeneration patients and matched controls in order to measure resting-state functional connectivity between peripheral V1 and functionally specialized visual areas, which were defined based on meta-analyses. Consistent with our hypothesis, macular degeneration patients showed stronger connectivity from peripheral V1 to functionally specialized visual regions, compared to healthy controls. This association likely reflects increased use of peripheral vision for everyday visual tasks. Overall, these results suggest that connectivity between visual cortex and higher order brain regions is influenced by the degree to which certain parts of the visual field are used. Together, these findings demonstrate a stable form of network plasticity that is observable at rest, even when no faces or words are present.

Furthermore, these findings help provide insight into the nature of visual cortical plasticity in the adult brain, a stage well beyond the “critical period” for visual development.

**Abstract:** Activity of cortical inhibitory interneurons is rapidly reduced in response to monocular deprivation during the critical period for ocular dominance plasticity and in response to salient events encountered during learning. In the case of primary sensory cortex, a decrease in mean evoked firing rate of parvalbumin-positive (PV) inhibitory neurons is causally linked to a reorganization of excitatory networks following sensory perturbation. Converging evidence indicates that it is deprivation, and not an imbalance between open and closed eye inputs, that triggers rapid plasticity in PV neurons. However, this has not been directly tested in-vivo. Using two-photon guided cell-attached recording we examined the impact of closing both eyes for 24 hours on PV neuron response properties in mouse primary visual cortex. We found that binocular deprivation induces a 30% reduction in stimulus-evoked mean firing rate, and that this reduction is specific to critical period-aged mice. In contrast to evoked mean firing rate, measurements of trial-to-trial variability revealed that stimulus-driven decreases in variability are significantly dampened by deprivation during both the critical period and the post-critical period. These data establish that open-eye inputs are not required to drive the deprivation-induced weakening of PV neuron evoked activity that defines critical period plasticity, and that other aspects of in-vivo PV neuron activity are malleable throughout life. In addition, we are testing the hypothesis that molecular perturbation of PV neuron development impacts maturation of cortical processing as assessed by two-photon calcium imaging in wildtype and PV-ErbB4 knock-out mice.

**Title:** Figure-ground modulation in higher visual areas in mice

**Authors: *H. E. VAN BEEST**, A. BARSEGYAN, M. W. SELF, U. H. SCHNABEL, P. R. ROELFSEMA
Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands

**Abstract:** One of the main questions in visual neuroscience is how an object is segregated from the background. Cells at early stages of the visual hierarchy receive inputs from a small region of the retina, knows as their receptive field (RF). Despite this, the activity of cells at these early stages can be modulated by contextual visual information from far outside the RF. An example of such a contextual effect is figure-ground modulation (FGM), in which the activity of a neuron in the primary visual cortex (V1) is enhanced when its receptive field falls on a figure-area of a stimulus, rather than on a background, even when the boundaries of the figure are well outside the RF. Although this modulation was first observed in monkeys, it has recently been shown by our lab that a similar modulation can be found in mouse V1. FGM occurs irrespective of the feedforward input to the neuron in V1, and it usually starts after the initial visual response onset to the stimulus (after 100ms). This has led to the idea that FGM in V1 is inherited from feedback projections coming from higher visual areas, which have larger receptive fields. The mouse-model provides many new technological possibilities, such as recording from specific cell-populations on a large scale, which makes it possible to identify cortical areas in which FGM occurs. In this study, we imaged through a clear-skull from four awake Thy1-GCaMP6 mice that were passively viewing orientation-defined figure-ground stimuli. Using this method, we could visualize the activity from excitatory cells in superficial layers of the entire cortex. Using population receptive field mapping, we were able to map out the locations of visually responsive areas in each mouse. Areas we could consistently map out in all four mice were V1, anterolateral (AL), lateral (LM), posteromedial (PM) and rostrolateral visual area (RL). As a measure of FGM, we calculated the difference in change in fluorescence (dFF) between the response to an orientation-defined figure compared to the response to a background. In all four mice we found FGM in V1 as expected. Higher visual areas that consistently showed FGM were AL, LM and PM. These findings suggest that FGM is broadly represented in higher visual areas surrounding V1, and does not seem to be limited to areas typically thought to belong to the ventral or ‘object’

pathway. Since GCaMP signals are rather slow compared to neuronal activity, additional proof to test the causal role of higher visual areas in FGM is needed.

**Title:** The role of the superior colliculus in figure-ground segregation and saccade planning

**Authors: *A. F. VAN HAM**, M. W. SELF, P. R. ROELFSEMA
Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands

**Abstract:** An important task of the visual system is to segregate objects from their backgrounds to guide behavior. Previous studies showed that neuronal activity in macaque primary visual cortex (V1) is modulated when the receptive field (RF) of a neuron falls on a figure compared to the background, a process called figure-ground modulation (FGM). FGM correlates with the percept of the animal and is modulated by behavioral relevance. We have recently shown that the pattern of FGM in V1 also impacts on the onset and end position of saccades that are planned towards a figure. It is unknown, however, how and through which pathways activity patterns in V1 can influence saccades. The superior colliculus (SC) is a good candidate, as this multi-layer subcortical structure receives visual input from V1 and is connected to motor-related structures. Here, we studied the role of the SC in the planning of saccades towards figure-ground stimuli. We investigated 1) whether FGM occurred in the SC, 2) whether the figure size affected FGM, 3) how the superficial and intermediate layers of the SC interacted to accomplish FGM read-out. Using Tungsten glass electrodes, single and multi-unit activity was recorded from the different layers of the SC of a monkey, while the animal performed a figure-detection task in which he had to make saccades towards the center of a figure. Stimuli were textured figures on a textured background. There were 16 possible figure positions. The RF of a neuron could fall on the background, the center or the edge of the figure. The 16th position was 180 degrees away from the RF and served as baseline. Figure sizes were 0.5, 1, 2 or 4 times the RF size. We found that FGM is present in SC, and that the presence of a figure is clearly signaled by the activity of single neurons. Compared to V1, FGM in SC is stronger and earlier and occurs for figure sizes that are much larger than the RF. The FGM profiles differed per layer. In the superficial layers we found a Gaussian-like profile for small figures (with the largest response for the center

position), while for larger figures the responses are strongest for edge positions and there is filling-in for the center positions. The intermediate layers only showed a center response. This suggests that the superficial layers have a detailed representation of the entire object, while the intermediate layers only represent the figure center, which is the target for the saccade. We conclude that the SC is involved in figure-ground segregation. The timing and the strength of FGM suggests that SC is involved early on and probably interacts with the visual cortex to accomplish FGM quickly after the appearance of a figure.

**Title:** Modeling spike synchrony in the visual cortex for figure-ground organization

**Authors: *N. WAGATSUMA**[1], B. HU[2], R. VON DER HEYDT[3], E. NIEBUR[2]
[1]Tokyo Denki Univ., Saitama, Japan; [2]Johns Hopkins Univ., Baltimore, MD; [3]Neurosci., Johns Hopkins Univ. Dept. of Neurosci., Baltimore, MD

**Abstract:** Border ownership indicates which side of a contour owns a border, it is a precursor of figure-ground organization. A large number of neurons in primate cortical area V2 exhibits border ownership selectivity (Border Ownership Selective (BOS) neurons; Zhou et al, J. Neurosci., 2000). Theoretical work shows that modulatory common feedback may underlie the observed synchrony between pairs of neurons with consistent border ownership preferences, i.e. with both neurons in the pair responding to the same visual object (Wagatsuma et al., J. Neurophysiol., 2016). Here we extend this model to explain synchrony observed between neurons with non-consistent BOS (Martin and von der Heydt, J. Neurosci 2015). In our model, the responses of BOS neurons are modulated by the activity of Grouping (G) neurons which receive their input from BOS neurons and whose activity represents the location of visual objects in the scene (Craft, et al., J. Neurophysiol., 2007). The G neurons provide modulatory feedback to BOS neurons according to their preferred radius (Mihalas et al, PNAS, 2011). The BOS neurons have different border ownership preferences, share their receptive field, and interact with one another through inhibitory cells. Simulations of the network model are in overall agreement with the experimental findings.

**Title:** Neural sensitivity to concavity and convexity of spatial boundary cues

**Authors: *R. CHENG**[1,2], D. B. WALTHER[3], S. PARK[1,4]
[1]Cognitive Sci., Johns Hopkins Univ., Baltimore, MD; [2]Psychology, Emory Univ., Atlanta, GA; [3]Psychology, Univ. of Toronto, Toronto, ON, Canada; [4]Psychology, Yonsei Univ., Seoul, Korea, Republic of

**Abstract:** Research in both humans and animals has collectively pointed to the importance of spatial boundary cues for an organism to regain its bearings after disorientation; however, little is known about what visual features intrinsic to a boundary can inform our location in an environment. A recent study proposes that mid-level visual features such as junction type and angle are important for scene categorization (Walther & Shen, 2014). In this study, we ask 1) whether there is a neural sensitivity that distinguishes concave and convex boundaries whose parts conjoin at different junction types and angles, and 2) whether sensitivity to junction angles is dependent on the boundary type (concave vs. convex). As these boundary features provide cues to the viewer's position within an environment, we hypothesize that scene-selective brain regions will be sensitive to variations of these properties.
To test this idea, we created artificial scene images of wall boundaries that vary in both Boundary Type (Concave or Convex) and Junction Angle (45, 90, 135). There were 7 stimulus conditions: Concave 45, Concave 90, Concave 135, Flat 180, Convex 135, Convex 90, Convex 45. Participants (N=10) viewed stimuli in blocks of 12s while performing a one-back repetition detection task in the fMRI scanner. We measured both univariate and multivariate response in scene-selective brain areas. Two-way within-subject ANOVA (Boundary Type X Junction Angle) revealed a main effect of Junction Angle in the univariate response of both parahippocampal place area (PPA) ($F(2,18)=4.165$, $p=.044$) and occipital place area (OPA) ($F(2,18)=14.569$, $p=.002$), suggesting a sensitivity to angular changes in both concave and convex boundaries. Importantly, there was a marginally significant interaction between Boundary Type and Junction Angle in OPA ($F(2,18)=3.755$, $p=.054$), showing a greater sensitivity to differences of junction angle (45, 90, 135) in concave boundaries than in convex boundaries. This suggests that OPA is highly sensitive to boundary features that are locally relevant to navigation, as concave boundaries surround the viewer and restrict navigation while convex boundaries don't. Moreover, using a linear SVM classifier on multi-voxel patterns of

activation, we found that OPA shows a significantly higher classification accuracy for Junction Angle within concave boundaries than within convex boundaries ($t(9)=2.451$, $p=.037$). Together, our study suggests that scene-selective brain regions have high sensitivity to boundary types (concave vs. convex) and junction angle, which are properties that can inform the viewer's location relative to boundaries and guide navigation.

**Abstract:** Arrows are one of the most widespread icons across cultures, which is classically considered to be a symbol and has been discussed to be acquired at around 3-5 yrs of age. In a series of eye-tracking studies in 4- and 8-month-old infants we suggest that the role of this icon is possibly not acquired through culture, but on the other hand this icon triggers the attentional system through its unique visual features, even after a long one-second blank delay between icon offset and target. By systematically changing the visual features of this icon, we showed that a triangle alone is enough for reorienting the attention; furthermore by analyzing the spatio-temporal dynamics of the gaze pattern over the different icons and during the delay-period between icon and target, and by comparing it with the identical results from adults, using a generalized linear model, we propose a bottom-up framework for an innate attention-reorientation system based on the gradient of salience in icons, which later accommodates a symbolic comprehension of arrows in toddlers. Furthermore, we are extending the experiment to macaques and an MEG design in adults to acquire a more coherent framework for re-orientation of attention induced by the vertices of triangular-like icons.

**Title:** Contour integration as a function of collinearity, task, and age: An EEG study

**Authors: *A. HASHEMI**[1], J. N. CALI[1], E. ROUDAIA[2], P. J. BENNETT[1], A. B. SEKULER[1]

**Abstract:** Shape perception requires detecting local orientation information and integrating elements along a contour, segregated from its background. One can assess contour integration by asking observers to detect a collinear set of Gabors embedded within an array of randomly-oriented Gabors. Contour integration is best when contour elements are collinear, and the extent to which deviations from collinearity can be tolerated provides a measure of contour integration ability. Older adults (OA) tend to be worse than younger adults (YA) at extracting contours from dense clutter; however, aging does not affect the sensitivity to collinearity (Roudaia et al., 2013). Collinearity also modulates neural responses to contours: N1 amplitudes are larger to high collinear (HC) contours relative to low collinear (LC) contours (Mathes et al., 2006; Shpaner et al., 2013), although this effect may only exist when the contour is task relevant (Volberg & Greenlee, 2014). Here, we asked if the collinearity ERP effects are modulated by task relevance *per se*, or by a lack of awareness of the contours. We also examined how collinearity ERP effects were modulated by age. Our stimuli were high-density Gabor arrays containing: 1) 8 Gabors positioned to form either a LC or HC contour within distractor Gabors; and 2) one Gabor of noticeably higher contrast than the others. Observers (12 younger, 12 older; mean ages 22.8 and 66.4 years) first completed trials in which they detected the high contrast Gabor without being told about the contour. In the second block, observers detected the tail of the contour, ignoring the high contrast Gabor. In the final block, observers completed the Gabor detection task again, but this time were aware of the presence of the contour. During the contour task we found that N1 amplitude in both age groups was greater for HC than LC contours, although the effects of collinearity were larger and more sustained in OA. When observers were unaware of the contours, we found no significant effect of collinearity on N1 amplitude in either age group. Critically, when the contours were task irrelevant, but observers were aware of them, we found no effect of collinearity on N1 amplitude in either age group, although there were significant age-related collinearity differences in later ERP components. Our results support the view that

the collinearity effect on N1 amplitude results from active top-down processing as opposed to stimulus-driven signals. The larger effect of collinearity in ERPs in older adults may indicate the need for stronger top-down modulation to generate behavioural performance similar to younger adults, indicative of declines in contour integration with healthy aging.

**Title:** 2D vs. 3D shape processing in area V4

**Authors: R. SRINATH**[1], K. J. NIELSEN[2], *C. E. CONNOR[1]
[1]Krieger Mind/Brain Inst., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Area V4 is a pivotal intermediate stage in transforming image information into knowledge about object structure and identity. V4 neurons are known to be sensitive to binocular disparity and 3D orientation. However, previous studies of more complex shape processing in V4 have focused on 2D shape. Here, we studied the relationship between 2D and 3D shape information in area V4. This experiment addresses fundamental questions about the transformation from 2D image signals to 3D shape perception. Are 2D contours and 3D surfaces processed in parallel? Or is shape processing inherently 3D from the start? Does tuning for 2D contours define V4 neurons? Or is it merely a slice through 3D shape tuning? We used microelectrode recording in awake fixating macaque monkeys to analyze the tuning of individual V4 neurons for complex 2D and 3D shape. Shape stimuli were constructed by combining 3D medial axis components with randomized connectivity, orientation, curvature, and surface structure. 3D stimuli were rendered with shading of matte surfaces or specularity of glossy surfaces. 2D stimuli were positive and negative contrast silhouettes with the same contours. Stimuli were flashed in random order inside the receptive field. After an initial generation of random stimuli, subsequent generations included partially morphed descendants of higher response ancestor stimuli. Thus, successive generations evolved toward denser sampling in and near the neuron’s response range. Stimuli evolved within two independent lineages so that tuning

models could be cross-validated between lineages. We parameterized stimulus shapes in terms of local geometric measures on contours, surfaces and medial axes. Dense sampling produced a point cloud description of each stimulus in a multi-dimensional geometric space. We fit multi-dimensional Gaussian models to describe tuning for 2D and 3D shape and predict responses across lineages. Consistent with previous findings, neurons were reliably tuned for local shape fragments with specific intra-object positions, orientations, and curvatures, reflecting parts-based ensemble coding of global shape. Early results suggest that neurons responding to contour fragments also respond to corresponding surface fragments at rotations for which the contour information disappears and only depth cues remain. Thus, 3D shape models might be more explanatory of V4 responses, and responses to 2D contour shapes might be explained by slices through these models. This would suggest that shape processing is already inherently 3D in area V4, two stages removed from primary visual cortex.

**Abstract:** Three-dimensional (3D) vision is essential for successful interactions with the world. To create accurate and precise 3D visual percepts, the brain integrates perspective and stereoscopic cues. Behavioral studies have shown that humans integrate these cues in a Bayes optimal fashion to estimate 3D surface orientation. The neural basis of 3D vision is widely studied with non-human primates (NHPs), but a tacit assumption of many studies is that the 3D visual perceptual processes of humans and NHPs are analogous. Here we test this assumption through psychophysical experiments with rhesus macaques. Theoretical and human perceptual studies show that the reliability of perspective information increases with orientation in depth (slant) and that the reliability of stereoscopic information decreases with distance. To manipulate

the reliability of perspective and stereoscopic cues, we varied the slant (rotation about an axis perpendicular to the line of sight) and distance of viewed planar surfaces. The animals were trained to report the tilt (rotation about the line of sight) of a center-fixated plane in an eight alternative forced choice (8AFC) task. Tilt ranged from 0° to 315° in 45° steps, and slant varied between 15° and 60° in 15° steps. The planar surfaces were presented at: 37, 57, 77, 87, 107, and 137 cm from the animal. To assess tilt sensitivity based on perspective and stereoscopic cues, as well as the integration of these cues, three sets of planar surfaces defined by random dot patterns were presented: mixed-cue stimuli (with perspective and stereoscopic cues), perspective-only stimuli (monocular presentation of otherwise mixed-cue stimuli), and stereoscopic-only stimuli (binocular presentation of stimuli with no perspective cues). Sensitivity was assessed as the width of probability density functions over the reported tilt. Consistent with previous human studies, sensitivity to perspective cues increased with slant and was independent of distance (after controlling for dot size). Sensitivity to stereoscopic cues decreased with distance from the fixation plane, but increased with slant. Bayes optimal predictions of the mixed-cue sensitivities were computed from the single-cue data, and compared to the measured mixed-cue sensitivities. Strong agreement was found between the measured and predicted sensitivities ($r = 0.97$, $p < 0.01$ Pearson correlation), which were tightly clustered around the identity line. These results indicate that, analogous to humans, accurate and precise 3D visual perception in NHPs is achieved through the integration of perspective and stereoscopic information.

**Abstract:** The transformation of two-dimensional (2D) retinal images into three-dimensional (3D) visual percepts is a fundamental function of the visual system. However, the cortical pathways supporting this transformation are largely unknown. Here we combine structural and diffusion magnetic resonance imaging methods to probabilistically map putative 3D visual cortical pathways in the macaque monkey. Scans were performed using a GE MR750 3T scanner and either 8- or 16-channel receive-only head coils. First, T1-weighted structural scans were registered with the F99 atlas using surface-based registration in the CARET software to define cortical regions of interest (ROIs). Probabilistic tractography was then performed in a pairwise fashion between 'seed' and 'target' ROIs predominantly located in the dorsal visual pathway using high-resolution diffusion-weighted scans (1 mm isotropic; 60 diffusion directions, b=1000 s/mm$^2$, NEX=10) with the FSL software. The initial seed ROI was the caudal intraparietal area (CIP), which is known to represent 3D object pose. Connectivity was assessed as the percentage of voxels in the seed ROI with tracts terminating in the target ROI. Consistent with previous anatomical data, connectivity between V3A (seed) and CIP (target) was observed (59%). We further found that V3A was strongly connected with the posterior intraparietal area (PIP) (65%) and that PIP was more strongly connected with CIP (68%) than V3A was to CIP. This finding suggests that PIP may be an intermediate stage between V3A and CIP in the 2D-to-3D visual transformation. The current tractography results together with previous anatomical and electrophysiological data suggest that the 2D-to-3D visual transformation is supported by the following hierarchical circuit: V1 -> V2d -> V3A -> PIP -> CIP. Strong connectivity was also observed between CIP, the lateral intraparietal area (LIP), and anterior intraparietal area (AIP). This pattern of connectivity is consistent with a circuit supporting 3D decision making and action. We additionally found strong connectivity between CIP and retroinsular cortex (Ri) (40%), a site of visual-vestibular integration within the visual posterior sylvian (VPS) that is implicated in verticality perception. To our knowledge, this is the first indication of connectivity between CIP and VPS, which may be the basis of gravity-centered visual representations previously found in CIP. The present tractography results suggest that the cortical circuitry supporting 3D vision is broader and more complex than previously recognized, and can guide future investigations into the neural basis of 3D visual perception.

**Abstract:** The image properties involved in object recognition include image components that are most informative for distinguishing between objects. The components used for recognition may be reflected in the stimulus selectivity of neurons at different stages of the ventral visual pathway. We therefore endeavored to develop a set of visual stimuli that was curated according to the psychophysics of object recognition and according to the object set that an animal is trained to recognize, with the idea that the features represented in the brain are based on their ethological value. Macaques were trained on a match to sample task: after being shown a cued object, using a touch screen monitor, they responded to presentation of the same or different objects, or object components that either belonged to the cued object or did not, by touching a green “match” spot or red “non match” spot. The object components were generated by making successively smaller crops of the original image from different regions of the object. The animals were readily able to associate even small object components, comprising as little as ~20% of the original image, with the object from which they were taken. As one moves the cropping window around the object image, we find that there are hot spots that are more conducive to recognition of the full object than adjoining regions. Further cropping within these regions, however, leads to a loss of recognition performance, suggesting that there is a minimal level of inclusion of object features that the animals need in order to recognize an object. Images may contain more than one hot spot and the level of cropping that leads to a loss of recognition may vary between them. These findings in a non human primate mirror those seen in human populations, where minimally independently recognizable components (MIRCs) constitute the elements used for object recognition. We anticipate that such components will therefore be useful for studying the shape selectivity of neurons at different levels of the visual pathway.

**Abstract:** Neurons in the primary visual cortex (V1) are adaptive processors, carrying different information when one shifts between perceptual tasks. To determine whether this phenomenon extends to other visual cortical areas, and to explore the character of the information that is conveyed in a top-down fashion from higher to lower order cortical areas, we implanted electrode arrays in V1 and V4 in a Macaque trained on a dual task paradigm. Here the animal was cued to perform either of two discrimination tasks with the identical 5 line visual stimulus - a 3 line bisection task or a vernier discrimination task. As we have found previously in V1, neurons in V4 show differential tuning to the identical stimulus attributes (flanking bar position or collinear bar position) in the two tasks, with strong modulation by task relevant inputs and weak modulation by task irrelevant inputs. Interestingly, the difference in tuning is itself very different in correct versus incorrect trials. The arrays were designed with longer electrodes implanted in V4 so we could measure the task dependent properties in deep layers, in order to study the neurons most likely to provide feedback from V4 to earlier visual cortical areas. The receptive fields of the V4 neurons changed their structure with task, showing a non-uniform responsiveness to test probes flashed in different positions within their RFs. These V4 neurons also showed a high level of activity between trial onset and stimulus presentation, potentially providing the prestimulus signal to V1 as to the identity of the task to be executed.

**Abstract:** Recent work in neuroimaging and electrophysiology has demonstrated macroscopic organization of semantic attributes in human cortex. The degree to which these semantic attributes are associated with a given stimulus can be assessed through the use of a semantic space—an embedding of words in a vector space that seeks to maintain spatial proximity of words that are semantically linked. Many such spaces exist, each with its own construction and characteristic dimensionality. However, these spaces are typically not subject-specific; for example, many are built from word co-occurrences in large text corpora. Recently, the notion of an internal state space has provided a fruitful framework for investigating neural population dynamics. We hypothesized that a space generated from a subject's own neural activity—an intrinsic feature space based on patterns of neural responses—might similarly provide a means of meaningfully describing population activity without proscribed semantic axes.
We recorded electrocorticography (ECoG) signals while a subject performed a picture naming task composed of simple line drawings of objects, and used cue-locked traces of high gamma (70-110 Hz; HG) power to construct a stimulus-by-stimulus neural response similarity matrix for each electrode. We then embedded the stimuli into a vector space by applying multidimensional scaling to these similarity matrices. Using data recorded from an independent picture naming task wherein a different set of full color images of objects was presented, we trained a linear model to map from electrode HG power to this intrinsic neural space. To test the model, held-out trials were projected into the intrinsic space and compared to stimuli in the corpus. The mean rank accuracy of held-out objects was significantly above chance, suggesting that the specific organization of intrinsic neural space facilitated generalization of information to stimuli unseen by the decoder in a dataset foreign to the space's construction.

**Abstract:** It has been known for centuries that damage to circumscribed brain regions can cause category-specific deficits in perception. This has led to an extensive search to build maps of category selective regions in the brain. Less is known about the spatiotemporal dynamics of visual category processing and the stages of this information processing. To help elucidate the spatiotemporal dynamics of visual object recognition, 25 patients with intractable epilepsy were presented images of faces, bodies, houses, hammers, words, or scrambled objects while intracranial electroencephalography (iEEG) data was collected from a total of 2,464 electrodes distributed across the cortex. Multivariate classification and time series analyses were applied to these data to produce movies of the dynamics of category sensitivity across the regions covered by these electrodes. Of these electrodes, 195 showed significant decoding accuracy at a conservative multiple comparisons corrected statistical threshold for at least one stimulus category at some point after stimulus presentation. Onset of category sensitivity began around 100 ms with peak sensitivity at 220 ms distributed across the cortex, concentrated in the ventral visual stream. Additionally, many locations in the ventral visual stream continued to show sensitivity beyond 600 ms post stimulus presentation, providing strong evidence of extended information processing dynamics. Object sensitive electrodes had a clear organization with houses represented medially, while words and faces were represented laterally. In addition to this, several electrodes were sensitive to more than one category and some of these electrodes had different time-courses of sensitivity between categories. Further analyses show the functional connectivity dynamics of these object-sensitive regions (time evolving graphs) and use time series approaches to model processing dynamics in a data-driven manner. Taken together, these results illustrate critical principles regarding extended neural information processing dynamics, information flow, and suggests multiple stages of processing underlying visual object processing and recognition.

**Title:** Mathematical processing of differential visualizations of numbers

**Authors: *S. R. BAEK**, A. L. DAITCH, J. PARVIZI
Stanford Univ., Stanford, CA

**Abstract:** Our prior observations with intracranial recordings have confirmed the presence of anatomically specific regions along the ventral temporal cortex (VTC) and lateral parietal cortex (LPC) within the human brain that are involved in mathematical cognition (Shum et al 2013; Daitch et al. 2016). However, it remains to be determined if the format of numerical symbols (e.g. numerals such as '5' or number words such as 'five') influences the way these brain regions process mathematical information. To address this issue, we collected data during two mathematical experiments from subjects implanted with electrodes in the ventral temporal cortex (VTC) and lateral parietal cortex (LPC) using electrocorticography (ECoG), taking advantage of its millimeter-scale anatomical precision and millisecond-scale temporal resolution. In the first task, subjects evaluated arithmetic statements with digits (e.g. "2+2=4") or autobiographical memory statements (e.g. "I ate fruit today") in a control condition. In the second task, subjects again evaluated arithmetic statements, but which were presented either in the form of digit numbers (e.g. "2+2=4") or textual numbers (e.g. "two plus two equals four"). From the first task, we replicated the existence of math selective regions in the VTC and LPC as established by previous research, which are selectively active during the math but not the memory condition. We then compared the responses to the two representations of numbers of each of these two math regions and found that they showed activation for math calculations regardless of the number format. Our results illustrate that while there are brain regions sensitive to visual object categories (e.g. numbers versus words), math-selective regions within the VTC and LPC appear to be engaged in quantity calculations regardless of the format in which the quantities are presented. This work provides important information about the mechanisms of arithmetic processing within the human brain.

**Abstract:** Human behavior is shaped by the evaluation of the external environment. Such evaluation is influenced by not only the contents of sensory stimulus but also the internal states of oneself. For example, it is a common experience that hunger makes trivial food look very attractive. The change of metabolic states modulates the value of the very same food, accompanying the change of its neural representation. Although previous fMRI studies have shown that the orbitofrontal cortex (OFC) represents the value of objects, it is unknown whether the OFC representations preserves the individual and concrete content (hereinafter referred to as "stimulus identity"). Because our previous study implied that representation maps increased in abstraction from physical features to object categories to subjective affect along a posterior-to-anterior neural axis, we hypothesized that the OFC might represent abstract value information without preserving stimulus identity. To test this hypothesis, we conducted a functional MRI experiment to estimate the stability of the neural representation of food stimuli in the OFC. Twenty four healthy male adults rated the value of 128 food pictures during the fMRI sessions before and after breakfast. The same experimental procedure was repeated on the separate experimental day (the interval: 17.0±9.0 (mean±SD)). This procedure enabled us to estimate the dissimilarity of the behavioral and neural data between the same metabolic states as well as between different states. If the OFC contains the stimulus identity, the OFC representations should be stable, at least to some extent, even if the value of objects changed, accompanied by the metabolic state change (satiated vs. hungry). If this is the case, neural representations of the same food should be similar both in the different (hungry-satiated) and the same (hungry-hungry or satiated-satiated) metabolic state comparison. The self-reported appetite scores for each food picture significantly decreased after having breakfast. Multivoxel pattern analysis revealed that the OFC activation patterns for the same object were similar only when the metabolic states were similar. In contrast, the fusiform gyrus (FFG) activation patterns for the same object were similar irrespective of metabolic states, suggesting that stimulus identity is represented by the FFG but not the OFC. Furthermore, the change of the activation patterns of the OFC was associated with the change of subjective value accompanied by the metabolic state change. Our findings suggest that the OFC represents abstract value information without preserving stimulus identity.

**Title:** Typical real-world locations impact object coding across the visual field

**Authors: *D. KAISER**, M. MOESKOPS, R. M. CICHY
Inst. of Psychology, Freie Univ. Berlin, Berlin, Germany

**Abstract:** Visual information in our everyday environments is structured. Objects often appear at typical locations in space: for example, lamps hang from the ceiling, whereas carpets lie on the floor. As a consequence, these objects repeatedly occupy similar visual field locations. The long-term experience with such spatial regularities prompts the hypothesis that the visual system is tuned to such retinotopic object locations. A key prediction is that typically positioned objects should be coded more efficiently. To test this prediction, we recorded electroencephalography (EEG) while participants viewed briefly presented objects appearing in their typical locations (e.g., an airplane in the upper visual field) or in atypical locations (e.g., an airplane in the lower visual field). Multivariate pattern analysis applied to the EEG data revealed that typically and atypically positioned objects evoked reliably different response patterns. This difference was related to enhanced processing for typically positioned objects: object identity could be decoded more accurately for typically positioned objects, as compared to atypically positioned objects. Crucially, this difference emerged within the first 200ms of visual processing and was most pronounced when the objects were best discriminable, suggesting that early object processing is tuned to typical retinotopic locations. Our results thus confirm the prediction that long-term experience with objects occurring at specific retinotopic locations leads to enhanced processing when these objects appear in their typical locations. The observed processing enhancement may indicate a neural mechanism for efficient natural scene processing, where a large number of regularly positioned objects needs to be processed.

**Title:** Mental rotation around the cardinal axes

**Authors: *B. P. GEE**, S. CONGDON, C. AQUINO, B. ROMAGNA
Psychology, Western Connecticut State Univ., Danbury, CT

**Abstract:** We heavily rely on perceptual, kinesthetic, and motor faculties to navigate through different environments (Fleishman & Rich 1963). Spatial reasoning is a central cognitive process, which assists in our understanding and interactions with external stimuli. Past studies have indicated a visualization preference of objects when imagined around the vertical axis (Z) compared to other orientations (Battista & Peters 2010). Here, we considered all three cardinal axes (X, Y, Z), both accuracy and speed, and more familiarity with the task to allow for optimal performance. A standard mental rotation task (Shepard & Metzler 1971) was used to test spatial reasoning speed and accuracy. For each trial, a pair of three-dimensional shapes was presented on a computer monitor. Human participants indicated, with a button press, whether the two geometric shapes were identical or mirrored images. The paired stimuli differed in orientation by displacement (disparity angle) around one of the cardinal axes. Disparity angles (40, 80, 120, 160 deg) were randomly varied across trials. A total of 432 trials were divided into six blocks, which were either homogenous (one axis of rotation) or heterogeneous (any axis for any given trial, randomly presented). Odd-numbered blocks were homogenous, and even-numbered were randomly ordered heterogeneous blocks (X, Y, or Z). The results indicated that homogenous trials were easier than heterogeneous blocks. Regardless of block type, subjects demonstrated the best accuracy and speed during Z trials, followed by Y and X, respectively. Across disparity angle, accuracy and speed reliably decremented, except Z trial performance was more resistant to this variable. Superior mental rotation ability with rotations around the Z axis may be attributed to the prevalence of vertically oriented objects in the natural environment (Waszak et al. 2005). This added experience could optimize mental templates and schemas in regards to expectations of what objects should look like (Tarr & Pinker 1989). The current experiment allowed for extensive practice with the task, and all trial types reached asymptotic performance. Nonetheless, vertically-based rotations may reflect real-world experiences, resulting in easier adaptations to viewpoint changes.

**Title:** A role for parietal area LIP in goal oriented object recognition

**Authors: *J. W. BISLEY**[1], K. MIRPOUR[2], W. ONG[3]
[2]Dept Neurobiol, [1]UCLA, Los Angeles, CA; [3]Univ. of Pennsylvania, Philedelphia, PA

**Abstract:** Visual object recognition in primates is an efficient and reliable cognitive ability. Psychophysical studies have shown that flexibility, efficiency and performance of visual object recognition is achieved by the representation of shape similarities as opposed to the decomposition and representation of parts of shapes. Stable versions of such neural representations have been found in the ventral pathway of non-human primates. However, some aspects of visual object recognition require dynamic comparisons of shape similarity in the context of goal oriented tasks. This form of representation is more likely to appear in an area that can integrate bottom-up sensory with top-down task relevant information. We tested whether neurons in the lateral intraparietal area (LIP) of posterior parietal cortex could fulfill this role by collating information from object specific similarity map representations to allow general decisions about whether a stimulus matches the object being looked for. Specifically, we hypothesized that the responses of LIP neurons should represent the relative similarity of each stimulus to the sample in our match to sample task and this should not depend on stimulus identity. We found that when animals compared two peripheral stimuli to a sample at their fovea, the response to the matching target remained stable, but the response to the distractor depended on how similar it was to the sample: the more similar, the greater the response to the distractor. These results could not be explained by standard decision making activity in LIP or by task difficulty. We propose that LIP integrates incoming visual information, including that from the ventral stream about object identity, to create a dynamic representation that is concise, low dimensional and task relevant, and which signifies the choice priorities in mental matching behavior.

**Title:** Knowledge of physical properties aids visual search for real-world objects

**Authors: *L. GUO**, S. COURTNEY, J. FISCHER
Psychological and Brain Sci., The Johns Hopkins Univ., Baltimore, MD

**Abstract:** Finding a missing earring in a jewelry box can be a frustrating challenge, but it becomes easier if the earring differs in color, shape, or size from other items in the box. These visual attributes and many others help to guide our attention toward items of interest. Does our

knowledge of objects' physical properties - e.g., that the earring is hard, smooth, and dense - also aid visual search? Would we be faster to locate the earring if it appeared among soft objects rather than hard ones? We conducted three experiments to test whether observers can use their physical knowledge about everyday objects to guide their attention in visual search. In Experiment 1, we presented participants with search arrays comprising sixteen objects. The objects were rated on perceived hardness by a separate group of online participants, and in each search array a target object was paired either with 15 distractors of similar hardness (e.g., soft target among soft distractors) or 15 distractors of different hardness (e.g., soft target among hard distractors). Participants ($n$=24) were asked to find the target object among the distractors after viewing a word label of that target for 1s. They pressed a key after locating the target and then indicated the target location with a mouse click. We found that participants were faster to locate a target object when it appeared among distractors of different hardness (1.28s±0.05) vs. distractors of similar hardness (1.64s±0.08; $t(23)=5.04$; $p<0.001$). Critically, this effect was intact after controlling for any influences of image luminance, contrast, color, shape, and semantic content, and was present despite the fact that in follow-up questioning, no participant reported paying attention to the hardness of the objects. In Experiment 2, the same experiment was conducted with a separate group ($n$=24) with the addition of eyetracking, and the reaction time results replicated those of Experiment 1. Further, the eyetracking data revealed that participants fixated on significantly fewer distractors when the distractors were of a different hardness than the target ($t(23)=-6.07$; $p<0.001$) - observers avoided wasting fixations on items of the wrong physical property. In a final experiment ($n$=24), we further controlled for local texture cues by presenting line drawings of objects rather than photographs. We nonetheless observed the same significant effects as in Experiments 1 & 2. These findings collectively demonstrate that observers can use their knowledge of objects' physical properties to guide their visual search toward likely targets, and they point toward an important role of physical knowledge in guiding how we engage with visual scenes in daily life.

**Title:** Using EEG to compare brain responses to graspable real-world objects versus 2D pictures

**Authors: *F. MARINI**[1], K. A. BREEDING[1], J. C. SNOW[2]
[1]Psychology, Univ. of Nevada, Reno, NV; [2]Psychology, Univ. of Nevada Reno Dept. of Psychology, Reno, NV

**Abstract:** Visual perception of objects has been investigated traditionally using 2D images. Importantly, however, unlike images, real-world objects provide observers with the potential for manual interaction. In line with this distinction, recent behavioral and fMRI research indicates that real objects may be processed and represented differently to 2D images, although the mechanism for these effects remains unknown. Here, we compared electrophysiological brain responses for real objects with matched pictures to examine whether the underlying temporal dynamics of brain activation differed across the two display formats. We hypothesized that the real objects would be associated with stronger motor preparation signals in dorsal cortex than pictures. Using high-density EEG, occlusion spectacles, and a custom-built experimental apparatus, we recorded brain responses to visual stimuli consisting of 96 real-world graspable objects and 96 2D photographs of the same items printed in high-resolution. We found significant reductions of event-related power for real objects versus pictures over bilateral centro-parietal electrodes in the mu frequency band, consistent with enhanced motor preparation processes. The temporal dynamics of recruitment of sensorimotor regions in the dorsal stream are different for real objects than 2D pictures.

**Abstract:** Stone toolmaking is a unique human motor skill that dates back to prehistoric times and involves the intentional shaping of a stone into a tool used for daily living. Neuroimaging studies demonstrate brain activation in areas associated with prehension, planning, and

visuospatial processing during execution and observation. Trained individuals exhibited brain activation in areas associated with saccades, visual learning, and visual attention while experts showed additional activation in areas that support stimulus driven visuospatial sequence learning. Due to the recruitment of these brain areas related to visual encoding related with learning, the purpose of this study is to determine if training causes changes in gaze patterns that may reveal the understanding of an underlying action structure and the anticipation of motor intent during observation of the task. All subjects' gaze positions were collected with an eye tracker while viewing an expert creating a stone tool in an egocentric perspective. Gaze behavior was collected in three separate occasions: naïve (0 hours of training), post 1 (50 hours of training), post 2 (100 hours of training). During each session, subjects were instructed to indicate correct and incorrect movements during action observation. With training, the subjects' perception of correct movements coalesced on common time points. Furthermore, subjects' gaze patterns exhibited greater complexity that matched the underlying action structure of the task and visual encoding of motor intent. This work demonstrates a change in action perception, notably the development of action syntax through motor learning

**Title:** Visual encoding of context and grasp posture throughout adolescent development

**Authors: *A. Y. BAYANI**[1], L. A. WHEATON[2]
[1]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [2]Applied Physiol., Georgia Tech., Atlanta, GA

**Abstract:** Learning how to plan and initiate the motor commands based on the visual scene is a skill that is gradually acquired in a variety of situations and contexts. Eye tracking has been shown to be a powerful tool in predicting motor intent through patterns of fixations and saccades when observing or evaluating motor tasks. In a tool-object scene, gaze patterns can be used to classify salient features that shape task facilitation, namely the operant end of the tool (e.g., bowl of a spoon) and objects (e.g., sugar dish). Grasp posture has been shown largely irrelevant in understanding tool-object motor intent. However, most neurobehavioral studies on grasp focus on simple reach and grasp paradigms. End state comfort (ESC), the ability to adapt the initial

hand posture to ensure a comfortable end posture, may reveal novel mechanisms of action intent that promote a deeper understanding of action planning. The purpose of this study is to determine how context and grasp posture affect gaze behavior on task-related features of a tool-object scene in children. We hypothesize that consistent with our previous work, visual encoding will still reveal object-oriented action priming processes, but with greater encoding of grasp intent for the non-ESC and ESC condition in children. Children between 4- to 12-years-old watched tool-object scenes while their gaze patterns were recorded. Each tool-object scene either had correct or incorrect tool-object pairs and had grasps that either afford or does not afford action. Contrary to previous studies, children visually encode not only the salient features of the scenes for object-oriented action priming but also encode grasp intent.

**Title:** The coding of navigational distance in scene-selective regions of human visual cortex

**Authors: *J. PARK**[1], S. PARK[1,2]
[1]Cognitive Sci., Johns Hopkins Univ., Baltimore, MD; [2]Psychology, Yonsei Univ., Seoul, Korea, Republic of

**Abstract:** To successfully navigate, it is important to detect local boundaries in an environment that impose limits to one's locomotion. Previous studies have shown neural representations of the size and height of a boundary, as well as the perceived egocentric distance in a scene. In this study, we aim to directly test whether scene-selective regions code the *navigational distance* defined by the local boundary by using artificially rendered indoor environments. In our experiment, we took advantage of a glass-wall, which minimizes perceptual change or visibility of the global boundary and presents a local boundary that limits one's navigation. The condition varied in 3 egocentric global distance levels (Near, Middle, Far) and 2 local boundary levels (Glass-Wall, No-Glass-Wall). All environments were rendered to have the same width and height, except for the distance to the back wall, which changed global distance in an environment. In the Glass-Wall condition, a transparent glass-wall was added to each environment. Critically, the navigational distance to the local boundary (glass-wall) was kept the same across all global distance levels. In the No-Glass-Wall condition, navigational distance equaled the global distance because there were no glass walls in the environment. We predicted

that if there is a neural coding of the navigational distance as opposed to the global distance, three different levels of distance (Near, Middle, Far) in No-Glass-Wall conditions will be distinguishable but not in the Glass-Wall conditions as the navigational distance is kept the same across conditions. During fMRI scan, participants (N=7) viewed the stimuli in a blocked design. First, we found a step-wise increment of BOLD response as the global distance increased in OPA for No-Glass-Wall conditions, but not in Glass-Wall conditions. When Near and Far conditions were directly compared, there was an interaction between Glass-Wall and No-Glass-Wall conditions. These results suggest a coding for navigational distance in OPA, rather than a global and visible distance that differed across environments. We found a similar pattern of results in PPA, although weaker at this point. In addition, using multivoxel pattern analysis and support vector machine (SVM), we found an above-chance 3-way classification for near, middle, and far distances in No-Glass-Wall conditions, but not in Glass-Wall conditions. These results provide a novel evidence that scene-selective regions of human visual cortex code for the navigational distance defined by the local boundary that is important for our daily navigation.

**Title:** Rapid allocentric coding in the monkey precuneus

**Authors: *M. UCHIMURA**[1,2,3,4], H. KUMANO[1,2,3], S. KITAZAWA[1,2,3]
[1]Grad. Sch. of Frontier BioSciences, Osaka Univ., Suita-Shi, Japan; [2]Grad. Sch. of Medicine, Osaka Univ., Suita, Japan; [3]Ctr. for Information and Neural Networks (Cinet), Suita, Japan; [4]Japan Society for Promotion of Sci., Tokyo, Japan

**Abstract:** We have recently shown in our behavioral studies that a target location for reaching, or for a saccade, is represented rapidly and automatically relative to a large rectangular frame in the background (Uchimura and Kitazawa 2013; Chakrabarty et al. 2017). By using an fMRI adaptation technique, such allocentric coding was suggested to take place in the precuneus of the human brain (Uchimura et. al. 2015). To further obtain neural evidence for the rapid allocentric coding, we recorded extracellular activity of single neurons in the monkey precuneus. In each trial, while the monkeys looked at a fixation cross, a red dot was presented in succession at

random locations in and around a rectangular frame that was placed in the background. Positions of the fixation cross and the frame were updated in each trial. To determine whether each neuron encoded truly allocentric information, we compared information on the stimulus position relative to the frame before and after shuffling the frame position across the trials. Of the 782 neurons in the precuneus, 77 neurons (9.9%) encoded significant allocentric information ($p < 0.05$, after Bonferroni correction for multiple comparison at 14 time points). The net allocentric information summed across the allocentric neurons started to increase as early as 50 ms after the stimulus onset, reached its peak at 150 ms and subsided thereafter. These results provide hard neural evidence that rapid and automatic allocentric coding takes place in the precuneus.

**Abstract:** A fundamental principle of vertebrate visual system relies on the functional separation of neuronal signaling into the ON and OFF pathways that generate visual contrast. These two pathways originate in depolarizing ON bipolar cells and hyperpolarizing OFF bipolar cells. Critical fusion frequency(CFF), defined as the frequency at which a flickering light is perceived as a continuous light, is useful for assessing the temporal characteristics of the visual system. Using electrophysiological analysis such as flicker electroretinogram (ERG) and visual evoked potential (VEP), CFF has been studied. It is important to analyze CFF in terms of behavioral performance to understand recognition of flicker frequency. We established a behavioral method for evaluating CFF of mice using the constant method that is one of the psychophysical techniques used for determining thresholds of various sensory functions. C57BL/6 mice were trained to perform a two-alternative forced choice task in which steady (250Hz) light and flickering (4-20Hz) light were presented on a green light emitting diode (green LED, 508nm) screen. The temporal frequency of flickering stimulus was randomly chosen on each trial. Mice

responded to steady light by making nose-poke toward touchscreen. The proportions of correct responses (PCRs) were measured. Results showed that PCRs became lower with increasing temporal frequency of flickering stimulus. In the 20Hz condition, PCRs were close to chance level. From the data obtained, we calculated a thresholdand the results suggest that CFF in behaving mice is approximately 14Hzthat was lower than our previous methods using method of limits. Our behavioral assay of mouse model would contribute to development of diagnosis of human retinal disease by applying genetically manipulated mice.

**Title:** Network level deficits in primary visual cortex underlie perceptual learning deficits in Fragile X mice

**Authors: *A. GOEL**[1], D. CANTU[1], G. CHAUDHARI[1], A. NEWADKAR[1], B. TODISCO[1], S. COHEN[2], C. PORTERA-CAILLIAU[1]
[1]Neurol. and Neurobio., [2]Electrical Engin., Univ. of California, Los Angeles, CA

**Abstract:** Fragile X Syndrome (FXS), the most common inherited form of mental impairment, is associated with abnormalities in sensory processing. Here, we set out to investigate whether *Fmr1* knockout (KO) mice show perceptual learning deficits and the alterations in neuronal function, at the circuit level, that are responsible for those deficits. Using a go/no-go visual discrimination task for head-restrained mice, we discovered that, compared to wild-type (WT) mice, *Fmr1* KO mice take significantly longer to discriminate between gratings drifting in two orthogonal orientations (median: *Fmr1* KO=6 days vs. WT=4 days; $p=10^{-5}$). To test the hypothesis that abnormal sensory processing of the visual stimuli might explain this delay in perceptual learning we used in vivo two-photon calcium imaging (with rAAV-syn-GCaMP6s) to record network dynamics in layer (L) 2/3 of primary visual cortex (V1). We found that *Fmr1* KO mice show an increase in visual evoked activity (p=0.016) and they have a significantly lower fraction of orientation tuned neurons in V1 than WT mice (*Fmr1* KO=40.7% vs. WT=57.9%,

p=0.012). Hence, we reduced the angle between “go” and “no-go” stimulus from 90$^{o}$ to 7.5$^{o}$ (after mice of both genotypes had learned the basic task) and found that the discriminability index (d’) was significantly lower in *Fmr1* KO than in WT mice (p = 0.006). Delayed learning and reduced cognitive inflexibility are well documented deficits in human subjects with FXS that are potentially mediated by alterations in cortical sensory processing and/or decision making. Parvalbumin (PV) neurons have been implicated in FXS because of evidence of hyperexcitability (Contractor et al., 2015) and the low density of PV neurons in the somatosensory cortex of *Fmr1* KO mice (Selby et al., 2007). PV interneurons exhibit broad orientation tuning (Caroline and Sur, 2012) and provide fast inhibition to sharpen the orientation selectivity of pyramidal neurons that could affect perceptual discrimination (Lee et al., 2012). Thus, we hypothesized that impaired performance of *Fmr1* KO mice on the reduced angle task and the lower proportion of orientation selective neurons in V1 could be due to abnormal activity of PV neurons or to an imbalance in the timing of their activity relative to pyramidal neurons, which ultimately affects the functional output in V1. We are testing this by selectively recording from PV neurons by expressing AAV-flex-GCaMP6s in PV-Cre x LSL-TdTom (ai9) WT and *Fmr1* KO mice.

**Title:** Fitting the neural dynamics in V1 during visual perceptual learning

**Authors:** ***L. YU**[1], Y. YAN[2], D. WANG[1,2], W. LI[2,3], M. J. RASCH[2,3,4]
[1]Sch. of Systems Sci., [2]State Key Lab. of Cognitive Neurosci. and Learning, [3]IDG/McGovern Inst. for Brain Res. at BNU, Beijing Normal Univ., Beijing, China; [4]IBM TJ Watson Res. Ctr., Yorktown Heights, NY

**Abstract:** Perceptual learning is an important form of adaption in sensory systems and beyond. Changes in the neural dynamics in response to repetitively solving a visual task has been shown to occur in the visual cortex of awake monkeys (e.g. Yan et al., 2014, *Nat. Neurosci.*). Yan et al. chronically recorded multiunit activities of V1 neurons, when two monkeys were trained to perform a contour detection task. They have found progressive strengthening in both facilitation

of neurons (with receptive fields (RFs) nearby the contour) encoding the contour elements and suppression of neurons (with RFs in the surround) responding to the background components during perceptual learning using *the temporal averages of the firing responses*. However, despite these observations, the particular shape of the temporal dynamics of the neural responses to stimuli also changes dramatically during the course of weeks of learning. How such temporal response changes relate to changes in the underlying circuit is difficult to assess without data-driven modeling.
To this end, we here first show that the high-dimensional neural population responses in V1 can be well described by the temporal dynamics of only two main components abstracted from original data using a modified non-negative matrix factorization (NMF) method. The two components are: a facilitatory component involving cells having RFs nearby the contour, and a suppressive component involving cells having RFs in the surround.
We then fitted a number of simple rate-based models to the temporal dynamics of the two components using gradient decent methods. The best model mainly consisted of three populations: two excitatory neuron pools representing the two components, and an inhibitory neuron pool to balance the network. All parameters of the model, such as connection and inputs strengths and facilitation of synapses, were fitted to match the dynamic temporal responses for individual days. We found that the model could well reproduce the data.
We finally asked how the learning affected the fitted parameters, which can be related to a clear biophysical meaning, such as strength of inhibition or inputs. For that we used ranking methods and the t-distributed stochastic neighbor embedding (tSNE) algorithm to reduce the space of parameters and found a largely consistent set of parameters that seems to be mostly affected by learning, including the strength of inhibitory balance, indicating the mechanistic basis and biophysical “turning knobs” that are targeted by perceptual learning in V1.
Our results are thus important for the mechanistic understanding of the possible underlying network changes induced by perceptual learning in V1.

**Abstract:** Whether and how changes in resting-sate functional connectivity (rs-FC) in context of visual perceptual learning are associated with later behavioural performance remains under debate. To investigate this question, task-fMRI (t-fMRI) data was obtained in two different days (day1 and day2) and resting-state fMRI (r-fMRI) data was obtained before and after t-fMRI on day1 only. This experimental paradigm allowed us to examine the relationship between post-task versus pre-task functional connectivity and subsequent improvement of task performance. Twenty healthy young adults participated in a perceptual learning task in day1 and day2 and performed a motion discrimination task using randomly moving dots to modulate visual perceptual learning. Moving dots were presented with three coherence levels (20%, 40% and 80%) and with two directions (upward and downward). To identify brain regions indicating activations associated with the coherence levels of moving dots, parametric regression was used in a general linear model. The area MT+ exhibited significant activation ($P < 0.05$, family-wise error [FWE] corrected) with increasing coherence level, while the dorsal anterior cingulate cortex (dACC) and the bilateral insula represented significant activation ($P < 0.05$, FWE corrected) with decreasing coherence level. These findings indicate that the MT+ is sensitive to motion coherence and that the dACC and insula are sensitive to task difficulty. Seed-based rs-FC analysis was performed using the MT+, dACC and bilateral insula as seeds on both resting scans. By contrasting r-fMRI sessions (post-task vs. pre-task), only significant increases ($P < 0.05$, FWE corrected) in connectivity with the MT+ were observed on regions namely: the bilateral postcentral gyrus (POG), the bilateral precentral gyrus (PrG), the left superior temporal gyrus (STG), the left middle temporal gyrus (MTG) and the left superior frontal gyrus (SFG). Further Pearson correlation analysis exhibited that change in accuracy rate from day1 to day2 is significantly correlated with connectivity enhancement from pre-task rest to post-task rest only between MT+ and bilateral PrG (left PrG, $r = 0.56$, $P = 0.01$ and right PrG, $r = 0.5$, $P = 0.023$). Our findings suggest that rs-FC between visual and premotor cortices may reflect the plasticity prior to actual behavioral changes and predict individual differences in subsequent perceptual learning.

**Title:** Visual familiarity evoked theta oscillations in primary visual cortex (V1)

**Authors: *S. T. KISSINGER**[1], A. PAK[1], S. MASMANIDIS[2], A. A. CHUBYKIN[1]
[1]Biol. Sci., Purdue Univ. Dept. of Biol. Sci., West Lafayette, IN; [2]Neurobio., UCLA, Los Angeles, CA

**Abstract:** The primary visual cortex (V1) has been long thought of as a simple feature detector that conveys basic visual information to higher order brain areas. More recent evidence, however, has shown that neural activity in V1 can also depend on previous visual experience. Individual neurons in V1 of awake rodents have been shown to fire persistently out to the timing of reward delivery after presentation of a visual cue, a phenomenon that is dependent on the cholinergic system. Repetitive presentation of phase reversing visual stimuli in awake animals results in significant potentiation of visually evoked potentials (VEPs) in V1, a phenomenon known as stimulus-selective response potentiation (SRP). Potentiation of VEP amplitude has also been shown to report learned sequences of visual stimuli. Persistent theta oscillations (4-8Hz) have been reported in the extrastriate visual cortex of monkeys during visual cue-reward working memory tasks. Interestingly, persistent theta oscillations have also been shown to report the timing of reward delivery after visual cue-reward training in rats. We sought to further explore the specificity of these visually evoked theta oscillations in V1 and the potential mechanisms underlying their generation. Using 64 channel silicon probes acutely implanted in binocular V1, we recorded visually evoked potentials (VEPs) and action potentials from individual neurons (units) in awake mice responding to sinusoidal grating stimuli. After training mice to visual stimuli, oscillations in the theta range emerged in VEPs and individual units. Unit-depth analysis and current source density (CSD) revealed a cortical layer specific distribution of oscillatory activity. Interestingly, these oscillations could be induced by training mice to visual stimuli with vastly different physical properties. Treatment with the muscarinic acetylcholine receptor (mAChR) antagonist scopolamine blocked theta oscillations, suggesting that the cholinergic system is required for their emergence after training.

**Title:** Use of awake fMRI in dogs to model learning of visual and olfactory stimuli

**Authors: *A. PRICHARD**[1], M. SPIVAK[2], G. BERNS[1]
[1]Psychology, Emory Univ., Stone Mountain, GA; [2]Comprehensive Pet Therapy, Rosewell, GA

**Abstract:** Through awake fMRI, we examined individual and group learning curves in dogs to previously neutral visual and olfactory stimuli. Visual stimuli were a toy pineapple and inflatable flamingo, and olfactory stimuli were Isoamyl acetate and Hexanol. During scanning, one stimulus of each pair was associated with food reward and the other with nothing. To generate learning curves for individual dogs, we examined activation within the caudate nucleus per trial following the presentation of each stimulus. The learning curves show that dogs did form stimulus-reward associations within a single MRI scan. Our results demonstrate the speed at which conditioning to stimuli associated with reward occurs in the dog brain, and the potential differences between modalities in learning acquisition.

**Title:** The role of the inferior temporal area TEO in visual categorization

**Authors: *T. SETOGAWA**, M. ELDRIDGE, M. FREDERICKS, R. SAUNDERS, B. J. RICHMOND
NIH, Bethesda, MD

**Abstract:** Inferior temporal cortical area TEO is located between areas V4 and TE in the ventral pathway of the visual system. Our previous studies demonstrated that monkeys with bilateral TE lesions were only mildly impaired in categorization of visual objects based on perceptual similarity. To investigate the relative importance of an adjacent brain region, we examined the effect of bilateral removal of area TEO on the same visual categorization task. We tested a cat vs. dog categorization task with one monkey. In this task, the monkey had to categorize morphed images of cats and dogs into either “cat-like” or “dog-like” to get reward. These stimuli were morphed (blended and warped) cats and dogs ranging between 0 and 100% dog, with a distribution biased around the category boundary (11 levels, 0, 25, 35, 40, 45, 50, 55, 60, 65, 75, 100% of dog). The monkey was trained to touch a bar to initiate a trial, and had to release the bar during one of two intervals; early (signaled by a red central dot) if he identified the stimulus as more “cat-like”, or late (signaled by a green central dot) if the stimulus was identified as more

"dog-like". If the monkey responded correctly, the color of the central dot turned into blue and liquid reward was given. We assessed performance on this task before and after bilateral TEO lesions. We analyzed the behavioral data for 4 days before the lesions, and four days afterwards. The percentage of response as "dog-like" for each morphed level was calculated and used as indicator of categorization accuracy. Our preliminary data suggest that the TEO lesions impaired categorization accuracy only transiently. In particular, the discriminability in the first day after lesion was significantly degraded when the morphing range was between 25-75%. As we previously observed in TE lesioned monkeys, the accuracy score improved over the first few days of exposure to the morphed stimuli, in this case recovering to pre-lesion levels of performance. These results suggest that TEO removal causes a temporary degradation of ability for visual categorization.

**Title:** Comparison between monkeys with bilateral removals of visual area TE and a deep neural network in categorizing feature-ambiguous stimuli

**Authors: *N. MATSUMOTO**[1], M. A. ELDRIDGE[2], B. J. RICHMOND[2]
[1]AIST, Tsukuba, Japan; [2]NIMH, Bethesda, MD

**Abstract:** In the canonical view of visual processing, the neural representation of complex objects emerges as visual information is integrated through a set of convergent, hierarchically organized processing stages, ending in the primate inferior temporal lobe (Mishkin et al., 1983). It seems reasonable to infer that visual perceptual categorization requires the integrity of anterior inferior temporal cortex (area TE). Nevertheless, monkeys with bilateral removals of area TE show only mild deficits of perceptual categorization (Matsumoto et al., 2016). Furthermore, the monkeys show greater deficits for feature-ambiguous stimuli of morphed cats and dogs than control monkeys (Eldridge et al., SFN abstract 2012). Here we evaluated the performance of a simulated hierarchical model of vision in discriminating the same categorization problems previously presented to the monkeys. We employed a deep neural network (DNN) consisting of 5 convolution layers (conv1-5) and 3 fully connected layers (fc6-8) (Krizhevsky, et al., 2012). In the behavioral experiments, the monkeys were trained to categorize using an image set of 20

cats and 20 dogs prior to TE removal. After the removals, the monkeys were tested using a trial-unique set of 240 cats and 240 dogs. In the modeling experiments, the set of 20 cats and 20 dogs was used to train the model. Linear support vector machine (SVM) analysis was applied to the output vectors for cat/dog images in each model layer to determine the cat/dog boundary in that layer. We then assessed the classification accuracy of the model layers when presented with the set of trial-unique stimuli. The accuracy increased at successive model layers (from superficial to deep). Even in the conv5 layer the accuracy was above 70%. This result indicates that the convolutional layers are sufficient for supporting a reasonable accuracy of categorization. It has been reported that the information derived from the fully connected layers of this DNN is consistent with the degree of information that can be derived from neuronal activity in area TE (Yamins and DiCarlo, 2016). For the trial-unique cat/dog stimuli, the output of the conv5 layer was similar to the performance of monkeys after area TE removals. However, the fully connected layers were necessary to recognize feature-ambiguous morphed cat/dog images, whereas the monkeys with TE removals retained some ability to perform this task, albeit at a lower level of accuracy than controls. These results indicate that some revision to the DNN may be necessary to increase flexibility across stimulus types if we wish to be able to map the function of modules of the visual processing hierarchy to layers of the network.

**Abstract:** We assign objects into categories based on similarities in their appearance in a process called visual perceptual categorization. The medial temporal lobe (MTL) has been implicated in learning, categorization, and memory. Inferior temporal (IT) cortex is considered as a late stage of visual processing in the ventral visual pathway, and provides input to areas in the MTL. Previously we have shown that rhesus monkeys quickly learn (in less than one testing session) a visual category task discriminating between cat-dog stimuli, and that intact monkeys can learn a more complex task containing computer-generated images that are morphed (blended and warped) between many dog-cat pairs. Three normal monkeys, 3 with bilateral TE ablations, and 3 with bilateral rhinal ablations, reported whether the morphed image was more dog-like or more

cat-like. The normal and rhinal lesion monkeys performed at a high level having difficulty only when the stimuli approached the category border. Monkeys with TE ablations were somewhat impaired when the images contained more than about 10% morphing.
This outcome led us to look elsewhere for candidate areas in the MTL that may play a role in visual categorization, such as the hippocampus. The hippocampus is important in declarative memory, e.g. processing memories that are recalled consciously. It seems reasonable to ask whether declarative memory may play a role in visual perceptual categorization; for example, if the monkeys were constructing 'prototype' representations for each category to which all stimuli are compared to for classification, the hippocampus might be necessary for this process. However, the categorization performance of monkeys with excitotoxic hippocampal lesions was indistinguishable from that of controls. Thus, from these data it seems as if the hippocampus is not necessary for the categorization of feature-ambiguous stimuli.

**Abstract:** A picture-plane inversion of a face reduces the ability to recognize both facial identity and expression in humans. To study the effect of face inversion on the neural activities in monkey area TE, we previously applied principal component analysis (PCA) to the responses of 119 face-responsive neurons to upright and inverted pictures of human faces (3 models with 4 expressions) and monkey faces (4 models with 4 expressions), and calculated a population activity vector for each picture consisting of averaged spike counts of the individual neurons in the windows of 115-165 ms and 140-190 ms after stimulus onset. The former and latter windows are known to be where the global (human vs. monkey) and fine categorizations (human

individuals or monkey expressions) take place, respectively. In the 115-165 ms window, separation of the vectors of the upright and inverted faces was observed. In the 140-190 ms window, the separations of human individuals and monkey expressions of the upright faces were larger than those of the inverted faces. The result suggested that the changes in the information represented by the TE neurons might cause the psychological face inversion effect. In the present study, we employed a convolutional neural network in an effort to understand the information processing of the face inversion effect. The model consists of 5 convolution layers (conv1-5) and 3 fully connected layers (fc6-8) (Krizhevsky, et al., 2012). Upright and inverted pictures of a human or monkey face used in the previous work (Sugase-Miyamoto, et al. 2014) were input to the model. We applied PCA to the activity vectors in each layer to visualize the relationship between the vectors of the upright and inverted faces. In conv1, the vectors of the human and monkey faces were separated. The vectors of the upright and inverted pictures of the monkey faces were overlapped, while those of the human faces were separated. In conv5, the vectors of the upright and inverted pictures of the monkey faces were separated, showing consistency with the neuronal data in the 115-165 ms time window. In fc6, the separations of the human individuals and monkey expressions of the upright faces were larger than those of the inverted faces, showing consistency with the neuronal data in the 140-190 ms window. These results indicate that the human and monkey categorizations develop even in the lower visual cortex, and the separation of the upright and inverted faces takes place progressively in feed-forward processing in the visual cortex.

**Title:** Escaping the frontal bottleneck: Extensive practice of a visual categorization task shifts category representations from dorsolateral prefrontal cortex to ventral occiptio-temporal cortex

**Authors: *P. H. COX**[1], C. A. SCHOLL[1], C. A. SPROUSE[1], J. C. RONKIN[1], R. L. KLEIN[1], K. WIMMER[2], K. GLOMB[2], N. E. JAIMES[1], G. DECO[2], X. JIANG[1], M. RIESENHUBER[1]
[1]Neurosci., Georgetown Univ., Washington, DC; [2]Univ. Pompeu Fabra, Barcelona, Spain

**Abstract:** The process of learning to assign a category to a sensory stimulus has been well studied in the visual domain, typically involving several hours of training and up to a few thousand trials, generally showing a sharpening of shape-tuning in visual areas and the formation of task dependent category responses in dorsolateral prefrontal cortex (dlPFC). However, experience with real-world stimuli is far more extensive and categorization of common objects happens independent of task context. Other studies have identified a bottleneck in PFC that limits processing to one task at a time, potentially limiting our ability to categorize objects in multitasking scenarios. Here we test the hypothesis that extensive training leads to a shift in the neural circuitry underlying categorization, from later in prefrontal cortex to earlier in more posterior brain regions, moving the decision out of the frontal bottleneck and increasing the ability to perform the trained task automatically.
We trained 14 subjects to categorize morphed car stimuli (as in our previous studies, Jiang *et al., Neuron,* 2007; Scholl *et al., JOCN,* 2014) using a training app and used fMRI and EEG rapid adaptation (RA) techniques to identify the brain regions and temporal dynamics underlying the categorization process after initial training (~4 hours over one week, as in our previous studies) and extensive practice (~16 more hours over 4 more weeks, ~30,000 trials in total). In agreement with previous studies, after initial training subjects show categorical responses in left dlPFC and shape-selective responses in occipito-temporal cortex (OTC) in fMRI-RA, and, in EEG-RA, a shape-selective signal over posterior channels ~170ms followed by a categorical signal starting just after 200ms over left frontal channels. After extensive training, fMRI-RA showed categorical responses in left OTC, as well as left parietal cortex and right striatum, but no longer showed a categorical response profile in dlPFC. Frontal regions also showed reduced effective connectivity with the rest of cortex. In agreement with our fMRI-RA results, EEG-RA reveals earlier categorical signals starting ~150ms over posterior channels. These data suggest that extensive practice changes the brain networks performing perceptual categorization, with category-selective representations being pushed out of the frontal bottleneck, down into OTC. These category-selective representations then could permit a direct recruitment of parietal or striatal circuitry for response selection, circumventing the frontal bottleneck. Indeed, after extensive single task training subjects' ability to categorize cars in dual task scenarios increased.

**Title:** A prefrontal long-term memory mechanism for discrimination of objects with stable reward associations

**Authors: *A. GHAZIZADEH**[1], O. HIKOSAKA[2]
[1]NIH, Bethesda, MD; [2]Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

**Abstract:** We have previously shown that given sufficient reward training, a single valuable object among others can be detected rapidly during visual search (single saccade <150ms). Such efficient detection is sustained in long-term memory for many weeks without seeing the objects or reward exposure (Ghazizadeh et al 2016 JOV). However, the neural mechanism for such long-term memory formation is not fully understood (but see Hikosaka et al 2014 Annu Rev Neurosci). Our recent results with whole brain fMRI revealed that the prefrontal cortex ventral to principal sulcus (vlPFC) is involved in discrimination of objects based on months-long memory of value associations (SfN 2016). To further study the neural mechanism of such long term memory, we trained two macaque monkeys to associate more than one hundred random fractal objects with either high or low reward (‘good’ and ‘ bad’ objects, 10+days, 300+ trials). We then recorded the activity of the visually responsive neurons in vlPFC in a passive fixation task while ‘good’ and ‘bad’ objects were presented inside the neurons receptive field and in the absence of reward. We did this hours, days, weeks or months after this reward training. Results showed that as a population, vlPFC neurons responded to ‘good’ objects more strongly than ‘bad’ objects (GB discrimination) and sustained the value-based response bias up to many months. The onset of GB discrimination in the vlPFC population was rapid (<120ms). This reveals a long-term high capacity memory mechanism in vlPFC for object’s old values. We also examined the interaction of GB discrimination and object eccentricity. Interestingly, the GB discrimination was stronger in the periphery (15-20 deg) than the center (0 deg). Such peripheral value-based discrimination can be the neural basis of efficient visual search reported previously. Together, the high capacity and the longevity of the value memories, as well as the rapid peripheral discriminability of ‘good’ vs ‘bad’ objects, can be critically useful for animals as they encounter many valuable objects (e.g. food) in their lifetime and have to quickly retrieve them any time in future.

**Title:** Visual image familiarity learning at multiple timescales in the inferotemporal cortex

**Authors: *K. MOHAN**, D. J. FREEDMAN
Dept. of Neurobio., The Univ. of Chicago, Chicago, IL

**Abstract:** Humans and other primates have an exceptional ability to learn to recognize familiar visual items, and to discriminate them from novel ones. This ability is thought to rely on experience dependent changes in neuronal representations in the ventral visual pathway, particularly the inferotemporal cortex (IT). Past work has shown that neurons in primate IT cortex differentiate between novel and familiar stimuli, with stronger activity on average for novel images. To date, experimental studies have primarily sampled from the extremities of the familiarity spectrum, comparing highly familiar to highly novel images. Thus, it is unknown whether IT supports the acquisition of familiarity or whether it merely reflects learned familiarity signals encoded elsewhere? To probe this question, we familiarized the monkeys with multiple sets of 40 novel images for up to 10 days each, while monitoring responses of IT neuronal ensembles in awake, behaving monkeys during the familiarization process. Additionally, on every session, we also presented the monkeys with 40 initially-novel images which were familiarized through repeated presentations (N~=30) in each session, as well as 40 highly familiar images. Neuronal responses and selectivity were compared between highly familiar, intermediately familiar, and novel stimuli. Consistent with previous reports, we observed a decrease in the average neuronal response (N=120) with familiarity, both within and across sessions. While the average transient response (80-150 ms) was comparable for all stimuli, the average sustained response (150-300 ms) was highest for novel, followed by intermediately familiar, and the lowest for highly familiar stimuli. We also investigated how firing rates and visual selectivity evolve across each session with repeated presentations of initially novel stimuli. This revealed a diversity of changes with neurons increasing their firing rates to some stimuli, while they decrease with others. A subset of neurons showed global increases in firing rates for all stimuli, independent of familiarity. For each neuron, we quantified the proportion of stimuli that elicit robust firing rates and in line with previous studies, found that individual

neurons (75%) responded to a smaller fraction of familiar than novel stimuli. Interestingly, within a session, we observed that the proportion of stimuli that evoked robust firing rates decreased more for novel stimuli than for familiar stimuli, suggesting that IT shows rapid changes in activity during learning. Together, these results give insight into how experience affects visual representations in ITC across multiple timescales.

**Title:** Differential roles of LIP and MST during motion categorization

**Authors: *Y. ZHOU**[1], K. MOHAN[1], D. J. FREEDMAN[2]
[1]The department of neurobiology, The Univ. of Chicago, Chicago, IL; [2]Neurobio. and Computat. Neurosci., Univ. of Chicago, Chicago, IL

**Abstract:** Categorization is an important cognitive function for recognizing the behavioral significance of sensory stimuli and choosing appropriate behavioral responses. Previous studies have shown that frontal-parietal cortical areas are closely involved in the categorization process. Specifically, studies from our lab have used a delayed match to category (DMC) task to reveal that activity in prefrontal (PFC), lateral intraparietal (LIP) and medial intraparietal (MIP) cortices all encoded learned visual categories, with evidence suggesting that LIP plays a preferential role in motion category encoding. Here, we further examine the roles of multiple cortical areas during motion categorization process by comparing neuronal activity in LIP with that in the medial superior temporal (MST) area, an important motion processing area which is interconnected with both LIP and the middle temporal (MT) area. We recorded from 100 MST neurons and 55 LIP Neurons in one monkey during performance of the motion DMC task. Interestingly, we found that many MST neurons appeared to eencode the learned motion categories, qualitatively similar to that observed in LIP. MST category selectivity peaked in strength during the late sample period, but also persisted during the delay of the DMC task. We further compared category encoding in LIP and MST by using several analyses including a category tuning index , percentage of explained variance, and support vector machine decoding. This gave several lines of evidence suggesting that LIP and MST play different roles during the DMC task. First, category selectivity in LIP and MST arose with a similar latency after sample onset. Second, LIP showed stronger average category selectivity during the early sample and delay periods than

MST. Third, LIP but not MST neurons showed reduced category selectivity in the error trials than in the correct trials during the delay period, indicating that category selectivity in LIP was more closely correlated with task performance than in MST. Fourth, LIP neurons showed relatively stable category encoding during the delay period, while MST neurons showed more dynamical category encoding during the delay. Finally, MST neurons showed stronger direction encoding than LIP neurons during the sample period. In summary, our results support the idea that LIP is closely involved in mediating categorical decisions and holding the category information within the short-term memory during the DMC task. MST neurons might be also involved in the transformation of direction tuning to category encoding during the sample period, but plays a lesser role in retaining category information within working memory.

**Title:** Tracking response changes due to familiarity and adaptation in AM and AF face patch neurons

**Authors: J. H. HONG**, K. W. KOYANO, B. E. RUSS, *D. A. LEOPOLD
NIMH, Bethesda, MD

**Abstract:** The ability to distinguish faces of unknown individuals from those of familiar ones is a crucial aspect of a primate's social life. However, the process of learning familiar faces is still not well understood because it is difficult to track activities of the same neurons across multiple days. Here, we report our preliminary results of longitudinal recording of neurons in AM and AF face patches while monkeys were repeatedly shown the same face stimuli. To track the changes of neuronal responses over weeks, we chronically implanted microwire bundles (McMahon et al., 2014; 2015) in the face patches whose locations were identified using fMRI (Russ et al., 2015). With the microwire bundles, we could longitudinally record more than 30 neurons from both patches for two weeks. More than 60% of neurons were selective for visual face stimuli. We prepared 120 novel face stimuli that the monkeys had never seen before and repeatedly showed them to the monkeys in consecutive days. During the two-week experimental period, neurons in AM face patch gradually decreased their responses to a subset of the novel faces. This response change was obvious in the sustained, late response phase between 200-400 ms after the stimulus onset, but nearly absent in the transient, early response during initial 200 ms. In contrast to the

plastic responses of AM face patch, responses of neurons in AF patch showed no overall change during the two-week experimental period, consistent with a previous study from this area (McMahon et al., 2014). However, neurons in the AF face patch did exhibit repetition suppression, or a decrease in response strength to repeatedly shown stimuli within in each session, whereas neurons in AM face patches did not. These decreased responses recovered by the following day, thus there was no accumulation of repetition suppression across days in AF. These results indicate that AM neurons change their activity to novel faces gradually over weeks, whereas AF neurons change their activity rather quickly within a few trials in a given day. This suggests the different roles across face patches in learning new faces through familiarity and adaptation mechanisms.

**Title:** Using real-time magnetoencephalography neurofeedback training to reduce the time of shifting spatial attention from one visual field to another

**Authors: K. D. RANA**[1], J. VOJTECH[1], S. BROWN[1], *L. M. VAINA[2]
[1]Biomed. Engin., Boston Univ., Boston, MA; [2]Biomed Engineering&Neurology, Boston Univ. & Harvard Med. Sch., Boston, MA

**Abstract:** Adaptive behavior requires rapid shifting of spatial attention among different locations in the environment. Even without any training, covert spatial attention can be shifted in just a few hundred milliseconds (Muller et al, 1998). In this project, our objective was to train subjects to increase their speed of shifting their spatial attention. To do this we developed a real time magnetoencephalography (MEG) neurofeedback training method that decodes spatial attention location (left (LVF) or right visual field (RVF)) over time using MEG sensors activation. Subjects were cued to attend to the direction of motion of one of two random dot kinematograms (RDK) displayed in either the LVF or RVF (“attend” period). After a variable time period (750-1500 ms), the motion direction in the attended RDK changed, cueing the subject to switch attention to the opposite visual field (VF) and report the color of a disk (red/green) superimposed on the RDK display in that VF (“switch” period). Feedback was presented as a thermometer where its level represented the speed of attention switching. To generate the feedback we trained a decoder to discriminate between LVF and RVF from

oscillatory activity across the 306 MEG sensors during the “attend” periods in the trials (n=80) of the previous block. After each trial in the current block, the decoder was applied to the time course of sensors activity in the “switch” period and then it computed the speed of switching attention from one VF to the other. In 5 of the 7 subjects trained on this task (6 days, 320 trials/day) the speed of switching attention significantly decreased (Wilkoxin Ranked Sum $p < 0.05$). Directional functional connectivity between active regions of interest (ROIs) was computed through frequency Granger causality within each stimulus period in the α, β, and γ bands. We calculated Dynamic Granger Causality (DGC), a sliding time-windowed form of Granger causality (Lin et al, 2009; Vaina et al, 2010), to compute the time segments in the stimulus when any two ROIs were significantly connected. During the “attend” period, increased switch speed was correlated with higher β-band Granger scores between bilateral MT+, precuneus, and frontal eye fields. During the “switch” period, increased switch speed was correlated with lower γ-band Granger scores among frontoparietal ROIs. DGC computed between these ROIs revealed shorter time segments after training. Taken together these results suggest that the engagement of preparatory top-down attention connections in the β-band prior to “switch” and the short lived γ-band connectivity among frontoparietal ROIs during the “switch” underlie successful training of switch speed.

**Abstract:** We have recently shown that in the absence of firing rate changes, a spatially-specific working memory (WM) signal drives subthreshold modulations in visual areas. Whether and how this subthreshold input results in enhanced visual processing is crucial for understanding how sensory processing is altered by WM. We simultaneously recorded the spiking activity and local field potentials from multiple sites within the middle temporal (MT) cortex during a modified version of the memory guided saccade task. In this task, a set of visual probe stimuli are presented during the fixation and memory periods. We quantified the receptive fields (RFs) in MT and altered the locus of WM relative to each RF to study the effect of WM in isolation and when interacting with incoming visual signals. In the absence of visual stimuli, there was a robust increase in the locking of spikes to the ongoing αβ oscillations when remembering a location near the MT RF, even though the overall firing rate remained unchanged. Interestingly, in the presence of visual stimuli during the memory period, the WM-induced change in the locking between spikes and ongoing αβ oscillations was sufficient to enhance the ability of MT neurons to encode visual stimuli (quantified using the mutual information between the visual stimulus location and the phase of αβ oscillations at which spikes occurred). Importantly, the increased gain and discriminability of the response to incoming visual stimuli occurs mostly during the preferred phase of ongoing αβ oscillations. This finding indicates that the WM-induced enhancement of the visual representation depended upon these oscillatory changes. These results provide a mechanistic understanding of how, by altering the oscillatory activity within visual areas, a spatially specific WM signal is capable of enhancing the efficacy of visual sensory processing, potentially underlying the behavioral benefits of WM for visual perception.

**Title:** Neural responses in non-memory tasks predict the likelihood that LIP neurons will exhibit environmental memory

**Authors: *M. SEMEWORK**[1], M. E. GOLDBERG[2]
[1]Dept. of Neurosci., Columbia Univesity, New York, NY; [2]Neurosci., Columbia Univ. Press, New York, NY

**Abstract:** Neurons in the lateral intraparietal area (LIP), demonstrate a form of environmental memory (EM)(Steenrod & Goldberg 2009, Semework et al 2012,), a memory for task-irrelevant objects that may become important in the future. When a monkey makes a saccade that brings the spatial location of a probe flashed in a recent trial (hence attention-grabbing) into the neuron's receptive field, the neurons respond even though the stimulus has not appeared on the current trial. However, we also discovered that classic statistical measures did not classify units precisely. We therefore used other approaches to increase our classification accuracy and create tools to predict precisely memory performance. Our analysis demonstrated that baseline and visual activity of these neurons in non-EM tasks can predict the likelihood of having EM. Using logistic regression models, we found that the strongest influence on memory activity came from pre-saccadic (baseline) mean activity. Moreover, maximum visual response is highly predictive of memory responses. There is a significant relationship between pre-saccadic baseline median and maximum visual response. Linear Discriminant Analysis (LDA) performed at about 72% correct classification rate when using maximum visual responses to predict memory responses (as "good", "none", or "not-defined"). Consistent with non-parametric data distributions, comparison between Principal Component Analysis (PCA) and LDA classification of memory responses into different classes resulted in first LD explaining 88.1% between-group variance, and first PC explaining 98.8% total variability in the data (based on baseline pre-saccadic max and median). Leave-One-Out and 10-fold cross-validation (CV) analysis on prediction of memory activity by baseline pre-saccadic median shows a similar (minimum) CV error for a degree 1 or 2 polynomial. A non-parametric clustering (k-Nearest Neighbors algorithm) using baseline pre-saccadic median and visual responses predicted memory responses with 73% accuracy. Together, these results indicate that, LIP neuron environmental memory dynamics can be predicted reasonably, suggesting this response is not a task-specific epiphenomenon but possibly useful neuronal activity which may help us process retino-spatial signals that this brain region is known to compute.

**Title:** Inhibition of polyamine catabolism leads to cerebellar injury and overt ataxia

**Authors: K. ZAHEDI**[1], S. BARONE[2], J. XU[1], R. CASERO[3], *M. SOLEIMANI[2,4]
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Med., Univ. of Cincinnati Med. Ctr., Cincinnati, OH; [3]The Johns Hopkins Sch. of Med., Baltimore, OH; [4]VA Res. Services, Cincinnati, OH

**Abstract:** Polyamines, spermidine and spermine, are aliphatic cations that play multiple indispensible roles in the regulation of DNA structure, protein-nucleic acid interactions, and cell growth and viability. Their cellular content is tightly regulated through the balance of their synthesis, degradation, import and export. Polyamine catabolism increases and exacerbates organ damage and dysfunction in a variety of injuries (e.g. ischemia/reperfusion, traumatic and toxic). However, the role of polyamine catabolism under normal conditions is not known. In order to address this, we developed mice with the complete deletion of polyamine catabolism pathway through the ablation of spermidine/spermine $N^1$-acetyltransferase and spermine oxidase (SSAT/SMOX) genes by generating mice with global double knockout (dKO) of SSAT and SMOX. Examination of the SSAT/SMOX dKO mice did not reveal any overt growth or developmental deficits. SSAT/SMOX dKO mice exhibited a general build-up of polyamines in various organs that were tested. The SSAT/SMO dKO mice developed progressively ataxia as verified by the worsening of neural deficits (average ataxia score of 5.07+/-0.26 at 3 months of age), while age matched WT mice did not show any neural deficits (average ataxia score of 0.51+/-0.07). The comparison of brain histology of WT and SSAT/SMOX-dKO mice revealed an increased presence of intensely stained contracted nerve cell clusters and vacuolization in the granular layer and white matter of the cerebellum. Our results also show that compared to WT mice, the number of Purkinje cells is decreased and staining intensity of calbindin-1 in Purkinje cells and α-synuclein punctates in the white matter of SSAT/SMOX-dKO is significantly increased. Analysis of brain structure by magnetic resonance imaging revealed increased hyperintensity and significant atrophy in the cerebellum of SSAT/SMOX-dKO but not WT animals. Chemical analysis revealed decreases in glutamate and N-acetylaspartate and an increase in the inositol content of the cerebellum. Gene expression analysis by RNAseq also revealed alterations in the expression of mRNAs that account for potential mechanisms that lead to the onset of ataxia in SSAT/SMOX-dKO mice. Our results indicate that polyamine catabolism is important in the maintenance of normal cellular polyamine levels, and that the accumulation of polyamines due to the disruption of their catabolism is cytotoxic, especially in cerebellum and causes overt ataxia in mutant mice with the combined deletion of SSAT and SMOX genes.

**Title:** Comparison of anodal and cathodal tDCS on cerebellum using an *In vivo* approach

**Authors: R. MANCHANDA**[1], A. KEITH[1], A. DE LA CRUZ[1], *H. LU[2]
[1]GA Campus Philadelphia Col. of Osteo. Med., Suwanee, GA; [2]PCOM - Georgia Campus, Suwanee, GA

**Abstract:** According to recent studies, the use of transcranial direct current stimulation (tDCS) has shown promise as a potential therapy for cerebellar movement disorders. Our previous studies explored the effects of anodal tDCS stimulation on the Purkinje cell firing rate and local field potentials (LFPs) in the cerebellar cortex. The aim of our current study is to investigate the effects of cathodal tDCS stimulation on Purkinje cell firing rates and cerebellar cortical LFPs. From 5 Sprague-Dawley rats, 6 Purkinje cells were isolated from the cerebellar cortex along with LFP recordings in the cerebellar and cerebral cortices. The intensity of cathodal stimulation was set at 100 µA and 200 µA. Power spectrum analysis was conducted to study the general cerebellar cortical activity changes by tDCS. The results revealed an increase in the amplitude at approximately 10 Hz in 2 out of 6 cells. The remaining 4 cells did not show any significant changes in amplitude. Analysis of the mean frequency was conducted to study the individual Purkinje cell output. Three cells showed a decrease in firing rate following cathodal stimulation, while other three cells showed an increase in firing rate following the same stimulation. In general, cathodal stimulation resulted in an average decrease of 20% in the Purkinje cell firing rate. Our previous studies using anodal stimulation resulted in a 13% decrease in firing rate of Purkinje cells on average. Cross correlation and coherence analyses were used to assess the relationship between the cerebellar and motor cortices. A cross-correlation level of 0.2-0.5 was observed in all recordings, which is consistent with result from anodal stimulation. Four out of 6 cells showed coherence between the cerebellum and cerebral cortices at 10 Hz. Two of those 4 cells showed additional coherences at 75 and 80 Hz respectively. These changes that occurred at the high frequency range are not consistent with either anodal or cathodal stimulation.

**Title:** Trajectories of myelinated axons that travel within the purkinje cell layer

**Authors: *M. ARIEL**[1], D. T. DALY[2]
[1]Pharmacol. & Physiol., [2]Ctr. for Anatom. Sci. and Educ., St. Louis Univ. Sch. of Med., Saint Louis, MO

**Abstract:** At SfN ’16, we described a transverse cerebellar commissure within the Purkinje Cell Layer (PCL) of red ear pond turtles, *Trachemys Scripta*. This path was observed by tracer transport in myelinated axons that connect each lateral edge of the cerebellar cortex (Cb) to one another. Those axons also connected with vestibular regions elsewhere, properties that were suggested by previous physiological recordings (Brown et al, J Neurophysiol 2011). However, these axons were only viewed as thick fibers in thin transverse sections near the Cb midline. The present work evaluates axonal orientations within the narrow (20-50 µm) layer of the PCL at the Cb midline, when sectioned tangential to the pia surface. Turtle brains were studied due to their unfoliated cerebellar cortex whose neurons transport tracers when maintained in vitro. One day following fluorescent dextran placement in the lateral Cb in vitro, the Cb was gently flattened between two glass coverslips, fixed (4% para in PBS) and cryoprotected (25% sucrose). 30-µm tangential sections were examined by confocal microscopy. Alternatively, a fresh Cb was immediately flattened, fixed, cryoprotected, sectioned and labeled immunofluorescently for Myelin Basic Protein (MBP). In these tangential sections, as previously observed in transverse sections, dextran filled axons were observed crossing the PCL at the midline. Using 120x magnification, orientations were measured for axons that extended at least 70 µm on either side of midline. Cluster analysis revealed that the orientation of the largest set of fibers (80% of the sample) was not statistically different than the 0° transverse plane (-6.3° ± 0.7; N= 289, $p < 0.05$ V test; Berens 2009). At 20x magnification, labeled axons were also observed with oblique trajectories, indicating a path to the Cb peduncle. For Cb with anti-MBP immunolabeled axons, orientations were also analyzed at the midline with 120x magnification. Surprisingly, two other sets of axons were observed in addition to the commissure. One large set of axons traveled primarily along the sagittal midline (Cb raphe) within the PCL and ventral to it. A second smaller group had transversely oriented axons dorsal to the PCL; a population of thin myelinated parallel fibers with varicosities. In summary, tangential Cb sections reveal myelinated axons with multiple orientations. Unlike white matter tracts, these thick axons traveled tortuously through the PCL, avoiding large Purkinje cell bodies in their path. Whereas the commissural axons that

connect the two vestibulocerebellar regions may enable bilateral vestibular processing, a function for a myelinated tract along the Cb midline remains to be elucidated.

**Abstract:** Inhibitory pathways are essential functional elements of the nervous system and the interaction between excitation and inhibition underlies key operations performed by neural circuits. The organisation of networks of inhibitory neurons into overlapping groups connected via direct synaptic connections and gap junction coupling provides a framework for diverse recruitment scenarios that expand on the classical roles of inhibitory influence on principal cells. While action potential-driven, chemical synaptic signalling is unidirectional in sign and necessarily involves a threshold, subthreshold electrical signalling is bidirectional in sign and does not involve a threshold. How these circuits interact to shape the functional output of a circuit is not well understood. In the cerebellar cortex, the sole output is provided by Purkinje cells (PCs), which are regulated by synaptic inhibition provided by molecular layer interneurons (MLIs). MLIs are interconnected by both chemical and electrical synapses, and both PCs and MLIs are spontaneously active. To explore the interactions between INs and PCs, we made paired and triple recordings from MLIs and PCs in cerebellar slices at physiological temperatures. In addition to the expected spike-triggered inhibitory connections between monosynaptically connected pairs of INs and PCs, we observed an unexpected effect of INs on PC firing. In some pairs, a steady state hyperpolarization of the MLI caused a subthreshold depolarization of the PC (0.29±0.26 mV n=36). Remarkably, this effect could be observed in both monosynaptically connected and unconnected pairs (71%, n=51). The effect was reversibly blocked by the $GABA_A$ antagonist gabazine. Recordings from cell triplets (MLI-MLI-PC) revealed that this effect was mediated by electrical coupling within the MLI network, such that

the manipulated MLI suppresses firing in coupled INs which, if directly connected to the PC, reduces inhibitory drive, thus disinhibiting the PC. This disinhibition is powerful enough to change spike output in Purkinje cells both during spontaneous and parallel fiber-evoked firing, increasing firing frequency, reducing ISI variability and enhancing the number of PF-evoked spikes. Importantly, the effect was both graded and bidirectional depending on the polarity of the membrane potential change in the IN, and could thus both enhance or suppress PC firing. This mechanism therefore allows both digital and analog, graded signalling modes, allowing the cerebellar network to implement a wide range of mathematical operations. We are currently exploring how this mechanism could influence sensory processing in the cerebellar cortex in vivo.

**Title:** Morphological constraints on cerebellar granule cell layer recombination

**Authors: *J. GILMER**[1], A. L. PERSON[2]
[1]Univ. of Colorado, Aurora, CO; [2]Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

**Abstract:** Granule cells are theorized to encode combinations of mossy fiber inputs, but their capacity to recombine mossy fiber inputs is naturally subject to spatial limitations created by the morphological specializations specific to the granule cell layer. Using computer modeling and anatomical measurements, we explored the consequences of the limitations of granule layer architecture on mixing of mossy fiber afferents by granule cells. We show that the number of unique combinations of mossy fiber inputs is rapidly saturated as mossy fiber inputs diversify in space, and that patchy mossy fiber ramification patterns produce unexpectedly robust representations of specific mossy fiber combinations. Several features of the granule layer organization positively enhance combinatorial diversity including sparse rosettes and mossy fiber filopodia. These predictions of the model were then validated in anatomical measurements from mouse cerebellum. Our results complement information theoretic studies of granule layer structure and provide insight into the contributions of granule layer anatomical features that may favor dense information representation useful for temporal expansion recoding.

**Title:** Diverse modes of cerebellar Golgi cell recruitment

**Authors: *S. TABUCHI**, A. L. PERSON
Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

**Abstract:** Temporal diversity of granule cell (GrC) activity is hypothesized to serve cerebellar associative learning, but the mechanisms of temporal diversification are obscure. Golgi cells (GoCs), the inhibitory neurons in the GrC layer, mediate both feedforward- and feedback-inhibition, and therefore are proposed to participate in the circuit mechanisms producing temporal diversity. We examined how GoCs mediate these different forms of inhibition and the consequences of these modes of recruitment on GrC activity. We focused on the recruitment of GoCs by a single mossy fiber type (nucleocortical MFs) using electrophysiology and anatomy. In some GoCs, optogenetic stimulation of nucleocortical MFs reliably elicited EPSCs which followed the stimuli and drove robust increases in firing rate. By contrast, other GoCs responded with low-probability EPSCs during stimuli despite dense labeling of MFs in the vicinity of the cell. To observe the detailed morphology of GoCs, we labeled GCL neurons sparsely by injecting full titer AAV.CAG.FLEX.eGFP and low titer AAV8.hSyn1.mCherry.Cre to the GCL in wild type mice. We imaged a single GoC and produced a complete 3D reconstruction, revealing sparse basal dendrites and a massive basal axonal arbor, which possessed over 4200 boutons and over 10000 $\mu m^3$ volume. This arrangement of input and output structures of the same GoC indicate that a spatially restricted population of MFs with access to basal dendrites and soma can drive feedforward inhibition compared to larger populations of MFs that must recruit large numbers of GrCs to drive feedback inhibition. In keeping with this idea that GoC-mediated inhibition is widespread relative to its excitation, optogenetic activation of the nucleocortical pathway elicited IPSCs in GrCs without necessarily eliciting EPSCs. We propose that these spatiotemporal recruitment patterns can produce diversification of activity in GrCs.

**Abstract:** In patients with Parkinson's disease (PD), as a possible compensatory mechanism for the cortico-basal circuitry deficit, the cerebellar function is altered by basal ganglia. For this, several studies support the idea that both structures function as an integrated system. The present study was designed to analyze the bioelectric activity of cerebellum´s granular neurons of sim B y crus II lobules and the dentate nucleus after ventrolateral striatum (VLS) electrolytic lesion. This lesion provoked a mandibular tremor similar to the patients with PD. Male Wistar rats (250 and 350 g) were assigned to 3 groups: 1) the intact group, were the cerebellar multiunitary activity (MUA) was recorded; 2) the sham group, in which only one electrode was descended in VLS, and 3) the lesion group, in which in addition to the cerebellar registration implant, an electrolyte lesion (3.5 mV/30 sec) were performed on the VLS. In all three groups three subgroups were formed to record single structures (lobes Sim b, Crus II and dentate nucleus) in which the MUA was recorded (steel electrode of 250 µ diameter). In all groups, the basal activity and the maximum/minimum amplitude reached during mandibular tremor provoked by the lesion were analyzed. Following MUA recordings, it was performed the histological verification of the implant. The results show differences in baseline MUA among groups and structures, evidencing a decreased basal activity in the sham and lesion groups compared to the intact group. On the other hand, we unexpectedly observed the presence of mandibular tremor in the sham group, as observed in the lesion group. Mandibular tremor was correlated with an increase in MUA,

especially in Crus II in both sham and lesion groups. These findings suggest a functional relationship of the cerebellum with the VLS.

**Title:** Direct current stimulation modifies activity of Purkinje cells: Using *In vitro* and in computo approaches

**Authors: *C. MOORE**, A. WANG, T. PHAN, H. LU
Philadelphia Col. of Osteo. Med., Duluth, GA

**Abstract:** The cerebellum plays essential roles in movement coordination and motor control. Modulation of cerebellar activity using transcranial direct current stimulation (tDCS) has become a potential method of treatment for cerebellar dysfunctions. tDCS has been shown to have an effect on Purkinje cell activity through *in vivo* studies, but the underlying mechanisms are not well understood. In this project, *in vitro* method was used to quantitatively measure the effects of DCS on basic properties of Purkinje cells using patch clamp technique. The frequency changes of Purkinje cell action potentials under anodal and cathodal stimulation were compared using a paired Student's *t*-test ($p=0.27$, $n=5$). No significant changes were observed in relationship with orientation of the Purkinje cell with the intensity of DCS set at 200 μA. We also analyzed the effect of graded intensity on the firing rate of Purkinje cells starting at 200 μA to maximum 800 μA. Additional efforts were made to study the relationship between the orientation of the dendrites of a cell and the electrical field using a multi-compartment model. A model with a single dendrite displays specific polarization along the soma-dendrite axis within an electric field (+0.5 to -0.5 mV) generated by DCS. To simulate the effect of DCS on a cell with branching dendrites, additional dendritic compartments were added to the model. With the same setting of electric field, the model with branches demonstrated less voltage change and a smaller increase in firing rate when anodal stimulation was delivered.

**Title:** Sensory and motor representations in Purkinje cell firing during spontaneous and sensory-evoked whisking

**Authors: S. BROWN**, *I. M. RAMAN
Neurobio., Northwestern Univ., Evanston, IL

**Abstract:** To explore sensorimotor processing associated with whisking in the cerebellum, we made extracellular recordings from 32 Purkinje cells in crus I of awake, head-fixed mice habituated to sitting in a tube. Simple and complex spikes were measured during non-contact whisking. During spontaneous whisking, 17 cells showed increases in simple spike rate triggered to the initiation of whisking. Cross-correlations indicated that the rate increase coincided with or preceded the onset of movement. Also, 13 cells showed increases in complex spike probability at the initiation of whisking, usually with a latency of 0-100 ms. Purkinje cell firing rates were correlated to slow varying parameters of whisking. To investigate which aspects of Purkinje cell firing relate to sensory input, sensory feedback from whisker movement (reafference), and/or motor commands, we evoked whisking with sensory stimulation and recorded Purkinje activity. Puffs (10-ms) applied to either the ipsilateral or contralateral whisker pad elicited bilateral whisking that lasted >250 ms, and also elicited increases in Purkinje cell simple spike rate that were correlated to whisker movement. The initial, short-latency component of the Purkinje cell response to the ipsilateral puff was altered when the puff was applied contralaterally, consistent with a dependence on the primarily ipsilateral trigeminal (sensory) projections to the cerebellum. Since the duration of the changes in Purkinje cell firing rates often correlated with the duration of evoked whisking, we tested whether sensory feedback from whisker movement was responsible for the prolonged Purkinje cell responses. Lidocaine was infused into the cheek to silence the ipsilateral facial nerve, which abolished ipsilateral whisking while leaving contralateral movement intact. Under these conditions, Purkinje cell firing was indistinguishable from control, suggesting that reafference does not contribute substantially to the response of these Purkinje cells during whisking. Therefore, to test whether the prolonged Purkinje cell activity following puffs contributes to evoked whisker movement, we inhibited Purkinje cell targets in the cerebellar nuclei. Optogenetically stimulating channelrhodopsin-expressing Purkinje cells in the vicinity of the recording sites inhibited even the earliest components of puff-evoked whisker

movements by ~30%. These results suggest that the targets of these Purkinje cells usually modulate reflexive whisking and that Purkinje cell firing sculpts normal puff-evoked whisker movement.

**Abstract:** The study of motor learning seeks to answer a fundamental question: how do we learn from error? When the outcome of our movement is different than expected, the brain learns from this sensory prediction error by adapting the next movement to partially compensate; a computation that crucially relies on the cerebellum. The hypothesis of cerebellar learning suggests that adaptation is driven by sensory prediction errors communicated via climbing fibers to Purkinje cells (P-cells), resulting in complex spikes (CSs). Here, we ask whether CSs encode both the magnitude and direction of sensory prediction errors experienced in a saccade adaptation task.

We trained monkeys to produce saccades to visual targets while recording P-cell activity from the oculomotor vermis (OMV). In every trial, the monkey made a saccade to a target. However in some trials, we jumped the target during the saccade. In other trials, the target was not displaced but the natural variability of the saccade produced an endpoint error. In each trial, we measured eye position at saccade termination and computed an error vector.

Following completion of the saccade, P-cells produced a complex spike with a probability that depended on the direction of the error vector. That is, following saccade termination, CSs exhibited cosine tuning with respect to the foveal error direction. When the error was in the

preferred direction, the probability of CS was three-fold higher than when it was in the anti-preferred direction. Therefore, the direction of sensory prediction error was encoded in the probability of CS.
The brain, however, learns from both error direction and magnitude. We quantified the trial-to-trial change in the saccade amplitude following an error. The magnitude of error significantly modulated the amount of learning: a large behavioral change occurred following a large error.
How do CSs encode error magnitude?
To answer this question, we considered trials in which a CS occurred during the post-saccadic period. We organized these trials based on the magnitude of the error in each P-cell's preferred direction. We found that when the error was large, the CS tended to occur soon after saccade termination. That is, while the direction of a sensory error was encoded in the probability of CS, the magnitude of the error was encoded in the timing of the CS. We found that trial-to-trial change in eye speed was greatest following an early CS, suggesting that CS timing directly affected the amount of learning from error.
Our results demonstrate that whereas the direction of the error vector is encoded in the probability of the complex spike, the magnitude is encoded in the timing of the spike.

**Title:** Unique circuit organization of novel cerebellar molecular layer interneurons receiving Purkinje cell feedback inhibition

**Authors: *J. KIM**, G. J. AUGUSTINE
Lee Kong Chian Sch. of Med. - NTU, Singapore, Singapore

**Abstract:** A subset of molecular layer interneurons (MLIs) receive inhibitory inputs from Purkinje cells (PCs). These MLIs have distinctive morphological and intrinsic electrical properties, indicating that they are a third type of MLI called PC-MLI. We have used optogenetics and paired whole-cell recordings in cerebellar slices to characterize the synaptic connectivity of PC-MLIs. While basket cells (BC), another type of MLI, form electrical synapses with other MLIs, PC-MLIs do not. Evidence for this is: (1) neurobiotin does not spread between PC-MLIs and BCs, while it does spread between BCs; and (2) although the input resistance of

PC-MLIs is higher than that of BCs, this difference is abolished by treatment with blockers of electrical synapses. In addition to inhibitory input from PCs, PC-MLIs rarely (~4%) receive inhibitory input from other MLIs. Thus, the main inhibitory drive of PC-MLIs comes from PCs. PC-MLIs also receive excitatory input from both parallel fibers and climbing fibers, suggesting that they have the same sources of excitatory drive as other MLIs. The output of PC-MLIs includes inhibition of neighboring basket cells (~33%) and PCs (~10%). No reciprocal connections were detected between PC-MLIs and PCs. Although input from PCs was readily detected in sagittal slices, synaptic connections between PC-MLIs and PCs were detected only in oblique slices. Thus, unlike other MLI circuits, the circuit between PC-MLIs and PCs apparently is not organized in the sagittal plane. This may provide a mechanism for synchronizing PCs in different layers via disinhibition. In summary, PC-MLIs are a third type of MLI with unique circuit organization. These neurons, and their circuits, are likely to play unique and important roles in cerebellar information processing.

**Title:** Purkinje cell inhibition charges the neural integrator

**Authors: *T. KODAMA**, S. DU LAC
Otolaryngology HNS, Johns Hopkins Univ., Baltimore, MD

**Abstract:** Cerebellar Purkinje cells (PCs) increase and decrease firing rate in specific contexts of behaviors. It is however not fully understood how downstream neurons respond to PC firing rate modulation to adaptively control behaviors. We investigated eye movements evoked by excitation and inhibition of PCs that directly innervate pre-oculomotor neurons in the brainstem, and discovered that PC inhibition preferentially induces persistent changes in eye position. In mouse lines expressing photoactivatable opsins (ChR2 or ArchT) selectively in PCs, both photo-excitation and inhibition of PCs reliably accelerated eye movements in opposing directions (Kodama and du Lac, 2016). Following PC excitation, the eye returns to the initial position in ~1 sec. However, after PC inhibition, changes in eye position are maintained for seconds, although PC firing rate returns to baseline within <0.5 sec. The asymmetric influence of PC activity is evident in extracellular recordings in downstream neurons. These results demonstrate that PC inhibition preferentially charges the neural integrator for gaze holding.

**Abstract:** The cerebellar cortex (CC) is considered to be essential for the learning of precisely timed tasks on the order of several tens of milliseconds to few seconds. Cerebellar adaptive filter models generally consider the CC as a three layered network where mossy fibers (MFs) and Purkinje cells (PCs) form the input and output layer, respectively, and granule cells (GCs) constitute a hidden layer. In this framework, for PCs to learn time-variant signals it is necessary that the GC population responds to MF inputs with sufficiently diverse time-varying responses. It still remains an open question by which mechanisms these time varying GC signals can be produced. Recent findings have established that synaptic transmission between MFs and GCs exhibits various forms of synaptic short-term plasticity (STP). Here we show that these synaptic dynamics can provide a sufficiently rich temporal modulation of GC activity to enable temporal learning by PCs on behaviorally relevant timescales. First, we re-analyzed data from whole-cell recordings of MF-GC synaptic currents from Chabrol *et al.* (2015) and extracted parameters associated with pre-synaptic depression, facilitation and post-synaptic receptor desensitization. This revealed the existence of a rich diversity of synaptic time-constants ranging from a few milliseconds to seconds. In a second step, we used the experimentally obtained synaptic parameter distributions to constrain a firing-rate-based model of the CC. In this model, GCs exhibit transient firing rate modulations in response to rapid changes in MF activity, as observed experimentally (Ishikawa *et al.* 2015). Due to the diversity of the synaptic parameters, GC transients exhibit a broad diversity across cells. Interestingly, during these transients the GC population is densely activated as suggested by recent in vivo recordings (Giovannucci *et al.* 2017). Furthermore, GC transients elicited strong modulations of model PC firing rates, similar

to experimental findings (Bosman *et al.* 2010). We also showed that GC firing transients form a temporal basis that is sufficient to enable PCs to encode stimulus duration and interval length, a critical requirement for rapid time scale auditory perception. We then took advantage of classical supervised learning to demonstrate that GC firing response diversity could also be used to teach PCs to predict delayed stimuli, as in the classical eye-blink conditioning paradigm. Our theoretical study demonstrates that the distribution of STP at the input layer of the CC is sufficient to elicit temporal computations in a purely feed-forward manner.

**Abstract:** Purkinje cells (PCs) in the mammalian cerebellum are remarkably homogeneous in shape and orientation, yet they exhibit regional differences in spiking activity which correlate with the expression of zebrin. The firing rates of both the simple spikes and complex spikes in zebrin-negative ($Z^-$) PCs are higher than those in the zebrin-positive ($Z^+$) PCs. However, the underlying cause and functional relevance of this physiological difference between zebrin-discriminated PCs remains unknown. We have previously suggested a role for the transient receptor potential cation channel type C3 (TRPC3) protein in the difference in simple spike activity. Here, we recorded the spiking activity of Z- and Z+ PCs in gain-of-function and PC-specific knockout TRPC3 mutants both *in vivo* and *in vitro*. The results indicate that bidirectional manipulation of TRPC3 results in corresponding regulation of PC simple spike activity, particularly in Z- PCs. Next, we performed vestibulo-ocular reflex adaptation and eyeblink conditioning as these tasks are predominantly controlled by Z+ PCs and Z- PCs, respectively.

Our results suggest that TRPC3 contributes to the physiological discrepancy between Z- and Z+ PCs, as it selectively affects the spiking activity of Z- PCs as well as Z- PC-dependent behaviors.

**Abstract:** The human brain contains ~60 billion cerebellar granule cells[1], which outnumber all other brain neurons combined. Through extensive closed-loop connectivity with most regions of the cerebral cortex[2,3], the cerebellum is poised to play a role in a wide variety of brain computations. Yet relatively little is known about the types of information that reach the cerebellum via granule cell inputs. To better understand the full range of cerebellar computations, we are studying granule cell signaling during motivated behaviors using two-photon $Ca^{2+}$ imaging. We have found that granule cells convey information about the expectation of reward during multiple types of operant and Pavlovian behaviors. Granule cells selectively encoded reward, reward omission, and reward anticipation in ways that were unexplained from sensorimotor signaling. Such reward representations were found throughout multiple cerebellar lobules. Individual granule cell reward representations emerged over several days of learning[4]. In other complex movement tasks, we have also found high-level representations of planning information in granule cells. Both reward and planning signals are reminiscent of known signaling in various prefrontal and premotor neocortical areas. Thus we are also studying neural representations of our tasks in cortical output ensembles to determine how cortex gives rise to cerebellar input signals, with the goal of understanding coordinated computations in these circuits.

**Title:** Presynaptic $GABA_A$ receptors can enhance or inhibit vesicle release depending on $GABA_B$ receptor activity

**Authors: *R. D. HOWELL**[1], Y. YANG[1], S. MELLEY SADANANDAN[1], J. R. PUGH[2]
[1]UT Hlth. San Antonio, San Antonio, TX; [2]Physiol., UTHSCSA, San Antonio, TX

**Abstract:** A wide variety of synapses in the CNS express $GABA_A$Rs at the presynaptic membrane. Many recent studies agree that these receptors depolarize the presynaptic terminal and enhance synaptic vesicle release. However, these studies were conducted with either $GABA_B$Rs pharmacologically blocked or using a $GABA_A$R specific agonist to avoid $GABA_B$R mediated inhibition of vesicle release. It has recently been shown that $GABA_B$R activation enhances currents through extrasynaptic, delta subunit-containing $GABA_A$Rs in the soma or dendrites of several neurons, including cerebellar granule cells (Tao et al., 2013, Connelly et al., 2013). This raises the possibility that presynaptic $GABA_A$Rs, which may also contain delta subunits, are also enhanced by $GABA_B$Rs. To test this possibility, we made whole cell patch clamp recordings from molecular layer interneurons in acute cerebellar slices and evoked parallel fiber EPSCs. On alternating sweeps GABA was applied 50 ms before the stimulus by photolytic uncaging of RuBi-GABA (60 μM). EPSC amplitudes and paired-pulse ratios were compared between control and uncaging sweeps. We found that GABA uncaging increased EPSC amplitudes, and this effect was blocked by the $GABA_A$R antagonist, picrotoxin. However, this increase was also blocked by a $GABA_B$R antagonist CGP55845, suggesting that without $GABA_B$R activity, the $GABA_A$R currents were not sufficient to enhance vesicle release. In fact, when we used high concentrations of RuBi-GABA (1-5 mM), we found that GABA increased EPSC amplitudes even in the presence of CGP55845. These data are consistent with $GABA_B$R

enhancement of presynaptic $GABA_AR$ currents.We then measured presynaptic $GABA_AR$ function over a range of GABA concentrations by systematically changing the uncaging laser intensity. Surprisingly, we found that in control conditions ($GABA_BR$ not blocked) presynaptic $GABA_ARs$ inhibit, rather than enhance, vesicle release at all but the lowest uncaging light intensities. There was only a very narrow range of light intensities over which GABA enhanced vesicle release. In picrotoxin, EPSC amplitudes were not altered at any laser intensity, suggesting both the enhancement and inhibition are mediated by $GABA_ARs$. In the presence of CGP55845, we observed enhancement of EPSCs only at high uncaging intensities and never saw inhibition, consistent with previous studies of presynaptic $GABA_ARs$. These data suggest that presynaptic $GABA_ARs$ are normally enhanced by $GABA_BRs$. Furthermore, when $GABA_BR$ activity is intact, the primary effect of presynaptic $GABA_AR$ activity may be to inhibit, rather than enhance, vesicle release.

**Abstract:** The functional interactions between neurons in the cerebellar cortex and the deep cerebellar nuclei (DCN) are crucial for understanding cerebellar computations, and yet are almost completely unexplored in behaving animals. This requires simultaneous recordings from neurons in the two brain areas, which is technically extremely challenging. We have addressed this problem by harnessing a new recording approach - Neuropixels silicon probes, which allow for sampling from 384 densely-spaced recording channels along a linear shank that is capable of spanning both cerebellar cortex and DCN. We have performed Neuropixels recordings in awake head-fixed mice performing a behavioural task. In these recordings, we could harvest up to 100

well-isolated units simultaneously recorded across a recording depth of almost 4 mm. We were able to classify a majority of these units into putative cell types using prior knowledge about the distinctive electrophysiological signatures of cerebellar neurons, as well as by post-hoc histology. In the cerebellar cortex, recordings typically spanned several folia, with the major cell types - Purkinje cells, molecular layer interneurons and granule cells - being readily identifiable. Typical recordings yielded 25 ± 5 Purkinje cells, 15 ± 5 molecular layer interneurons and 10 ± 2 granule cells (n = 3 mice). We also identified units consistent with published firing patterns of mossy fibre bouton terminals and Golgi cells. Recordings from interpositus nucleus revealed units (typically about 15) with diverse firing properties and spike shapes consistent with recordings from principal cells and inhibitory neurons. Thus, we have been able to record simultaneously from all the major cell types in the cerebellar cortex while also sampling from the targets of Purkinje cells in the interpositus DCN. Our preliminary results have identified both inhibitory and excitatory relationships between neurons in close proximity (both Purkinje cell and DCN neuron pairs) as well as between neurons separated by hundreds of micrometres. We are now using this system to probe the dynamics of interactions between these cell types during a sensorimotor integration task in virtual reality, allowing us to determine how sensory and motor variables are encoded in the patterns of activity. This approach highlights the power of this new generation of silicon probes for examining millisecond timescale cellular-resolution interactions between multiple brain regions, and will provide unprecedented insights into how the cerebellar cortico-nuclear interactions govern sensorimotor behaviour.

**Abstract:** During vestibulo-ocular motor learning, Purkinje cells (PCs) acquire phase shifts in their pattern of spiking thus providing a neural correlate for the expression of adaptive movements. Temporal re-patterning of PC spiking has long been attributed to synaptic plasticity

at their parallel fiber inputs. However, inhibitory molecular layer interneurons (MLIs) also form connections onto PCs. Therefore MLIs are poised to influence PC excitability and spike output. To assess for their role in the expression of motor learning, we measured MLI activity in the flocculus during recalibration of the vestibulo-ocular reflex (VOR) using genetically encoded $Ca^{2+}$ indicators. We found that over the course of gain increase learning, MLIs progressively developed a shift in the phase of their activation induced by passive head rotation. Although optogenetic stimulation of MLIs could induce eye movements in quiescent animals, suppressing their activity had no effect on baseline VOR performance indicating that MLIs were dispensable for accurate movement in naïve mice. . In contrast, after gain increase learning, suppressing MLI activity led to the immediate reversal of adapted eye movements. Interestingly, MLI activity remained unchanged following gain decrease learning and its expression was not susceptible to reversal upon MLI suppression pointing to mechanistic distinctions between different types of learning. Together, our results indicate that a change in MLI activity is required for the accurate expression of certain forms of motor learning. This points to their synaptic connections as potential storage sites for motor memory.

**Title:** Recordings across sessions is the foundation for using eyelid conditioning as a model system to study aging

**Authors: *H. E. HALVERSON**[1], M. D. MAUK[2]
[1]Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX; [2]Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

**Abstract:** Characterizing change in neural responses across time allows for identification of the mechanisms supporting learning in the short term (days) and how age might interact with those mechanisms in the long term (years). Extracellular recording of single unit activity with tetrodes in rabbits provides a method to track the same neuron(s) over the course of a training session (1 hour), possibly across many sessions (multiple days) and even the same population over the entire life span of the animal (years). Tracking the activity of neurons across different training

sessions allows for investigation of neural responses within a given brain area in response to changes in task demands. Comparing recordings from the same neuron types at different points across the life span allows for investigation of how aging interacts with neural mechanisms of learning and memory. Single unit tetrode recordings from the cerebellum of rabbits were done during eyelid conditioning at different inter-stimulus intervals. Recordings focused on the subset of neurons controlling the kinematics of conditioned eyelid responses that are solely driven by the cerebellum. Recordings were done over multiple sessions from eyelid Purkinje cells and eyelid interpositus neurons during eyelid conditioning. Recording protocol focused on tracking individual single units until the recording was lost. Identification of the proper neurons in the cerebellum combined with the ability to record the same neurons across sessions provides a method to investigate how learning mechanisms might change over time in response to changes in task demands. Stable recordings across sessions also allowed for longitudinal investigation of single unit activity of the same population of eyelid cells in the cerebellum over the life span. Tetrode recordings in the cerebellum during eyelid conditioning over the life span of rabbits provides a good model system to investigate how aging interacts with the mechanisms supporting learning and memory.

**Title:** Structured synaptic input to spiny branchlets of cerebellar Purkinje cells

**Authors: *A. ROTH**, M. BOZNAKOVA, S. RIEUBLAND, M. JAKUBOWSKA, M. HAUSSER
Univ. Col. London, London, United Kingdom

**Abstract:** The dendrites of cerebellar Purkinje cells receive up to 200,000 parallel fibre inputs, one climbing fibre, and inhibitory inputs from molecular layer interneurons. Different synaptic inputs to Purkinje cells are uniquely identifiable in EM data, providing the singular opportunity to examine their spatial distribution across an entire neuron with ultrastructural resolution. Here we use 3D reconstructions of rat Purkinje cell spiny branchlets (including all spines and input

synapses) from data obtained with focused ion beam scanning EM to map the spatial distribution of spines and synapses on Purkinje cell dendrites. Synapses were classified as excitatory or inhibitory based on the orientation and branching pattern of the presynaptic axon. On average, spiny branchlets received 7.1 ± 2.6 excitatory and 0.45 ± 0.49 inhibitory synapses per micron of dendritic length (n = 68 branches). The average ratio of the number of excitatory and inhibitory synapses was 14.3. Interestingly, 40% of inhibitory inputs arrive on spines. Of all spines, 98.3% receive excitatory input (10.4% more than one excitatory input), 3.51% receive inhibitory input, and 1.86% receive both types of inputs. We use this data to ask whether the placement of excitatory and inhibitory synapses on Purkinje cell dendrites is random, or whether fluctuations in local synapse density - and in particular the ratio of excitatory and inhibitory synapses - deviate from those expected from random placement. To test these hypotheses, we compare the actual data and a hierarchy of different models of random synapse placement using three different measures: nearest neighbour distance distributions, the output of the clustering algorithms UPGMA and DBSCAN, and network K-functions. We find that excitatory and inhibitory synapses are non-randomly distributed, but most of the deviations from randomness can be explained by the fact that some spines receive multiple synapses. However, even in models accounting for the grouping of synaptic inputs on spines, the distribution of nearest neighbour distances between inhibitory synapses in the data shows an excess at distances between 0.7 and 1.0 µm when compared with most models. Spines themselves are spatially clustered and not randomly distributed. We conclude that the distribution of synaptic inputs on Purkinje cell spiny branchlets is non-random due to non-random placement of spine necks along the dendrite, grouping of synapses on spines, and due to an as yet unexplained association of inhibitory synapses at short distances. This structured input may have direct consequences for the rules of synaptic integration and synaptic plasticity in Purkinje cell dendrites.

**Title:** Loss of serine rasemase lead a transient delay in CGC migration

**Authors: *H. ZHANG**[1], S. WU[2]
[1]Sch. of Optometry and Ophthalmology and the Eye Hosp., Wenzhou Med. Univ., Zhejiang, China; [2]Wenzhou Med. Univ., Zhejiang, China

**Abstract:** Inward migration of cerebellar granule cells (CGCs) after birth is critical for lamination of cerebellar cortex. CGCs migrate across Purkinje cell layer, and reach the final destination, the deep strata of inner granule cell layer. N-methyl-D-aspartate subtype of glutamate receptor (NMDAR) tethering CGCs into Bergmann glial fiber mediates this inward movement during the glial-dependent migratory phase. D-Serine, a co-agonist of NMDAR, has been reported to account for CGC migration in cerebellar section. We hypothesized that D-Serine and its synthesizing enzyme serine racemase (SR) may mediate the inward movent of CGCs *in vivo*. Thus, we analyzed cerebellar cortical architecture in wild-type (WT) and *Srr* (the gene for coding SR) mutant mice ($Srr_{null}$) during postnatal stage-- CGC migration is seminal at this time period. The thickness of external germinal cell layer (EGL) in $Srr_{null}$ at postnatal, P7 were37.7±1.7 μm, which were significantly different with WT at P7 29.9±1.8 μm (p=0.00), but the difference disappeared on P12 ($Srr_{null}$ at 10.2±1.7μm *vs*.WT at 10.6±0.6 μm, p=0.484). To elucidate the underlying mechanism, we examined the content of NMDAR ligands and the subunits of NMDAR in cerebellum at this postnatal stage. We found that the level of glycine increased on P7, 10, 12, and the expression of GluN2B on P10 was upregulated in $Srr_{null}$ compared to WT. We are exploring whether additon of D-Serine to cerebella could rescue the temporay postponement before P7. In conclusion, our study revealed that loss of SR lead a transient delay in CGC migration towards the IGL and was compensated by upregulation of Glycine and GluN2B on P10 *in vivo*.

**Title:** Conditional deletion of Cadherin13 perturbs inhibitory synaptic function in the cerebellum and disrupts cognitive behaviors

**Authors: *L. GUO**, M. TANTRA, A. CHEN
Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore

**Abstract:** Members of the Cadherin superfamily have been linked to neurological disorders. Because of the diversity in structures, expression pattern and function, the functional significance of Cadherins in mediating neuronal processes and behavior is not clear. Cadherin13 (Cdh13) has recently been implicated in autism spectrum disorder (ASD) and extreme violence in genome-wide association studies (GWAS). We found that *Cdh13* is expressed specifically in a subtype of inhibitory neurons in the cerebellum. To examine the function of *Cdh13* in the cerebellum and other glycinergic neurons in the CNS, we generated *Cdh13* conditional knockout mice through *GlyT2::Cre* mediated deletion, analyzed the synaptic strength in the Golgi cells and examined a range of motor and cognitive functions in mice with *Cdh13* ablation. We found that inhibitory synaptic strength is reduced in Golgi cells lacking *Cdh13*. Interestingly, deletion of *Cdh13* has no impact on general motor function. Instead, we observed impairments in cognitive function using several behavioral paradigms. Together, our findings indicate that *Cdh13* is critical for inhibitory function and that disruption of *Cdh13* in GABAergic/glycinergic neurons in non-executive centers of the brain, such as the cerebellum, may contribute to cognitive behavioral deficits linked to neurological disorders.

**Title:** Cerebellar modulation of substantia nigra

**Authors: *S. G. KEE**, R. BHUVANASUNDARAM, K. KHODAKHAH
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

**Abstract:** The basal ganglia and cerebellum are two components of a complex system of interconnected brain regions that coordinate body movement. The long-held view that these structures interact primarily at the level of the cerebral cortex through closed-loop circuits has been challenged by a growing body of evidence suggesting the presence of a number of cortex-independent pathways that mediate direct communication between these two structures. Understanding how the cerebellum communicates with the nuclei of the basal ganglia may

provide insight into motor disorders caused by dysfunction of these brain regions, including Parkinson's disease and dystonia. The substantia nigra pars compacta (SNc) is a nucleus in the basal ganglia that gives rise to the nigrostriatal tract, which provides dopaminergic input to the striatum and degenerates in Parkinson's disease, leading to motor deficits. Multiple studies using lesions of the cerebellar nuclei and viral tracing have suggested that the cerebellar nuclei send monosynaptic projections to dopaminergic neurons of the SNc. The strength of this connection and its relevance to motor activity is unknown. It has also been shown that trains of electrical stimulation to the cerebellar nuclei can alter dopamine levels in both the substantia nigra and the striatum. Whether this is mediated directly, through the monosynaptic cerebellar projection to the SNc, or indirectly, via other brain regions, remains to be established. Here, we test the hypothesis that the cerebellum can drive the activity of neurons in the SNc through a direct, monosynaptic connection. To test this hypothesis, Channelrhodopsin (ChR2) was expressed in cerebellar nuclei neurons. Immunohistochemistry confirmed that cerebellar fibers expressing ChR2 were present in SNc. Cerebellar fibers in substantia nigra were activated by light, and the responses of neurons in substantia nigra were recorded. We found *in vivo* that short light pulses increased the firing of neurons in substantia nigra with a short latency. We performed complementary whole-cell voltage clamp recordings from neurons in SNc in slices from mice injected with ChR2 into the cerebellum and found that stimulation of ChR2-positive fibers evoked inward currents in recorded neurons. Both tyrosine hydroxlase (TH)-positive and TH-negative cells respond to stimulation of cerebellar fibers. Taken together, these data provide support for a monosynaptic, cortex-independent pathway capable of relaying information directly from the cerebellum to the substantia nigra. Future studies aim to characterize this pathway in more detail and scrutinize its role in motor control.

**Title:** Cortico-subthalamic projection stimulation increases maximum running speed in 6-OHDA lesioned mice

**Authors: L. HOGEWOOD**, *T. H. SANDERS
Pharmacol., Vanderbilt Univ., Nashville, TN

**Abstract:** Open field locomotion has been shown to increase in 6-OHDA lesioned mice during optogenetic stimulation of motor-cortico-subthalamic projections (Sanders et al., 2016). Here I report that the maximum running speed of these mice when tested on a variable speed treadmill is increased during stimulation as well. Surprisingly, the maximum running speed of the unlesioned control was decreased when tested using the same stimulation protocol and treadmill. Electrophysiological measures showed increased power during stimulation for both lesioned and unlesioned animals. However, cortico-subthalamic (M1-STN) theta coherence was decreased in the lesioned mice while M1-STN coherence was increased in the control. The results suggest that while the local neural population response may be similar between lesioned and unlesioned mice, circuit effects lead to different behavioral and synchronization responses.

**Title:** Enhancement of K-ATP currents by AMP kinase activation is modified by phosphoinositol metabolism in substantia nigra dopamine neurons

**Authors: *S. W. JOHNSON**[1], A. C. MUNHALL[1], K.-Z. SHEN[2]
[1]Dept Neurol, Portland VA Med. Ctr., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

**Abstract:** Our lab reported recently that ligand-gated ATP-sensitive K+ (K-ATP) current is potentiated by AMP-activated protein kinase (AMPK) that is activated during whole-cell patch-clamp recordings of substantia nigra compacta (SNC) dopamine neurons (Neurosci 330:219-228, 2016). Although it is not yet known how whole-cell recordings activate AMPK, it is well known that K-ATP channel function is enhanced by the presence of phosphatidylinositol 4,5-biphosphate (PIP-2) in cell membranes. Therefore, we used whole-cell patch-clamp recordings to characterize effects of phospholipase C (PLC) activators and inhibitors on AMPK-dependent changes in K-ATP currents in SNC dopamine neurons in slices of rat midbrain. As we reported previously, recording in whole-cell configuration caused a time-dependent 220% increase in diazoxide (200 μM)-evoked outward current, from an initial current of 38 ± 5 pA to 122 ± 24 pA

as measured 60 min after starting recording. This enhancement of diazoxide current was AMPK dependent because diazoxide current remained at baseline when slices were superfused with the AMPK inhibitor Compound C (20 μM). Because PLC activity cleaves PIP-2, we reasoned that an inhibitor of PLC might increase diazoxide current by reducing PIP-2 degradation. Consistent with this hypothesis, we found that the PLC inhibitor U73122 (5 μM) significantly enhanced the diazoxide current to 177 ± 18 pA at 60 min (P less than 0.001) Moreover, this increase in current was blocked by Compound C. Enhancement of diazoxide current was also completely prevented by superfusing either the PLC activator m-3M3FBS (25 μM) or the metabotropic glutamate agonist DHPG (3 μM). Results of these studies suggest that AMPK activation, which occurs during the course of whole-cell recording, enhances K-ATP channel function by a process that requires PIP-2. Experiments are in progress that will characterize effects of phosphoinositol metabolism on firing properties of dopamine neurons. Results should further characterize how the excitability of dopamine neurons are regulated by the combined influences of K-ATP channels, AMPK, and lipid membrane constituents.

**Title:** ST8 alpha-N-acetyl-neuraminide alpha-2,8-sialyltransferase 3 (ST8SIA3) mediates sialylation of striatal proteins and functions as a signal coordinator in the striatum

**Authors: *C.-Y. LIN**, H.-L. LAI, H.-M. CHEN, J.-J. SIEW, C.-P. CHANG, Y. CHERN
Academia Sinica/Institute of Biomed. Sci., Taipei, Taiwan

**Abstract:** ST8 alpha-*N*-acetyl-neuraminide alpha-2,8-sialyltransferase 3 (ST8SIA3) exists in the Golgi apparatus and belongs to the type II membrane protein. It is responsible for transferring one or multiple sialic acids to the terminal galactose of the *N*-linked or *O*-linked glycan chains of glycoproteins. ST8SIA3 is highly expressed in the striatum, the brain area that controls motor coordination *in vivo*. To investigate the pathophysiological function of ST8SIA3, we generated a *St8sia3*-knockout (KO) mouse model using the CRISPR/Cas9-mediated genome engineering technology by disrupting the translation start site to ablate RNA expression. No apparent abnormality was observed in the embryonic viability, gross development and fertility of *St8sia3*-KO mice. Interestingly, *St8sia3*-KO mice revealed reduced performance on the accelerating rotarod test, designed to evaluate maximal motor performance. Magnetic resonance imaging

(MRI)-based *in vivo* morphometric and volumetric assessment revealed that *St8sia3*-KO mice had a smaller striatum, but not other brain areas tested, than their littermate controls. To identify the protein substrates of ST8SIA3, we evaluated the expression of several striatum-enriched proteins in *St8sia3*-KO mice. Western blot analyses suggested that the $A_{2A}$ adenosine receptor ($A_{2A}R$), the type V adenylyl cyclase (AC5) and the $D_2$ dopamine receptor ($D_2R$) might be potential substrates of ST8SIA3, because these proteins harvested from the striatum of *St8sia3*-KO mice traveled faster in SDS-PAGE gels than those in their littermate controls. Treatment with sialidase, which released all sialic residues from sialylated glycans, eliminated the difference in protein sizes of $A_{2A}R$, AC5, and $D_2R$ between WT and *St8sia3*-KO mice, further suggesting that these three proteins might be modified by the ST8SIA3-mediated sialylation. Consistently, locomotor activity analyses suggested that the motor responses to an $A_{2A}R$ agonist (CGS-26180, intraperitoneally injection (i.p.)), an $A_{2A}R$ antagonist (SCH-58261, i.p.) and a $D_2R$ antagonist (L-741626, i.p.) were altered in *St8sia3*-KO mice. Collectively, ST8SIA3 appears to play a critical role in the striatum by mediating sialylation of several important striatal proteins and subsequently modulate striatal functions.

**Title:** Real-time striatal measurements of oxidative stress and dopamine in the dyskinetic rat during chronic l-dopa treatment for parkinson's disease

**Authors: *C. MASON**, L. R. WILSON, C. A. LEE, L. A. SOMBERS
Chem., North Carolina State Univ., Raleigh, NC

**Abstract:** Parkinson’s disease (PD) is a neurodegenerative disease characterized by the slow degeneration of dopaminergic neurons found in a region of the midbrain called the substantia nigra. Dopamine (DA) plays a key role in regulating motor function. Thus, the destruction of these neurons and the consequential decrease in DA concentrations in the striatum leads to the deterioration of motor control. The drug Levodopa (L-DOPA) has been used to treat PD by helping to increase the concentration of DA in the brain. This drug has been proven to alleviate the motor symptoms of PD; however, after a short period of time, dyskinetic symptoms can develop. It is thought that oxidative stress is a principal contributor to the destruction of

dopaminergic neurons, and possibly to the development of dyskinesias, in PD and its treatment. To date, oxidative stress has been difficult to measure due to the high reactivity of oxygen radicals, however the generation of hydrogen peroxide (H2O2) can serve as an indicator of the presence of oxidative stress. This experiment uses fast-scan cyclic voltammetry coupled with carbon-fiber microelectrodes to simultaneously monitor rapid, real-time, fluctuations of DA and H2O2 in the dorsal striatum. These neurochemical dynamics can be time-locked to dyskinetic episodes. Overall, these studies will aid in our understanding of how oxidative stress modulates nigrostriatal DA signaling, as well as the behavioral consequences of this interaction. The results will inform improved therapeutic strategies for the treatment of PD.

**Title:** Untangle glycinergic immunoreactivity in the basal ganglia

**Authors: *R. A. PEREZ**[1], V. GARCIA[2], R. ORTEGA[2], E. CASTAÑEDA[3], M. MIRANDA-ARANGO[4]
[1]Bio-Science, Univ. of Texas At El Paso, El Paso, TX; [3]Psychology, [4]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., [2]Univ. of Texas at El Paso, El Paso, TX

**Abstract:** The basal ganglia circuitry involves the modulation of GABAergic medium-sized spiny neurons within the striatum by dopaminergic (DA) projections from the substantia nigra pars compacta (SNc), via the direct and indirect pathways. Although the involvement of glycinergic circuitry has not been considered to be part of the basal ganglia, the data to be presented suggests the presence of glycinergic immunoreactivity within several basal ganglia structures. Staining of rat coronal and saggital sections with the microtubule associated protein MAP2 showed co-localization with glycine transporter 1 (GlyT1), a transporter believed to be expressed in glia cells. Moreover, GFAP staining clearly demonstrate that the majority of GlyT1 immunoreactivity is absent from astrocytes. Further staining with glycine receptor antibodies

showed immunoreactivity in the globus pallidus (GP) and the striatum, suggesting the presence of pre- and post-synaptic glycinergic fibers. In addition, Injection of retrograde tracers and adeno- associated viral particles into the GP of rodents suggests that the cell bodies of these putative neurons are located within areas of the midbrain. Additional characterization of these neurons and the postsynaptic connections are currently under development. These data together suggest that glycinergic neurons may contribute to the regulation of the indirect pathway of the basal ganglia.

Bonn, Bonn, Germany

**Abstract:** Tardive dyskinesia (TD) is a serious motor side effect that may appear after long-term treatment with neuroleptics and mostly mediated by dopamine $D_2$ receptors ($D_2$Rs). Striatal $D_2$R functioning may be finely regulated by either adenosine $A_{2A}$ receptor ($A_{2A}$R) or angiotensin receptor type 1 ($AT_1$R) through putative receptor heteromers. Here, we examined whether $A_{2A}$R and $AT_1$R may oligomerize in the mice striatum to synergistically modulate dopaminergic transmission. Initially, we observed high overlapping in the distribution of $AT_1$R and $A_{2A}$R in transfected cells that transiently expressing the receptors, through the fluorescence detection of CFP/YFP tagged receptors. Then, we demonstrated a physical $AT_1$R-$A_{2A}$R interaction in cultured cells by using bioluminescence resonance energy transfer (BRET), indicating a heteromers formation in living HEK-293T cells. Interestingly, by protein-protein docking and molecular dynamics simulations by computacional modeling, we described that a stable

heterotetrameric interaction may exist between $AT_1R$ and $A_{2A}R$ bound to antagonists (i.e. losartan and istradefylline, respectively). In addition, angiotensin II ($AT_1R$ - agonist) significantly increased intracellular $Ca^{2+}$ mobilization from co-transfected cells ($AT_1R$-$A_{2A}R$) by Fluo4 determinations, when compared with cells expressing only $A_{2A}R$ or $AT_1R$, suggesting a functional interplay between $AT_1R$ and $A_{2A}R$ might exist, upon expression in these cells. Once demonstrated these functional interaction complexes in living cells, we determined the existence and functionality of these heteromers in CD-1 mice. We initially demonstrated the distribution of both $AT_1R$ and $A_{2A}R$ in mice striatum by immunofluorescence and interestingly, both receptors showed a high degree of co-distribution throughout the striatal neuropil. Subsequently, by proximity binding in the *in situ* assay, a positive signal was observed in the striatum of wild-type mice that strongly support the existence of $AT_1R/A_{2A}R$ heterodimer in the striatum. Finally, we took advantage of a TD animal model, namely the reserpine-induced vacuous chewing movement (VCM), to evaluate a novel multimodal pharmacological TD treatment approach based on targeting the $AT_1R/A_{2A}R$ complex (all procedures aforementioned were approved by local Ethical Committee in Animal Research). Thus, reserpinized mice were co-treated with sub-effective losartan and istradefylline doses, which prompted a synergistic reduction in VCM. Overall, our results demonstrated the existence of striatal $AT_1R/A_{2A}R$ oligomers with potential target for pharmacological intervention in TD.

**Title:** Histamine deficient mice display altered exploratory activity and striatal monoamine neurotransmitter metabolism

**Authors: *S. ABDURAKHMANOVA**, S. SEMENOVA, P. PANULA
Anat., Helsinki Univ., Helsinki, Finland

**Abstract:** Histamine is a biogenic amine synthesized by histidine decarboxylase (HDC) from L-histidine. It is stored and released in both periphery and CNS. In concert with other neurotransmitters such as dopamine, acetylcholine, serotonin and noradrenaline, hypothalamic

histamine regulates homeostatic and cognitive functions in the brain. Decreased locomotor activity and increased striatal dopamine turnover have been shown in histamine deficient HDC knock-out (HDC KO) mice. Furthermore, a functional mutation in *HDC* gene has been found in a family diagnosed with Tourette syndrome. We investigated novelty-induced exploratory activity, monoamine turnover and mRNA levels of monoamine neurotransmitter degrading enzymes in HDC KO mice. Näive HDC WT and KO male mice without prior handling and habituation were tested in an open field. While both genotypes showed similar distance travelled and velocity, detailed analysis of the recorded behavior revealed distinct behavioral patterns in HDC KO mice. Locomotor activity of HDC KO mice was interrupted by seated rearing to a greater extent than in control group. Moreover, mutant mice displayed a higher number of stereotypic behaviors such as jumping, head and paw twitching and wall licking. The level of blood plasma corticosterone was similar in both groups. The measurement of monoamine content in striatal homogenates showed decreased levels of dopamine and serotonin in HDC KO mice. The level of dopamine metabolite 3,4-dihydroxyphenylacetic acid (DOPAC) and DOPAC/dopamine ratio was increased in histamine deficient mice. Also, the ratio of serotonin metabolite 5-hydroxyindoleacetic acid /serotonin was increased in the striatum of HDC KO mice. Quantitative PCR showed a decrease of striatal monoamine oxidase B and catechol-O-methyltransferase mRNA levels in HDC KO mice. Our data suggest that lack of brain histamine leads to impaired novelty-induced exploratory activity and alterations in dopamine and serotonin metabolism accompany this behavioral phenotype. These changes could be due to lack of striatal histamine receptors activation; alternatively, histamine neurotransmission could modulate the activity and transcriptional level of monoamine neurotransmitter degrading enzymes.

**Abstract:** The $A_{2A}$ adenosine receptor ($A_{2A}R$) is a G protein coupled receptor, which is widely expressed in the brain with the highest level in the striatum. Cross-regulation between $A_{2A}R$ and the dopamine D2 receptor ($D_2R$) plays a critical role in the control of basal motor function. Several laboratories including ours had demonstrated that the c-terminus of $A_{2A}R$ acts as a scaffold domain to recruit various functional partners (such as TRAX, α-actinin, and calmodulin), and contributes to the dimer formation of $A_{2A}R$ and $D_2R$. We have previously reported that Gas2-like 2 (Gas2l2) is a novel interacting protein of the c-terminus of $A_{2A}R$, and functions in the fine-tuning of Gsα-mediated cAMP signaling during $A_{2A}R$ activation. Results of reverse transcription polymerase chain reaction (RT-qPCR) demonstrated that Gas2l2 is expressed in most brain areas with moderate levels. Through the direct interaction with Gas2l2, the $A_{2A}R$-mediated adenylyl cyclase (AC) activity is enhanced. To study the physiopathological role of Gas2l2 in the $A_{2A}R$-mediated signaling *in vivo*, we developed a conditional knockout mouse model of Gas2l2. The profile of gene expression measured by RT-qPCR revealed that the deletion of Gas2l2 slightly increased the transcript levels of $D_2R$ and α-actinin in both the striatum and hippocampus. Interestingly, the level of $A_{2A}R$ in the striatum was also enhanced. The effect of lacking Gas2l2 on the signaling and functions of $A_{2A}R$ *in vivo* will be discussed.

**Title:** Stereological estimations and neurochemical characterization of neurons expressing $GABA_A$ receptor gamma 2 subunit in the rat pedunculopontine and laterodorsal tegmental nuclei

**Authors: B. PATERNAIN**, E. LUQUIN, *E. MENGUAL
Depto. Anatomía, Fac Med, Univ. de Navarra, Pamplona, Spain

**Abstract:** Both the pedunculopontine (PPTg) and laterodorsal tegmental (LDTg) nuclei receive abundant GABAergic projections from basal ganglia components. Thus far, the presence of $GABA_A$ receptors ($GABA_ARs$) in the PPTg and LDTg has been reported both electrophysiologically and pharmacologically; however, their anatomical localization has not been investigated yet. Furthermore, both nuclei comprise three different neurochemical phenotypes - cholinergic, GABAergic and glutamatergic - which play different roles in locomotion and sleep/wake behavior. To better understand GABAergic transmission in these

nuclei we aimed 1) to estimate the total number of neurons in PPTg and LDTg expressing $GABA_AR$ gamma 2 subunit ($GABA_AR$ γ2), and 2) to identify which of the three neurochemical subpopulations expresses this $GABA_AR$ subunit. Unbiased stereological methods were used in sections dually labeled for $GABA_AR$ γ2-immunoreactivity ($GABA_AR$ γ2-ir) and NADPH-diaphorase staining, a marker of cholinergic neurons. Cell counts were carried out within the nuclear boundaries of the PPTg and LDTg, demarcated around the most peripherally located cholinergic neurons. The mean number of cells expressing only $GABA_AR$ γ2 -ir was 9,848 ± 1,856 in the PPTg and 8,285 ± 962 in the LDTg, whereas those of cholinergic cells were 3,850 ± 580 and 3,235 ± 510, respectively. Dually labeled sections immunoreacted against choline acetyltransferase (ChAT) and $GABA_AR$ γ2 revealed a ≈ 100% expression of the γ2 subunit in cholinergic cells of both nuclei. Subsequently $GABA_AR$ γ2-ir was combined with *in situ* hybridization against either GAD67 or Vglut2 mRNA, and also with ChAT immunoreactivity for delineation purposes. Quantification of dually labeled cells revealed that 76% of GABAergic cells in the PPTg and 45% in the LDTg also expressed $GABA_AR$ γ2, indicating that there are at least two different subsets of GABAergic neurons in the PPTg and LDTg, represented in different proportions in the two nuclei. Finally, 90% of glutamatergic cells in the PPTg and 65% in the LDTg also expressed $GABA_AR$ γ2. These differences in the presence and/or subunit composition of $GABA_A$Rs in the glutamatergic and GABAergic cell subpopulations of PPTg and LDTg may account for some of the reported functional differences between the two nuclei.

**Abstract:** Recently, the molecular diversity of midbrain dopamine (DA) neurons has been under intense scrutiny and several distinct subtypes of DA neurons have been identified. How molecular profiles are related to other properties like axonal projections or neuronal functions, remains to be determined. Progress in this regard has been hindered by the lack of genetic tools to study genetically-defined DA neuron subtypes. Here, we present a genetic toolbox and three distinct intersectional strategies to target these subtypes based on combinatorial gene expressions. The genetic toolbox we generated includes a mouse expressing Flp recombinase under the control of tyrosine hydroxylase promoter, as well as two novel Cre drivers, to gain genetic access to key DA neuron subtypes in the substantia nigra pars compacta (SNc) and ventral tegmental area (VTA). Using our intersectional genetic labeling strategies, we mapped the projections of molecularly defined DA neuron subtypes of the SNc and VTA. Our approach revealed the underestimated diversity of the DAergic innervation of the striatum, nucleus accumbens and amygdala. Together, the genetic toolbox and DA neuron subtype projections presented here constitute a resource that will accelerate the investigation and understanding of the functions of this clinically significant neurotransmitter system.

**Abstract:** The dopamine transporter (DAT) is a membrane glycoprotein expressed in dopaminergic neurons and is responsible for the uptake of dopamine (DA) into presynaptic neurons after its release into the extracellular space. DAT dysfunction has been involved in different neurological and psychiatric disorders, including Parkinson's disease, depression and attention deficit hyperactivity disorder. DAT activity is regulated by different factors, including DA $D_2$ and $D_3$ autoreceptors. Current data indicate that $D_2$ receptor ($D_2R$) promotes DAT recruitment to the plasma membrane and an increase of DA uptake, but $D_3$ receptor ($D_3R$) seems to have a dual effect on DAT. Its acute stimulation induces an increase in DAT activity, but after prolonged stimulation, DA uptake becomes lower than in basal conditions. The mechanisms underlying this phenomenon are still poorly known. To shed light on this issue, DAT-$D_3R$ transfected HEK cells, midbrain dopaminergic neurons and rats were treated with the $D_3R$ preferential agonist pramipexole (PPX). The results show that prolonged treatment with PPX (10µM for 90 minutes in cell cultures; 0.15mg/kg/d/6d in rats) causes: 1. A decrease of [$^3$H]DA uptake and glycosylated DAT levels in the plasma membrane (an effect that was blocked by the protein kinase C inhibitor bisindolylmaleimide-IV), 2. A decrease in total DAT levels together with an increase in DAT phosphorylation, ubiquitination and binding to p62, and 3. DAT colocalization with LC3 and lysotracker (two markers of the autophagy-lysosome pathway). These findings indicate that PPX induces internalization and degradation of DAT through the autophagy pathway. The modulatory effect of PPX on DAT can contribute to strengthening dopaminergic transmission in the mesostriatal system, suggesting new therapeutic possibilities of $D_3R$ agonists in neurological and psychiatric conditions.

**Title:** Ontogenetic effects of DA receptor inactivation on the efficacy of D2 receptors and the cAMP and Akt signaling pathways

**Authors: V. REAL**, A. TERAN, C. A. CRAWFORD, *S. A. MCDOUGALL
Dept. of Psychology, California State Univ., San Bernardino, CA

**Abstract:** DA receptor inactivation causes dramatic age-dependent behavioral effects across ontogeny. In adolescent and adult rats, D2 receptor inactivation fully attenuates the locomotion caused by DA agonist treatment. In preweanling rats, on the other hand, agonist-induced locomotion is paradoxically enhanced after IP or IC injection of the irreversible DA antagonist EEDQ. Although EEDQ inactivates a similar percentage of D2 receptors in young and adult rats, the affinity of the remaining receptors varies according to age. Specifically, EEDQ-treated preweanling rats, relative to older rats, have a disproportionate number of high affinity D2 receptors. This finding led us to propose that an excess of $D2^{High}$ receptors is responsible for the potentiated locomotor response in preweanling rats. If this explanation is accurate: (a) the efficacy of D2 receptors should be enhanced in EEDQ-treated preweanling rats, and (b) age-dependent changes in $D2^{High}$ receptors should differentially affect down-stream signaling. To test these hypotheses, we examined the efficacy of D2 receptors by measuring stimulated [$^{35}$S]GTPγS binding in EEDQ-treated rats. We also measured the effects of EEDQ on the cAMP and Akt signaling pathways. In both experiments, rats were given an IP injection of vehicle or EEDQ (2.5 or 7.5 mg/kg) on PD 17, PD 39 or PD 84. After 24 h, CPu sections were dissected and stored at -70 °C. Agonist-effect curves of [$^{35}$S]GTPγS binding were performed in assay buffer containing 10 µM GDP and NPA. Nonspecific binding was determined using 10 µM cold GTPγS. Western blots were used to quantify the functional status of the cAMP and Akt systems. Namely, the PKA catalytic subunits α and β (PKA-Cα and PKA-Cβ) were measured, as were phosphorylated PKA-Cα (pPKA-Cα) and the PKA regulatory subunit (PKA-RII). Phosphorylated and nonphosphorylated forms of Akt and GSK-3β were also measured using immunoblotting. We found that EEDQ increased the efficacy ($E_{max}$) of NPA-stimulated [$^{35}$S]GTPγS specific binding to a greater extent in preweanling rats than adults. Age-dependent differences in second messenger system functioning were apparent, as striatal Akt levels were greater in preweanling rats than adults, while adolescent rats had reduced pGSK-3β relative to the other age groups. Receptor inactivation had minimal effects on these signaling pathways, with the exception that EEDQ reduced pAkt in all age groups. In sum, the GTPγS data are consistent with the hypothesis that EEDQ's age-dependent behavioral effects are caused by changes in the affinity and efficacy of D2 binding sites, but there is no evidence that alterations in the cAMP and Akt signaling pathways mediate these behavioral effects.

**Abstract:** DA neurons play critical roles in procedural learning, action selection and motivation, and perturbations of dopaminergic influences on basal ganglia circuitry contribute to neurological and psychiatric disorders. It is assumed that the main modulator of these processes is DA. However, DA neurons communicate with their targets by a host of secreted cell signaling factors in addition to DA. The physiological functions of these auxiliary modes of dopaminergic communication are only beginning to emerge.
We found previously that all DA neurons release the secreted cell signaling factor sonic hedgehog (Shh) in the striatum. Only cholinergic- and fast spiking (FS), gabaergic- interneurons among all dopaminergic targets express the receptor for Shh. We further revealed that Shh signaling, in a dose dependent manner, inhibits the transcription of the dopaminotrophic factor GDNF and the muscarinic autoreceptor M2 leading to a graded modulation of extracellular acetylcholine (ACh) (Gonzalez-Reyes et al., Neuron 75, 306).
Here we exploit unilateral optogenetic stimulation of DA neurons in conjunction with cholinergic and Shh signaling specific pharmacology, to show that Shh signaling to ACh neurons specifically from DA neurons plays a critical role in the formation of locomotion. The effect of Shh signaling is seen within 2 minutes and reveals an antagonistic relationship of DA and Shh when co-released from DA neuron terminals in that DA inhibits while Shh stimulates ACh signaling. Continuous, forced burst stimulation of DA neurons reveals a rapid onset and linear exhaustion of Shh signaling over the course of 40 minutes while DA signaling remains constant. These results indicate that the physical identity of the reward prediction error signal, which is critical for reinforcement learning and is encoded by trains of dopaminergic bursts, changes over the course of several bursts. Consistent, we find that mice with selective ablation of Shh from DA neurons reveal a learning deficit but increased motor habit formation. Our results are likely

of clinical relevance since the co-administration of L-Dopa together with Shh agonists inhibits the formation of L-Dopa induced dyskinesia (LID) in animal models of Parkinson's Disease (SFN poster Lauren Malave & Andreas H. Kottmann).

**Abstract:** Substantia nigra reticulata (SNr) is the output nucleus of the basal ganglia whose modulation of their neural firing rate by GABA and Glutamate allows to explain the modulation of movement through basal ganglia circuit. In the SNr, GABA, Glutamate and Dopamine release is controlled by presynaptic dopamine receptors. D1 receptors modulate GABA and Glutamate release from striatal and subthalamic afferents whereas D4 receptors modulate GABA release from pallidal terminals. D3 dopamine receptor has been located at striatal and subthalamic afferents and in dopaminergic dendrites as well; however, the participation of D3 receptor in the modulation of motor behavior at this level is uncertain.
Here we performed in vivo microdialysis experiments in the SNr of naive rats to measure dopamine, glutamate and GABA levels and correlate them with motor behavior. The blockade of nigral D3R with the highly selective antagonist GR-103691 (100 nM i.c.) produced an increase of Dopamine, Glutamate and GABA levels correlating with an increase in the ambulatory distance and non-ambulatory behavior. Systemic blockade of D3 receptors with U99194 (25 mgrs/kg i.p.) mimicked the effects of local blockade in SNr. Co-perfusion of SCH 23390 (1µM i.c.) with GR-103691 prevented the effects of D3 receptor blockade in GABA but not in Dopamine and Glutamate increases. Co-perfusion of Kinurenic acid (3 µM i.c.) prevented the effects of D3 receptor blockade in Dopamine and GABA but not in Glutamate.
These data suggest that D3 receptors tonically modulate (decrease) Glutamate release from subthalamo-nigral terminals. Glutamate in turn, as previously suggested (Rosales et al., 1977), increases Dopamine through NMDA receptors, and Dopamine stimulates GABA through D1

receptors. These increases in GABA levels decreases firing rate of output neurons and increases motor behavior, in consequence local or systemic blockade of D3 receptors increases locomotor activity by increasing Glutamate release at SNr.

**Title:** Dissecting the biochemical properties of dopamine D1-D3 receptor heterotetramers and their role in the modulation of locomotor activity

**Authors: *X. GUITART**[1], E. MORENO[2], W. REA[1], C. QUIROZ[1], M. SANCHEZ-SOTO[1], V. KUMAR[1], A. CORTES[2], E. I. CANELA[2], C. BISHOP[3], A. H. NEWMAN[1], V. CASADO[2], S. FERRE[1]
[1]Natl. Inst. On Drug Abuse, IRP/NIH, Baltimore, MD; [2]Univ. of Barcelona, Barcelona, Spain; [3]Univ. of Binghamton, Binghamton, NY

**Abstract:** A quaternary structure of the dopamine $D_1$ receptor (D1R)-$D_3$ receptor (D3R) heteromer has been proposed as constituted by D1R and D3R homodimers coupled to their respective cognate Gs and Gi proteins. The use of biophysical techniques and specific disruptive peptides in mammalian transfected cells demonstrated a D1R-D3R heteromer-dependent positive synergistic interaction of D1R and D3R agonists on MAPK signaling. In addition, D1R and D3R agonists interacted antagonistically at the level of adenylyl cyclase (AC) signaling, with D3R activation counteracting D1R agonist-induced cAMP accumulation. For adenosine $A_{2A}$-dopamine $D_2$ receptor heteromers, this canonical Gs-Gi antagonistic interaction at the level of AC has been demonstrated to depend on receptor heteromerization. We now show that synthetic peptides that disrupt D1R-D3R heteromers also disrupt the canonical Gs-Gi-AC interaction in transfected cells, demonstrating that it is also a biochemical property of the D1R-D3R receptor heteromer. This would support the hypothesis that the synergistic effect of D1R and D3R

agonists on MAPK signaling should involve G protein-independent D1R signaling. However, also in transfected cells, D1R-agonist induced activation of MAPK was found to be dependent on Gs-AC signaling, since it was counteracted by a PKA inhibitor. The results support a model where, in the D1R-D3R heteromer, D1R activation induces MAPK activation by a Gs-AC-mediated mechanism, but not when D3R is co-activated. In this case, a D1R agonist cannot signal though MAPK, because of the canonical Gs-Gi-AC interaction, but can allosterically potentiate D3R-mediated MAPK activation. This would imply that, if dependent on D1R-D3R heteromerization, the main mechanism behind the strong locomotor activity produced by co-administration of D1R and D3R agonists in reserpinized mice, should be mostly dependent on D3R-mediated MAPK activation. The biased antagonism of a novel and highly selective D3R antagonist, VK4-116, provided strong support to our hypotheses. In transfected cells, when compared with the non-selective $D_2$-like receptor antagonist eticlopride, VK4-116 was equipotent at counteracting D3R agonist-mediated forskolin-induced cAMP accumulation, but 300 times less potent at counteracting D3R agonist-mediated MAPK activation and locomotor activation in reserpinized mice induced by co-administration of D1R and D3R agonists. Ongoing *ex vivo* and *in vivo* experiments with infusion of disruptive peptides should unequivocally demonstrate that the effects of co-administration of D1R and D3R agonists on MAPK activation and on locomotor activity depend on D1R-D3R heteromerization.

**Title:** Beyond "high" and "low" dopamine: complex spatio-temporal concentration maps and receptor activation in the striatum

**Authors: *L. HUNGER**[1], A. KUMAR[2], R. SCHMIDT[3]
[1]Dept. of Psychology, The Univ. of Sheffield, Sheffield, United Kingdom; [2]KTH Royal Inst. of Technol., Stockholm, Sweden; [3]Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom

**Abstract:** Dopamine (DA) plays an important role for reward-related learning, motor control and action-selection. While single DA neuron firing has been linked to reward prediction error

responses, direct measurements of DA concentration in the striatum have indicated a more complex picture of the DA signal. For example, the spatio-temporal DA concentration in the striatum does not seem to be a straightforward result of the DA cell firing. Furthermore, the activation of D1 and D2 DA receptors of striatal neurons does not follow the time course of the DA concentration directly, but is altered by the slow binding kinetics of DA receptors.
To better understand how DA cell firing determines changes in DA concentration and receptor activation, we created a restricted diffusion model that takes into account the reduced rate of diffusion in the brain due to obstacles like neurons and glia cells (Nicholson 2000; Dreyer et al. 2010). In our model we incorporate non-homogenous DA uptake, DA axonal tree morphologies, detailed DA receptor kinetics, and spike trains based on rat DA cell recordings (Hyland et al. 2002). Thereby, we obtain three-dimensional DA maps describing how DA concentration varies over time in a striatal cube. We find that the DA maps have complex spatio-temporal dynamics that cannot simply be classified as "high" or "low" DA concentration. For example, for tonic DA cell firing the time course of the DA concentration at a given location in the striatum strongly depends on the distance to the nearest DA synapses.
Furthermore, we calculate the activation of D1 and D2 receptors in the striatum. During tonic DA cell firing the average DA concentration is constant long enough so that the DA receptor activation equilibrates. In this case the receptor affinity describes the fraction of activated receptors accurately. However, the timescale of the phasic DA cell firing is too short for the receptors to reach equilibrium. In this non-equilibrium case the affinity of the DA receptors does not accurately describe their activation. In particular, even though D2 receptors have a high affinity for DA, not all D2 receptors are activated during phasic DA signals due to the slow kinetics of DA receptors. Therefore, during phasic DA cell firing the DA receptor activation does not simply follow the time course of the DA concentration, but is also determined by the interplay with receptor kinetics. Moreover, we find that the time course of the DA receptor activation is very similar for D1 and D2 receptors. We conclude that the kinetics of the DA receptors might be more important for disentangling the effects of phasic and tonic DA cell firing than the differences in D1 and D2 receptor affinity alone.

**Title:** Phasic dopamine response in the dorsal striatum correlates with specific movements

**Authors: *H. R. KIM**, N. UCHIDA
Mol. and Cell Biol., Harvard Univ., Cambridge, MA

**Abstract:** Dopamine (DA) in the striatum is critical for the generation of movements as indicated by motor impairments in Parkinson's disease. However, the exact mechanism by which DA regulates movements remains elusive. Previous studies have long failed to find a tight relationship between specific movements with phasic DA activities, but recent studies in rodents have begun to show the presence of phasic DA responses at the time of motor initiations (Jin and Costa, 2010; Barter et al., 2015; Howe and Dombeck, 2016). It was argued, however, that movements studied in these studies (e.g. locomotion) involve the activity of many muscles as well as various sensory experiences (Schultz et al., 2017). Whether striatal dopamine correlates with specific movements remain to be clarified.
To examine whether dopamine signals in specific striatal regions correlate with specific movements, we monitored calcium signal in dopamine axons in the striatum while head-fixed mice voluntarily ran on a treadmil in the absence of appetitive reward. Viruses expressing GCaMP6m in a Cre-dependent manner were injected in VTA and SNc of mice expressing Cre recombinase under the control of the DAT gene. DA axonal activity in the dorsomedial and dorsolateral striatum (DMS and DLS, respectively) was measured using fiber fluorometry (photometry). In addition to locomotor speed, we recorded whisking and whole-body movement using high-speed videography.
Whisking preceded locomotion with a variable interval ranging from zero to two seconds, which allowed us to examine the behavioral correlate of phasic DA activity in DLS. We found that phasic DA activity in DLS was more tightly correlated with the onset of whisking rather than locomotion (median d' = 0.20 for locomotion, d' = 0.54 for whisking, p = 0.003, n = 6 mice). Furthermore, whisking also occurred without initiating locomotion. The magnitude of DA activity at the onset of spontaneous whisking was comparable to that of whisking preceding locomotion (d' = 0.60 for spontaneous whisking and d' = 0.54 for whisking with locomotion). In contrast, we did not observe clear spontaneous whisking-related activity in DMS (median d' = -0.02, n = 5 mice), as opposed to locomotion onset-related activity (median d' = 0.29). These results indicate that DA signals in different parts of the dorsal striatum are correlated with specific types of movements. These results also suggest that movement-related DA signals are wide-spread in the dorsal striatum.

**Title:** Regulation of midbrain dopamine systems by oxytocinergic projections

**Authors: *L. XIAO**[1], M. F. PRIEST[1], J. NASENBENY[1], T. LU[2], Y. KOZOROVITSKIY[1]
[1]Dept. of Neurobio., [2]Roxelyn and Richard Pepper Dept. of Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

**Abstract:** The hormone and neuromodulator oxytocin has been linked to the function of dopaminergic reward systems through its effects on social behavior including pair bond formation, parenting, and mating. The possibility of oxytocinergic modulation of midbrain dopaminergic systems has been suggested by behavioral and anatomical studies, but the neural circuits and physiological consequences of this potential modulation remain elusive. Here, we anatomically and functionally characterize hypothalamic oxytocinergic projections that regulate the activity of midbrain dopaminergic neurons. This oxytocin source derives from parvocellular neurons in the hypothalamic paraventricular nucleus (PVN). Electrophysiological recordings of dopaminergic neurons reveal a functional oxytocinergic pathway that modulates neuronal activity of VTA and SNc neurons in a location-specific manner. Since hypothalamic oxytocinergic projections also target the striatum, oxytocin is poised to bias the balance of dopamine tone through multiple sites in vertebrate reward circuits.

**Abstract:** Neurotransmitters dopamine (DA) and serotonin (5-HT) homeostasis in presynaptic neurons is regulated by the DA transporter (DAT) and 5-HT transporter (SERT) respectively and by the vesicular monoamine transporter (VMAT2). Dysregulated release of DA as a false neurotransmitter from 5-HT neurons following L-DOPA therapy may lead to L-DOPA-induced dyskinesias as a consequence of DAT loss. Changes in membrane cholesterol levels were shown to modulate ligand binding activity and function of DAT and SERT. This study investigated the effect of cholesterol removal and replenishment *in vitro* on DAT in rat and monkey brain homogenates as compared to VMAT2 and SERT. Incubation of rat striatum with methyl-β-cyclodextrin (MCD) to deplete membrane cholesterol or with cholesterol-MCD complex to increase membrane cholesterol content showed no change of DAT protein levels measured by Western blot. By contrast, striatal DAT specific binding labelled with [$^{125}$I]-RTI-121 decreased in a dose-dependent manner after incubation with MCD (-82% in rat striatum; -56%, -54%, and -62% in monkey caudate nucleus, putamen and nucleus accumbens respectively with 10 mM MCD) while the opposite was measured with cholesterol loading (+34% in rat striatum; +12%, +17% and +31% in monkey caudate nucleus, putamen and nucleus accumbens respectively with 0.1 mM cholesterol). Moreover, [$^{125}$I]-RTI-121 specific binding of striatal membranes depleted of cholesterol with MCD was restored to their initial DAT content with addition of cholesterol showing a rapid and reversible effect of cholesterol. By contrast, no change of rat striatal SERT specific binding labelled with [$^{3}$H]Citalopram was observed following cholesterol manipulations. In monkey brain, incubation with MCD left unchanged SERT specific binding in the caudate nucleus and putamen whereas it increased in the nucleus accumbens (+25%). Incubation with cholesterol decreased SERT specific binding in the caudate nucleus and putamen (-49% and -34% respectively with 10 mM cholesterol) while no effect was observed in the nucleus accumbens. Incubation of rat striatal membrane with MCD decreased VMAT2 specific binding labelled with [$^{3}$H]Dihydrotretrabenazine (-26% with 10 mM MCD) whereas no change was observed in monkey brain. Incubation with cholesterol decreased VMAT2 specific binding in the caudate nucleus and putamen only at higher cholesterol doses (5 and 10 mM). These results show an important modulatory effect of cholesterol on monoamine transporters mainly DAT suggesting a close relationship between the membrane lipid environment and DAT function.

**Abstract:** Background: Synchronous, rhythmic changes in the membrane polarization of neurons form oscillations in local field potentials. High-frequency brain activity reflects local cortical information processing and a low-frequency brain rhythm projects information flow across larger cortical networks. This provides for a complex form of information transmission based on interactions between oscillations at different frequency bands, which can be displayed by cross-frequency coupling (CFC) metrics such as phase-amplitude coupling (PAC). PAC reflects the coupling of the phase of oscillations in a specific frequency band to the amplitude of oscillations in another frequency band. Methods: In awake patients undergoing functional neurosurgery for Parkinson's disease or essential tremor, we used a parametric spectral estimation method for modelling band limited oscillations. We used a state space-based Bayesian algorithm for estimation and optimization of the model parameters with time-varying coefficients that adapt according to a band limited oscillation of the brain. The optimal parametric model allows temporal prediction of the brain signal and increases the accuracy of Hilbert-transform-based instantaneous frequency and phase estimation. Results: Using electocorticography data recorded intraoperatively on patients with Parkinson's disease or essential tremor during deep brain stimulation surgery, we were able to detect PAC (Figure 1) and used auto-regressive modeling to predict the future phase of slow oscillations on which high frequency gamma was entrained. Conclusions: We established a system for PAC monitoring and then predicted future phase of the slower rhythm oscillations. This is a first step toward phase-dependent cortical stimulation and may allow cortical neuromodulation to enhance intraoperative physiology recordings to guide functional neurosurgery and potentially, as a therapeutic intervention. Figure 1. PAC between slow cortical oscillations and gamma activity in a PD (A) and ET (B) patient.

**Title:** Variability and motor learning: Neural processing noise supports visuomotor adaptation

**Authors: *J. N. VAN DER GEEST**[1], R. VAN DER VLIET[1,2], L. DE VREEDE[1], Z. JONKER[1,2], G. RIBBERS[2], R. SELLES[2], M. A. FRENS[1,3], O. DONCHIN[4,1]
[1]Erasmus MC - Neurosci., Rotterdam, Netherlands; [2]Rehabil., Erasmus MC, Rotterdam, Netherlands; [3]Erasmus Univ. Col., Rotterdam, Netherlands; [4]Ben Gurion Univ., Be'er Sheva, Israel

**Abstract:** The nervous system seems to exploit variability (noise) to support behavioural learning. However, this claim has not been consistently observed in experiments on human motor learning. This may be because the noise that underlies the motor variability in human movements is comprised of two components that contribute to motor adaptation in different ways: neural processing noise and output noise. If people learn from errors, optimal control theory using a Kalman filter suggests that learning rate will correlate positively with neural processing noise (state noise) and negatively with output noise. We tested this hypothesis in a visuomotor reaching adaptation experiment in 69 participants. They made rapid pointing movements in 450 baseline trials with and without visual feedback, and in 450 adaptation trials in which the feedback was perturbed. We extracted state noise, output noise and adaptation rate using a state-space model of trial-to-trial behaviour. We found that adaptation rate during perturbations correlates positively with baseline state noise but negatively with baseline output noise. This suggests that motor noise can be decomposed into a supporting factor for motor adaptation and a factor that hampers learning.

**Title:** Simulation of inertial augmentation to counteract abnormal synergies in arm movement

**Authors: *F. C. HUANG**
Arms + Hands Lab., Shirley Ryan Abilitylab, Chicago, IL

**Abstract:** This study examined how a simple model of arm impedance can reveal configuration dependent changes in abnormal synergies in stroke survivors. We also present methods for designing a custom training intervention, by relating the desired change in acceleration covariance in planar motion with a corresponding change in inertia matrix. Using data from a previous study in which stroke survivors (n=10) performed self-directed motor exploration, we first characterized movement in terms of overall covariance in acceleration, and secondly as covariance in acceleration as a function of position in the workspace. Using a forward dynamics simulation of the hand endpoint impedance, we found that the variable change in endpoint inertia resulted in greater reduction in acceleration covariance compared to the fixed change in inertia method. These findings provide support for the use of custom augmentation of limb inertia for upper extremity rehabilitation.

**Title:** Error-augmented feedback accelerates adaptation to nonlinear visuomotor distortions but leads to unstable learning

**Authors: *P. N. PARMAR**[1,3], J. L. PATTON[2,3]
[1]Arms + Hands Lab, Floor 22, Core Area, [2]Arms + Hands Lab., Shirley Ryan Ability Lab., Chicago, IL; [3]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL

**Abstract:** Although error-based mechanisms play an important role when acquiring novel motor skills and adapting to perturbations, the dynamic effects of error feedback are not well understood. Recently, Patton et al. (2013) demonstrated how the size of error feedback results in faster learning rates by testing only 3 selected gain values. In this study, we comprehensively tested error feedback gain values from 0 to 3. In addition, we tested interaction effect of these gain values with error bias that was proportional to initial exposure error. We recruited 5 control and 10 test subjects, whose task was to adapt to 8 nonlinear visuomotor distortions by making target-to-target reaching movements. All control subjects perceived normal error feedback (gain 1 and bias 0), while all test subjects perceived augmented error feedback (gain and bias combinations randomly selected for all 8 tasks per every 2 subjects). Results reveal fastest inter-trial change in the feedforward component of movement trajectory error (error calculated from the first 150ms of movement in reference to the straight-line reach) with gain 2 and bias 0. However, this condition led to continue learning beyond zero error with steady-state error lower than the control (unstable learning). As expected, no error-feedback (gain 0, bias 0) led to the slowest inter-trial change in the feedforward component with steady-state error higher than the control (incomplete learning). We also tested the linear, quadratic, and cubic polynomial models to predict the inter-trial change in error. Here, the linear model performed the best, and adding higher order polynomial terms did not improve the model performance.

**Title:** Influence of haptic feedback on exploration of movement variability during motor learning

**Authors: *R. LOKESH**[1,2], R. RANGANATHAN[3,3]
[2]Mechanical Engin., [3]Kinesiology, [1]Michigan State Univ., East Lansing, MI

**Abstract:** Several studies have established that haptic assistance facilitates motor learning in tasks that require minimizing movement errors. However, in tasks with motor redundancy, haptic feedback can be used to modulate two aspects of movement variability - task space variability, which affects task performance; and null space variability, which has no direct effect on task performance. The purpose of this study was to examine the influence of haptic feedback on task and null space variability during motor learning. Participants performed a bimanual task which required them to control a cursor on the screen and navigate a 12mm wide “W-shaped track” as fast as possible. Critically, the cursor on the screen was placed at the mean position of the two hands, which meant that the same trajectory could be achieved with different motions of the left and right hands. We examined two groups - (a) a no-haptic feedback group that learned the task only using visual feedback, and (b) a haptic feedback group that received error-correcting haptic force feedback along a small 6mm wide inner “channel” within the track. The haptic feedback was provided using a spring-like force acting perpendicular to the track when they reached the edge of the channel. Participants practiced for 288 trials distributed equally over two days, and we measured movement time and movement variability during learning. Results showed that movement time decreased with practice for all participants, with haptic group having lower movement times throughout practice. Analysis of movement variability showed greater task space variability for the haptic feedback group, but there were no differences in the null space variability. These results suggest that haptic feedback has differential effects on movement variability in the task and null space, which may be used to facilitate motor learning.

**Title:** Modifying coordination pattersn in throwing by reinforcement

**Authors: *T.-H. LIN**[1], R. RANGANATHAN[2]
[1]Dept. of Kinesiology, [2]Dept of Kinesiology, Michigan State Univ., East Lansing, MI

**Abstract:** The redundancy in the musculoskeletal system allows humans to perform same movement with multiple coordination patterns. This feature of the motor system means that motor learning is not only about improving task performance, but can also involve in shifting between different coordination patterns that all yield the same performance. However, how participants learn to use an alternative coordination pattern to perform a task is still poorly understood. Here, we examined the use of reinforcement feedback to shift participants from one coordination pattern to another. We used a virtual throwing task that required coordination between the trunk and the hand. Specifically, participants threw a virtual ball to a target on the screen, but the motion of the ball was determined by a combination of the participants' trunk and hand velocity (indicating there was redundancy). Typically, participants perform the task with high hand velocities, and low trunk velocities. We examined whether we could shift this pattern to a strategy with lower hand velocities and higher trunk velocity. We provided reinforcement feedback by deviating the trajectory of the ball out of the screen if their trunk velocity did not go above a specific threshold value. We compared two reinforcement schedules - an abrupt change, where this threshold value was introduced immediately at the beginning of practice; and a gradual change, where the threshold was increased gradually with practice. Results showed that although trunk velocities increased in both groups, indicating that the reinforcement was successful in altering their movement strategy, there was not a significant difference between the abrupt and gradual groups. Further analysis revealed that the rate of increase in the threshold in the gradual group have been too high, which resulted in effectively acting like an abrupt group. These results suggest that reinforcement feedback has the potential to alter movement strategies, but that reinforcement may be more effective if it is based on the actual performance of the individual, rather than on a pre-determined schedule.

**Abstract:** This study investigates a method to measure patient involvement during robot-assisted force training. An important lesson in therapy is that stroke survivors fail to improve when they allow the robot to passively move their affected limb. We assert that successful approaches require patients to attempt to actively contribute to movement. Current theories suggest that such active involvement promotes the reorganization of neural pathways - a critical component of motor recovery and learning. While the specific force algorithm likely affects involvement we wish to investigate other factors that could also contribute. We evaluated patient involvement during our recent study in which we investigated our design of a customized force intervention. Patients were allowed to move any way they wanted while forces were pre-programmed to push their hand towards their *neglected* velocities. We adopted a simple approach of using inverse dynamics to estimate elbow and shoulder joint torques and then quantified involvement in terms of power exertion at each joint. In our preliminary analysis, we examined how joint power varied across different movement states (position, velocity). We found that some patients often engaged in repetitive cyclic motions or were only active when their hand reached workspace boundaries while other patients were active throughout their state-space ranges. These observations suggest that some patients altered between modes of active and passive involvement. Further analysis will provide insights on whether degree of severity between patients correlates with involvement. This work provides a tool that can be used to develop and evaluate effective strategies for robot-assisted intervention. It can also be used to fine-tune forces during robotic therapy in order to optimize patient involvement.

**Authors: *D. DE SANTIS**[1], L. FEENEY[2], F. A. MUSSA-IVALDI[1]
[1]Physiol., Northwestern Univ., Chicago, IL; [2]Dartmouth Col., Hanover, NH

**Abstract:** Studies have shown that the brain is able to seamlessly incorporate external tools into a motor plan by learning their inherent properties (or structure). This process generally involves remapping of postures between our body and the position of the tool. One particular example is offered by Body-Machine Interfaces (BMIs), in which the user operates external assistive devices using body postures/movements as control signals.
In a BMI, a linear map that performs dimensionality reduction describes the transformation from a high-dimensional space of body movement signals to a lower-dimensional space of device movements. In order to skillfully operate the BMI, the user must effectively learn a suitable inverse of this map.
One of the greatest challenges is facilitating learning through the adaptation of the BMI without interrupting the continuous operation of the device. This feature is relevant not only for providing stable assistance through time, but also to use the system for tracking or for driving functional improvements after neurological injury.
Here we present a novel approach that focuses on the characteristics of the body motions the subject performs while trying to control the BMI. Our hypothesis is that it is possible to modulate learning by adapting the map so as to minimize the variance associated with motions in the map's null-space. This approach draws from the finding that exploration in redundant tasks tends to favor strategies of coordination that lie in the task space (i.e. that are orthogonal to the null space).
To test this hypothesis we trained subjects over multiple days controlling a cursor on a screen using shoulder motions. They practiced a reaching task using either a constant map or a co-adaptive BMI that modified the initial map over time. The co-adaptive mapping algorithm implemented an online PCA for incrementally shifting the task space towards movements that express greater variability. We compared the groups according to their performance in trained locations and non-trained locations of the cursor space as well as in a tracking task.

Subjects who trained with the adaptive BMI learned faster than the control group and performed on average better when tested on reaching to untrained locations.

**Title:** The effect of discrete versus continuous training in hand movement remapping

**Authors: *N. SHAKERDGE**[1], D. DE SANTIS[2], F. MUSSA-IVALDI[1]
[1]Biomed. Engin., [2]Physiol., Northwestern Univ., Chicago, IL

**Abstract:** Previous research has demonstrated that participants are able to learn to make novel directed hand movements to control a cursor. However, the effect of discrete versus continuous training in hand remapping tasks has yet to be explored, though it has been shown that continuous training impedes in the proficiency of discrete facial remapping tasks. Here, we aim to evaluate which training protocol - continuous or discrete -participants learn more quickly with and then determine which training protocol leads to a more proficient completion of the respective tasks. We hypothesize that discrete training will be more beneficial as a training system because there is less cognitive overload and it requires the participants to be less precise. Participants wore the Cyberglove that recorded hand motions. Hand motions produced signals, which controlled the cursor position on the computer monitor. The study consisted of two phases, training and testing. Participants were trained on one system for three sessions and then tested on the untrained system. The continuous training task consisted of a screen with a cursor providing visual feedback and one target box. Participants were instructed to move the cursor to the target. Once the cursor entered the target box there was no visual feedback of the cursor and the box turned red. The discrete training task consisted of a four by four grid with the controlled cursor being invisible. As the cursor entered each tile, the tile turned red. Once the cursor entered the target tile the tile turned green.
Our performance metrics were smoothness, path length, variance in the task space in relation to variance in the null space, and time. Our preliminary findings support the hypothesis of a greater efficiency of the discrete training protocol.

**Title:** Gradual practice is not superior to random practice for leg motor skill learning during gait

**Authors: C. REID**[1], E. P. WASHABAUGH, IV[2], A. DHARIA[1], R. RANGANATHAN[3], *C. KRISHNAN[1]
[1]Physical Med. & Rehabil., [2]Physical Med. and Rehabil., Univ. of Michigan, Ann Arbor, MI; [3]Dept of Kinesiology, Michigan State Univ., East Lansing, MI

**Abstract:** Motor learning is an important part of rehabilitation; therefore, it is critical to understand the role of different practice structures when learning a motor skill. Here, we compared the benefits of gradual practice with random practice on motor skill learning using a target-tracking paradigm that has been specifically used for gait rehabilitation. Twenty-two right-foot dominant adults (12 male and 10 female) between the ages of 18-26 participated in this study. The participants were asked to walk on a treadmill while performing a motor learning task that required participants to modify their gait pattern to match a template projected on a monitor. Eleven participants practiced matching templates that gradually increased by 3% in size until they were 30% larger than their baseline walking template (gradual group). The remaining participants received the same templates used for the gradual trials, but in a pseudo-random order (random group). Both groups were then required to match a 40% template to evaluate transfer effects, as well as match the 30% and 40% templates without visual feedback. We then compared the tracking-error observed at 30% and 40% templates between groups for both the target-matching with visual feedback and no visual feedback conditions. There were no significant differences between the gradual and random groups when learning to match the template. This finding was consistent between the two groups regardless of whether they were tested with or without visual feedback. Further, there was no difference in retention when subjects returned on the second day for testing. Results indicate both gradual and random practice yielded the same level of tracking-error, and there is no significant difference between the two methods of training. Future studies comparing these paradigms to conventional learning paradigms will further expose the potential benefits of these learning structures.

**Title:** Force production during holding suggests the presence of a neural integrator in reach adaptation

**Authors:** ***S. T. ALBERT**, R. SHADMEHR
Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD

**Abstract:** In a point to point movement, the brain first moves the body to a desired position, and then produces commands to maintain that position over time. Is it possible that these moving and holding processes are mediated by different populations of neurons? In the oculomotor system, burst neurons that drive saccades are silent when the eye is held in eccentric gaze. Gaze-holding activity is instead directed by a separate neural integrator that receives an efference copy of velocity-related motor commands from the saccadic burst generators, integrates these commands in time, and communicates a position-related signal to motor neurons of the eye. Is this serial relationship between moving and holding a fundamental property of other parts of the body? In

search of an answer, we noted that during force field adaptation of reaching movements, compensatory forces produced by subjects can continue long after the movement ends, while the arm is held still, despite the absence of external force. We wondered if these “force tails” provide evidence about the arrangement of moving and holding circuits of the arm. Subjects (n=10) held the handle of a robotic arm and made reaches to a peripheral target. We gradually imposed a force field to perturb their outward movements. At the end of every movement, we applied an error-clamp to hold the hand in place and measure force tails. After ramping the force-field magnitude in the CCW or CW direction, we then gradually removed the field, and ramped it in the opposite direction. In each of the four conditions (i.e. adaptation and de-adaptation to CCW and CW force fields) force tails were aligned with the direction of force compensation, with a magnitude that was linearly proportional to the level of adaptation of the movement (linear regression of force tails onto adaptation index; $R^2 = 0.889$). We hypothesize that, like the oculomotor system, motor commands that move the arm may serve as input to an integrator that helps to hold the arm in place. During force field adaptation, integration of additional forces required to counteract the field may lead to a disparity between the true position of the hand at the end of the movement, and the integrated position, which in turn gives rise to the force tail observed during the holding period.

**Title:** Motor learning rate is influenced by prior motor learning through reconfiguration of directional preference of motor primitives

**Authors: *T. HAYASHI**[1], K. TAKIYAMA[1], D. NOZAKI[2]
[1]Engin., Tokyo Univ. of Agr. and Technol., Koganei-Shi, Japan; [2]Grad School, Univ. of Tokyo, Tokyo, Japan

**Abstract:** The central nervous system (CNS) corrects motor commands to decrease prediction error. We have previously suggested that the way the CNS corrects motor commands is flexible rather than rigid (Hayashi et al., eNeuro, 2016). Specifically, while reaching towards 30°

clockwise and counter-clockwise targets from straight-ahead (indicates 0°), imposing clockwise or counter-clockwise visual rotation to the cursor, respectively (i.e., outward rotation), led the direction of hand movements to shift inward. This visuomotor learning procedure did not apparently alter the hand movement towards 0° target. However, when a visual rotation was further applied, we found that the induced aftereffect (i.e., motor-learning rate) was significantly reduced. The result suggests that visuomotor learning could change not only how we generate motor commands but also how we learn to generate the commands. This novel finding, which can be considered as evidence of "meta-learning" (Harlow, Psychol Rev, 1949) in motor learning, cannot be reproduced by conventional motor primitive frameworks (e.g., Thoroughman & Shadmehr, Nature, 2000) since they assume that the motor-learning rate is independent of experience of the visuomotor learning. Here, we aimed to account for the novel phenomenon by incorporating a new factor into the framework. A previous neurophysiological study has demonstrated that the preferred directions (PDs) of neurons in motor-related areas rotated towards the direction of an error (Li et al., Neuron, 2001). Inspired by this finding, we assumed that visuomotor learning induces PD rotation towards the directional error. According to this new model, after the procedure of outward rotation described above, the number of motor primitives recruited for the movement towards 0° target should be reduced because the PDs rotate outward. Theoretically, the reduced number of recruited primitives should decrease the motor learning rate. A simulation confirmed that the proposed model could successfully reproduce our experimental results. The success of this new model suggests that visuomotor learning influences how we learn in the subsequent visutomotor learning through the reorganization of the PD distribution of motor primitives.

**Title:** The effect of energy-matched exercise intensity on brain-derived neurotrophic factor and motor learning

**Authors: *J. BAER**, M. GAUGHAN, H. SAFFER, M. SARZYNSKI, T. HERTER, S. FRITZ, D. DEN OUDEN, J. C. STEWART
Univ. of South Carolina, Columbia, SC

**Abstract:** High-intensity exercise induces an increase in brain-derived neurotrophic factor (BDNF), a protein that facilitates synaptic plasticity, suggesting that an exercise-induced rise in BDNF prior to practice may enhance motor learning. Previous studies comparing high and low-

intensity exercise have observed larger increases in BDNF and better motor learning after high-intensity exercise. However, these studies failed to control for total energy expenditure, thus it is unclear if these results were related to the intensity of exercise or the overall amount of work. The purpose of the current study was to examine the effect of different exercise intensities on BDNF levels and motor learning while controlling for exercise-related energy expenditure. Thirty non-disabled, young participants were randomized into three groups: High-intensity (80% maximal resistance determined from an exercise test), Low-intensity (40% maximal resistance), and Rest (sit quietly for 20 minutes). Durations of the High and Low exercise bouts were individually adjusted so that each participant expended 200 calories. Blood samples were collected immediately before and after each intervention. After the intervention period, all participants completed 144 trials of a 3-dimensional (3D) implicit motor learning reach task. Stimuli were presented in 8-target sequences, and alternated between random and repeated sequences that were matched for difficulty. Retention was assessed 24 hours after initial task practice. Results indicated that BDNF levels increased 36.72% in the High group, while changes were less than 16% in both the Low and Rest groups. All three groups exhibited improvements in task performance, as measured by time to complete a sequence ($p < .001$), and all groups completed the repeated sequence faster than the random sequence ($p < 0.001$). While initially the slowest group at the start of task practice, the Low group showed the greatest change in performance for both the random (High = -22.52% ± 13.28; Low = -25.92% ± 13.80; Rest = -20.49% ± 9.48) and repeated (High = -21.62% ± 11.38; Low = -25.83% ± 12.34; Rest = -21.10% ± 8.80) sequences, although differences between groups were not significant. All groups maintained performance improvements at retention. Although these findings should be interpreted with caution, they suggest that other exercise-related mechanisms that are independent of both intensity and increases in BDNF may be involved in facilitating motor learning. Future work will include investigation of the rate of change of performance and the effects of a BDNF polymorphism.

**Title:** Adaptation to visuomotor rotation along a three-dimensional axis has two components

**Authors: *S.-H. YEO**
Sch. of Sport Exercise and Rehabil. Sci., Sportexr Univ. of Birmingham, Birmingham, United Kingdom

**Abstract: Objective:** Previous studies on adaptation to visuomotor rotation primarily focused on a two-dimensional setup: when hand movement is constrained in the horizontal plane and the axis of the visuomotor rotation is always kept vertical. In this study, we tested how the adaptation behaviors observed in two-dimensional (2D) studies generalize to the three-dimensional (3D) setup: subjects adapting horizontal reaching movements in 3D while visuomotor rotation is applied along an arbitrary axis in 3D. Additionally, we test if the observed adaptation behaviors are affected by a positional incongruency between the visual and the physical hand position. **Methods:** Sixteen healthy right-handed subjects participated in the experiment. Subjects grasped a robotic manipulandum and made quick out-and-back reaching movements from a central home position to one of eight peripheral targets on the horizontal plane in a 3D virtual reality (VR) environment using an Oculus Rift. Subject's physical hand position, tracked by the manupulandum, and the home and target positions were presented as spherical objects in VR. After a brief familiarization, a visuomotor rotation along a 3D axis was applied around the home position, and subjects were asked to adapt to the environment to make a visually horizontal reaching movement toward the target. In this environment, we tested two hypotheses. First, is there is a difference in the patterns of the "to-the-plane" adaptation (TP: when the axis of rotation is on the horizontal plane) and the "on-the-plane" adaptation (OP: when the axis of rotation is perpendicular to the horizontal plane - this corresponds to the traditional 2D visuomotor adaptation)? Second, are the observed adaptation speeds affected by the incongruency (a constant positional offset) between the visual and the physical hand positions? Both OP and TP were tested in separate and mixed conditions, during which trial-by-trial adaptation was assessed by maximum perpendicular error to the plane (MPE-TP) and on the plane (MPE-OP) respectively. **Results:** When TP and OP were tested separately, there were no differences between the speed of TP and OP in the congruent condition. In the incongruent condition, however, OP was significantly slowed down ($P < 0.05$) while TP remained at a similar level to the congruent condition. Same results were observed in the combined condition, showing only a significant effect of congruency on OP. Importantly, there were no significant differences in both MPE-TP and MPE-OP between the separated and the combined condition. **Conclusions:** The result suggests that there are two components in 3D visuomotor adaptation.

**Title:** Low-dimentional modification of musculoskeletal variables in motor adaptation

**Authors: *S. HAGIO**[1], M. KOUZAKI[2], D. NOZAKI[3]
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Kyoto Univ., Kyoto, Japan; [3]Grad School, Univ. of Tokyo, Tokyo, Japan

**Abstract: INTRODUCTION** Humans can modify motor commands to learn to move in novel environments. The central nervous system (CNS) faces a fundamental problem of how it controls high-dimensional variables in joint and muscle coordination space. To reduce the huge number of variables, motor commands would be constrained in low dimension by organizing the neuromuscular control (Hagio and Kouzaki, 2014; Sadtler et al., 2014). However, how the musculoskeletal variables were modified in motor adaptation is still unclear. In the present study, therefore, we examined the regulation of high-dimensional variables during the adaptation to a novel dynamical environment.
**METHODS** The participants performed horizontal reaching movements holding robotic handles by their right hand. They sat in an adjustable chair to which their trunk was strapped. They were instructed to move cursors representing the hand positions from a start position located at approximately 30 cm in front of their body to one of the 8 equally placed targets by 45° on a horizontal display, as straight as possible. For the training, the participants performed reaching movements under the presence of a velocity-dependent curl force field (Shadmehr et al., 1994). To equalize the endpoint kinematics, we randomly interleaved the error-clamp (EC) trials, with which the movement trajectory of the handle was constrained to a straight path from the start position to the target by a virtual force-channel (Scheidt et al., 2000). The experimental tasks were composed of null field, 384 force field (FF) and 96 washout trials across targets. During the tasks, surface electromyograms (EMGs) were recorded from 14 muscles spanning wrist, elbow and shoulder joints. In addition, the joint torques were estimated from the kinematic data obtained using a motion capture system. The EMGs and estimated joint torques in EC trials were compressed into low dimension using statistical calculation.
**RESULTS AND DISCUSSION** The lateral deviations due to the velocity-dependent force field exponentially decreased to a plateau by approximately half in the FF trials. Both EMGs and joint torques in high-dimensional space were largely explained by computed 3 dimensional variables, the structures of which were maintained throughout the trials across each subject. Low-dimensional variables organizing joint torques and muscle activations were modified with different adaptation rates. The results indicate that the CNS would reduce the high-dimensional musculoskeletal variables modified in the motor adaptation by modularly regulating the motor commands.

**Title:** Target size effects on sensorimotor adaptation

**Authors: *H. E. KIM**[1], D. E. PARVIN[1], M. A. HERNANDEZ[1], R. B. IVRY[2]
[1]Dept. of Psychology, [2]Univ. of California, Berkeley, Berkeley, CA

**Abstract:** Task performance and sensory prediction errors are two feedback signals thought to drive motor learning. In attempts to isolate learning from sensory prediction error, the difference between expected and actual sensory consequences of a motor command, we have used clamped visual feedback (Morehead et al. 2017). Here the angular trajectory of a feedback cursor is invariant with respect to the target location and thus spatially independent of hand position. Participants are fully informed of the manipulation, and are instructed to ignore the cursor and aim directly to the target. This task was designed to make task performance error irrelevant. To test this hypothesis, we conducted several experiments in which we manipulated the size of the target, while holding the clamp size constant. By doing so, we altered the relationship between the cursor and target such that the same clamp offset could result in either persistent target hits or misses. Experiment 1 examined responses to a 1.75° clamp over 220 movement cycles (one movement to each of 4 targets). In a between-subjects design, participants (n=14/group) made fast center-out reaches on a digitizing tablet, with the terminal position of the clamped cursor either fully embedded within a large target (IN) or partially overlapping a small target (IN/OUT group). All participants adapted, evidenced by a shift in heading direction opposite that of the clamp. There was a significant effect of target size: Asymptotic adaptation averaged ~12° for the IN group, compared to ~20° for the IN/OUT group ($p=.02$). In Experiment 2, we increased the clamp to 3.5°. For large, medium, and small target groups (n=12/group), the terminal position of the clamped cursor was fully embedded within the target (IN), halfway in (IN/OUT), or outside (OUT), respectively. The IN group's asymptote was again reduced, ~8° lower than that of both the IN/OUT and OUT groups. In Experiment 3, using a within-subjects manipulation, we tested two groups (n=10/group) on a 1.75° clamp. Following 120 movement cycles with a large (IN) or small target (IN/OUT), the target size switched to the other size for a final 80 cycles. Consistent with Experiments 1 and 2, the initial IN group produced a lower asymptote than the initial IN/OUT group by the end of the first block. As predicted, the IN group's heading angle increased when the target decreased in size, whereas the IN/OUT group's heading angle decreased when their target became larger ($p<.001$). Combined, these results show that target

"hits", even when task irrelevant, attenuates adaptation. Ongoing work is focused on testing whether this effect is due to an interaction between reward and error based learning systems.

**Title:** Practicing a de novo skill alters the adaptive response to subsequent perturbations

**Authors: *A. M. HADJIOSIF**[1], A. M. HAITH[2]
[1]Neurol. and Neurosci., [2]Neurol., Johns Hopkins Univ., Baltimore, MD

**Abstract:** The motor system uses a variety of approaches to compensate for perturbations to movement - e.g. adapting to a 30° rotation of visual feedback about the origin of movement. Foremost, the motor system uses a recalibration mechanism that temporarily and reversibly modifies an existing controller. Alternatively, however, it may maintain the original controller but change the movement aims - e.g. aim to a different target to compensate for a visuomotor rotation (VMR). Another potential solution is to permanently reconfigure the original controller in a way specific to the perturbed environment. Here we examined which of these modes of compensation the motor system employs when compensating for perturbations to a newly acquired skill. We hypothesized that sufficiently practiced de novo controllers could, like baseline controllers, be adapted using recalibration and/or re-aiming, whereas less practiced ones would tend to be permanently reconfigured.
Participants controlled a single on-screen 2-D cursor using both hands. Each hand controlled one dimension of cursor movement so that hand and cursor motion were orthogonal. We compared two groups who practiced this challenging task for either 1 or 4 sessions, during which they primarily moved the remapped cursor to a series of random target locations.
To evaluate how the newly learned skill would adapt to a perturbation, we subsequently exposed them to a 45° VMR of the cursor in a center-out, target-shooting paradigm. We taught them a simple strategy of aiming to a neighboring target, enabling them to counter the perturbation while still experiencing the sensory prediction errors that can drive recalibration (Mazzoni & Krakauer, 2006). We further tested participants for aftereffects by withholding cursor feedback and instructing them to aim directly to each target.
We found that, although both groups adapted similarly to the VMR, neither one exhibited the usual hallmarks of sensory-prediction-error-based recalibration; there was no drift in performance when participants used a provided strategy to counter the VMR, and aftereffects, though present, did not decay during subsequent trials without visual feedback. The sustained

aftereffects, indicative of a permanent reconfiguration of the previously learned controller, were weaker in the 4-session group, suggesting a controller more stable against permanent reconfiguration, and on which re-aiming could be more easily applied. We speculate that this reconfiguration may occur even in conventional adaptation paradigms which apply similar perturbations to more strongly established baseline controllers.

**Title:** Trial-by-trial updates of internal models during interactive motor learning

**Authors: *S. GAKU**[1], S. KASUGA[1], J. USHIBA[2]
[1]Grad. Sch. of Sci. and Technol., [2]Dept. of Biosci. and Informatics Fac. of Sci. and Technol., Keio Univ., Kanagawa, Japan

**Abstract:** We empirically know that in some situations motor skills can improve greater when multiple persons practice together, compared to when they practice alone. A previous study experimentally showed such a synergistic effect during motor learning (Sacheli *et al*, 2012); however, behavioral changes were only investigated in a pre-post design. Therefore, it is unclear how behaviors are interacted in a trial-by-trial manner. In the current study, we aimed at investigating the mechanism in which the visual error information resulting from one person's motor action implicitly updated another person's motor adaptation process. In order to quantify a trial-by-trial interaction of adaptation, we applied Granger causality analysis for the data of an arm-reaching task with visiomotor rotation. Nine pairs of healthy adults participated in this study. They performed 600 trials of a planner center-out reaching task on a computer monitor, using a custom-made manipulandum. Participants were able to see their own and the partner's cursor at the same time on the personal monitor. The cursor of either participant was rotated in ±30 degrees at about 20% of random trials, in the same amount of trials for each participant. As a control experiment, the same participants performed the same task individually in a separate day. To investigate the effect of a partner's movement on one's motor adaptation process, firstly we analyzed the amount of error correction in the next trial of rotation for both perturbed and unperturbed participants. Error correction was significantly decreased compared with the individual control condition ($p$=0.011 ) implying that adaptation of the perturbed participant was interfered by the unperturbed partner's movement that exhibited little error. To further examine the variability of this effect, we computed Granger causality by using trial-by-trial time series of a pair of participants' initial movement direction. We found a significant effect in 6 participants,

indicating the influence from one participant's movement on the other's movement. Furthermore, we found a positive correlation between the difference in the maximum speed of reaching between 2 participants, and a measure of goodness-of-fit for Granger causality model (i.e., F-value; $r = 0.507$, $p = 0.002$), suggesting that the more the speed is different within a pair, the more the slower one is influenced by the faster partner. Overall, the current findings suggest that the brain has the implicit motor learning process which is updated by both own and another person's visually fed-back errors, and that knowledge of the difference on kinematic properties may be related to the strength of the interaction.

**Abstract:** The human motor system is capable of a range of actions that are modified through experience. Significant work has tested various hypotheses on the underlying learning mechanisms by measuring human behavior in simple behavioral paradigms. This has provided the basis for different theoretical models on how the central nervous system interprets errors and subsequently modifies motor commands. Although these studies have provided significant insight, the changes in biomechanics during learning have been given little attention. In this study, we developed an integrated framework to concurrently probe the biomechanical and muscle activation patterns involved in a simple and highly studied motor learning paradigm. Here, subjects interacted with a robotic manipuladum, and adjust reaching movements in response to a physical perturbation to the limb motion. We provided no mechanical support to the arm so that we could examine the motion of the upper extremity (upper arm, forearm and hand) about the elbow during the compensation. These motions were measured by a custom designed motion capture device, and muscle activities were measured by a wireless EMG system, both synchronized with the robotic manipuladum. The data were used to develop subject specific OpenSim models of the upper extremity dynamics in order to analyze the unique joint kinematics and muscle activation patterns during the motor learning trials. We observed a

significant variation between subjects on how the compensatory response utilized the redundant degree of freedom (the elbow joint in this setting). Together, our subject specific results demonstrate that a thorough understanding of the changes in the biomechanics and muscle activation patterns that accompany motor learning may provide additional insight into the concurrent mechanisms that drive motor learning.

**Title:** The influence of sequence learning on force adaptation

**Authors: *Y. LIU**, H. BLOCK
Dept. of Kinesiolgoy, Indiana Univ. Bloomington, Bloomington, IN

**Abstract:** Sequence learning and sensorimotor learning occur together in nature. For example, to play the violin, a student must learn not only the sequence of notes, but also how to move each hand and arm to the correct position with the correct timing, how much force to exert with the bow on the string, and so on. Sensorimotor and sequence learning have much in common, including dependence on working memory and developmental stage, and similar activation of the motor cortex, left dorsal prefrontal cortex, and cerebellum. However, these processes are often studied in isolation. It is unclear whether an implicit sequence would enhance sensorimotor learning, perhaps by making the movements easier to predict, or whether it would interfere with sensorimotor learning, for example by increasing working memory demands. Here we combined a serial reaction time task (SRTT) and a force field adaptation task to investigate this question. Participants performed 40 trials in total: 5 baseline, 25 adaptation, and 10 washout. Each trial consisted of 12 sequenced or randomized reaches among four targets arranged in a square. Subjects grasped a robotic manipulandum (KINARM) throughout. In the block of adaptation trials, an external force was applied perpendicular to the ongoing reaching direction for the sequence/force (N = 3) and random/force (N = 2) groups, while the sequence/null group (N=1) performed sequenced reaches with null force throughout. Participants were asked to reach as fast and straight as possible. The change in reaction time was quantified as the difference in seconds between the last washout trial and the first adaptation trial. This was -0.059 ± 0.016s vs 0.009 ± 0.011s vs -0.059s for the sequence/force, random/force, and sequence/null groups. The decrease in reaction time for the sequence groups suggests that sequence learning occurred. Movement

error was quantified as max perpendicular deviation from the straight line path connecting start and end target. Force adaptation magnitude was quantified as the difference between max perpendicular error on the first and last trials of the adaptation block. This was 3.93 ± 0.11cm in the sequence/force group and 3.69 ± 0.45cm in the random/force group. Negative aftereffect of force adaptation was quantified as the difference between the last baseline trial and the first trial of the washout block. This was -2.94 ± 0.05cm vs -4.17 ± 0.26cm for the sequence/force and random/force groups, respectively. Preliminary data thus suggests that negative aftereffect, reflecting learning and storage of the adaptation, may be reduced when force field learning is accompanied by sequence learning.

**Title:** Increasing motor noise impairs reinforcement learning in healthy individuals

**Authors: *A. S. THERRIEN**[1,2], D. M. WOLPERT[3], A. J. BASTIAN[1,2]
[1]Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Ctr. for Movement Studies, Kennedy Krieger Inst., Baltimore, MD; [3]Univ. of Cambridge, Cambridge, United Kingdom

**Abstract:** Motor variability is crucial to the process of reinforcement learning. It allows the system to explore possible solutions to a task and select those that yield rewarding outcomes. However, in addition to exploration, motor variability also reflects signal noise from stochastic and/or faulty neural processing. While the motor system may possess an internal estimate of exploration variability, it cannot estimate (and thus cannot learn from) variability from noise. Thus, a high proportion of motor variability from noise may impair reinforcement learning by disrupting the mapping between an action performed and the outcome feedback received. We have previously shown that increased motor variability from noise may underlie reduced reinforcement learning performance in individuals with cerebellar damage. Here we examine whether increasing noise in neurologically healthy individuals impairs reinforcement learning in a similar manner to that seen in cerebellar patients. Our experimental task requires participants to use binary feedback signaling to learn to rotate their reach angle in a series of directions. By comparing task performance between conditions with different levels of added noise, we show that adding a small level of noise does not impair learning, but adding a larger level – matched to a group of cerebellar patients – does. Using a mechanistic model, we find that adding a low level

of noise leaves a sufficient proportion of motor variability that can be estimated by the motor system allowing subjects to learn. However, adding a high level of noise leaves participants with an insufficient proportion of estimable variability and this reduces learning performance. Importantly, in a second experiment, we show that clamping the reinforcement rate to that observed in the high noise condition does not impair learning. Finally, by comparing performance between healthy individuals with noise added to their movement and a group of cerebellar patients, we find that the added noise does not impair the control group's learning to the same degree observed in the patient group. We suggest that this may be attributed to a discrepancy between the nature of the added noise in the present study and the source of noise in the cerebellar patients. Overall, our results suggest that motor variability from noise interferes with reinforcement learning. Additionally, we show that a threshold may exist for motor noise, above which the remaining proportion of variability that can be estimated is too small for the motor system to learn from effectively.

**Title:** Dissociating learning- and non-learning-related performance changes during motor skill training in older adults

**Authors: *S. Y. SCHAEFER**[1], N. SCHWEIGHOFER[2]
[1]SBHSE, Arizona State Univ., Tempe, AZ; [2]USC, Los Angeles, CA

**Abstract:** Motor learning has long been thought to decline with age, given that older adults tend to show less improvement from before to after a training session compared to younger adults. Recent data has challenged this idea, however, showing that 'old old' adults (over age 75) do not necessarily learn a novel motor skill less or slower than 'young old' adults (ages 65-74) (Schaefer et al. 2015). A nonlinear mixed-effects model of motor learning may give new insights into the true effects of aging by dissociating learning from other factors unrelated to learning, like fatigue (Park and Schweighofer, 2017). This approach models non-learning-related changes as an increasing linear term that captures performance decrements later in training, in addition to the more traditional 'learning curve' that shows exponential (nonlinear) improvements in

performance early on in training. In other words, older adults' final performance at the end of a training session may not necessarily reflect their motor learning ability. Currently this nonlinear mixed-effects model has been developed to quantify learning of only a reaching task. Thus, the purpose of this study was to test whether this model generalizes to the learning of a more functional, real world motor skill that involves reaching, grasping, and object manipulation. Twenty-eight adults (ages 39-89; median 73 years) completed 150 trials of a functional upper extremity motor task over three days (50 trials/day). Each trial equaled 15 repetitions, where one repetition required participants to use a plastic spoon to transport two raw kidney beans at a time to one of three distal targets using their nondominant hand. Most improvement occurred by the $30^{th}$ trial within the first day. Participants did vary, however, on how much they retained one month later (-9.5% to 46.29% of initial performance). Model fits from the first 30 trials showed a significant relationship between the amount of learning parameter, A, and the observed amount of skill retention one month later ($r=0.44$; $p=0.02$). Normalizing the learning parameter to each participant's initial performance improved the prediction of one month retention ($r=0.50$; $p=0.007$). Interestingly, the non-learning-related parameter, C, was significantly related to age ($rho=0.48$; $p=0.009$). These findings not only demonstrate the robustness of this model in predicting how responsive older adults will be to training on more complex motor skills, but also provides new insights into how fatigue or other age-related effects may have been misinterpreted as impaired motor learning in previous studies in older adults.

**Abstract:** Motor learning diminishes with aging, such that older adults tend to learn less and at a slower rate than younger adults. Poorer motor learning may, in part, be linked to more general age-related cognitive impairments. For example, in patients diagnosed with amnestic Mild

Cognitive Impairment, their ability to learn a functional motor task is related to their performance on a battery of visuospatial tests. The purpose of this study was to test whether these findings generalized to a sample of 24 age-matched older adults with no memory impairment. All participants were assessed with the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS), from which age-adjusted scores for five cognitive domains were extracted. Participants' baseline performance on a motor task designed to improve upper extremity motor function was also measured prior to a short (9-trial) practice session; motor performance was re-assessed one week later. Motor performance was quantified as the time to complete a given trial of the task, with faster times indicating better performance. Stepwise regression indicated that the visuospatial/constructional index of the RBANS was the only cognitive domain that significantly predicted one-week follow-up motor performance ($R^2$=0.24; p=0.04) once baseline performance was accounted for. As the visuospatial/constructional index is comprised of a line orientation subtest and a complex figure copying subtest, further regression analysis indicated that the line orientation scores were most related to the amount of improvement at one week (p=0.02). These findings are consistent with prior work showing that visuospatial tests may be used prognostically to identify motor learning deficits in older adults, irrespective of any other memory impairments. Future directions will explore the underlying neural mechanism of why visuospatial tests appear to uniquely capture the aging brain's motor learning capacity.

**Title:** Predicting motor skill retention in older adults with the visuospatial/executive subtest of the Montreal cognitive assessment

**Authors: *P. WANG**, S. Y. SCHAEFER
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

**Abstract:** Older adults tend to learn novel motor skills at a slower rate and to a lesser extent than younger adults, yet cognitive decline may in part explain the effect of age. In fact, older adults'motor learning capacity may depend on their visuospatial function, rather than on their global cognitive status or their age itself. In adults over 65 with and without significant memory

deficits (i.e., Mild Cognitive Impairment), lower scores on standardized visuospatial tests like line orientation and complex figure copy are associated with less retention of a motor skill. These tests, however, can take tens of minutes to complete, and are typically administered as part of a much longer and comprehensive neuropsychological battery. Thus, the purpose of this study was to determine whether a briefer cognitive screening tool could predict motor skill retention as well. To do so, data from 36 adults over age 65 with no diagnosis of Mild Cognitive Impairment were retrospectively analyzed. Cognitive status was tested with the Montreal Cognitive Assessment (MoCA), which is very brief (under 5 mins) and yields individual subtest scores (Visuospatial/Executive, Naming, Language, Attention, and Delayed Recall) that are summed for a total score of 0-30. Participants also completed fifty trials of a functional novel upper extremity motor task involving reaching, grasping, and object manipulation with their nondominant hand. Skill retention was measured as the amount of improvement retained on the motor task at a 24-hour follow-up, relative to their first trial. Some participants improved by +47%, while others were worse 24 hours later (-19% change). Stepwise regression revealed that the Visuospatial/Executive score alone significantly predicted skill retention ($R^2$=0.25; p=0.003). For reference, the Visuospatial/Executive subtest includes drawing the face of a clock from memory and copying a simple drawing of a cube. Moreover, the effect of age on skill retention was accounted for by Visuospatial/Executive score, such that age was not a significant predictor (p=0.14), nor were any other MoCA subtest scores. Thus, older adults may have less motor learning capacity than younger adults due to age-related declines specifically in visuospatial function, rather than due to just their chronological age alone or other cognitive deficits. While clinical visuospatial tests may be used to predict the extent of motor skill learning in older adults, future research is needed to determine which aspect of visuospatial function (e.g., visual perception, visual attention, mental rotation) is the most critical.

**Title:** Using a real-world chopping task to study motor memory of competent and expert choppers

**Authors: *A. H. NEPOTIUK**, L. E. BROWN
Trent Univ., Peterborough, ON, Canada

**Abstract:** As we learn as specific skill, we develop a motor memory for that task. As people practice to become an expert at a particular task, they may practice specific strategies to achieve a larger skill goal. For example, when practicing to throw a ball, someone might focus on different aspects of the movement in order to achieve the goal of an accurate throw. This may lead to the development of separate motor memories for different task-relevant variations in experts that are not present in people who are competent, but not experts, at performing the task. Task interference is a tool used to study the representation of task performance in motor memory. This paradigm has been used with reaching adaptation tasks (visuomotor rotation and/or force-field learning). Participants in these experiments are already experts at the base task (point-to-point, planar reaching) and their ability to adapt reaching to the imposed perturbation is studied. The pattern of data induced by the perturbation is used to make inferences about the nature and neural correlates of our performance and memory for reaching perturbations, specifically, and motor performance in general. These studies have revealed that memory for the perturbation is formed, and that it is fairly general (it generalizes somewhat to other locations in the workspace or to other hands, for example). We will pair this interference paradigm with an ecologically valid vegetable-chopping task, where we can easily recreate natural performance settings using a task for which we can easily identify experts and competent performers, to compare the representations of knife-skill memory of these two groups.
Participants' performance will be recorded using a motion tracker. Subjects perform a chopping task in which they are asked to chop a sweet potato into 5 mm-wide slices, matching the beat of a metronome (120 bpm). Following this initial performance, participants are exposed to an interference condition where the frequency of chopping is increased or decreased. Participants then perform trials of the original task again. Measures of movement time, slice width and variability are taken. Interference is inferred if the second performance of the original task is impaired, compared to initial performance and that of controls. We believe that competent performers will experience more interference than experts, and that the type and direction of error experienced will illustrate the nature of the differences in motor memory between competent and expert performers

**Title:** Dissociating the influence of postural and visual shifts on the transfer of motor adaptation to novel workspace locations

**Authors: *W. ZHOU**[1], K. COLUCCI-CHANG[1], S. M. CHASE[2,3], W. M. JOINER[1]
[1]Bioengineering, George Mason Univ., Fairfax, VA; [2]Dept. of Biomed. Engin., [3]Ctr. for Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

**Abstract:** Adaptation paradigms that alter the relationship between movement and their sensory consequences provide a method to study the properties of short-term motor learning. Here, we examined how the transfer of such error-driven motor learning to a novel workspace is influenced by dissociated changes in posture and vision. We trained two groups of right handed subjects (N=32 in both groups) to move a robotic manipulandum and perform point-to-point reaching arm movements with their right hands. One group adapted arm movements in response to novel dynamics (force-field perturbations, FF). The other group adapted to alterations in visual feedback (visuomotor rotation perturbations, VMR). There were two workspace locations: A (9 cm right of midline) and B (9 cm left of midline). After reaching asymptotic performance in one workspace, subjects were either tested for retention in the same workspace or transfer to the other workspace under three conditions. (1) Visual transfer: movements made in the trained workspace, but visual feedback provided at the other. (2) Postural transfer: visual feedback at the trained workspace, but movements made in the other. (3) Combined transfer: both visual feedback and movements provided/made in the untrained workspace. The perturbation direction (toward vs. away from midline) and transfer direction (A to B vs. B to A) were counterbalanced across subjects. For both FF and VMR perturbations, we found that the combined transfer condition resulted in the lowest amount of generalization ($P < 0.001$), with intermediate generalization for postural and visual transfer. There was no significant difference between the postural and visual transfer when all results were combined regardless of perturbation or transfer directions ($P > 0.3$). However, by specifically comparing the transfer by perturbation directions, we found that for FF perturbations towards the body, the postural transfer was significantly greater than the visual transfer ($P < 0.001$). Further, visual transfer was significantly greater than postural transfer ($P < 0.001$) when perturbations were away from body. For VMR, we found that the reverse relationships were significant (e.g., the visual transfer was significantly greater than the postural transfer for perturbations towards the body). Together, these results suggest that movement planning and perturbation modality collectively influence the extent of motor adaptation generalization, implicating an important role of higher level cortical processing.

**Authors: *R. B. SINGH**[1], L. ALHUSSEIN[2], M. A. SMITH[3]
[1]Sch. of Engin. and Applied Sci., [2]SEAS, [3]Sch. Engin., Harvard Univ., Cambridge, MA

**Abstract:** Motor skills that require high spatio-temporal precision often develop over years of practice. Studies of simple motor skills, which can be mastered over a few hours of practice, regularly show an initial period of rapid improvement with practice, but diminishing gains with additional practice as performance approaches ideal levels. In realistic every-day movements however, asymptotic performance is often less than ideal. Basketball provides a poignant example: despite improved training methods and years of dedicated player practice, the mean free-throw shooting percentage of professional basketball players in the NBA has remained essentially unchanged over the past 50 years, with the league-wide shooting percentage at 73.2% in the 1966-67 season and 77.2% in the 2016-17 season. Seeing such stark constancy, we wondered what may be limiting free-throw shooting performance. As temporal delays in

feedback have been shown to impair both reinforcement learning and neuronal plasticity, we hypothesized that the temporal delay between movement execution and the resulting success/failure in free throw shooting may be limiting performance, and that substantially reducing this delay will increase performance. To test this hypothesis, we can provide shooters with feedback indicating shot outcome well before they would normally see it themselves (~1 second after ball release). However, providing such early feedback is a challenge in that it requires an accurate prediction of shot outcome based on information available early in the free throw. While the biomechanics of postural changes during the act of shooting should, in theory, predict shot outcome, the relationship between biomechanics and shot outcome is idiosyncratic. In contrast, the physics of ball motion after release is universal, depending on the physics of projectile motion rather than the biomechanics of shooting. Thus, we focus on predicting shot-outcome based on the initial position and velocity of the ball immediately after release. To estimate the initial state, we have developed a high accuracy stereo computer-vision system to detect ball position in 3D. In particular, we developed novel methods for detecting ball position with subpixel accuracy from video frames, and for improving the 3D stereo camera calibration via better localization of calibration features. With this system, we are currently able to detect a basketball's position within 1 mm on average within a scan volume of approximately 10 cubic meters. The current accuracy would allow for 90% accuracy in predicting shot-outcome.

**Abstract:** How the human brain controls arm movement is important in refining brain-computer interfaces (BCIs) for the development of upper-limb neuroprostheses. Many earlier decoding methods used recorded sensorimotor signals, as well as the parietal and premotor cortices. However, it is unknown whether movement-related signals in these regions can predict force

magnitudes generated by the upper-limb, or how these regional cortical activation occurs as a function of upper-extremity kinetic output. We investigated electrocorticographic (ECoG) data collected from 3 patients, undergoing epilepsy monitoring with normal pre-operatively motor function, during directed isometric arm force and power grasp tasks.

In one task, one subject was prompted via visual cues to apply isometric force in one of 6 directions (up, down, left, right, forward, backward) to an affixed AMTI force transducer handle with approximately 15lbs (67N) of force; there were 3 seconds of rest after each hold. In a separate task, two subjects prompted to grasp a pneumatic dynamometer and applied one of 3 force conditions (0kPa, 20kPa, 40kPa) which was displayed on a pressure gauge. γ- and β-band spectral power were extracted across implanted ECoG electrodes and compared to captured force and pressure in the two tasks respectively.

We found a time-averaged linear relationship between γ-band log-spectral power and sustained grasping force output with visual feedback. However, the same linear relationship between spectral power and cued isometric force generation, without concurrent visual feedback, in arm force application was not found. We find that a combined feature of γ- and β-band spectral power can be successfully used to predict sustained kinetic outputs that are generalized in both grasping and arm force applications.

**Title:** Transient paresthesias experienced during closed-loop deep brain stimulation

**Authors: *M. C. THOMPSON**[1], B. C. HOUSTON[2], T. E. BROWN[3], J. G. OJEMANN[4], A. L. KO[4], H. J. CHIZECK[1]
[1]Electrical Engin., [2]Neurosci., [3]Philosophy, [4]Neurosurg., Univ. of Washington, Seattle, WA

**Abstract:** Introduction: Paresthesias, defined as unnatural tactile sensations such as “pins-and-needles,” are a known side effect of deep brain stimulation (DBS) for neurological movement disorders. In traditional DBS therapy, paresthesias are experienced only briefly (less than 1 minute) after stimulation is initiated. It has not previously been shown how paresthesias may manifest during closed-loop DBS (CLDBS), where stimulation parameters are modified in real time based on feedback from worn or implanted sensors. We investigated subject-reported paresthesias as a function of stimulation parameters for CLDBS.
Methods: Perceptions of paresthesias were tested in 2 subjects with a DBS system (Medtronic Activa PC+S) for essential tremor implanted in the ventral intermediate nucleus (VIM) of the thalamus contralateral to the affected limb. Paresthesias were intentionally evoked during a pseudorandom series of stimulation updates (bipolar stimulation of clinically effective contacts, 0-4 V, 0-2.5 V/s) while subjects were asked if they experienced physical sensations. Subjects were at rest and blinded to the stimulation parameters. Queries were made to subjects during both ramp and hold periods. The location, strength, and quality of sensations were recorded at each query (ex: “In my right arm I feel weak tingling”). After the experiment, paresthesias for each test were coded on a scale from 0 (no paresthesias experienced) to 3 (strong paresthesias experienced).
Results: Paresthesias were experienced in the upper and lower limbs contralateral to the implanted electrode (Patient 1) and in the scalp (Patient 2). Patients described paresthesias as a radiating tingling or “electric” feeling ranging from very mild to very strong. Paresthesias were only experienced during and immediately following increasing ramp periods, and were not experienced during decreasing ramp or hold periods. We found that slew rate, absolute voltage, and total change in voltage all contributed to the strength of paresthesias. Particularly, slew rates above 1 V/s often caused noticeable paresthesias at therapeutic voltage levels.

Conclusion: Our results indicate that paresthesias could be more prevalent during CLDBS than during traditional DBS. Furthermore, prevention of paresthesias may be at odds with development of algorithms that respond quickly via high slew rates. In addition to precautions that are typically taken during patient programming to avoid high voltages that may elicit side effects, CLDBS requires consideration of additional parameters—such as slew rate—to avoid undesirable side effects.

**Title:** Neural prediction of motor activity in natural data with multimodal techniques

**Authors: *X. WANG**, A. FARHADI, J. OJEMANN, R. RAO, B. BRUNTON
Computer Sci. and Engin., Univ. of Washington, Seattle, WA

**Abstract:** There have been many successes in using experimental ECoG (Electrocorticography) and EEG (Electroencephalography) studies to decode brain activity; however, natural data has been rarely analyzed. Signals collected from humans “in the wild” are affected by a noisy environment and modulated by a complex range of behaviors. The goal of home Brain-Computer Interface (BCI) use and long-term neural monitoring will need to be robust to these factors. As well, with the great advancements in machine learning and computer vision in recent years, recordings of multiple modalities can provide information about a patient’s behavior without the need of strict experimental protocols. In this project, we collected thousands of hours of simultaneous video (including a depth channel), audio and neurophysiological data from patients undergoing clinical long term monitoring for more than 10 ECoG patients. Previously, we were able to show that the latest state-of-the art techniques based on deep learning can track human upper arm joint coordinates accurately from the video. Our current results show and compare the brain mapping and decoding as well as prediction of motor movement from the natural ECoG signals using various neural network models. We also begin to elicit some insight into neural functions using this novel data and technique. Our approaches overall show the value and

opportunity of natural data, especially when combined with fully automated video and audio analyses.

**Title:** Human parahippocampal dynamics during visuomotor rotation tasks

**Authors: *J. WU**[1], L. LEVINSON[5], K. CASIMO[2], R. P. RAO[3], J. G. OJEMANN[4]
[1]Ctr. for Sensorimotor Neural Engin., [3]Dept. of Computer Sci. and Engin., [4]Dept Neurosurg., [2]Univ. of Washington, Seattle, WA; [5]Wesleyan Univ., Middletown, CT

**Abstract:** Cortical decoding of dexterous upper-body movements, especially during dexterous manipulation, relies on the consistent understanding of the representation of spatial coordinates in visual and motor systems. However, the mechanisms and cortical regions that underlie our ability to rapidly adapt to visuomotor rotation is unclear. A generalized model of how visual processing of spatial cues combine with existing motor skills to effect future motor planning behavior is required for the development for future decoding of volitional control of assistive prosthetics.

We investigated spatial-time-frequency models of cortical signals during a touchpad-navigated virtual maze task, recorded in epileptic patients with implanted clinical stereotactic EEG (sEEG) electrodes and clinical electrocorticography (10mm spacing). Patients were instructed to repeatedly navigate an avatar through a virtual maze, following a mandated path through a series of markers. Maze navigation were performed while observing the same maze in world-centered reference frame, from one of 4 possible camera angles, panned at 0° (unrotated), 45°, 90°, and 180° around the maze.

We observed viewing-angle-specific tuning of γ-band spectral power in sEEG recordings of dorsal parahippocampal regions. The tuning depth of the spectral power are task-performance dependent to the degree of visuomotor adaptation, controlled for instantaneous finger movement velocity and movement direction. We further observe two behavioral correlates of the strength of

visuomotor adaptation as a characteristic tradeoff between task performance error and performance speed, and examine the relationships between viewing angle and the relative success rate of transferring adaptation between viewing angles. The temporal dynamics and connectivity between primary motor cortex and dorsal parahippocampal regions may offer a high degree of information about visuomotor adaptation learning.

**Title:** Electrodeposited platinum-iridium coating (EPIC) improves in-vivo chronic recording performance of microwire electrode arrays (MEA)

**Authors: *I. R. CASSAR**[1], C. YU[1], A. PETROSSIANS[5], J. J. WHALEN[5], C. D. LEE[5], J. SHARKEY[6], W. M. GRILL[1,2,3,4]
[1]Biomed. Engin., [2]Neurobio., [3]Neurosurg., [4]Electrical and Computer Engin., Duke Univ., Durham, NC; [6]Engin. R&D, [5]Platinum Group Coatings LLC., Pasadena, CA

**Abstract:** Chronic recording of single unit neural activity is an essential tool of neuroscience and useful for neuroprosthetic applications, i.e., brain-machine interfaces. Although single unit recordings are highly informative, unit yield and signal quality degrades over time. One potential cause of this degradation is biofouling of the electrode tip, which can increase electrode impedance, contribute to loss of neurons, and ultimately reduce unit yield and signal quality. We quantified the performance of chronically implanted microwire electrode arrays (MEAs) coated with electrodeposited platinum-iridium coating (EPIC) and compared the performance to uncoated electrodes on the same arrays in the same animals. We implanted seven rats with 16 channel, 0.5 MOhm platinum-iridium MEAs in the substantia nigra pars reticulata. The individual electrodes within each MEA were randomized between a coated and uncoated group. Every week to two weeks we measured electrode impedance at 1 kHz and conducted five-minute unit recordings between 0 and 12 weeks after implant. Electrode impedance, unit yield, and signal to noise ratio (SNR, calculated as the peak amplitude of the unit over the RMS of the noise) were compared via repeated measures ANCOVA, with results given as mean ± SE. The initial impedance of the EPIC microwires (365 ± 88 kOhm) was significantly lower than the uncoated group (991 ± 77 kOhm, $p < 0.01$). The impedance of the uncoated microwires significantly increased over time (+45 kOhm/week, $p < 0.01$), as is typical for implanted arrays. However, the impedance of the EPIC microwires did not change significantly over the same period ($p = 0.73$). The EPIC microwires also had a higher average number of discernable units per electrode in each array (0.80 ± 0.06) than the uncoated microwires (0.39 ± 0.06, $p < 0.01$). In addition, the number of units per electrode increased over time in the EPIC group (+0.045

units/week, $p < 0.01$), but did not change in the uncoated group. There was no significant difference in the SNR between the coated and uncoated microelectrodes. Immunohistochemistry to visualize gliosis (ED1, GFAP) in select animals did not reveal any discernable difference between the response to coated vs uncoated electrodes. This suggests that the increases in recording performance are due to a reduction in biofouling and not prevention of gliosis. The EPIC coating appeared to maintain low electrode impedance over time, and resulted in more discernable single units. With this improved performance, chronically implanted microwires should provide higher quality units for longer durations, thus increasing the feasibility of future brain-machine interfaces.

**Title:** The “Oops” Detector: Spontaneous vs in-task error-related potentials in long-term humanelectrocorticography

**Authors: *N. R. WILSON**[1], X. WANG[2], R. C. SHEAN[3], J. G. OJEMANN[4], R. P. RAO[2], B. BRUNTON[5]
[1]Bioengineering, [2]Computer Sci. and Engin., [3]Microbiology, [4]Neurosurg., [5]Biol., Univ. of Washington, Seattle, WA

**Abstract:** In interaction with our surroundings, we constantly receive and interpret feedback regarding our actions, allowing our brain to assess discrepancies between expected and actual outcomes. These error-related signals are vital to how we adjust our behavior. Reward and error have been the subjects of extensive study over the past decades in multiple modalities and timescales; however, these studies have primarily focused on in-task error in well controlled experiments.
Here, for the first time, we compare in-task errors that occur in an instructed context with spontaneous errors committed by the same subjects in a naturalistic, task-free setting using a long-term human electrocorticography (ECoG) dataset. For the in-task errors, the subjects performed a word and picture association task. Spontaneous errors were extracted from 4 days of recordings per patient using automatic speech recognition of error-related keywords (e.g., “oops,” “sorry,” and various expletives). These keywords indicated the patient had realized their mistakes; we sorted each instance based on if they had been uttered in an error or non-error (control) context.
In preliminary results (n=3 patients), we compared high-gamma (70-100Hz) power across spontaneous and in-task errors. We found increased activation in the ventrolateral prefrontal cortex in both conditions; in addition, we found activation in Brodmann Area 8 (BA8) only in the natural condition (Figure 1). As activation in BA8 is thought to be associated with uncertainty estimation, this increased high-gamma power implies the subjects may be more uncertain of mistakes made in the natural context. These results suggest there may be important differences between error-related potentials for mistakes made inside and outside of strictly controlled experiments; further, they motivate further investigation of error and reward in spontaneous behavior, an analysis enabled by automated algorithms for extracting features from long-term monitoring.

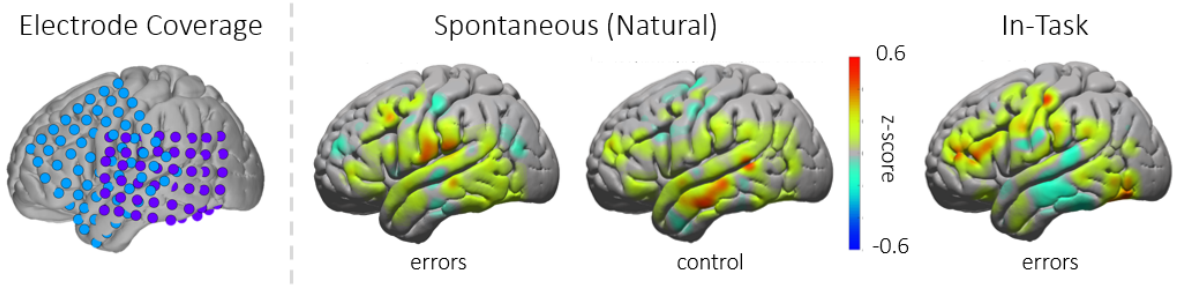

**Figure 1. Differences in high-gamma activation between errors committed in the naturalistic vs in-task contexts.** Mean high-gamma power (normalized to baseline) from two subjects were plotted on a standard MNI brain. A third subject was analyzed with electrode coverage on the right hemisphere (results not shown). Error-related potentials were computed for in-task errors, spontaneous errors, and also compared to a spontaneous control condition.

**Title:** Changes in network properties of a neuronal ensemble with acceleration and deceleration of point-to-point arm movements

**Authors: *M.-K. KIM**[1], J.-W. SOHN[2], S.-P. KIM[3]
[1]UNIST, Ulsan, Korea, Republic of; [2]Daegu-Gyeongbuk Med. Innovation Fndn., Daegu, Korea, Republic of; [3]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

**Abstract:** A point-to-point arm movement generates a bell-shaped speed profile. It implies that the acceleration and deceleration at two end-point always sequentially occurs with almost equal distribution. Whether and how such coordination of acceleration and deceleration is directed by motor cortical neurons has been of great interest but it is still not fully understood. One of the reason is that speed information is poorly encoded in single neuronal level. However, there is a possibility that an ensemble of neurons, rather than individual ones, may represent speed modulation more clearly. Particularly, dynamics of networking among neurons may be related to the coordination of acceleration and deceleration in point-to-point arm movements. Hence, we aimed to study network properties of primary motor cortical (M1) neurons of non-human primate performing a two-dimensional center-out task. In the analysis, we first divided spiking activities into subsets for the acceleration and deceleration periods during each movement. Then, we fitted a linear regression model to individual firing rates against the hand speed for every subset and utilized the fitted model parameters to build correlation matrices between neurons. In doing so, the correlation matrices were attained for acceleration and deceleration periods, respectively. From the correlation matrices, an adjacency matrix among M1 neurons was constructed by selecting significantly correlated pairs. The network analysis based on the graph theory was conducted to evaluate a number of network metrics, including a small-world-ness index (SWI). The analysis results revealed that SWI was higher for acceleration than deceleration during arm-reaching movements. On the contrary, SWI was higher for deceleration than acceleration during arm-pulling movements. It indicates that M1 neuronal network became more efficient when accelerating arm movement from the body toward a distal location while it became more efficient when decelerating arm movement from a distal location toward the body. Our results suggest that inter-neuronal networking dynamics in M1 may be related to the coordination of

acceleration and deceleration of point-to-point arm movements, which can depend on movement directions pivoting on the body.

**Title:** Chronic intracortical recordings from microelectrode arrays implanted in common marmosets (Callithrix jacchus)

**Authors: *S. DEBNATH**[1], N. W. PRINS[2], R. MYLAVARAPU[1], E. A. POHLMEYER[4], S. GENG[1], J. C. SANCHEZ[5], A. PRASAD[3]

**Abstract: Background:** Current neuroprosthetics rely on stable, high quality recordings from chronically implanted microelectrode arrays in neural tissue. Microelectrodes implanted in brain tissue can be affected by multiple abiotic and biotic factors that lead to degradation in recording quality, ultimately resulting in electrode failure. While chronic electrophysiological recordings and electrode failure modes have been reported from larger non-human primates, chronic recordings in primary motor cortex from the marmoset model have not been previously described. This study tracks the recording stability and signal quality of microelectrode arrays chronically implanted in behaving marmosets.
**Methods:** Six adult male marmosets were trained to complete reaches for two or four targets and cortical activity was recorded while the animal performed the reaching tasks. After the animals were trained, one 16-channels microelectrode array (MEA) was implanted in the hand and arm region of the primary motor cortex (M1) and another MEA in deep brain structures (targeting the nucleus accumbens). Spike sorting was used to isolate single unit activity from background noise. Signal stability and quality was quantified as a function of single-to-noise ratio, array yield (defined as the fraction of active electrodes that recorded neuronal activity), and neuronal yield (defined as the number of isolated units during a recording session).
**Results:** Neuronal yield and array yield were calculated weekly for the implant duration for each

animal. Out of 11 implanted electrode arrays, 9 arrays provided functional recordings for at least 3 months, with 2 arrays functional for 10 months. In general, all implants had high array and neuronal yield after implant, which remained stable for up to several months. Exceptions resulted from mechanical failure of the MEA itself. In the longest implants, signal degradation occurred, characterized by gradual decline in signal-to-noise ratio, reduced number of isolated single units, and changes in the waveform shape of action potentials.
**Conclusions:** This study shows the feasibility of long-term recordings from marmosets using microelectrode arrays implanted in cortical and deep brain structures. Good quality signals, used to control a brain-machine interface, were recorded up to several months in this animal model. Electrode failure modes could be identified, with mechanical failures related to the MEA occurring most often. The ability to chronically record cortical signals for neural prosthetic applications in the common marmoset suggests the potential of this model in neural interface research.

**Abstract:** Chronically implanted microelectrodes in the neural tissue elicit inflammatory responses that are time varying and have been shown to depend on multiple factors. Among these factors, BBB-disruption has been hypothesized as one of the most dominant biotic factor resulting in electrode failure. Studies have shown the chronic sequelae of electrode-implant related cortical injury in slow-inserted microelectrode arrays (MEA). Typically, microwire arrays and silicon probes are inserted slowly into the neural tissue whereas the silicon Utah MEAs (UMEA) are inserted at a high speed using a pneumatic inserter. Here, we report the sequelae of

electrode-implant induced injury at various acute time-points in fast-inserted UMEA in the brain tissue. Adult, male Sprague Dawley rats (n=50) were used in the study. Animals were divided into implant and stab control groups. All stab animals underwent similar surgical and implantation procedure, however, the UMEA was taken out of the tissue slowly after implantation for stab control animals. We used quantitative polymerase chain reaction (qPCR) to quantify the expression of genes directly involved in the inflammatory and BBB-disruption. For qPCR, we evaluated animals (n=5 for each time-point) implanted for 6-hr, 24-hr, 48-hr, and 72-hr time points, respectively with matched stab controls (n=5) for each time points. We used n=10 rats as naïve controls with no implant or surgery to obtain a baseline of the expression in healthy unimplanted animals. Gene expression was quantified using the $RT^2$ PCR primers for rat inflammatory cytokines for key genes mediating the inflammatory response and tight junction (TJ) and adherens junction (AJ) proteins that form the BBB and are critical to the functioning of the BBB. Our results indicate significant inflammation as suggested by >10-fold expression relative to naïve controls for most pro-inflammatory genes in both groups across all time points. Moreover, there was no significant difference between the stab and implant groups at these time-points suggesting the effect of insertion on both groups. Expression levels for the genes that form the TJ and AJ of the BBB were downregulated suggestive of extensive vascular disruption and BBB-damage. The results of this study provide an insight into the physiological events following BBB-disruption that can lead to neuroinflammation and neuronal degeneration. The gained mechanistic insights into BBB-disruption following fast insertion of UMEAs may provide new opportunities for targeted therapeutics to prevent or reduce neurodegeneration normally observed following UMEA insertion and improve electrode performance.

**Title:** The effect of task dimensionality on BMI performance

**Authors: *N. EVEN-CHEN**[1], S. VYAS[2], S. RYU[3], K. V. SHENOY[4,5,6]
[1]Electrical Engin., Stanford Univ. Dept. of Electrical Engin., Stanford, CA; [2]Bioengineering, Stanford Univ., Stanford, CA; [3]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [4]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA; [5]Stanford Neurosciences Inst., Stanford, CA; [6]Bio-X Program Stanford, Stanford, CA

**Abstract:** In recent years, non-human primate brain-machine interface (BMI) studies have demonstrated 2D cursor control (e.g., using the ReFIT-KF algorithm) that is approaching native arm control. This approach has been successfully translated into human clinical trials. There have also been promising demonstrations of high degree-of-freedom (DOF) robotic arm control using different algorithms. However, the performance of these studies is not yet close to native arm control. Most high DOF studies focus on functional tasks (e.g., object manipulation) and assess performance with clinical metrics (e.g., ARAT). These metrics are quite important but nevertheless are an indirect measure of underlying control quality. This makes it challenging to directly gleen the reasons for performance limitations. To better understand the sources of performance limits, we compared 2D and 3D BMI control using alternative task designs and metrics.

We designed a virtual reality environment for 3D BMI control that dissociates the effects of 3D control from the confounding effects of studying 3D control with a robotic arm (e.g, dynamics, latency). We trained a rhesus macaque to perform 2D and 3D center-out-and-back tasks using an intracortical BMI system (two 96-channel Utah arrays in M1 and PMd) and the ReFIT-KF control algorithm. To develop an appropriate task to evaluate the BMI control quality (e.g., speed and stability), we manipulated target radius (1, 2, 3 cm) and required hold time (0.1 - 1 sec). We found that a 2 cm sphere with a 500 ms hold time is a good regime to assess the control quality in 3D, and compare it to both a 2D task, and native hand control.

When comparing hand control to BMI control, the average trial length increased by 50% during a 3D task, while only by 20% during a 2D task ($p<0.001$, t-test). To understand this performance difference, which can be a result of slow and/or unstable cursor control, we computed time-target-first-acquired (tFA, as a speed metric) and time required to hold the target once acquired (tDwell, as a stability metric). When comparing 2D vs. 3D native hand control, we found that tFA increased by 10% while tDwell did not change ($p<0.001$, t-test). Surprisingly, when comparing 2D vs. 3D during BMI control, we found that tFA increased by 14% while tDwell increased by 25% ($p<0.001$, t-test). These results suggest that when increasing BMI control dimensionality, both speed and stability differ from native arm control with the latter differing more. This might be explained by the number of task-related dimensions in each phase of the reach. Such underlying control analysis can guide, and likely improve, future BMI designs.

**Title:** Long-term performance of intracranial electrodes and their effects on brain tissue

**Authors: *Y.-R. GAO**, M. YE, C. M. ALTIMUS, H. RAFI, D. X. HAMMER
US Food and Drug Admin., Silver Spring, MD

**Abstract:** Microelectrode arrays that directly interface with neurons in the nervous system provide high fidelity control signals for advanced neuroprosthetic applications. Those devices have the potential to restore movement capabilities and provide sensory feedback to patients with paralysis or amputation. Although implanted electrode arrays perform well short after implantation, the devices often fail when implanted for durations exceeding one year; and their long-term viability and reliability are unpredictable. We are investigating the dynamics of brain morphological changes with a multimodal approach to correlate the recording signal degradation and brain tissue response. We performed weekly optical coherence tomography (OCT)-guided two-photon microscopy (TPM) through a cranial window. A Thy1-YFP transgenic mouse model was used to image cerebral blood vessels and neurons after implantation. Single-shank, 16-channel, Michigan-style microelectrodes were inserted under the window at a 15-20° angle with an insertion depth up to cortical layer 5. Electrophysiological recordings were conducted for 15 minutes while the animals moved freely in their home cages. Cellular and vascular morphology were monitored using TPM and OCT at time-points matched to the recordings. We found that layer 2/3 dendrite length gradually decreased over time following implantation while layer 1 dendritic tufts density remained relatively stable. There was vascular remapping of the superficial layers of the cortex with an increase in vascular total length, branch number and tortuosity. The deeper capillary network remained relatively stable. We observed a decay of

neural firing rates in most of the channels within two weeks after implantation, while the gamma band power of the LFP signals gradually increased in the first month after implantation and then stabilized. These findings indicate that LFP may have better long-term performance for neural decoding for prosthetic device control. Future studies of the microglia and astrocyte changes after implantation will be conducted to further pinpoint the causes of recording degradation. Our multimodal approach combining electrophysiology and optical imaging provides a broader picture of brain tissue chronic changes to implanted electrodes. It may also provide insight into the long-term performance of implanted electrodes and identifying potential biomarkers for device failure.

**Abstract:** A central goal of systems neuroscience is to relate an organism's neural activity to behavior. Neural population data analysis often begins by reducing the dimensionality of the raw neural data in order to focus on the neural population patterns that are most relevant to a given task. A major practical hurdle to data analysis is contending with the time consuming and inexact identification and separation of action potentials from individual neurons, and this problem is

growing rapidly as the number of neurons measured increases inexorably. Here we experimentally and theoretically investigate if `spike sorting' is necessary to accurately estimate neural population states and dynamics. Dimensionality reduction linearly combines neurons, suggesting that separating them prior to analysis may be unnecessary, and compressed sensing theory lends support to this hypothesis. We re-analyzed data from three previously published studies and found that it is straightforward to accurately estimate neural population states without spike sorting. Neural population dynamics and subsequent scientific conclusions are quite similar when multi-unit threshold crossings are used in place of isolated single neurons. This finding unlocks large repositories of existing data for new analyses without time-consuming manual sorting or error-prone automatic sorting, it enables scientific measurements using chronically-implanted electrode arrays that, due to their necessarily lower impedences, do not afford high quality spike sorting, and it informs the future design and use of electrode arrays for laboratory and clinical investigations.

**Title:** Methods for analyzing electrocorticographic signals during motor execution and imagery

**Authors: *T. PAILLA**[1], K. J. MILLER[2], V. GILJA[3]
[1]Electrical and Computer Engin., Univ. of California San Diego, La Jolla, CA; [2]Dept. of Neurosurg., Stanford Univ. Sch. of Med., Stanford, CA; [3]Electrical and Computer Engin., UCSD, La Jolla, CA

**Abstract:** Electrocorticography (ECoG) based brain-computer interfaces (BCIs) decode user intent from neural recordings taken from the cortical surface. Previous studies (Leuthardt, Eric C., et al.,2006) have shown that volitional cortical activities during kinesthetic imagery, i.e. imagining motor movement, can be used as control signals for BCIs. There is a significant difference in cortical activities during actual movement and motor imagination (Lotze, Martin, et al.,1999). In this work, we analyze ECoG data collected from 5 subjects who performed movement and imagery tasks (Miller, Kai J., et al.,2010). Our analysis is two-fold. Firstly, we present a deep learning approach to robustly decode tongue and hand movements. Secondly, we use unsupervised methods to find neurophysiological markers for imagery and actual movement. Most ECoG based BCIs use spectral powers in specific frequency bands in fixed time windows as features (Shenoy, Pradeep, et al., 2008). However, precise ranges of informative spectral bands vary across subjects and throughout the duration of task (Wander, Jeremiah D., et al.,2013). Decoding ECOG signals with good accuracy would require features that are more robust to timing and magnitude of changes in cortical activity. We use autoencoders to extract time-frequency(t-f) patterns that summarize cortical activity across brain areas and subjects. We show that this automated feature extraction method coupled with a deep neural network outperforms classifiers using spectral powers in specific frequency bands (Eg: 8-32 Hz and 76-100 Hz) as features by more than 15% across all subjects. Our approach eliminates the need for handpicking spectral bands and electrode channels with discriminable features and is more robust to changes in cortical activity that are hard to model.
We cluster the electrode channels based on activity during actual movement and imagery using low dimensional representations from autoencoders. The clustering of channels across cortical

areas is different for the two modalities suggesting different dominant activity patterns during imagery and movement.

**Abstract:** Minimization of electrode insertion trauma, enhanced biocompatibility, and chronic, high-resolution functionality are critical for the success and clinical translation of emerging brain-computer interface systems. Penetrating microelectrodes and electrocorticography (ECoG) grids give access to high resolution neural signals. However, insertion of these devices requires craniotomy and direct contact with brain tissue, and a fibrotic response may degrade signal quality. We have developed a stent-based endovascular interface that is implanted within the brain via the vascular system through the jugular vein. Evaluation of the maximum neural information accessible and the long-term behavior of this device will strengthen the potential clinical applicability of the technology. Here, we aim to quantify the chronic signal quality recorded from an endovascular neural interface using visual evoked potentials and compare this with signals from a subdural grid implanted adjacent to the same cortical areas. Full-field visual flashes of light were delivered binocularly while neural signals were recorded with endovascular electrodes adjacent to the motor and visual cortices in awake sheep. The signal-to-noise ratio (SNR) was calculated on the filtered (2-400Hz) trial-averaged signal for each electrode, as the ratio of the root-mean-square values of the signal amplitude in two 130ms time-windows. One

window was centered at the peak of the response and the other in the baseline period (85ms pre-stimulus). The variability of the SNR was measured as the standard deviation across electrodes and animals. Electrochemical impedance spectroscopy was also measured to test the electrochemical properties of the stent in vitro and monitor electrode viability in vivo. Visual evoked responses were recorded, peaking at 60.94 ± 12.38 ms (mean ± std) after the visual stimulation. SNR values significantly greater than 1 were recorded from day 1 (8.516 ± 1.164 dB, p < 0.05) using the endovascular interface. The mean SNR was stable over recordings up to 57 days after implantation on both devices (linear fit, stentrode: slope = 0.0006 dB/day, CI = [-0.009:0.02] dB/day; subdural: slope = -0.02 dB/day, CI = [-0.004:-0.009] dB/day). The variability of the SNR decreased with time (days 1-30: 1.1077 ± 0.86 dB; days 30-57: 0.13 ± 0.136 dB, Wilcoxon Rank Sum test, p < 0.05). We have demonstrated the capability of electrodes placed within a cortical vessel to record visual evoked responses immediately after implantation. We also showed stability of the SNR over time, with a significant decrease in SNR variability beyond a month after implantation.

**Abstract:** Peripheral Nerve Interfaces (PNIs) are medical devices that bridge between peripheral nerves and external hardware such as neuro-prosthetic devices. PNIs sense nerve impulses and/or evoke neural signals through electrical stimulation. There are PNIs currently under investigation for intuitively controlling neuro-prosthetic devices in amputees, and to restore motor and sensory function. To reap the maximum benefit, these devices should be safe and effective over long periods of time, ideally the lifetime of the patient. The current study aims to assess the chronic safety and performance of off-the-shelf Utah arrays and low-impedance Utah Arrays, all with a 4x4 set of electrodes that are 1.0 mm in length.
Off-the-shelf Utah arrays (UA) were purchased from Blackrock Microsystems and low impedance modified Utah arrays (mUA) were provided by Dr. Loren Rieth at the University of Utah. Arrays were implanted into the rat sciatic nerve along with custom EMG wire based arrays implanted into the gastrocnemius and tibialis anterior. Connectors from the arrays were secured to the lumbar fascia using 3D printed connector mounts. To record evoked potentials, two cranial screws were implanted over the somatosensory cortex. Weekly impedance measurements, recordings of spontaneous peripheral neural activity, and EMG evoked by electrical stimulation were recorded for 12 weeks. Nerve function tests were obtained bi-weekly to monitor motor and sensory function for up to 12 weeks. At 13 weeks, the animals were sacrificed to harvest the implanted nerve electrode for analysis under scanning electron microscopy (SEM). Tissues were harvested for histological assessment around the electrode shanks.
Spontaneous electrophysiological analysis indicated no difference in recording performance between UA and mUA arrays, while stimulation evoked responses indicated session-to-session variability. Walking track analysis and von frey tests indicated recovery of function around 2 weeks post-implantation. The surface morphology of the electrodes was characterized by SEM before implantation and after explantation, and showed fracture of recording tips in some cases. Further assessment is under investigation to establish the chronic safety and efficacy of these electrode arrays.

**Title:** Utah electrode arrays for cortical neural recording in rat

**Authors: R. RIHANI**, C. FREWIN, A. KANNEGANTI, B. J. BLACK, B. CHAKRABORTY, R. AYUB, *J. J. PANCRAZIO, S. F. COGAN
Univ. of Texas At Dallas, Richardson, TX

**Abstract:** Utah electrode arrays (UEAs) are used chronically for high signal-to-noise ratio (SNR) recordings. However, there have been few studies involving UEAs implanted in rat cortex and have only shown a limited capabilities in chronic recordings [12]. Therefore, we have investigated the stability of UEAs for long-term single unit cortical recordings *in vivo* in a rat. 4x4 UEAs with sputtered iridium oxide (SIROF) electrodes were implanted into the barrel cortex of a Long-Evans rat using a pneumatic insertion tool. The electrode array was connected by a flexible cable to a connector mounted on the rat's head. Weekly 10-minute recordings were collected 2 weeks post-implantation. Animals were lightly anesthetized via 2.5% Isoflurane to minimize movement artifacts. Raw signals were band-pass filtered (250-7000 Hz). Using a threshold set at 4σ of the calculated root mean square (RMS) noise, spikes were identified and manually sorted offline. An active electrode was defined as a site with at least one well-defined unit. SNR was calculated from, $SNR = (RMSs/RMSn)^2$
Where RMSs and RMSn are the RMS amplitudes of the signal and noise, respectively. Fluctuations in the number of active electrodes were apparent on throughout 111 days. Out of 16 electrodes, the maximum number of active electrodes (12) was obtained on week 2 (Fig. 1A). SNR increased after day 38, and reached maximum values of 16-18 between days 74 and 103. SNR values decreased after day 106 and remained low until the end of the study (Fig. 1B).
Our initial *in vivo* characterization of UEAs suggests viability of chronic cortical recordings in rats. The reduced number of active electrodes at the end of the study and their lower SNR values, suggests degradation via either biotic or abiotic mechanisms. More experiments are underway to examine the stability of single unit recordings and relationship to electrode failure mechanisms.

**Title:** The Nanoclip: A microscale interface for recording and manipulating activity in small nerves

**Authors: *T. M. OTCHY**, C. MICHAS, T. J. GARDNER
Boston Univ., Boston, MA

**Abstract:** There is growing evidence of the therapeutic benefit of targeted modulation of the peripheral nervous system (PNS). Positive clinical trials are reported for vagal nerve stimulation to treat inflammatory diseases, depression, and epilepsy, and beyond these initial results, it is thought that a broad range of chronic diseases may be treatable through precise modulation of the autonomic PNS.
However, many large peripheral nerves, like the vagus, contain fascicles that innervate a variety

of organs, and hence bulk stimulation is often accompanied by undesirable off-target effects due to incidental stimulation of axons unrelated to the targeted organ. Fortunately, the organization of the PNS, whereby functional branches diverge and become more specific and homogenous as they near their target organ, can be exploited to avoid these off-target effects. These terminal nerve branches can be very small: the carotid sinus nerve, a possible treatment target for hypertension, is 400μm in diameter in humans and only 50μm in pre-clinical disease models. Thus, to advance basic research in bioelectronic medicine, highly miniaturized nerve interfaces will be necessary; however, the scale, fabrication method, and implant process of many currently available devices limit their consistency, reliability, manufacturability, and in vivo performance. Here, we present a nanoclip nerve interface for recording and stimulation that overcomes these limitations. Using two-photon direct laser writing to structure an acrylic photopolymer, we can tailor with micron resolution the geometry of the device to match the dimensions of the target nerve. The integration of thin film polyimide electrodes allows for precise and robust manufacturing of the electrical interface. In addition, fine design details were tuned to develop a device that is compact, easy to handle and implant, and capable of securely latching onto the nerve without disrupting nerve function.

We tested the polyimide-integrated nanoclip interface in acute and chronic preparations for efficacy in both recording and stimulation of functionally relevant nerve activity. We made single and multiunit recordings from whole nerves and found activity to be stable at chronic timescales. In addition, we stimulated nerves, using both bulk and current-steering techniques, to assess the precision, specificity, and repeatability of effects. The results of these tests indicate that multicontact polyimide-integrated nanoclips can be used as a robust, reliable, and highly manufacturable interface for peripheral nerves. Future research aims at adapting the current design for a variety of PNS targets.

**Title:** 3D visualization of cellular biomarkers surrounding MicroProbes/NeuroNexus/Blackrock "hybrid" arrays implanted chronically in cats

**Authors: *N. NOLTA**, M. HAN
Biomed. Engin. Dept., Univ. of Connecticut, Storrs, CT

**Abstract:** Intracortical microelectrode arrays allow for direct communication between the brain and external devices such as sensory or motor prostheses. It is widely believed that healthy, functioning neurons within the recording radius of microelectrode recording sites are critical for successful long-term performance. Neuronal density and other biomarkers have traditionally been assessed using 2D serial histological sections. However, the recording radius, the layered structure of cerebral cortex, and the foreign body response are all part of a 3D system that is difficult to accurately visualize and quantify with 2D methods. The problem becomes even more severe for large, complex, clinically-relevant devices that create anisotropic cortical tissue loss, compression, and fibrosis, and that often become tilted in brain tissue. In this work, we used 2D serial horizontal sections to build 3D reconstructions of the tissue surrounding “hybrid” microelectrode arrays implanted in cat sensorimotor cortex up to two years. The hybrid arrays consist of MicroProbes, NeuroNexus, and Blackrock microelectrodes assembled together into one monolithic, functional device. A variety of image processing techniques were employed to improve the quality, consistency, and automation of the 3D reconstruction process compared to our previous efforts. Finally, we show how this technique provides unique insights into the mechanisms of recording success/failure that 2D histology might otherwise overlook.

Dept. of Electrical Engin., Stanford, CA; [7]Dept Neurosurg, Palo Alto Med. Fndn., Palo Alto, CA; [8]EE, BioE & Neurobio., Howard Hughes Med. Inst. - Stanford Univers, Stanford, CA

**Abstract:** Brain machine interfaces (BMIs) can assist people with paralysis and improve their independence (e.g., by restoring communication or motor function). Discrete decoders, which classify the most likely movement endpoint from a discrete set of possible endpoints, show promising results for communication (e.g., Shenoy et al. 2003; Musallam et al. 2004; Santhanam et al. 2006). However, the spatial-accuracy limits of this approach have not yet been explored. To investigate these limits we quantified the accuracy of direction and distance classification using data from a high-density target reaching task. We trained a rhesus macaque to reach to a visual target after an instructed delay period (400 - 800 ms) in a center-out-and-back task. Using delay activity recorded from two 96-electrode arrays in primary (M1) and pre-motor (PMd) cortex (-4.5 RMS threshold crossings used), we classified the direction and the distance of the reach with SVMs. To quantify the accuracy of predicting direction, we used 24 uniformly-distributed targets arranged radially around an 8 cm circle. For distance, we used 12 targets spaced 1 cm apart in a line extending from the center of the screen going rightward (or leftward). For the radial task, we found that 95% of trials were classified within 38.9 degrees of their true target location. For the line configuration, 95% of trials were classified within 3.9 cm of their true target location. To see whether the target distance influences direction decoding (and vice-versa), we used 48 targets arranged in 3 concentric circles with radii 4, 8, and 12 cm, where each

ring had 16 evenly spaced targets. While distance decoding was consistent across directions, classifying the direction of reaches to each separate ring yielded accuracies of 28.1%, 45.5%, and 51.7% respectively (6.25% chance level when classifying the most likely target), increasing significantly with distance ($p < 0.01$). In designing communication BMIs an important measure of throughput is the information transformation rate (ITR) which is a function of success rate, number of targets and the neural activity integration time. To maximize ITR we calculated offline the effect of varying the number of targets in each configuration. In the ring configuration, the maximum ITR (4.63 bps) was achieved with a 6 target configuration (60 degrees between targets). For the line, the maximum ITR (1.1 bps) was achieved with 6 cm target spacing (2 targets in a given direction). Higher ITR may be achieved with target configurations that combine direction and distance or using larger radii. Such results can provide benchmarks that inform viable task environments for preparatory-activity based clinical BMIs.

Ctr., Pittsburgh, PA

**Abstract:** Introduction and objective: Brain Computer Interface (BCI) technology has the potential to benefit individuals with severe functional impairments. Previously, researchers have proposed the use of action observation paradigms for neural decoder training - involving

watching videos of hand and arm movement or a neuroprosthetic arm movement and attempting the same movement. However, the time required by an individual with paralysis to learn and use the action observation paradigm may vary from a few days to several weeks. In this study, we evaluated the motor and pre-motor cortical activity for various neural decoder training paradigms including attempted, observed, passive, and overt movements in an individual with intractable epilepsy.
Methods: Testing was performed in an individual with intractable epilepsy. A high-density electrocorticography (ECoG) array was placed on the pre-motor and motor cortices of the participant. The participant performed four video-cued hand/arm movements: attempting, observing, passive movement by an experimenter while the participant was blindfolded, and overt movements. The videos included 13 body movements of shoulder, elbow, wrist, and fingers. Neuronal data included high-gamma band features. The decoding analysis used Naïve Bayes algorithm to predict the movements.
Results and Discussion: Attempted, visual, somatosensory, and overt movements induced motor and pre-motor cortical activity. Ten-fold classification analysis indicated that 10 channels within each paradigm of attempted, observed, passive, and overt movements resulted in an accuracy of 95.8% (chance level is 7.7%), 94.2%, 89.9%, and 87.7%, respectively. The top ten ECoG electrodes, from the high-density array, that contributed to the highest classification accuracy within each paradigm varied for the four paradigms. Developing a neural decoder for data transformed from one paradigm to another (e.g. passive to attempted movements) resulted in a reasonably high accuracy (82.0%). Based on the results, we postulate that various types of paradigms including visual and somatosensory can potentially be used for neural decoder training.

**Abstract:** Recently, we presented a first case where a woman who was Locked-In due to late-stage ALS could successfully use a BCI to communicate in daily life using a simple click-based letter selection approach involving attempted hand movements (UNP system [Vansteensel et al. 2016]). Neural signals were recorded with subdural electrode strips and an implantable amplifier, making the UNP easy to use and available 24/7. Next generation BCI implants for communication aim to decode attempted speech. Promising results have been obtained with high-density ECoG grids in patients monitored for epilepsy, in decoding the smallest elements of speech, phonemes, from sensorimotor cortex [Mugler et al. 2014, Freudenburg et al. 2013]. These results motivate the use of chronic HD-ECoG implants as a platform for an intuitive multi-degrees of freedom communication-BCI using attempted speech production. However, the decoding studies involved labeled events, whereas the real use of a BCI would require continuous decoding of unlabeled events, to be able to translate attempted speech to computer-generated speech. In this study we investigated whether neural events generated by spoken phonemes can be detected and classified asynchronously.ECoG signal was collected from 5 intractable epilepsy patients who had high density-ECoG grids (3-4 mm center-to-center) implanted alongside standard clinical ECoG electrodes. While coverage and grid size varied across subjects, the mouth sensorimotor cortex was well covered in all 5 subjects. The subjects were visually cued to pronounce the phonemes /p/, /k/, /u/, and /aː/ or rest and fixate on the screen. Including only electrodes that displayed a response to the task, the ECoG gamma (65-95 Hz) response from a 0.5s time period around peak activity was used to build spatial-temporal match filters (STMF) on a subset of labelled trials (80% repeated 20-fold). Decoding of test trials (20%) was done by simply sliding the STMFs in time and detecting a neural event when the STMF fit of any phoneme was larger than the STMF fit for rest. The detected event was then given the class of the best fit STMF. Our results demonstrate that four spoken phonemes can be detected and decoded at a mean level of 51.6% over five subjects within 0.5s of the start of neural activity. While this level of accuracy is not sufficient for a reliable 24/7 BCI system it does encourage further work for improvement.

**Title:** Amplitude bias in low-frequency oscillatory activity: Experimental evidence and implications

**Authors: *A. VATO**[1], G. SCHALK[2]
[1]Ctr. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy;
[2]Wadsworth Ctr, NYSDOH, Albany, NY

**Abstract:** Several studies have shown that low-frequency oscillatory activity plays an important role in neural communication across brain regions by differentially modulating excitability across the cortex. These observations are commonly based on analysis methods that extract oscillatory power and phase from band-pass filtered signals in canonical frequency bands. The recently proposed Function-through-Biased-Oscillations (FBO) hypothesis [1] suggests that oscillatory voltage amplitude of low-frequency oscillations, rather than power or phase, is the most direct measure that reflects cortical excitability. It also suggests that changes in the peak-to-peak amplitude of oscillatory activity does not affect the peaks and troughs of oscillatory activity the same way, i.e., oscillatory activity does not symmetrically vary about a mean and, instead, has an amplitude bias that depends on oscillatory power. Even though this amplitude bias has substantial implications for optimal analysis of oscillatory activity, experimental evidence for it has been scarce.

In our study, we comprehensively evaluated the presence of biased oscillations in electrocorticographic (ECoG) signals recorded from 28 patients with intractable epilepsy who underwent temporary placement of subdural electrode grids. We extracted oscillatory activity in the alpha range (7-12) Hz (i.e., a measure of cortical excitability) and broadband activity in the gamma band (70-170) Hz (i.e., a measure of cortical excitation). Using data from a motor and auditory task, we established the presence of an amplitude bias in alpha oscillations in 88% of 126 task-related locations. Our results also suggest that this amplitude bias has important implications on the traditional interpretation of the relationship between oscillatory activity with cortical excitability, and may also help to explain a range of time-domain phenomena often observed in scalp-recorded EEG. Overall, our study provides experimental evidence to demonstrate that the instantaneous voltage amplitude of biased oscillations can be used as an alternative to the more traditional measurements of power and phase, and pinpoints areas in which those traditional measurements can be misinterpreted.

**Title:** Lifetime improvements for penetrating electrodes in chronic clinical investigations

**Authors: *L. RIETH**[1], R. B. CALDWELL[2], B. BAKER[3], R. SHARMA[4]
[1]Electrical and Computer Engin., [2]Bioengineering, Univ. of Utah, Salt Lake City, UT; [3]Electrical and Computer Engin., Univ. of Utah, University of Utah, UT; [4]Electrical and Computer Engin. Dept., Univ. of Utah, Salt Lake City, UT

**Abstract:** Maintaining high performance bi-directional interfaces for periods > 1 year continues to be a challenge that limits the clinical impact of high density neural interfaces. This includes interfaces that are able to decode single unit activity, and able to safely evoke selective and graded sensory or motor responses through stimulation. As part of the DARPA HAPTIX program we have performed the longest implant of a Utah slanted electrode array (USEA) to date with 11 months of implantation to date. This report presents the performance of the electrodes arrays, identifies their failure modes, and communicates the improvements made to the arrays to mitigate these failure modes and improve performance and lifetime. The three primary aspects addressed include the percutaneous lead, encapsulation, and tip metallization. The percutaneous lead has previously been reported to be the source of significant failures for arrays used with human subjects. Arrays with the second-generation lead have been implanted in a subject for 11 months, and > 75% of the wires appear to have broken based on measurements of impedance and electrophysiological performance. We have some evidence that the wires fracture in the extracorporeal segment of the lead. We have developed a third generation lead for the USEA, and will report the performance of this lead. With regard to encapsulation, we have used advanced SEM and materials characterization techniques to investigate degradation of Parylene-C in-vivo. These results show degradation that commonly occurs with this encapsulation, and systematically analyze the surface morphology and character of the degradation. Evidence from chemical analysis suggests that oxidative mechanisms are a strong component of the degradation. This was further supported by use of an in-vitro degradation model reported in a separately. In addition, degradation of the tip metallization due to extended

stimulation pulsing was investigated. We continued to find that damage to the silicon under the tip metallization is the main degradation mechanism for the tip metallization. This research has enabled us to make substantial improvements to the lead, encapsulation, and tip metallization of the arrays, improving their lifetime and performance.

**Abstract:** Blackrock microelectrode arrays (MEAs) are used in intracortical recording and stimulation devices employed in FDA-approved clinical trials involving brain-machine interfaces. Pre-clinical studies in small and large animal models have evaluated various aspects of these devices including optimal implantation techniques, electrode coatings, insertion trauma, foreign body response, and *in vivo* electrochemical properties. These studies were performed in a variety of animal models over different implantation times and with different experimental methods. Herein, we report on a comprehensive characterization of Blackrock MEAs implanted chronically in rat motor cortex for up to 120 days. We selected rat as an animal model for this study because of the established disease models in these animals and their comparatively low cost. The electrode coating used was low-impedance sputtered iridium oxide (SIROF). Electrochemical characterization of implanted electrodes included impedance spectroscopy (EIS), cyclic voltammetry (CV), and voltage transients during current pulsing. The neural recording performance of the MEAs was characterized by single-unit yield per electrode, unit amplitudes, and signal-to-noise ratio (SNR). Observations from pre-implantation saline measurements and weekly *in vivo* monitoring showed the expected increase in impedance over pre-implantation values with no significant subsequent changes observed in the 1 kHz impedance

over five weeks. Electrode charge storage capacities (CSCs), calculated from CV measurements over a 50-50,000 mV/s sweep rate range showed differential changes as a function of sweep rate, which were attributed to different rate-dependent contributions to the CSC. The capability of the electrodes to deliver stimulation pulses was determined by measuring voltage transients in response to 4nC/phase current pulses. Considerable variability in the polarization of the pulsed electrodes was observed and correlations between pulsed, CV and EIS behavior investigated in an effort to identify sources of the variability. Distinguishable single units were observed across multiples electrodes in anesthetized recording sessions with an array yield of 42% at five weeks' post-implantation. Average root mean square noise calculated for 350Hz to 6kHz signal window showed no significant change over time. In summary, the study investigated the changes in electrochemical properties and neural recording behavior of Blackrock MEAs in chronic rat preparations over a 120 days implantation period. The rat proved to be a convenient and inexpensive model for studying the chronic performance of the MEAs.

**Abstract:** Intracortical neural electrode arrays provides the ability to resolve high-frequency electrophysiological activity from single neurons, enabling high-fidelity brain-computer interfaces, surgical brain-mapping, and neuroscience research. Implantation of these devices, however, is a traumatic process. Post-mortem histological studies have demonstrated that this acute insertion injury is associated with neuronal death and gross tissue deformation [1]. We

extend these findings by mapping the extent of neuronal injury and deformation during implantation with high spatial and temporal resolution *in vivo* 2-photon microscopy. By tracking the positions of blood vessels during array insertion, we generated a map of mechanical strain in the neural tissue caused by implantation. Immediately following probe insertion, we observed a spike in $Ca^{++}$ transients in transgenic GCaMP+ neurons within 200μm of the implantation site. Using our implantation strain maps, preliminary data showed that 95% of this neural activity occurs where mechanical strains are > 0.3 at a strain rate of 0.075 $s^{-1}$, suggesting that mechanical deformation plays a role in neuronal activation. Similar strain values have been shown to be lethal to neurons *in vitro* [2]. By 2 hours, we noted the formation of hypertrophic, spherical regions on axons, which may indicate axonal degeneration. Using oligodendrocyte reporter mice (CNP-eGFP), we further quantified that cortical layer I axons surrounding the implanted device were oriented parallel to the array's face, while axons in healthy layer I had no orientation preference. This suggests that axons stretch to accommodate neural probes during insertion.
In sum, our findings indicate that mechanical forces during electrode array implantation are associated with aberrant neural activity and changes in axonal morphology. Future studies will elucidate how altering the magnitude of insertion strain (via variation of implant design and insertion methods) will alter neuronal outcomes. While the functional consequence of these changes has yet to be determined, this work provides a framework to study the interplay of implantation mechanics and long-term neural viability.

**Abstract:** A growing body of research has demonstrated that there exists the potential to create a chronic interface between technological devices and aspects of the nervous system. Such interfaces can provide a clinical benefit to patients with a wide range of conditions including deafness, blindness, and nervous system disorders. A common goal shared between CNS and PNS interface research is the improvement of implantable devices ranging from modifications of material formulas to completely novel device designs. Making any such improvements, however, necessitates a firm understanding of how the biological tissues surrounding implanted devices interact with the device itself. This understanding is critical to making informed modifications to future devices.

The traditional method for examining the biological response to implanted devices is to use a tissue-sectioning approach, which segments the tissue into thin slices that can then be examined via microscope with further techniques. This approach has many drawbacks, however. For example, the device may need to be completely removed from the organism before the tissue can be examined. If devices are left in during sectioning they may become dislocated from the tissue, making further analysis less informative. Also, tissue slices can easily be physically distorted when placed onto glass slides. This physical distortion varies from slide to slide which can make serial slide analysis complicated.

This study demonstrates the application of a whole-tissue histological approach based on a modified version of the CLARITY protocol, originally developed by Kwanghun Chung and Karl Deisseroth. The samples examined are a novel tissue-engineered electrical nerve interface (TEENI) implanted into the rat sciatic nerve and explanted for analysis after six weeks of regeneration. The multiphoton and lightsheet imaging data presented shows how this whole-tissue approach was used to identify specific proteins of interest to inform future design changes. While this technique is proving useful for investigating the tissue-device interface of peripheral nerves, it may also be useful to other researchers investigating PNS structure and function.

**Title:** Modification of perineuronal nets following implantation of intracortical neural interface devices

**Authors: *J. B. GRAHAM**, J. GAIRE, E. ATKINSON, K. J. OTTO
Univ. of Florida, Gainesville, FL

**Abstract:** Intracortical devices have the capacity to transduce neurochemical and electrical signals from excitatory neurons into recordable data with the goal of driving complex prosthetic devices. While acute recordings are often described as clean and replicable within the first few weeks following implantation, signal strength often decreases over time. Several studies have revealed that the foreign body response and subsequent glial scarring may be responsible for decreased signal to noise ratio and increased impedance yet direct histological evidence is circumstantial and rarely correlates with recorded data variability. Although additional studies have shown slight reductions in reactive astrocytes, microglia, and neuronal death by adjusting the device dimensions, stiffness, or adding protective coatings, temporal diminishing of recordable signals persists indicating that additional factors are involved in signal reduction. Local disruption to the blood brain barrier and subsequent micro hemorrhagic events are inevitable during device implantation. Although most resolve themselves, evidence of blood induced damage has been reported up to several millimeters from the electrode tips. Furthermore, persistent irritation and movement of the device relative to the local brain tissue can exacerbate disruption of the microvasculature over time. The resulting cascade of cytokine production could disrupt the local extracellular matrix through upregulation of matrix metalloproteinases known to target proteoglycans, a major component of perineuronal nets. While perineuronal net disruption has been described following ischemic stroke and traumatic brain injury, very little evidence has been reported on how the injury resulting from device implantation affect the local tissue. Interestingly, experimental disruption of perineuronal nets located within the visual cortex with chondroitinase ABC corresponds to a transient opening of the critical period where increased plasticity and hyperexcitability modify optical dominance. Additionally, reformation of perineuronal nets correlates with reduction of induced hyperexcitability. This led us to hypothesize that device implantation may cause disruption of local perineuronal nets and alter recorded excitatory signals. Additionally, the cyclical

reconstitution of nets may contribute to observed signal reduction. Here we investigated the spatial temporal modifications of perineuronal nets following implantation of a intracortical device. To preserve the device/tissue interface, we incorporated advanced histological techniques using Clarity and light sheet microscopy.

**Title:** RAA 2.0: an automated and high throughput reactive accelerated aging (RAA) system to evaluate performance of neural implants

**Authors: *M. G. STREET**[1], C. G. WELLE[2], P. A. TAKMAKOV[1]
[1]CDRH\OSEL, US Food and Drug Admin., Silver Spring, MD; [2]Dept. of Neurosurg., Univ. of Colorado, Aurora, CO

**Abstract:** The explosive growth in number and variety of new neuromodulation therapies is partly accelerated by device miniaturization made possible by novel fabrication techniques and materials that do not have a history of clinical use. Pilot clinical studies with such novel devices demonstrated that limited in vivo device lifetime is a major bottleneck for translation of this technology to patients. Lifetime evaluation of different neural implants in animal models requires lengthy experiments to establish their safety and performance on clinically relevant timescales. To accelerate testing of innovative materials and device configurations, and with a future goal to supplement or replace chronic animal testing, we developed a reactive accelerated aging (RAA) technique to rapidly simulate chronic device performance. RAA incorporates elevated temperature and reactive oxygen species (hydrogen peroxide) to simulate foreign body response contributing to implant degradation. To overcome laborious maintenance and performance variability inherent in our first system design, we implemented automation, modularity and multiplexing in RAA 2.0. First, to enable real-time automatic closed-loop control of hydrogen peroxide concentration, we used direct in-line optical (UV) and electrochemical measurement of hydrogen peroxide. Secondly, we developed an electrical heating system to

maintain desired temperature. Thirdly, we fully automated the system operation with a Raspberry Pi based controller that allows us to perform in situ optimization of operating parameters and data logging. These solutions for RAA 2.0 allow us to operate several modules simultaneously to expose neural implants to different conditions, such as temperature and hydrogen peroxide concentration to obtain a more comprehensive picture of device failure modes.

**Abstract:** Intracortical implants enable multiple dimensional control and precise feedback of Brain Machine Interface by providing high quality single-cell resolution signals. However, foreign body responses to the device is a challenging problem that attenuate recorded signals over time. Post-mortem histology has been widely used to evaluate inflammatory responses of brain tissue to invasive implants. However, conventional section and staining approaches are low in output efficiency and prone to lose or damage samples. In many cases, the implants need to be removed before tissue processing, which inevitably destroy the device-tissue interface. Two-photon microscopy allows direct imaging of neural electrodes in live animal, but usually requires special transgenic strains and the imaging depth is limited to a few hundreds micrometers. Tissue clearing techniques like CLARITY have revolutionized the way of visualizing tissue structure by making tissue transparent. Here we developed and optimized CLARITY based 3D imaging method for assessing histology of intact brain tissue around the neural implants. Multiple stains were applied after tissue clearing, allowing for visualization of types of cells in the same tissue block. These methods were used to evaluate tissue response to neural electrodes modified with a zwitterionic coating following implantation into a transgenic mouse model with GFP expression

in microglia. We also quantified tissue deformation caused by clearing procedures through comparing CLARITY cleared tissue with in vivo two-photon microscopy results. In summary, with optimization, CLARITIY provides a new way for analysis of the foreign body response to intracortical neural electrodes and offer information complimentary to conventional histology and two-photon microscopy.

Center, Ctr. for Neurorestoration and Neurotechnology, Providence, RI

**Abstract:** Chronically implanted cortical electrodes are the leading technology for collecting high resolution spatiotemporal recordings from the brain and are essential for enabling neural decoding for both research and clinical applications. However, acute and long-term interactions at the device-tissue boundary often lead to production of inflammatory molecules, glial encapsulation, electrode material damage, and neuronal cell death, all contributing to long term recording instability. While acute tissue responses to devices are easily tested in vivo, many of the long-term complex biomarkers correlated with the foreign body response pathology are difficult and time consuming to test in animals. We propose that a physiologically relevant in vitro model may be a more efficient platform for assessing the device-tissue interface for development and screening of novel biocompatible materials and neuroimmune modulating drug treatments. Currently, the most complex in vitro models of CNS foreign body response to devices approximate the device-tissue interface by a monolayer of cells co-cultured with microwires. Such models produce only a subset of the in vivo hallmarks of foreign body response. Here we leverage physiological interactions between cortical cells in a newly developed 3D primary rat neural microtissue culture implanted with a microelectrode as a foreign body. The self-assembled tissue better models the in vivo microenvironment with

migration of immune cells and diffusion of cell signalling molecules. The microtissue-electrode platform has the potential for high throughput testing of tissue response to novel biocompatible materials and neuroimmune modulating drug treatments. We hope to have a broader impact on the optimization of signal quality and functional recording life of chronically implanted microelectrodes.

**Title:** Increasing base permeability of the utah electrode array improves integration in cortical tissue

**Authors: *B. VELAGAPUDI**, M. D. POLEI, P. A. TRESCO
The Univ. of Utah, Salt Lake City, UT

**Abstract:** Electrophysiological recordings from cortical neurons using the Utah Electrode Array (UEA) can support a broad range of clinical applications including neuroprosthetic control. However, long-term recording inconsistency, which is attributed partly to the brain's foreign body response (FBR), limits clinical potential. Recent studies indicate that FBR associated dural fibrosis surrounding UEAs in non-human primate cortex is sufficient to change the position of the implanted UEAs from their original trajectory, and in some cases, pull the device out of brain tissue. Other studies indicate that the FBR is a neuroinflammatory reaction mediated by proinflammatory cytokines released from immune cells at the biotic abiotic interface surrounding the implanted devices. Therefore, approaches that reduce the proinflammatory cytokine production may reduce the FBR and its associated negative sequela. We hypothesized that a hydrogel base coating added to the underside of the UEA may lower the brain's FBR by sequestering secreted molecules within the hydrogel while better matching the mechanical properties of brain tissue. To test this approach, finite element models were used to define the specifications of the base coating. To validate the models' predictions, adult Sprague Dawley rats were implanted with unwired control UEAs (n=7) and unwired UEAs with a 500μm thick, permeable hydrogel coating underneath the array (n=7). Each cohort also had four bone screws and an acrylic headstage to mimic a recording scenario. 12 weeks after implantation, both

cohorts were transcardially perfused. We observed that the craniotomy edges grew to surround the hydrogel coated arrays but remained similar to the original size in the solid base (control) cohort. Moreover, the hydrogel coated cohort was better integrated into rat cortex with significantly thinner dural tissue surrounding the implant site suggesting a lower level of inflammation during the indwelling period. A more detailed histological analysis comparing the two cohorts is ongoing and will be presented at the meeting. These findings suggest that a simple modification to the UEA that may improve biocompatibility and long-term recording performance.

**Title:** The effect of headstage tethering on the orientation of high density electrode arrays implanted in rat cortex

**Authors: *M. POLEI**[1], B. VELAGAPUDI[3], P. A. TRESCO[2]
[1]Bioengineering, [2]Univ. of Utah, Salt Lake City, UT; [3]The Univ. of Utah, Salt Lake City, UT

**Abstract:** Available evidence indicates that untethered microelectrode arrays have a reduced foreign body response (FBR) compared to devices that are fixed to the skull either directly or with a head stage. Many of these early studies were performed using single shank Michigan style microelectrode arrays where the brain volume displacement, device surface area and insertion trauma are considerably less when compared to more clinically relevant and higher density devices like the UEA or microwire arrays. Moreover, several recent publications indicate that the FBR following chronic implantation of UEAs in non-human primate cortex results in significant dural fibrosis sufficient to change the position of the implanted UEAs from its original trajectory, and in some cases pull the device out of brain tissue. In these studies, the devices were not attached from above and were described as free floating being only secured by the trailing wire bundle. To gain insight into the mechanism of UEA movement following implantation, we compared unwired 4x4 Utah electrode arrays left free-floating (untethered) to a cohort tethered from above to an acrylic headstage. In both cases, unwired UEAs were implanted similarly into adult male Sprague Dawley rat cortex, covered with an *in situ* curing silicon elastomer (Kwik-Cast), but only one group was fixed in place from above with a UV-curable acrylic (Dymax

1187-m) and bone screws. The other was left free floating in cortical tissue. 12 weeks after implantation, rats were transcardially perfused and the device orientation and FBR was investigated. All tethered devices maintained their original implantation position and orientation (N=7) while five of the six free floating UEAs had orientations that deviated from their original implantation trajectory and position. One device had shifted 90 degrees medially relative to its original position with half of the microelectrode shafts being lifted above the cortical surface with the others ranging from 20 to 45 degree changes in position relative to vertical. The observations indicated that FBR tissue remodeling that follows implantation is sufficient to move the array and may be a significant mechanism that underlies changes in recording performance with untethered approaches. A more detailed histological analysis is ongoing and will be presented at the meeting. These findings have important implications on the design and future use of untethered, unwired high density stimulating and recording arrays.

**Title:** Drg stimulation prevents inflammatory arthritis in the rat CIA model

**Authors: *Q. H. HOGAN**, Z. ZHANG, B. PAN
Med. Col. of Wisconsin, Milwaukee, WI

**Abstract:** Electrical field stimulation of the dorsal root ganglion (i.e. ganglionic field stimulation, GFS) is a neuromodulation modality that has recently been established for controlling pain. Its mechanism in uncertain, but electrophysiological recordings from DRG neurons [1] indicate that GFS blocks transmission of pain signals through the DRG. We hypothesize that GFS initiates impulse trains in C-type neuronal somata that propagate down the stem axon to the T-junction, where peripheral and central processes join. There, use-dependent inhibition then causes failure of impulse transmission through the T-junction [2]. This predicts that GFS should block not only afferent impulse trains that generate pain but also block efferent impulses on sensory neurons, which support neurogenic inflammation underlying inflammatory arthritis [3]. We therefore applied GFS, according to our established rat model [4], in rats subjected to the collagen-induced arthritis (CIA) model of rheumatoid arthritis (RA), in which intradermal collagen type II immunization causes inflammation of distal extremity joints. We show that GFS limits development of arthritis ipsilateral to stimulation (Figure - top panel: control with saline rather than collagen immunization; middle panel: CIA but only sham GFS,

i.e. stimulator in place at lumbar 4 DRG but inactive; bottom panel: active GFS). Measurement showed that GFS diminished paw volume, paw width, and ankle width on the side treated with GFS. Arthritis score decreased with GFS, as did cold sensitivity (acetone), and mechanical allodynia (von Frey) and hyperalgesia (pin) on the treated side. We conclude that GFS may be a neuromodulation approach for controlling clinical RA and other forms of inflammatory arthritis.

**Title:** Intracortical stimulation affects synaptogenesis and long-term potentiation in the sensorimotor cortex

**Authors: *J. NGUYEN**[1], D. J. GUGGENMOS[2], S. BARBAY[3], J. D. MAHNKEN[4], R. J. NUDO[2,3]
[1]Sch. of Med., [2]Landon Ctr. on Aging, [3]Dept. of Rehabil. Med., [4]Dept. of Biostatistics, Univ. of Kansas Med. Ctr., Kansas City, KS

**Abstract: Background:** Activity-dependent stimulation (ADS) uses recorded neural activity to trigger stimulation of the brain. Open-loop stimulation (OLS) is independent of neural feedback, thus relying on a machine-generated pattern of stimulation. A previous study found that ADS and OLS both promote fine motor control recovery in a rat model of traumatic brain injury in the primary motor cortex. ADS enhanced recovery of motor function compared to OLS. Investigation of the underlying mechanisms driving motor recovery in response to ADS and OLS is needed.
**Methods:** Six healthy, adult male rats were implanted with recording electrodes in the premotor cortex (PM) and stimulating electrodes in the somatosensory cortex (S1). Three of the rats were treated with ADS; action potentials (spikes) recorded in the premotor cortex triggered stimulation in S1. Three rats were treated with random OLS mimicking the same rate of stimulation as ADS. After 21 days of stimulation, brain tissue was processed for evidence of morphological differences between the two types of stimulation. Immunohistochemistry was used to label sections for synaptophysin, BDNF, GluR1, and GluR2. Densitometry was used for semiquantitative analysis.
**Results:** As this was a pilot study with a small sample size, analyses were exploratory. Observed synaptophysin and GluR1 immunoreactivity (IR) averages were greater in ADS rats compared to OLS rats, whereas BDNF and GluR2 lacked such trends. In all rats the stimulated hemispheres expressed significantly more synaptophysin ($p$= 0.0132) and GluR1 ($p$=0.0062) than the non-stimulated hemispheres. BDNF and GluR2 expression were significantly lower in the stimulated hemispheres ($p$=0.0030 and $p$=0.0054 respectively).
**Conclusions:** The data suggests that ADS and OLS both enhance synaptogenesis and LTP

induction. At least qualitatively, ADS appears to induce greater synaptogenesis and LTP than OLS. This pilot study elucidates the impact of intracortical stimulation on synaptic plasticity in the cerebral cortex.

**Abstract:** Functional electrical stimulation of the peripheral nervous system (PNS) has the potential to restore functions of amputees and to treat neuromuscular atrophy. Electrodes that are chronically implanted in the PNS use conventional conductive materials such as stainless steel (e.g.Cooner wire) and platinum wires, which are significantly stiffer than neural tissue and cause inflammatory tissue response and performance failure. Many efforts have been made to develop flexible electrodes for PNS interfaces, such as the polyimide based thin film longitudinal intrafacicular electrode (Navarro et al, 2007) and the polydimethylsiloxane based flat interface cuff electrode (Tyler et al, 2002). We have developed a soft and elastomeric electrode capable of electrophysiological recording and stimulation for the brain (Kolarcik et al, 2015; Du et al, 2017). The soft electrode consists of a blend of a PEG-modified PEDOT conducting polymer and polydimethylsiloxane elastomer and utilizes an electrically-insulating fluorosilicone coating. This composition had a Young's modulus of 974kPa, and showed excellent chronic tissue integration with healthy neurons at the interface and reduced BBB leakage and gliosis. To translate this technology to the more dynamic and mechanically demanding peripheral environment, carbon nanotubes have been incorporated into the conducting elastomer core to enhance electrical properties of the composition while maintaining favorable mechanical properties. In acute *in vivo* evaluations, electrical stimulation is achieved through implanting a

stimulating soft wire electrode (90 um) in the rat's sciatic nerve, and two recording soft wire electrodes (180 um) in the rat's gastrocnemius muscle. The 90 um soft wires successfully elicited muscle twitch at 2 uA (biphasic pulse, 500 uS pulse width, 50uS interphase delay), and resulted in a graded increase in compound muscle action potential of the rat gastrocnemius measured by the 180 um soft wires. For recording, a 90 um soft wire was implanted in the tibial nerve, and manual brushing of the posterior hind limb elicited multiunit activity and sortable single units. Chronically, the soft wires implanted in the muscle remained intact and demonstrated efficacy in eliciting muscle twitch one month after implantation. Post mortem histology showed decreased fibrotic scarring around the soft wire implant compared to the stiff wire control implants. Our soft wires have the potential to improve the interface with the peripheral nervous system, and to improve the control of prosthetic limbs for research and clinical applications.

**Abstract:** Intracortical electrode arrays suffer from reliability and variability issues that impact their long-term performance. The large variability in performance has led to a growing number of questions regarding the relationships between the recorded signal and the neurons around the implant. Previous attempts to correlate recording and histological outcomes have led to results that are sometimes contrary to expectations. We show that the challenges of correlating recording performance to impedance and histological outcomes are due to several sources of error and artefacts that need to be addressed. Electrophysiological recording and GCaMP

imaging demonstrate that neurons in resting state are largely quiescent compared to driven activity. This has led to increased studies in awake, free-moving, non-behaving, animals. However, while motion artefacts in NHP are easy to identify, motion artefacts in rodents have time-constants like action potentials often leading to misclassification even with common average referencing. Visual stimulation to head-fixed subjects is used to drive activity in V1 while eliminating motion artifacts. Visually evoked current source density analysis is used to identify cortical layers. Then, the electrophysiological layer map is compared to a histological layer map based on neural morphology, and neural density. However, good histology coupled with loss of recorded signal revealed that several modes of material failure can impact performance. Even when electrically and mechanically intact arrays were examined, poorly performing recording sites were identified with good histological outcomes. Functional intrinsic blood flow imaging and GCaMP activity around implants demonstrated a dramatic decrease in activity over the first two weeks, without a substantial decrease in GCaMP expression. Detailed two-photon analysis revealed axonal protrusion injuries, oligodendrocyte myelinosome injuries, and a decrease in blood flow perfusion around the array. These tissue responses may impact the neural network activities around the implant. Our findings revealed our limited understanding of the biology governing the host tissue responses and their impact on longitudinal electrophysiology, and highlight the need for a new level of neurobiology research at the neuroelectronic interface.

**Title:** Network degeneracy and the dynamic of task switching in the feeding circuit in *Aplysia*

**Authors: *Y. WANG**, *Y. WANG, M. CAMBI, K. R. WEISS, E. C. CROPPER
Dept. of Neuroscience, Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY

**Abstract:** Degeneracy in network function has been described in several model systems leading to speculation as to why it occurs (e.g., Prinz et al., 2004). We utilize a multi-tasking network-the feeding circuit in *Aplysia*, to address this issue. The feeding circuit generates egestive and ingestive motor programs. Egestive activity can be triggered using two paradigms, egestive repetition priming and positive biasing. We hypothesize that circuit parameters differ in the two situations. Experiments here probe this idea and the idea that degeneracy in this context has functional consequences for task switching. In the feeding circuit, motor activity is in part reconfigured by changing the phasing of activity in motor neuron B8. This can happen either by changes in B8 excitability or alterations in B8 synaptic input. Here we show that B8 excitability is decreased after egestive repetition priming. Presumably, this is at least in part due to the induction of a persistent outward current that we demonstrate develops as priming progresses. In contrast, in the positive biasing paradigm, we find that the persistent current in B8 is either inward, or if it is outward, very little current is induced. Previously we have shown that after egestive repetition priming, stimulation of the ingestive command-like neuron CBI-2 triggers egestive activity—i.e., there is a task switch cost. The persistent outward current that develops during egestive repetition priming would be expected to contribute to this phenomenon. Additionally, previous studies have demonstrated that egestive priming decreases the excitability of B40, an interneuron that produces an ingestive firing pattern in B8. We now demonstrate that the B40 excitability remains elevated after positive biasing. We hypothesized that egesitive to ingestive switches would occur more readily after positive biasing in part due to the fact that virtually no outward current develops in this situation. Further we postulated that there would be less suppression of B40 activity. Consistent with this hypothesis, we demonstrate that if we induce positive biasing and then stimulate CBI-2, programs are ingestive (instead of egestive as they are after repetition priming). Taken together, these data suggest that degeneracy in network function is observed in the feeding network. In addition, our results support the idea that this degeneracy is of physiological importance due to its implications for the dynamic of task switching.

**Title:** Synaptic and circuit mechanisms for variability in motor programs elicited by a command neuron in a feedforward network

**Authors: T.-T. CHEN**[1], G. ZHANG[1], K. YU[1], W.-D. YUAN[1], S.-Y. YIN[1], S.-A. CHEN[1], D.-D. LIU[1], E. C. CROPPER[2], K. R. WEISS[2], *J. JING[1,2]

**Abstract:** When one repeats a motor act, the executions vary as a result of variable expression in the activity of the behavior mediating neurons. Although there is a debate as to its functional significance, variability must originate, at least in part, from mechanisms in the corresponding network. Previously, there are some computational and molecular studies on network variability. Despite these efforts, circuit and synaptic mechanisms are not well understood. In part, this is a reflection of the fact that it is inherently difficult to study phenomena that are variably expressed. We study variability in the *Aplysia* feeding motor system, where behavioral and motoneuronal variability has been well characterized. Here, we report the identification of a command-like neuron, cerebral-buccal interneuron-10 (CBI-10), that is active during feeding behavior. We demonstrate that CBI-10 drives motor programs that are more variable than programs driven by a previously-identified command-like neuron, CBI-2. The difference in variability is partly attributable to differences in the strength of synaptic connections between command-like neurons and pattern-generating interneurons that excite motoneurons. One of these interneurons, B34, fires at a relatively low frequency when programs are triggered by CBI-10. In contrast, the B34 firing frequency is higher when programs are triggered by CBI-2. Importantly, stimulation of CBI-10 together with subthreshold depolarization of B34 makes programs less variable, and more similar to programs evoked by CBI-2. This suggests an obligatory role of B34 in generating variability when programs are induced by CBI-10. Our results establish how variability may arise through specific mechanisms in a single feedforward network. These findings are likely to be broadly relevant. Many neural circuits, including cortical circuits, are feedforward and show various degrees of variability.

**Abstract:** Resting state activity that occurs in the absence of any obvious stimulus is a feature of all nervous systems from humans to fruit flies. Little is known, however, about the purpose of this activity or its relationship to directed brain activity elicited in response to environmental or homeostatic signals. To characterize the relationship between resting state and elicited brain activity, we are analyzing a hormonally-induced state transition in the nervous system of the fruitfly, Drosophila melanogaster. Using GCaMP6s to image activity specifically in the motor system of animals at the pupal stage, we observe that rhythmic spontaneous activity throughout the central nervous system (CNS) is rapidly reconfigured by exposure to Ecdysis Triggering Hormone, ETH. ETH governs the execution of a developmentally essential behavioral sequence called the pupal ecdysis sequence, and previous work has shown that ETH can induce a fictive pupal ecdysis sequence in an isolated CNS. The pupal ecdysis sequence consists of three serially executed motor programs defined by distinct abdominal movements and in the excised CNS, ETH induces three stereotyped patterns of motor neuron activity that replace resting state activity. Because there are no known behavioral correlates of the resting state activity, we sought to determine if the motor neuron activity was communicated to muscles. We expressed GCaMP6s in the muscles and, surprisingly, observed spontaneous activity along the long body axis prior to the onset of the pupal ecdysis sequence. This spontaneous muscle activity—as well as spontaneous motor neuron activity in the excised CNS—remained even when neurons in the pupal ecdysis central pattern generator were suppressed, a manipulation that eliminates the ecdysis-specific reorganization of motor activity in both the excised brain and the muscles. We are currently using a custom light-sheet microscope to interrogate the brainwide dynamics of this system at cellular resolution with and without ETH stimulation. Using two-color imaging, we are comparing the activity of a subset of motor neurons implicated in ecdysis-specific movements with that of all motor neurons using RCaMP1f and GCaMP6s. Our goal is to identify the cellular determinants of spontaneous and ecdysis-specific motor activity and the effects of ETH on each.

**Title:** Output variability in a motor system: From CPG to motor plant

**Authors: *A. WENNING**[1], B. J. NORRIS[2], R. L. CALABRESE[1]
[1]Biol., Emory Univ., Atlanta, GA; [2]California State Univ., San Marcos, CA

**Abstract:** Rhythmic behaviors vary across individuals. We interrogated a feedforward motor control system – leech heartbeat – to determine the extent of this output variability for each level, from the CPG to the heart motor neurons and the heart muscles and potentially identify its sources.

While bilaterally symmetrical in its layout, burst and beat patterns are inherently left/right asymmetrical. The same CPG orchestrates different intersegmental coordinations for the two hearts: rear-to-front peristaltic on one side and synchronous on the other. Superimposed on this ongoing activity is periodic switching of the coordination side to side about every 15 to 60 burst and beat cycles (70-350 s). The system thus alternates episodes of two states: left synchronous/right peristaltic and right synchronous/left peristaltic.

We considered four types of variability: 1) inherent variability owing to the stochastic nature of biological processes (quantifying cycle-to-cycle variabilities within a coordination mode episode), 2) population variability including, but not limited to, genetic variability and variability in individual experience (comparing across animals), 3) repetition variability taking advantage of the unique feature of the leech heartbeat system as the same function is performed multiple times by the same elements (comparing across episodes), and 4) developmental variability (comparing bilaterally homologous elements). We compare these types across levels and coordination modes. As a metric to characterize the two coordination modes, we used the difference between the activity phases of two segments.

Cycle-to-cycle variability within a switch episode is low indicating a precise system. Across individuals, variability is high. Interestingly, variation at one level is not predictive of variation on the next and, on the same level, differed between coordination modes. In seeking to elucidate the sources of this population variability, we show that repetitions of a coordination vary little and thus contribute little. On the other hand, we show that when bilaterally homologous neurons and muscles perform the same motor act, variability can be as large as in the population itself, again depending on level and coordination mode.

Across levels, phase variation was either similar (synchronous) or varied non-monotonically (peristaltic): high for the CPG and hearts but low for the motor pattern. We argue that the mechanisms that transform CPG output to motor neurons, namely, the bursting pattern and synaptic output of the CPG interneurons, and the properties of the motor neurons, may limit the range of output variation of the motor pattern.

**Title:** Variation across network output, excitatory post synaptic potentials, ionic conductances, and ion channel and receptor mRNAs within motor neurons of the crustacean cardiac ganglion

**Authors: *D. R. KICK**[1], B. J. LANE[2], J. L. RANSDELL[3], S. S. NAIR[4], D. J. SCHULZ[1]
[1]Div. of Biol. Sci., Univ. of Missouri, Columbia, MO; [2]Brandeis Univ., Waltham, MA; [3]Departments of Developmental Biol. and Med., Washington Univ., Saint Louis, MO; [4]Electrical & Computer Engin., Univ. of Missouri Columbia, Columbia, MO

**Abstract:** Central pattern generators (CPGs) are critical in producing many behaviors including locomotion, respiration, and swallowing. Despite the consistency of network output, a significant degree of variation has been documented in the magnitude of ionic conductances and the abundance of ion channel mRNAs. Not only has this variation been observed between animals, but within the neurons of a single CPG as well. Several mechanisms have been proposed to explain how appropriate output can be reached despite underlying dissimilarities including activity independent regulation, synaptic scaling, and correlated mRNA abundances. In this study we seek to indirectly address whether regulation of mRNA abundances, ionic conductances, synaptic excitation, or network output is more tightly constrained through a population level approach. We have examined a crustacean CPG, the *Cancer borealis* cardiac ganglion at these levels and report our findings below.
We report that while there is low variability in network activity for a single animal the same cannot be said between animals, where we have identified a nearly 6 fold range in cycle period. We find higher variability in the duration of the pace making interneuron small cells (scs) burst duration and the burst duration of the large cell motor neurons (Coefficient of variance (cov) 0.80 and 0.70 respectively). Less variable burst characteristics were the duty cycle and termination of the scs and LCs (duty cycle coefficient of variance 0.30 and 0.40, termination coefficient of variation 0.27, 0.30). We have used a resampling method to determine the simulated median fold range and cov. The scs EPSP were found to have a 5 fold range in regard to peak amplitude (cov 0.50). At 0mV we report a 13 fold range in the magnitude of the A-type potassium ($I_A$) and an 8 fold range in the high threshold potassium current. The latter is a composite of the calcium activated potassium current and the delayed rectifier ($I_{Kd}$) which had fold range of 7 and 5.9 respectively (cov 0.53, 0.48, 0.43, 0.37 respectively). The mRNA abundances for channels contributing to $I_A$, *shal* and *shaker* varied by 1.74 and 6.26 fold range.

The genes of the large and small calcium activated potassium currents varied by 31.90 and 6.18 fold range respectively. Finally, those genes encoding $I_{Kd}$ channels *shab, shaw1,* and *shaw2,* varied by 5.99, 5.51, and 8.07 fold range. From these results we suggest that the tolerable variability is lower at the network level and higher at the level of currents and mRNAs. This finding aligns with previous computational and experimental work that multiple and varied solutions exist to arrive at a CPG's target output.

**Abstract:** INTRODUCTION. 1. An important function of neurons is to generate a coordinate movement. Locomotion is one of the simplest forms of movement with elementary modes of rhythmicity (oscillatory modes). Because basic microcircuits of interneurons in cortical modules might reuse similar mutual inhibition mechanisms as those present in central pattern generators (Gomez-M 2003), the study of insect ganglia and the control of legs and antennae give us a good opportunity to understand robust mechanisms of coordination of neural systems. 2. Grooming of various body parts is organized in particular sequences (Sachs 1988). Sequential motion during turning behavior has been also described in many species. 3. Based on previous experimental work (Griego, Salazar, Ricoy 2017; Wu, Liu, Chen, Wang, Bai, Li and Ren 2014; Gomez-Molina 2007), we present additional analysis for locomotion responses to sugar and turning behaviors in cockroaches and ants. -METHODS. Theoretical and experimental (videorecordings) methods. Sensors for locomotion.--PRELIMINARY CONCLUSIONS. 1. Regardless of the frequency of oscillation, the total number of cycles can be a good indication of local activity in neural modules and systems. 2. One important advantage of these models is that the states of activation (alert-like, sleep-like and relax-like states) have direct correlates in the observed behavior of the animal (e.g. running, walking and resting for example). 3. Sugar increases locomotor activity, as can be expected given the positive correlation between activation states and glucose consumption (Fig. 1). 4. For cockroaches walking in a flat terrain, small differences

in phase between oscillations in small turnings (Fig 2) can be interpreted as general and robust mechanisms of waves for sequential activation in multiple types of neural modules (Gomez JF, 2007, 2015). 5. Recording of insect behavior is a good way to test for robust associations between rhythmicity, activation, total number of cycles and wave-like neural communication (Griego, Salazar, Ricoy 2017).

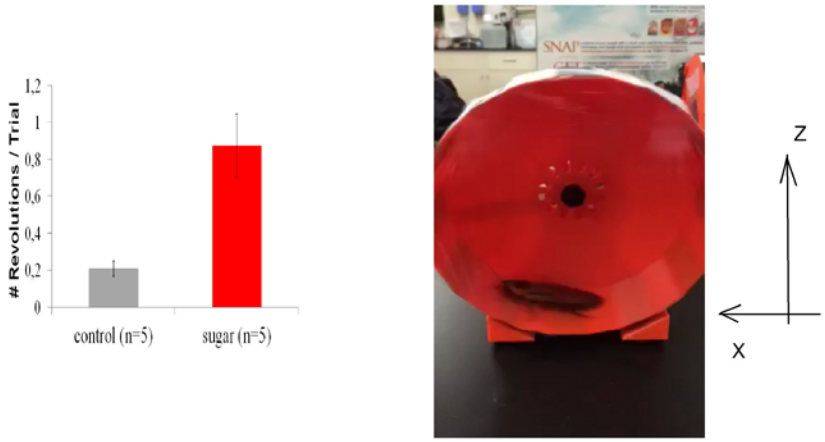

Figure 1. Relation between sugar and locomotor activity (running behavior in cockroaches, Griego et. al. 2017). Cockroaches were tested one by one in a running wheel, and their level of activity was recorded.

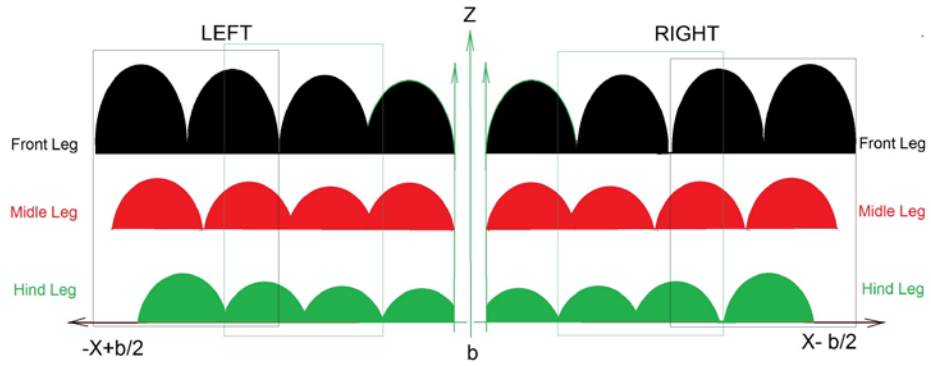

Figure 2. Graphical Analysis (not real data) for the movement of legs in insects (based on Wu et al. 2014 and Gomez-M 2007).

**Title:** Short and long-term effects of high potassium ion concentration saline on the crab pyloric rhythm

**Authors: *L. HE**, E. JAMES, D. POWELL, M. KAR, E. MARDER
Brandeis Univ., Waltham, MA

**Abstract:** The pyloric circuit of the stomatogastric ganglion (STG) of the crab Cancer borealis produces the triphasic rhythmic output pattern that drives filtering of food. This circuit robustly maintains consistent output for years despite ongoing neuromodulation, membrane protein turnover, and fluctuating environmental conditions. To better understand the specific regulatory mechanisms underlying the robust output, we searched for an appropriate perturbation to study, settling on studying the effects of superfusing saline with varying amounts of potassium ion (K+) concentration (1.5x, 2x, 2.5x, 3x) on the pyloric rhythm. In a series of extracellular recordings, we found that high [K+] saline produced a short term increase in rhythmic frequency followed by a decrease and sometimes complete loss of activity. Subsequently, the rhythm recovered, despite continued superfusion of high [K+] saline. At higher [K+] concentrations, a greater percentage of preparations lost activity within the first few minutes of superfusion of high [K+] saline. In baseline conditions, intracellular recordings of the Pyloric Dilator (PD) neurons showed regular slow-wave bursting activity. In the superfusion of 2x [K+], the neurons depolarized by 10-12 mV, and, after an initial transient, the amplitudes of the slow wave in the PD waveform decreased and the amplitude(s) of the spike(s) increased. The neurons transitioned from firing robust bursts to firing tonically or to firing single spike bursts with small slow waves at the depolarized resting membrane potential. Over the next 10-15 minutes in 2x [K+] saline, the neurons slowly repolarized and resumed stereotypical slow-wave bursting activity. This recovery of rhythmic activity appears indicative of a homeostatic process that regulates the pyloric neurons' resting potential and thus the neurons' ability to generate rhythmic slow wave bursts and action potentials. When the preparations were returned to control saline, the rhythms reverted to activity patterns that were nearly indistinguishable from those recorded in the baseline condition.

**Title:** Neuromodulators differentially affect the motor output of the stomatogastric ganglion across temperature

**Authors: *S. A. HADDAD**[1], E. E. MARDER[2]
[1]Brandeis Univ., Waltham, MA; [2]Volen Ctr. and Biol. Dept., Volen Ctr., Waltham, MA

**Abstract:** As global temperatures increase, the question of how organisms will respond to this change arises. How do neuromodulators affect the persistent and essential pyloric rhythm of the marine invertebrate, *Cancer borealis*, as temperature is increased? Previous work showed that the triphasic phase relationships of the pyloric neurons were maintained as temperature increased within a permissible range. Above this range, the neuronal activity patterns decay and do so differently across individuals, revealing underlying differences in network parameters. The stomatogastric ganglion, which contains the cell bodies of the pyloric motor neurons, is modulated by substances that are released locally from descending inputs and ascending sensory feedback, as well as hormonally from substances in the hemolymph. We made extracellular recordings from the motor axons of the pyloric activity at temperatures from 11°C-31°C. When the descending modulatory inputs were silenced the pyloric rhythm became more temperature sensitive. To convey the variety of activity patterns observed across individuals as the rhythm becomes unstable, we devised a categorization-based system. When preparations become unstable, they transition between activity patterns. In the absence of modulatory inputs, the number of transitions increases as temperature increases, significantly by 27°C and 31°C. The types of activity patterns present are also less robust (least like the standard triphasic rhythm) at higher temperatures. When the decentralized preparations are superfused with saline that contains $10^{-6}$M proctolin or $10^{-5}$M oxotremorine, both which activate the modulatory inward conductance $I_{MI}$ on different subsets of pyloric neurons, the rhythms are more robust and temperature invariant. In both modulatory conditions, a phase invariant triphasic rhythm is maintained through a temperature range of 11°C-31°C and the preparations do not transition across activity patterns. When the superfused saline contains $10^{-5}$M serotonin the triphasic rhythm becomes more temperature sensitive. Serotonin increases the variability of activity patterns observed across decentralized preparations. Preparations transition across activity

patterns significantly more than their decentralized counterparts at 19° and 23°C. When modulatory inputs are intact, the presence of serotonin does not produce this effect and the number of transitions and activity patterns observed are similar to the intact preparation at comparable temperatures in normal saline.

**Title:** Neuromodulators stabilize the activity phase of neurons in an oscillatory network

**Authors: *H. ANWAR**[1], D. M. FOX[3], F. NADIM[2]
[1]Biol. Sci., [2]Federated Dept Biol. Sci., New Jersey Inst. of Technol., Newark, NJ; [3]Biol. Sci., NJIT, Newark, NJ

**Abstract:** Neurons in oscillatory networks often fire at a constant activity phase, yet the underlying mechanisms for such phase stability are unknown. Our previous work in the pyloric network of the crab stomatogastric ganglion showed that activity phase can be stabilized if the maximal conductance and peak phase of synaptic conductance changes in a frequency dependent manner, for example through short-term synaptic plasticity (STSP). In addition to STSP, neuromodulators also alter synaptic properties. We aimed to determine the respective roles of STSP and neuromodulators in stabilizing the activity phases of neurons in the pyloric rhythm. We explored whether pyloric pacemakers used STSP to communicate changes in rhythm frequency to the follower neurons by modifying the shape of the IPSC. For this, we recorded the oscillatory waveform of the pacemaker PD neuron, suppressed the network activity, and played back the PD waveform into the voltage clamped PD neuron periodically at different cycle frequencies ($F$ = 0.5-4 Hz). We recorded the resulting IPSC in the follower LP neuron. As $F$ increased, the peak IPSC amplitude decreased and the peak phase of the IPSC was delayed, confirming our hypothesis.
To find out whether this change in IPSC shape was sufficient to stabilize the activity phases of follower neurons as $F$ changed, we removed the neuromodulatory inputs by decentralizing the preparation. As above, we drove the PD neuron with its prerecorded waveform and measured the activity phase of the LP and PY follower neurons relative to the PD burst onset. The activity phases of the LP and PY neurons did not remain constant across different $F$s, indicating that short-term synaptic dynamics are not sufficient to stabilize the activity phase.

Finally, we investigated whether activity phase becomes more stable in the presence of neuromodulators. We repeated the above protocol in the presence of the endogenous modulatory neuropeptide proctolin (bath applied at $10^{-7}$M). We found that proctolin significantly stabilized the activity phases as *F* changed. To understand if this effect is due to changes in synaptic dynamics, we examined the effect of proctolin on the peak amplitude and peak phase of the IPSC. We found that proctolin increased the peak amplitude but did not alter the peak phase at all frequencies. We are exploring whether the increased stability in activity phases is due to the direct modulation of the synapse or the modulation of excitability of the postsynaptic neurons. Together, our results show that neuromodulators can stabilize the activity phases of neurons in oscillatory networks across different frequencies.

**Title:** Variability in modulator innervation of the stomatogastric ganglion

**Authors: *J. PIPKIN**[1], E. E. MARDER[2]
[1]Brandeis Univ., Waltham, MA; [2]Volen Ctr. and Biol. Dept., Volen Ctr., Waltham, MA

**Abstract:** The synaptic strengths and conductance parameters that constrain neuronal computations are constantly influenced by neurochemical modulation. Modulation entails flexibility, and can be employed to either maintain or alter circuit activity patterns in response to environmental changes without any change to circuit connectivity. In the stomatogastric ganglion (STG) of the crab, *Cancer borealis*, a slew of neuromodulators ensure the robustness of the pyloric and gastric rhythms, two motor activity patterns that govern the filtering and chewing of food respectively. The STG, which sits in a blood sinus, is influenced by modulators released broadly into the circulatory system and those that are locally-released by descending and ascending projections into its neuropil. Of this latter class, immunohistochemical staining and electron microscopy reveal that many modulators are packaged into both large and small vesicle-packed boutons that widely innervate the neuropil. Staining patterns vary between different modulators, and even the same modulator may be stained slightly differently from animal to animal. To address these areas of variability quantitatively, we sought to measure the size and number of immuno-stained modulator-containing boutons in the STG. To be enable us to differentiate all boutons, in some cases we employed expansion microscopy to enhance effective

imaging resolution. When stained for allatostatin B (AST- B), preliminary findings indicate that the number of boutons greater than 1.5 microns in diameter vary across a 3-fold range from animal to animal. Very large boutons (those greater than 4 microns in diameter) vary across a 5-fold range. We further explore several modulators in expanded and unexpanded tissue, adding to our understanding of the complex and variable neuromodulatory system of the STG.

**Title:** An *In vivo* exploration of cardiac and pyloric activity in Cancer borealis

**Authors: *D. KUSHINSKY**, J. HALEY, E. MARDER
Biol., Brandeis Univ., Waltham, MA

**Abstract:** To simultaneously examine the *in vivo* motor output of the cardiac and pyloric rhythms, which generate the heart contractions and filtering behaviors in the marine crustacean *Cancer borealis*, respectively, we developed a technique using photoplethysmography (PPG). In this method we attach an infrared sensor to the carapace of the animal with dental wax and record movement as deflections in the signal. Local and hormonal neuromodulation and sensory inputs onto these CPGs play a significant role in the actual responses to perturbations in an animal, but are usually lost or removed during *in vitro* studies. Over long term, 24 hour recordings, animals appear to have a 3 hour cycle of increase and decrease in frequency. In the population tested (n = 54), cardiac rhythms were bimodal with means at 0.7 Hz ±0.1 and 1.3 ±0.24 Hz. The pyloric rhythms were normally distributed with a mean of 0.9 ± 0.4 Hz. To investigate how these rhythms behave in response to perturbations, we conducted temperature ramps on *in vivo* animals by heating or cooling the saline in tanks while recording both the cardiac and pyloric muscle movements. The change in frequency with temperature was lower in intact animals than those previously studied *in vitro* (Tang et al., 2010), consistent with previous *in vivo* experiments using extracellular recordings (Soofi et al., 2014). Critical temperature, defined as the temperature that rhythmic motor movements were no longer apparent in PPG recordings, were determined for both the pyloric and cardiac rhythms of 8 animals. The critical

temperatures of the cardiac and pyloric rhythms were significantly different (29.2 °C and 22.2 °C, respectively, $p < 0.01$, pairwise t-test).

**Title:** Neuromolecular imaging and BRODERICK PROBE® nanobiosensors reveal temporal synchrony patterns between neurotransmitter concentration and movement in the physiologic state and temporal asynchrony between neurotransmitter concentration and movement in the pathologic state

**Authors: *L. WENNING**, P. A. BRODERICK
Dept. of Molecular, Cell. and Biomed. Sci., City Col. of New York, CUNY Sch. of Med., New York, NY

**Abstract:** Temporal synchrony describes the simultaneous, rhythmic regularity between neurotransmitter concentration and movement frequency. Using neuromolecular imaging (NMI) and BRODERICK PROBE® nanobiosensors, a point-by-point temporal synchrony was imaged between the synaptic concentration of 5-HT released from dorsal striatum $A_9$ terminals and natural open-field behaviors such as ambulations, fine movements, and rearing in freely moving, male, Sprague Dawley rodents. Indeed, 5-HT synaptic concentration increased and decreased in parallel with the rise and fall of open-field behavior frequency. Thus, temporal synchrony occurs when the symphony of physiologic neurochemistry and behavior is uninterrupted by drugs, disease, or injury. In contrast, neurotransmitter concentration and movement frequency are not in concert when monitoring psychostimulant-induced behaviors. After cocaine administration, NMI and BRODERICK PROBE® nanobiosensors revealed temporal asynchrony between endogenous 5-HT release at $A_{10}$ terminals and both cocaine-induced ambulations and fine movements in freely moving, male *Rattus norvegicus*. Intriguingly, the psychostimulant effect of cocaine on dopamine $A_{10}$ somatodendrites in the ventral tegmental area remained rhythmic and episodic but not synchronous. Thus, psychostimulant effects on temporal synchrony appear to occur more intensely in somatodendrites compared to nerve terminal nuclei. Temporal asynchrony was also

imaged during *in vivo* studies of anterior temporal lobe epilepsy in human patients. After EEG monitoring, 6 to 10 recordings with γ-irradiated (11.6-12.7 kilograys), laminar biocompatible carbon-based BRODERICK PROBE® laurate biosensors were taken at a cortical depth of microns to less than 2 mm for 20-30 minute intervals. Results of these studies revealed the presence of L-tryptophan (L-TP) and peptides in high concentrations in the neocortex of epilepsy patients during surgery. Therefore, L-TP and peptides may serve as markers for pharmaco- and/or gene therapy for neurodegenerative processes. In this manner, temporal patterns may be used to create a dynamic data profile in the clinical setting. Although static neurotransmitter levels are currently the standard, these static parameters become more valuable when empirically studied within the context of movement rather than solely focusing on whether a neurotransmitter level has increased or decreased. Not only does this dynamic data provide a more complete portrait of the temporal harmony of physiology, but it may also be used to distinguish the intensity of disease or drug-induced temporal cacophony on specific parts of microneuroanatomy.

**Title:** A novel sublethal mouse model of botulism using running wheel activity as an indirect readout of respiratory function

**Authors: *A. B. BRADFORD**, M. J. STENSLIK, E. J. VAZQUEZ-CINTRON, M. C. MANGKHALAKHILI, M. EISEN, D. L. NGUYEN, C. A. ONDECK, P. M. MCNUTT

**Abstract:** Botulinum neurotoxins (BoNTs) are exceptionally potent poisons that cleave presynaptic proteins essential for neurotransmission. The resulting impairment of neurotransmitter release manifests as long-lasting muscle paralysis, leading to death by respiratory collapse at lethal doses. Although botulism victims can be maintained with supportive care, such as mechanical ventilation and parenteral feeding. Treatments to reverse paralysis and accelerate recovery of neuromuscular function are critically needed. However, testing of potential antidotes in rodent models is complicated by the rapid progression from symptomatic onset to mortality. An alternative approach has been to measure longitudinal changes in muscle function in gastrocnemius or inguinocrural muscles following local

administration of paralytic doses of toxin. However, these treatments fail to evaluate the effects of intoxication and recovery on the diaphragm, which is the clinically relevant target of botulism, and involve profound paralysis of the injected muscle, which presents a therapeutically challenging model. Therefore, we sought to establish a sublethal model of botulism that enabled evaluation of therapeutic treatments on diaphragm function. Here we demonstrate that systemic administration of a sublethal dose of BoNT/A caused robust changes in running wheel activity (RWA) that closely correlated with *ex vivo* measurements of diaphragm function. Following establishment of stable RWA, mice were administered a single intraperitoneal injection of BoNT/A that resulted in botulism symptoms in ~70% of mice, but caused less than 10% mortality. Symptomatic mice exhibited a greater than 95% reduction in RWA that lasted for up to 7 d, followed by a gradual, linear recovery to baseline levels over the subsequent 14 d. In contrast, mice that remained asymptomatic or received antitoxin concomitant with BoNT/A exhibited no significant differences in RWA. To determine if changes in RWA were correlated to diaphragm impairment, we measured nerve-elicited twitch and tetanic contraction in isolated hemidiaphragms from symptomatic mice at 3, 7, 14 and 21 d post-intoxication. Force-frequency relationships demonstrated that longitudinal changes in diaphragm function were closely correlated to RWA, suggesting that voluntary running behavior can serve as a simple, reliable correlate of diaphragm paralysis in mice. This model is currently in use to evaluate lead candidate therapeutics for botulism, including intraneuronal delivery of single chain antibodies (Cyto-111). Our studies indicate antidotal efficiency of Cyto-111 at all stages of disease and in multiple animal models.

**Title:** The effect of exercise on aging spinal cord and peripheral nerves

**Authors: *E. GIORGETTI**[1], M. PANESAR[2], M. RONCO[2], C. LAMBERT[3], M. OBRECHT[3], N. ACCART-GRIS[3], N. BECKMANN[3], S. BRACHAT[4], D. SHIMSHEK[5], M. BIDINOSTI[2], M. NASH[2]
[1]MSD-PN, Novartis Inst. For Biomed. Res., Basel, Switzerland; [2]MSD-PN, [3]MSD-Imag/Histo, [4]MSD-CompBio, [5]MSD-NS, Novartis Inst. for Biomed. Res., Basel, Switzerland

**Abstract:** Denervation and motor neuron degeneration are key features of aging and motor neuron diseases. Gradual loss of motor neurons is observed after 60 years of age and old age is itself the biggest risk factor in many neurodegenerative diseases. A similar decline in functioning motor units is observed in mice, where a decline in motor units begins at 12 months. Moreover, there is a slower recovery following sciatic nerve crush in old mice compared to young, highlighting the impairment of regenerative mechanisms with aging. Preventing this decline in motor neuron function may be fundamental to improve mobility and overall life quality in the elderly population.
The beneficial effects of exercise have been extensively documented. Here we describe the effect of exercise on Motor Unit Number Estimation (MUNE) and gene expression in spinal cord. Interestingly, age-related MUNE decline is prevented by exercise in mid-age mice, and even restored to levels observed in young mice, suggesting that nerve-muscle communication can potentially be re-established at that age. Moreover, muscle and spinal cord samples were analyzed by RNA sequencing. Exercise was able to reduce muscle atrophy and to promote a shift towards a slower-oxidative muscle fiber phenotype. On the other hand, pathway analysis in aged spinal cord revealed upregulation of genes related to microglia and, surprisingly, the same set of genes was downregulated by exercise. The results were validated by RT-qPCR.
These data prompted us to assess whether any correlation exists between the over-activation of microglia in aged spinal cord and the decline in MUNE and whether motor unit loss could be reduced or slowed by depleting harmful microglia in the CNS. To first prove a link between over-activation of microglia in spinal cord and motor unit loss, we performed a sciatic nerve crush study in young mice. Interestingly, at 1 and 2 weeks post-surgery a partial activation of microglia was observed in spinal cord. These data suggested that motor neuron damage could trigger microglia activation in spinal cord. Over-activated microglia, in turn, could be harmful to many cell types, especially neurons: in fact, a large body of evidence suggests that abnormally activated microglia in the aged CNS can be neurotoxic. Therefore, a study with a CSF1R inhibitor to deplete microglia and reduce their migration/proliferation in the CNS, in mid-aged mice is ongoing and we aim to demonstrate a beneficial effect on MUNE. The study will potentially open new therapeutic opportunities for the treatment of the aging neuromuscular system.

**Abstract: Introduction:** Mutations in the *SCN4A* gene, which encodes $Na_v1.4$, the skeletal muscle voltage-gated $Na^+$ channel, underlie several skeletal muscle ion channelopathies with two major phenotypes: enhanced excitability (myotonia) and transient loss of excitability (periodic paralysis). Alternations between these two conditions cause a severe loss of function (myasthenia). We report here the functional characterization of two dominant *SCN4A* missense mutations targeting the R1451 residue located in transmembrane segment S4 of DIV composing the voltage sensor domain and resulting in distinct biophysical phenotypes: The R1451L is a novel mutation found in two unrelated patients. The first patient was diagnosed with SMC, and the second with a mixed hyperPP-hypoPP phenotypes. The second mutation (R1451C) was previously reported by our group in one patient with a single attack of PP induced by glucocorticoids. **Methods:** To elucidate the mechanism underlying the phenotypes caused by the R1451C/L mutations and their roles in different types of sodium channelopathies, we used the whole-cell patch-clamp technique to study tsA201 cells expressing WT, R1451C or R1451L channels. **Results:** Our results showed that both mutations shifted the steady-state inactivation to hyperpolarized potentials, reduced the current density, slowed the recovery from slow inactivation and exhibited a slow of the overall kinetics of fast inactivation. Cooling further enhances the abnormalities of fast inactivation kinetics in R1451L channels. Homology modeling revealed a dissimilar disruption of hydrogen bonds in the VSD of R1451C/L mutant channels. **Conclusion:** We concluded that the altered biophysical properties of R1451C/L channels account for the clinical phenotypes seen in our patients but that additional factors are likely to play a role in the diversity of symptoms.

**Title:** Real time monitoring system for lactic acid released from *Ex vivo* preparations

**Authors: *K. SHOTO**[1], S. NEGISHI[1], I. TAKASHIMA[2], H. KUDO[1], R. KAJIWARA[1]
[1]Meiji Univ., Kanagawa, Japan; [2]AIST, Tsukuba, Japan

**Abstract:** The lactic acid is well known substance involved in muscle fatigue. However, recent report suggested that the lactic acid can improve the function of depolarized muscles. In our previous study, we have constructed an continuous LA monitoring system using a micro-fluidic dual-analyte (LA and glucose) (Negishi et al, 2016). The system is suitable for organ level experiments in conjunction with the recording chamber for ex vivo preparations. This system is expected to be free from the effects of movement, breathing, or interactions with other organs or larger organ systems, and allow a physiological experiment under special conditions that cannot be conducted in in vivo. In the present study, we applied the LA monitoring system to various recording chamber, and measured the change of micro amount LA released from the biological organs such as nerve-muscle and brain tissue preparations. Our system consists of a multi-analyte (LA and glucose) biosensor, poly vinyl chloride (PVC) adhesive sheet with micro flow channel (width: 500μm) and polydimethyl siloxane (PDMS) sheet with inlet/outlet tubes for supplying artificial cerebrospinal fluid (aCSF) and experimental solutions. We used polyethylene terephthalate (PET) as a substrate material of the biosensor and printed carbon graphite electrodes on the substrate by conventional screen printing method. The biosensor utilizes the redox reaction of osmium-wired horseradish peroxidase (Os-HRP) by enzymatic reaction. Owing to the Os-HRP redox reaction, the sensor is operated under the low potential of 0 V vs. silver / silver chloride electrode, which is possible to reduce the effect of interferences such as Ethanol. The biosensor has four electrodes (working electrode 1 on which lactate oxidase (LOD) is immobilized, working electrode 2 on which glucose oxidase (GOD) is immobilized, silver / silver chloride reference electrode and counter electrode). LA and glucose measured by amperometric method as a change of hydrogen peroxide which is produced by enzymatic reaction of LOD and GOD. The ex vivo monitoring of LA from nerve-muscle preparations was performed using the our system. We placed the 1cm nerve fiber of the mouse gastrocnemius muscles to the recording chamber, and supplied the aCSF via the inlet cannula. The LA concentration in the experimental solution was continuously monitored from the outlet port of

the chamber. By perfusing the high-[K+] solution, we observed the increase of the LA level. This increase should be caused by the neuromuscular activity of the preparation.

**Title:** Evidences of mitochondrial dysfunction in the muscle biopsy of patients with lipid storage disorders

**Authors: *D. BANDOPADHYAY**
Neurochemistry, Natl. Inst. of Mental Hlth. and Neuroscien, Bengaluru, India

**Abstract:** Lipid storage disorders are a group of inherited metabolic disorders in which lipid accumulates in cells and tissues. Defects in lipid metabolism affect either the mitochondrial transport and oxidation of exogenous fatty acid or the catabolism of endogenous triglycerides. These disorders impair mitochondrial bioenergetics in skeletal muscle causing progressive myopathy with muscle weakness. However, a comprehensive study involving histology, biochemical and proteomic approaches in human ipid storage disorders is lacking. We assessed the mitochondrial function in clinically evaluated and histopathologically confirmed cases of lipid storage disorders (n=5) vs control (n=5). Enzyme histochemistry (COX-SDH staining) on these samples indicated the presence of COX deficient fibres suggesting mitochondrial dysfunction. Ultrastructure analysis revealed presence of cytoplasmic lipid droplets, disarray of myofibril, Z-band streaming and loss of connectivity of myofibril. Apart few mitochondria showed presence of lipid droplet and electron dense material. Mitochondrial dysfunction was indicated by lower activity of respiratory complex (I, II, III & IV) and elevated ADP/ATP ratio. At 10 plex proteomic experiment of mitochondrial extract from 5 lipid storage disorder and 5 controls revealed a upregulation of 38 and downregulation of 60 mitochondrial proteins. Most of the differentially regulated proteins were part of respiratory complexes and tricarboxylic acid (TCA) cycle. Enzyme assay of selected proteins validated the proteomic data. Together we propose that mitochondrial dysfunction play a role in lipid storage disorders and similar metabolic disorders. On a therapeutic note, addressing mitochondrial protection via targeted drugs could be a treatment modality in such metabolic diseases.

**Title:** Comparison of small ankryin 1 and sarcolipin regulation of SERCA1 in myocytes to SERCA2B in neurons

**Authors: *A. LABUZA**, P. F. DESMOND, J. MURIEL, M. L. MARKWARDT, A. E. MANCINI, M. A. RIZZO, R. J. BLOCH
Physiol., Univ. of Maryland Baltimore, Baltimore, MD

**Abstract:** Sarco(endo)plasmic reticulum $Ca^{2+}$-ATPase (SERCA) regulates intracellular $Ca^{2+}$ concentrations by clearing cytosolic $Ca^{2+}$ into the lumen of the endoplasmic reticulum, and, in muscle, the sarcoplasmic reticulum (SR). Three major isoforms of SERCA include SERCA1, primarily expressed in skeletal muscle, SERCA2A, primarily expressed in cardiac muscle, and SERCA2B, which is ubiquitously expressed. SERCA1 is known to be inhibited by sarcolipin (SLN), a small transmembrane protein. We have recently shown that SERCA1 activity is also inhibited by small ankyrin 1 (sAnk1), a ~20kDa transmembrane protein that also binds to the cytoskeletal protein, obscurin. We have demonstrated SERCA1, SLN, and sAnk1 can form a three-way complex.
SERCA2B is known to be expressed within the ER of glial cells and neurons, where it is found particularly in dendrites and spines. However, it is unknown if sAnk1 regulates SERCA2B in brain tissue. Here, using qPCR we show mRNA expression of sAnk1, SLN, and SERCA2B in cortex and cerebellum. SERCA2B expression is at least 5 fold higher than the SERCA1 or SERCA2A isoforms in cortex. SERCA2B expression was lower than SERCA1 and SERCA2A in muscle and heart, respectively. We are now determining if, like SERCA2B, SLN and sAnk1 are expressed in neurons, and if so, if they regulate the activity of SERCA2B in the same way that they affect SERCA1. These results have significant implications for the development of therapeutic approaches to treat a variety of diseases linked to calcium misregulation such as muscular dystrophies and neuropathies.

**Authors: *T. LEMAIRE**[1], S. MICERA[2]
[1]Translational Neural Engin. Lab., Swiss Federal Inst. of Technol. Lausanne (EP, Geneva, Switzerland; [2]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland

**Abstract:** Ultrasonic Stimulation (US) is an emerging technology that has the potential to achieve reliable and selective neuromodulation of central and peripheral neural structures from a distance. However, in order for US to become a reliable neuromodulation technology, we need a deeper understanding of the fundamental mechanism(s) by which ultrasonic waves can modulate neural activity. In this study, two morphological models were developed to predict the behaviour of myelinated and unmyelinated peripheral axons subject to US. For that purpose, the recent model of *Neuronal Intramembrane Cavitation Excitation (NICE)* has been implemented, and a new optimization method has been developed. The previously bidirectional coupling of the electrophysiological and cavitation mechanics parts has been broken up and further pre-computation allowed to derive a new set of Hodgkin-Huxley coefficients grasping the net effect of mechanical oscillations on the membrane dynamics with a virtually constant capacitance. This approach accelerated the resolution time by more than two orders of magnitude without significant impact on the results. Compartmental cell models were then developed in the *NEURON* simulation environment, and resonant sonophores structures were modelled both as continuous distributions and stochastic occurrences in specific compartments. Membrane dynamics was defined using the pre-computed Hodgkin-Huxley coefficients. Myelin was modelled as a mechanical resistor that could either partially or totally block the transmission of ultrasonic waves to the membrane. Models were evaluated with simple acoustic amplitude distributions along the axon, and fundamental differences in the responses of myelinated and unmyelinated axons were characterized. We plan to couple these morphological models with computational acoustic models of nerve anatomy to evaluate the behaviour of the framework in more realistic conditions.

**Abstract:** Over recent decades, myoelectric prostheses have demonstrated their potential to vastly improve autonomy and quality of life for upper-limb amputees by restoring some lost mobility. However, current upper-limb myoelectric prostheses are very limited in their number of controllable degrees of freedom, often allowing only a few discrete grasp types, while also requiring substantial visual attention. Here, we demonstrate surface electromyogram decoding of individual finger joint angles in real time using a multilayer perceptron model. The decoder is able to achieve simultaneous high-accuracy predictions of these many degrees of freedom during numerous sessions with both able-bodied and amputee subjects. In addition, we provide a proof-of-concept of a shared-control scheme. In this mode, the user is able to control preshaping and grasp intention while an assistive compliant controller automates fine digit movements to maximize object contact during actual grasping. This combination of multi-degree-of-freedom proportional control and automated grasp tuning allows for both precise positioning as well as lower user attention. We believe from our encouraging results that the future of myoelectric prostheses will lie within such a synergy between robotic automation and user intention.

**Title:** Rostrocaudal activation patterns in the human cervical spinal cord identified by fMRI during upper limb motor tasks

**Authors: *N. KINANY**[1], E. PIRONDINI[2], R. MARTUZZI[3], L. MATTERA[3], D. VAN DE VILLE[1], S. MICERA[1]
[1]Ecole Polytechnique Fédérale De Lausanne, Geneva, Switzerland; [2]Med. Image Processing Lab., Univ. of Geneva, Geneva, Switzerland; [3]Fondation Campus Biotech, Geneva, Switzerland

**Abstract:** The spinal cord is the main interface between the brain and the periphery. Rather than acting as a simple relay, it actively participates in the sensorimotor processes. However, the nature of the underlying spinal mechanisms remains to be investigated. In this regard, non-invasive imaging of the spinal cord stands as a promising tool. Nevertheless, many challenges (e.g., small cross-sectional area, field inhomogeneities or also physiological noise) have hindered the development of functional magnetic resonance imaging (fMRI) approaches for the spinal cord. Although new technological advances in terms of equipment and pre-processing have allowed to circumvent these constraints, a thorough characterization of the potential and limitations of the technique is still lacking. Notably, the precision and the reliability of spinal cord fMRI are still debated.
Here we aimed at assessing whether spinal activity can be reliably detected in different segments of the spinal cord during upper limb motor tasks. We performed spinal cord fMRI in right-handed healthy volunteers using a T2*-weighted gradient-echo echo-planar-imaging sequence on a 3.0 Tesla MRI system. We probed blood oxygenation level-dependent signal changes in the cervical spinal cord during a task-based experiment involving alternating periods of rest and upper limb movements. The movements were selected to include different myotomes, in order to potentially elicit activations in different spinal segments. Electromyographic recordings were also employed to relate muscular and spinal activities. Finally, physiological signals (pulse oximetry and respiration) were acquired over the course of the experiment and further used for noise removal.
Task-related activity was observed at the individual and group level. More specifically, the selected movements were characterized by specific patterns of activation, distributed rostrocaudally and in distinct segments consistently with anatomy. Our results suggest that the recorded fMRI signals stem from a neural origin and reflect the underlying activation of the

motoneuron pools innervating the task-related muscles. Spinal cord fMRI thus offers the prospect of a novel tool to study motor processes, as well as their modification following neuro-motor disorders.

**Title:** Effect of tibialis anterior fatigue on the recruitment curve of the soleus h-reflex

**Authors: *I. E. JESUS MAGALHÃES**[1], R. B. NETO[1], M. BOTTARO[2], R. A. MEZZARANE[1]
[1]Lab. of Signal Processing and Motor Control, [2]Univ. of Brasilia, Brasília, Brazil

**Abstract:** Fatigue is a reduction in the maximal voluntary force that occurs after constant muscle activation. Changes in the excitability of reflex pathways indicate neurophysiological effects of the fatigue. The analysis of parameters obtained from sigmoidal fitting of the soleus (SO) H-reflex recruitment curve (RC) was presently used to evaluate the neuronal adaptations in different populations of motor units followed fatigue of tibialis anterior (TA) muscle. Such adaptations have already been reported in previous works, however, there are scarce information about the fatigue effect of the antagonist muscle on the excitability of the stretch reflex pathway. Therefore, the aim of the present study was to investigate the possible effects of fatigue in TA on the recruitment pattern of the SO H-reflex. Seventeen healthy and physically active male subjects, between 18 and 35 years, participated in the present study. The recruitment curve (32 points) of the right SO H-reflex was built by changing the electrical stimulus in seven different moments: at rest, after a maximal isometric voluntary contraction (MIVC) of the anterior tibialis in the isokinetic dynamometer, immediately after the MIVC, and 5, 10, 15 and 20 minutes after the fatigue protocol. It was asked the subjects to maintain a contraction level between 40 and 60% of the MIVC, with visual feedback from the dynamometer software. Fatigue was determined as the incapacity to maintain the selected level of force for 5 consecutive seconds. Parameters from a sigmoid function fitted to the RC values were obtained. An ANOVA of repeated measures was used to detect differences in these parameters across conditions. The significance level was set at $p<0,05$. There was no statistical difference in parameters extracted from the RC, despite a tendency of increased amplitude of the threshold H-reflex (from the first motor units being recruited), as compared to the remaining conditions. This result could suggest a higher excitability of the first recruited low threshold motor units after fatigue of the antagonist muscle. Additional experiments will be performed to confirm or refute this hypothesis.

**Title:** Primary motor cortex TMS-evoked ERPs decomposed using ICA

**Authors: *M. MIYAKOSHI**[1], M. R. BORICH[2], T. MULLEN[3], S. MAKEIG[4]
[1]Swartz Ctr. For Computat. Neuroscience, INC, UCSD, La Jolla, CA; [2]Emory Univ., Atlanta, GA; [3]Qusp Labs, San Diego, CA; [4]Inst. of Neural Computation, UCSD/INC/SCCN, La Jolla, CA

**Abstract:** To test whether high-density encephalographic (EEG) recording during transcranial magnetic stimulation (TMS) allows effective source-resolved imaging of localized cortical activities that are broadly projected to the scalp by volume conduction, we investigated the cortical sources of event-related potential (ERP) responses to TMS stimulation over primary motor cortex. Twelve healthy participants participated in the study. Single TMS pulses were delivered at 120% of resting motor threshold (RMT) over right or left primary motor cortex (M1) during eyes open rest. We replaced pulse-contaminated data points (0-10 ms) with autoregressively-extended EEG that we then blended into the original data (10-20 ms). Preprocessed EEG data were decomposed by adaptive mixture independent component analysis (AMICA). Resulting independent component (IC) processes were clustered across subjects based on dipole locations. Results indicated: 1) the same small set of IC clusters dominated both the early (10-30 ms) and late (30-300 ms) ERP time courses; 2) the largest difference between right- and left-stimulation ERPs (near 60 ms) was earlier than first major ERP peak (near 100 ms); 3) the primary effective sources of the ERPs were in primary sensorimotor, anterior cingulate, and cuneus; 4) primary motor sources showed strongest side-of-stimulation response differences. Thus, source-resolved EEG analysis of TMS-evoked responses can identify, localize, and quantify the activities of major ERP generators in cortical locations that were here largely in common across subjects. Source-resolved EEG imaging before, during, and after TMS could improve both our understanding and therapeutic targeting of abnormal cortical activities associated with many neurologic conditions.

**Title:** Primary motor cortex (M1) inhibition increases during fatiguing repetitive movements but force and central drive to the muscle are preserved

**Authors: P. ARIAS**[1], E. MADINABEITIA[1], A. MADRID[1], *J. CUDEIRO[2,3]

**Abstract:** Muscle fatigue has central and peripheral origins. While the central origin of muscle fatigue induced by isometric activities is well defined, little is known about the central determinants of fatigue for repetitive movements. Perhaps for this reason, the gold-standard reference to determine central fatigue in clinical practice is the reduction in both, muscle force and central drive to the muscle during isometric activities. This reduction appears in parallel with an increase in inhibition of M1 and spinal cord circuits. In this work, we tested if force and central drive to the muscle are reduced after fatiguing repetitive movements; we also tested the state of inhibitory circuits in the motor cortex right at the end of the fatiguing activity.
Eleven young healthy subjects participated in different experimental blocks involving the execution of several sets of finger tapping (*ft*), all performed at the maximal possible rate for 30secs. Before and immediately after *ft* we tested: i) muscle force ii) the level of central drive to the muscle; iii) the silent-period (SP) induced by transcranial magnetic stimulation which is a surrogate marker of the excitability of inhibitory M1-interneurons (GABAb-dependent).
The *ft* rate decrease rapidly, ≈18% at the end of the task ($p<0.001$); while SP increased (≈18%; $p<0.001$). Force and central drive to the muscle were not different before and after *ft*.
Neither, the reduction of force nor the central drive to the muscle are underlying factors of fatigue induced by repetitive movements. This type of fatigue presents a central component, which physiological mark is the increased inhibition of M1. These results might be of importance in the fields of sport, ergonomics, and in the study of diseases where fatigue is a clinical sign.

**Title:** Modulations in corticospinal excitability accompanying contraction mode conversion during joint movements

**Authors: *A. HIGASHIHARA**[1], K. NAKAGAWA[2,4], K. NAKAZAWA[3]
[1]Fac. of Sport Sci., Waseda Univ., Saitama, Japan; [2]Grad. Sch. of Arts and Sci., [3]The Univ. of Tokyo, Tokyo, Japan; [4]The Japan Society for the Promotion of Sci., Tokyo, Japan

**Abstract:** Lengthening (LEN) and shortening (SHO) contractions are the fundamental patterns of muscle activity underlying movement. Previous studies have shown that excitability of the corticospinal pathway is significantly lower during LEN than during SHO contractions, despite the similarity of their background electromyographic activity (BGA) levels (Abbruzzese et al., 1994; Sekiguchi et al., 2001, 2003; Uematsu et al., 2010). However, modulation of corticospinal excitability accompanying contraction-mode conversion during joint movements is unclear. The present study investigated phasic modulation in corticospinal excitability during wrist joint movements. Participants performed single, rapid wrist movements by resisting and lifting weights (20% maximal voluntary, isometric contraction force) connected to a dynamometer through a pulley system. Single transcranial magnetic stimulation (TMS) at 130% of the active motor threshold was applied to the left M1 at random timing before and after wrist movement conversion. Motor evoked potentials (MEPs) were measured as the peak-to-peak amplitude value from the right flexor carpi radialis muscle (FCR). The BGA of the FCR was averaged in a 20-ms window just before the TMS was delivered. The timing of the TMS was rearranged referencing to the timing at which the wrist movement converted, and each data were sorted into 5-degree bins and were averaged within each bin. A two-way repeated analysis of variance was used to compare the differences between before (LEN phase) and after (CON phase) wrist movement conversion for corresponding symmetric angles. The results showed that the BGA of the FCR during the LEN phase was significantly larger than that of the CON phase, whereas there were no differences in the MEPs between two phases. These results suggest that during the LEN phase before the wrist movement conversion, the inhibitory component of the corticospinal pathway was relatively higher than that during SHO contractions.

**Title:** Influence of passive finger movement with & without duty cycle on corticospinal excitability

**Authors: *S. TSUIKI**[1,2], R. SASAKI[1,2], S. MIYAGUCHI[1], S. KOJIMA[1], K. SAITO[1], Y. INUKAI[1], M. MASAKI[1], N. OTSURU[1], H. ONISHI[1]

[1]Inst. for Human Movement and Med. Sci., Niigata Univ. of Hlth. and Welfare, Niigata city, Japan; [2]Grad. School, Niigata Univ. of Hlth. and Welfare, Niigata city, Japan

**Abstract: Background/Objective:** Previous study reported corticospinal excitability decreases after passive movement (post-exercise cortical depression). However, there are also reports stating that corticospinal excitability increases or does not change after repeated passive movement. These conflicting results are likely due to the use of different intervention conditions. However, it is unclear whether corticospinal excitability is influenced by passive movement with duty cycle. Here we aimed to clarify the effect of passive finger movement with & without duty cycle on corticospinal excitability. **Methods:** Nine healthy subjects participated in this study. Motor-evoked potentials (MEPs) were used to evaluate corticospinal excitability before intervention (pre) & immediately (post0), 5 min (post5), & 10 min (post10) after intervention with transcranial magnetic stimulation (TMS). MEPs were recorded from the right first dorsal interosseous (FDI) muscle. The intensity of the stimulator output was adjusted to baseline recordings so that the average stimulus produced an MEP of 1 mV in the relaxed FDI muscle. TMS was delivered over 15 trials. For passive movement, repetitive abduction-adduction movements of the right index finger were performed for 10 min; movement ranged from a neutral position to 20° of abduction. Experiments were completed using three conditions: (1) movement velocity of 40°/s & consecutive repetitive passive movement (600 times); (2) movement velocity of 40°/s & intermittent repetitive passive movement (240 times) with a configured duty cycle of 4 s on/6 s off; & (3) movement velocity of 100°/s & intermittent repetitive passive movement (600 times) with a configured duty cycle of 4 s on/6 s off. All experiments were performed in the afternoon, and the three interventions were performed in a repeated measurement design in a random order with an interval of at least 3 days between each condition. Mean MEP amplitudes were calculated from peak-to-peak amplitudes. **Results:** A two-way repeated measures analysis of variance revealed a significant condition & time interaction ($p < 0.05$). MEP amplitudes elicited at post0 & post5 under condition 1 were significantly smaller than pre-intervention values ($p < 0.05$). However, MEP amplitudes at pre-intervention & post-intervention under conditions 2 & 3 were not significantly different. **Conclusion:** These results demonstrate that 10 min of consecutive repetitive passive movement, but not intermittent repetitive passive movement with a configured duty cycle, reduces corticospinal excitability.

**Title:** Integration of sensory and motor inputs in spinal motoneurons

**Authors: *A. A. MAHROUS**, S. M. ELBASIOUNY
Neuroscience, Cell Biology, and Physiol., Wright State Univ., Dayton, OH

**Abstract:** Motoneurons in the spinal cord represent the final common pathway for the motor commands processed in the nervous system. A motor intent that originates in the brain reaches spinal motoneurons through descending tracts (motor input). The motoneurons also receive feedback from their target muscles through the dorsal root ganglia sensory neurons (sensory input). Each of these two inputs has been separately investigated in many studies. However, the ability to perform precise movements and develop motor skills require closed-loop motor control in which both inputs are integrated. We investigated the interaction between motor and sensory inputs to motoneurons in the adult mouse spinal cord in vitro. Sensory inputs were induced by electrical stimulation of the dorsal roots, while motor inputs were induced by stimulation of the descending axons through an electrode placed on the surface of the cord. The two inputs were induced separately and then simultaneously at different frequencies, intensities, and neuromodulatory states. The motor output in response to stimulation was recorded from single motoneurons using sharp electrodes, or from ventral roots using bipolar wire electrodes. Our results show a non-linear fashion of summation of the two inputs at the cellular as well as the motor pool levels.

**Authors: *C. DEWITZ**[1], P. HACKEL[1], N. ZAMPIERI[1,2]
[1]AG Zampieri, Max Delbruck Ctr. For Mol. Med., Berlin, Germany; [2]Charité - Universitätsmedizin, Cluster of Excellence NeuroCure, Berlin, Germany

**Abstract:** Circuits controlling the activity of motor neurons are crucial for the execution of motor programs that underlie movement. The precise organization of different motor neuron subtypes into spatially distinct and conserved structures, termed pools, is a potential strategy to simplify the problem of wiring pre-motor circuits (Surmeli et al., 2011). Thus, it is of great interest to define the mechanisms controlling motor neuron positioning during development in order to better understand the processes regulating the assembly of motor circuits. Previous studies show that classical cadherin (type I and type II) adhesive signaling is a determinant of motor neuron spatial organization (Price et al., 2002; Demireva et al., 2011; Bello et al., 2012). However, the mechanisms and relative contributions of different cadherins are still unclear. Expression patterns, as well as phylogenetic and binding affinity analyses suggest that distinct subsets of type II cadherins conspire to generate an "adhesive code" driving accurate motor neuron positioning into pools. On the other hand, the type I N-cadherin, which is expressed by all motor neurons, may provide a basal level of adhesion necessary for type II cadherins to promote specific recognition. In order to test these hypotheses, we established a quantitative assay to analyze positioning of motor neurons in three dimensions and compared changes in spatial organization after eliminating different combinations of classical cadherins in the mouse spinal cord.

**Abstract:** Spinal motoneurons integrate the central nervous system information and translate it into movement, requiring a control of its excitability to respond accurately to the requirements of the environment. GABA is an inhibitory transmitter that regulates neuronal excitability and neurotransmitter release via $GABA_B$ Receptors ($GABA_BR$). The aim of this work was to determine whether the $GABA_BR$ located in excitatory and inhibitory terminals of the Dorso

Lateral Funiculus (DLF) that synapse motoneurons are tonically activated by ambient GABA, inhibiting the transmitter release and regulating the excitability of the motoneurons. In slices of the spinal cord of *Trachemys sp* turtles, motoneurons intracellularly recorded were identified by their input resistance, time constant and adaptation of the action potential firing. The action of $GABA_BR$ was evidenced by applying the agonist baclofen, which inhibited synaptic potentials by ~ 50% action that was completely reversed by CGP 54626 ($GABA_BR$ blocker). Interestingly, after recovery of the synaptic potential about 15% facilitation was observed, suggesting a possible tonic inhibition of transmitter release mediated by $GABA_BR$, tonically activated by ambient GABA. In addition, it was found that the excitability of the motoneurons is also regulated by these receptors. Furthermore, blockade of the GABA transporters increased the depression of the synaptic potentials, which suggested that GABA of the extracellular medium does not come from the inversion of the transporters. Our results suggest, that $GABA_BR$ are tonically active by ambient GABA, regulate the strength of synaptic transmission between the DLF terminals and motoneurons and the excitability of these neurons.

**Title:** Restoration of motoneuron KCC2 following peripheral nerve injury is dependent on successful muscle reinnervation

**Authors: *E. T. AKHTER**[1], A. W. ENGLISH[2], F. J. ALVAREZ[3]
[1]Cell Biol. & Physiol., [2]Cell Biol., [3]Physiol., Emory Univ., Atlanta, GA

**Abstract:** Following peripheral nerve injury (PNI), axotomized motoneurons undergo many changes within the spinal cord that are not well understood. One such change is the disappearance of the potassium-chloride cotransporter-2 (KCC2) from the membrane of motoneuron somata and proximal dendrites. In the dorsal horn, KCC2 is downregulated within interneurons due to microglial release of brain-derived neurotrophic factor (BDNF). However, this is not the case for motoneurons that are themselves axotomized after PNI. In this case

microglia-specific deletion of BDNF did not prevent the removal of KCC2 from the proximal somatodendritic membrane of motoneurons. We are investigating alternative mechanisms regulating motoneuron KCC2 after PNI, including a possible role of BDNF from non-microglial sources. We also illustrate that KCC2 is only restored in animals that have undergone successful nerve repair, not those that have had regeneration prevented by tightly ligating their axons. We confirmed these findings by correlating the degree of KCC2 restoration on motoneurons with the success of reinnervating neuromuscular junctions after a sciatic nerve transection followed by repair with fibrin glue. Based on these results we suggest that the regulation of KCC2 on motoneuron proximal cell membranes cannot be entirely explained by cell autonomous mechanisms or release of BDNF from microglia. Instead it is likely that a retrograde signal from the periphery plays an important role in regulating this significant intrinsic motoneuron property.

Fndn., Gulf Breeze, FL; [6]Dept Physiol & Biophysics, Univ. Washington, Seattle, WA; [7]Spinal Neuromotor Lab., Temple Univ., Philadelphia, PA

**Abstract:** Differences in neural drive to motor pools of proximal vs. distal muscles of the upper limb likely reflect the distinct roles of these muscle groups in skilled motor control. Proximal muscles optimize arm stability to allow distal muscles to interact with the environment through fine, precise movements. While both proximal and distal muscles are innervated by corticospinal and brainstem-spinal motor pathways, proximal muscles receive a greater proportion from brainstem-spinal pathways, and distal muscles receive a greater proportion from corticospinal pathways. Both of these motor systems transmit motor commands that culminate as excitatory and inhibitory inputs alpha motoneurons. However, brainstem-spinal pathways also provide

crucial neuromodulatory input (via the release of serotonin and norepinephrine) that dramatically affect motoneuron excitability and thus change how motoneurons respond to excitatory and inhibitory input. One mechanism by which this occurs is through facilitation of persistent inward currents (PICs) that amplify and prolong the response of motoneurons to excitatory input. Presumably, this effect of PICs is beneficial for the strong, sustained contractions required of proximal muscles but detrimental to the fine, rapidly-changing activation characteristic of distal muscles.
The purpose of this study was to estimate the amplitude of PICs in deltoid, biceps, triceps, and extrinsic finger flexors and extensors in 5 individuals without neurological impairment. Using motor unit discharge decomposed from high-density surface EMG (Negro et al, 2016) recorded from each muscle, we quantified two aspects of motor unit discharge that are characteristic of PICs during slowly increasing and then decreasing triangle contractions: hysteresis of the firing rate at recruitment vs. de-recruitment (quantified using the delta-F technique), and saturation of the firing rate after the initial recruitment acceleration (quantified using the rate modulation slope). We expected that delta-F would be high in proximal muscles and low in distal muscles, with rate modulation slopes showing the opposite pattern. Group mean values for the DELT, BIC, TRI, FF, and FE for delta-F were 6.4, 3.9, 6.2, 3.6, and 3.2 pps, respectively, and values for rate modulation slopes were .01, 0.38, -0.07, 0.18, and 0.28 pps/%MVT. Values for both metrics were similar for DELT and TRI and fit our expectation; however, BIC was similar to more distal FF and FE. Across all muscles, there was a significant correlation between individual mean delta-F and rate modulation slopes ($r = -0.52$, $p = 0.03$), demonstrating a relationship consistent with activation of PICs.

**Title:** A nova-dependent microexon splicing program controls neuromuscular junction in the tunicate ciona robusta

**Authors: *M. HOSSAIN**[1], A. STOLFI[3], L. CHRISTIAEN[3], M. RUGGIU[2]
[1]Biol. Sci., [2]Dept. of Biol. Sci., St. John's Univ., Jamaica, NY; [3]Biol., New York Univ., New York, NY

**Abstract:** Alternative splicing (AS) is a major driving force in amplifying the coding capacity of eukaryotic genomes. By generating multiple transcript variants from a single gene, AS produces proteome diversification, modulates protein function, and contributes to tissue specificity. The central nervous system comprises the tissues and cells with the highest rate of AS in the body, and RNA-binding proteins play a major functional role in neurons. Microexons -that is, exons smaller than 50 nt- are of particular interest for nerve cell biology as more than 90% of regulated microexons show the highest rate of inclusion in neurons. Moreover, 1/3 of all neuron-specific AS events conserved between mouse and human are microexons, and microexons engage in critical functions in neurons. The large proteoglycan agrin is a major player at the neuromuscular junction (NMJ), a synapse between nerve cells and muscle cells, and the best-studied model synapse. Interestingly, NMJ function is completely regulated at the level of AS: while agrin is transcribed in every cell of the body, only neurons make a splice variant -termed Z agrin- that is responsible for the formation, development, and maintenance of the NMJ. Interestingly, agrin undergoes AS at 3 different sites termed X, Y, and Z, and all these splice variants encode for microexons, making agrin a unique model gene to study evolution and function of biologically-relevant microexons. In mammals, there are two microexons at the Z site, termed Z8 and Z11 as they encode for 8 and 11 amino acid (AA) peptides, respectively. The Z exons are also of particular interest as they are potential mutation sites in congenital neuromuscular diseases. By using the tunicate *Ciona robusta* as our animal model, here we show that a neural-specific microexon program is conserved between tunicates and mammals, and is regulated by the paraneoplastic neurologic degeneration antigen Nova. We cloned both Nova and agrin from *Ciona* and discovered that the Z exons are even smaller in tunicates, encoding for only 6 and 5 AA respectively. Nova is a neuron-specific splicing regulator with three RNA-binding domains of the KH type. While in mammals Nova appears to regulate splicing via its third KH domain, in *Ciona* Nova requires the first two KH domains to mediate Z exon inclusion, and it does so via a bipartite intronic splicing enhancer downstream of exon Z5. Our work establishes the tunicate *Ciona robusta* as a model organism to study microexon function and its relevance to synapse biology and neurodegenerative diseases.

**Title:** Acute MeHg exposure alters immunofluorescence of the Renshaw Cell Area in the C57BL/6J mouse model

**Authors: *M. RIOS CABANILLAS**, W. ATCHISON
Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

**Abstract:** Renshaw cells (RCs) are spinal cord inhibitory interneurons that receive excitatory collaterals from alpha motor neurons mediated through cholinergic transmission. RCs send inhibitory axons that synapse back on the same motor neuron through both GABAA- and glycinergic neurotransmission. This completes the negative-feedback circuit named “recurrent inhibition”. Methylmercury (MeHg) is an environmental contaminant that easily binds to cys-loop ligand-gated receptors and it accumulates on spinal cord motor neurons. MeHg neurotoxicity leads to calcium dysregulation and hyperexcitability, which may lead to motor neuron cell death and loss of recurrent inhibition. Chronic MeHg treatment of SOD1 G93A mice hastens the onset of ALS-like phenotype. RCs have been reported to degenerate in both ALS rodent models and patients. Thus, disruption of RC function, or their loss by MeHg could contribute to the hastened development of ALS-like phenotype in the SOD1 mouse model. The goal of this study is to determine if acute (1hr) in situ MeHg exposure alters the expression of proteins associated with RCs (calbindin, gephyrin and ChAT), suggesting loss of RCs which could, in turn affect recurrent inhibition, thereby leading to enhance motor neuron excitability in the lumbar region of the C57BL/6J mouse. The RCs area is determined by the characteristic presence of gephyrin clusters, calbindin d28k immunoreactivity and the presence of cholinergic contacts. Immunohistochemistry demonstrate MeHg toxicity effects on the RCs area measured by the presence of ChAT, calbindin d28k and gephyrin primary antibodies. Staining of all three antibodies was markedly decreased at 5μM MeHg by at least 40 fold from control (ChAT 90%, calbindin d28k 36% and gephyrin 24%). At higher MeHg concentrations, there was first an increase and then decrease in staining intensity. All experiments $n \geq 4$. Research supported by NIEHS/NIH grant R01 ES024064.

**Authors: *H. BAGHERZADEH**, Q. XIE, K. DEMMERLE, D. GUPTA, F.-S. CHOA
Computer Sci. and Electrical Engin. Dept., Univ. of Maryland, Baltimore County, Baltimore, MD

**Abstract:** It is believed that conscious brain may go through higher level brain hubs to indirectly influence lower level subconscious circuits, particularly those in the deep brain regions, like the roots of cranial nerves and brainstem. It would be interesting and beneficial to understand the mechanisms employed by such activity. One of the potential paths to study these mechanisms is through mirror neurons, which play critical roles in linking doing, seeing, imagination, mind reading (theory of mind), social cognition, language and speech processing, and neural disorders like Autism. Mirror neuron activities usually can be monitored by observing Mu wave suppression at motor cortex. Mu rhythm is an electroencephalography (EEG) brain wave between 8 and 13 Hz recorded by scalp electrodes over the sensorimotor cortex in non-active states. To understand mirror neuron's role in activating subconscious brain circuits, we would like to first quantitatively calibrate a person's mind reading ability. We also would like to separate their influence over spinal cord path and cranial nerve path. Mu wave ERS (Event-Related Synchronization) and ERD (Event-Related Desynchronization) have been proposed as signatures of voluntary movements. Various techniques such as MEG, EEG, and fMRI have been deployed to detect mu wave. In the current study, mu rhythm suppression was investigated using EEG in response to speaking (cranial nerve activity), fist making (spinal cord activity), and their corresponding imagination. Four subjects performing these tasks were studied. Referential (monopolar) EEG montage was obtained using 18 electrodes spread over the scalp including 2 electrodes on sensorimotor cortex (C3 and C4) with each action responding to contralateral hemisphere brain structures. Since left hand was used to press time marker (right brain hemisphere activity), only the signals from the left hemisphere electrodes were analyzed. As expected, significant mu wave suppression was observed in sensorimotor cortex in response to the performed tasks. While the imagination of speaking and fist making could be affected by different neurons, the suppression of mu rhythm on both cases was observed. The signals on the electrodes close to the C3 electrode also changed to a lesser degree during the mu wave suppression. The data show that the mu wave suppression on speaking and fist making action may employ the same mechanism and not separable even though the degree of the mu wave suppression of imagination of speaking is slightly less than that of first making. The results also imply that EEG and mu wave detection can be quantified and possibly used to calibrate a person's mind reading ability.

**Title:** A unique adult insect muscle with polyneuronal innervation displays distinct domains of innervation from different segmental nerves

**Authors: *M. J. VALESKY**, G. W. SMITH, R. J. BAYLINE
Washington & Jefferson Col., Washington, PA

**Abstract:** Motor neuron innervation patterns can heavily influence adult muscle development in a variety of insects. Specifically, innervation can influence myoblast proliferation and accumulation in both *Drosophila melanogaster* and *Manduca sexta*. In the moth *Manduca sexta,* diverse muscles types such as the dorsolongitudinal flight muscle, thoracic leg muscles, and abdominal body wall muscles all require innervation for proper proliferation and growth. One muscle, the tergosternal muscle (TSM), does not show an absolute requirement for innervation. The TSM is unique in that its appearance and development differs from other adult skeletal muscles in *Manduca*. The TSM develops later than other skeletal muscles, beginning accumulation and proliferation 2-3 days later than other abdominal muscles, and forms a sheet of parallel fibers positioned dorosoventrally along the lateral epidermis surrounding the spiracle. In contrast to other adult *Manduca* skeletal muscles that typically receive innervation from single motor neurons, the TSM receives innervation from eight motor neurons with axons in both the dorsal and ventral segmental nerves. Considering that the TSM is the only abdominal muscle to receive innervation from multiple neurons via different nerves in the adult, single TSM fibers may be polyneuronally innervated via both the dorsal and ventral nerves. If true, this would suggest that the mechanism by which motor neurons target individual muscles fibers may differ for the TSM when compared to other abdominal muscles. Anterograde nerve fills reveal that motor neurons derived from the dorsal nerve innervate the anterior two-thirds of the TSM, and motor neurons derived from the ventral nerve innervate the posterior third. Initial physiological recordings support the findings from histological data that the domains of innervation of the TSM from the ventral and dorsal nerve are completely segregated. Taken together, these data reveal that, although the TSM has a unique pattern of development and reduced dependence upon innervation during development, the innervation that it receives is restricted to different domains that is not distinct from other abdominal muscles.

**Title:** Changes in spinal motor networks when cocultured with astrocytes or striated changes in spinal motor networks when cocultured with astrocytes or striated muscle

**Authors: *A. THARANEETHARAN**, M. A. HARRINGTON
Delaware State Univ., Dover, DE

**Abstract:** Co-cultures are a traditional method for studying the network properties of cell to cell interactions among different cell types. How cellular properties in these multicellular synthetic systems vary from monocultures are of particular interest. Understanding these changes in cell behavior can provide new insights into *in vivo* systems and how to develop models that better reflect physiological conditions - something of paramount importance to the progress of synthetic biology. Through synthetic biology positive social impact can be delivered by the development of future biomedical applications.
*In vitro* models of spinal motor neurons have been customarily studied as a monoculture, and the overwhelming consensus is that in culture they are different in nature from their *in vivo* counterparts. All vertebrate motor neurons are cholinergic, but under common cultured conditions they are primarily glutamatergic. As a control we used E7 embryonic chick spinal ventral horns cultured on a hydrogel matrix substrate, we compared them with those co-cultured with spinal astrocytes or striated muscle also from embryonic chicks.
We studied the electrophysiological properties of these networks using 64 channel multielectrode array (MEA) systems. An increase in synchronous firing was observed when ventral spinal motor neurons were cocultured with astrocytes. Cholinergic receptor activity in spinal motor neurons was notably increased in striated muscle cocultures. We also examined levels of ChAT, GFAP, HB9, VACht, and neurofilament via in the cultured neurons with western blot and immunocytochemistry. Particular attention was given to changes in ChAT, HB9, and VAChT in striated muscle cocultures; while changes in GFAP levels were noted in astrocyte cocultures. Traditional culturing techniques involving a monolayer of uniform cell type might not be the best way to mimic *in vivo* systems. A synthetic ecosystem of various cell subtypes is beneficial to replicating cell behavior *in vitro*, thus is a necessary refinement to the commonly used technique of cell culture. With a more accurate model system, the questions that we ask about interacting systems can be addressed with greater accuracy.

**Abstract:** Some cells in the motor-related cortices directly control muscles via spinal motoneurons (MNs) by monosynaptic connection in higher primates. It is generally accepted that this direct connection in primates is essential for dexterous hand movements. We previously showed that corticospinal (CS) synapses are once formed throughout the spinal cord, but are eliminated from the ventral horn during development in rodents, raising the possibility that CS axons transiently make direct connections with MNs located in the ventral horn of the spinal cord. Indeed, it was disclosed that MNs innervating distal forearm muscles receive monosynaptic inputs from CS axons electrophysiologically by whole cell recordings and with optogenetic stimulation of CS axons in mice. We then employed a genetically modified rabies virus that spreads only monosynaptically and demonstrated that CS neurons make direct connections with MNs innervating distal forearm muscles in juvenile mice, but lose them by postnatal day (P) 22. Based on these findings, here, we used genetic approaches to elucidate the molecular mechanisms for which MNs transiently make direct connections with CS neurons in juvenaile stage and lose them late in the development. We payed special attention to identify defined MN subtypes as follows. MNs innervating distal forearm muscles of mice were retrogradely labeled via intramuscular injection of fluorescent cholera toxin B subunit to ascertain the location of their MN pool in the spinal cord. Thereafter MNs located in the MN pool of distal forearm

muscles stained with 0.1% toluidine blue, were isolated by laser microdissection from spinal cord slices of P10 and P21 mice. Gene expression profiling of these two samples using microarray was performed and we compared the obtained array data. Among the 22,341 genes surveyed, 278 displayed an increase of more than 2-fold expression and 725 displayed a decrease of less than half in MNs of P10 mice. Of these, genes involved in synaptic function and cell adhesion accounted for 61 and 35 genes, respectively. These findings would contribute to elucidating the molecular mechanisms for emergence of direct connections between CS axons and MNs, which serve as the basis for dexterity in primates.

**Title:** The functional role of activity-dependent plasticity in motoneurons during development revealed by metabotropic glutamate receptor activation

**Authors: *S. S. BERTRAND**, J.-R. CAZALETS, M. SOURIOUX
INCIA CNRS UMR5287, Bordeaux, France

**Abstract:** In neuronal networks, synaptic strength is not constant but depends on the past activity of the synapse. This change in synaptic efficacy called activity-dependent synaptic plasticity (ADSP) is paramount to synaptic processing and maturation. Using spinal cord slices from mice at two developmental stages, 1-4 and 8-12 postnatal days (P1-P4 ; P8-P12), we have previously shown that high-frequency stimulation of presumed reticulospinal neuron axons in the ventrolateral funiculus (VLF) induced either a long-term depression (LTD), a short-term depression (STD) or no synaptic modulation in limb MNs depending on both spinal cord developmental stage and functional flexor or extensor MN subtype.
In the spinal cord, metabotropic glutamate receptors (mGluRs) modulate synaptic transmission and undergo subtype-specific regulation of their expression and localization during development. In the present study, we investigated the impact of mGluR activation on ADSP expression in P1-P3 and P8-P12 MNs. We found that mGluR agonists differentially and selectively modulated ADSP at VLF-MN synapses in a developmentally regulated manner. We then used mGluR activation as a tool to indirectly access the functional role of high-frequency-induced-synaptic plasticity at VLF-MN synapses in locomotor pattern generation. For this purpose, the effects of mGluR agonists were analysed during VLF-induced fictive locomotion in the *in vitro* spinal cord preparation and *in vivo* during swimming episodes recorded from newborn mice.

**Authors: E. D. GRIBKOVA**[1], *R. GILLETTE[2]
[1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Dept Physiol., Univ. Illinois, Urbana, IL

**Abstract:** A wide variety of learning algorithms are known that can establish simple associations between sensory stimuli and rewards. However, few have explored extinction and recovery of these learned associations using the delicate balance of excitation and inhibition often observed in natural neuronal circuits. We used our agent-based foraging simulator, Cyberslug™, to compare three different algorithms for learning: the Rescorla-Wagner model, a temporal difference learning (TDL) model, and a novel learning and extinction circuit. In particular, for this novel learning and extinction circuit we hypothesized that extinction and spontaneous recovery of learned associations can occur primarily due to the spontaneous activity of a central inhibitory neuron. The learning circuit consists of 1) sensory neurons that monitor the agent's perceived odor signatures, 2) reward neurons that monitor the agent's received positive and negative rewards, and 3) a spontaneously active "no-reward" neuron that is in reciprocal inhibition with the reward neurons. Associations between sensory and reward or no-reward neurons are learned through a simple Hebbian learning rule that includes eligibility traces for sensory and reward neuron activity. Forgetting is implemented as a constant and steady decay of learned association strengths. When compared to the other algorithms, this learning and extinction circuit appears to adapt more quickly to changes in environment, including arrival and departure of different types of prey that may express the same odor signatures but provide very different rewards.

**Title:** Computational strategies underlying arm coordination of Octopus rubescens during naturalistic foraging

**Authors: *D. M. SIVITILLI**[1], V. GOPAL[2], A. SEMINARA[3], J. A. SISNEROS[1], D. H. GIRE[1]
[1]Psychology, Univ. of Washington, Seattle, WA; [2]Physics, Elmhurst Col., Elmhurst, IL; [3]Lab. de Physique de la Matière Condensée, CNRS, Univ. Nice Sophia Antipolis, Nice, France

**Abstract:** The ability to locate food has been one of the main selective pressures during the evolution of cognition. We studied *Octopus rubescens* to define how an evolutionarily distant yet cognitively sophisticated species of animals forages for food under semi-naturalistic conditions. Despite their high degree of visual acuity, octopuses are primarily nocturnal hunters, using the highly concentrated chemoreceptors located in the suckers on their arms to detect and discriminate odors emanating from food sources, and can distinguish objects by their chemical composition alone. This sensitivity is crucial for nocturnal hunting and navigation strategies through the use of chemical trails and plumes. While their chemosensory abilities rival that of macrosmatic mammals, octopuses have evolved divergent behavioral and neural mechanisms to process chemical information. Each arm of the octopus is highly autonomous neural processing within peripheral ganglia along the arms allows the octopus to locally integrate large amounts of sensory information in parallel. In fact, more of the octopus nervous system is located in the

periphery than in the central brain. To study how this distributed nervous system processes chemical information to guide natural behavior we have developed a food foraging task for the octopus and combined this task with semi-autonomous arm tracking algorithms. We placed food items as well as inert objects at a distance (75cm) from the octopus's den in an aquarium (120x30x45cm). The octopus then foraged for these food items, discriminating between them to locate its preferred food. Octopus behavior was imaged at a high rate (220 Hz) and automated segmentation was performed to quantify the trajectory of the animal and its arm configuration. We found that during nocturnal foraging octopuses alternated between sampling and movement. A typical trajectory involved pausing at a distance from the food source while maximizing the area sampled by its arms, retracting the arms back toward the animal and then moving toward the food source. We compared these trajectories to odor plumes imaged from the food locations (obtained with laser-induced fluorescence of fluorescein) and found that the octopus obtained odor information almost entirely during the sampling phase and not during movement. Taken together, these data suggest that octopuses are capable of extracting directional information from odor plumes by using their arms to sample large areas of a plume, and that this information directs movement toward the probable location of the odor source. Further work will define the algorithms used to integrate odor information across the arms during this behavior.

**Abstract:** Soft-bodied animals, such as earthworms, are capable of locomotion in diverse environments. Duplicating these behaviors for robotics would be valuable in constrained-space applications (such as burrowing, exploration and, search and rescue). However, soft-bodied locomotion is a challenging problem for robotics and biological insights can be valuable in both the control and mechanical design. Here, we present a robotic platform for exploring the biomechanics and neurobiologically inspired control of soft-bodied peristaltic locomotion. Our

initial focus in determining the roles of circumferential and longitudinal stiffness for locomotion and turning. The robotic platform is inspired by earthworm locomotion. Earthworms locomote using traveling waves of segment contraction and expansion. Because of the hydrostatic coupling, as the diameter of a segment increases, its length decreases. Segments can also bend. The mechanics of the body result in large range of body shapes which both comply with the environment and contribute to directed locomotion. This is true for both animals and our new twelve DOF soft robotic platform: Compliant Modular Mesh Worm robot with Steering (CMMWorm-S). The CMMWorm-S is a mesh-based robot that uses cables for actuation. The mesh, composed of 3D printed rigid pieces and flexible tubes, allows us to interchange components easily to vary the stiffness of the robot. On this robotic platform, we show that locomotion efficiency is highly sensitive to body stiffness. High longitudinal stiffness improves turning locomotion, whereas higher circumferential stiffness improves straight-line locomotion. However, softness is advantageous to comply with its surroundings in order to access tight spaces, getting traction from irregular surfaces and recovering from external perturbations. Earthworms could be adjusting body stiffness to suit to their particular task based on sensory feedback. In future work, to better model the animals' responsiveness, mechanosensors, such as pressure and stretch receptors, could provide input to neurobiologically inspired control circuits.

**Title:** Algorithms underlying olfactory navigation in walking fruit flies

**Authors: *E. ALVAREZ-SALVADO**, K. NAGEL
Neurosci. Inst., NYU Langone Med. Ctr., New York, NY

**Abstract:** In order to locate food sources in the complex, natural environments, fruit flies rely on multi-sensory integration, using odors and wind cues simultaneously. This combined use of environmental information applies beyond the olfactory system, and it is critical for many other organisms. We want to understand the computations necessary to turn complex sensory input into a goal-directed, successful behavior.
To achieve this goal, we have developed a high-throughput assay to monitor olfactory-driven behavior in walking flies, while precisely controlling wind and odor stimuli. Using this apparatus we have identified the major behavioral components that underlie the search for an attractive odor's source. In the presence of odor, flies move faster and straighter towards upwind ("odor-ON"), and following odor offset, a slower searching pattern dominates flies' movements ("odor-OFF"). Surgically blocking the ability of flies to sense wind direction precisely eliminated any directional specificity to these responses, showing that wind is exclusively determining flies' orientation. However, changes in speed and straightness/tortuosity of movements were still observable independently of wind-sensation, therefore being triggered by odor onset/offset alone. These results suggest parallel processing of different sensory cues and provide evidence of cross-modal interaction.
We are currently investigating the intra- and inter-individual variability observed in the different parts of this behavior. Our goal is to test whether there are consistently different patterns of response between individual flies and also across genotypes. These can be expressed in uniquely shaped trajectories or different probabilities of exhibiting odor-ON or OFF responses.
Based on our experimental measurements, we developed a computational model that is capable of reproducing the behavior of real flies. We use this model to show that the algorithms described are sufficient to solve more complex and realistic tasks. Furthermore, our model provides insight into the specific roles played by each of the different components of the flies' behavior.
Together, our data and model help us understand the computations taking place in the fly brain during olfactory search behavior, and represent a first step towards dissecting the neuronal substrates of these computations.

**Title:** The role of neural activities in AIY interneurons for controlling behavior of *Caenorhabditis elegans*

**Authors: *H. MORI**[1], H. SHIDARA[2], K. ASHIDA[3], T. NIKAI[1], K. HOTTA[1], K. OKA[4]
[1]Ctr. for Biosci. and Informatics, Keio Univ. Sch. of Fundamental Sci. and, Yokohama / Kanagawa, Japan; [2]Dept. of Biol. Sciences, Sch. of Sci., Hokkaido Univ., Sapporo, Hokkaido, Japan; [3]Dept. of Biosci. & Informatics, Keio Univ., Yokohama-Shi, Japan; [4]Keio Univ., Yokohama, Kanagawa, Japan

**Abstract:** Interneurons integrate information from sensory neurons, and calculate motor commands for behavioral control. It is known that behavioral strategies are organized by the neural processing in *Caenorhabditis elegans*. For example, when the worms are transferred from on-food plates to off-food ones, they travel in local area at first. Then after 15 minutes, they travel and search in global area. Several interneurons contribute this travel and search behavior, demonstrated by their ablation. AIY interneurons also involve in several behaviors: head movement, reversal initiation and run speed [Kocabas *et al*., 2012; Li *et al*., 2014]. Interestingly, AIY has been known to show sporadic $Ca^{2+}$ responses when worms are stimulated by odor under restricted condition in microfluidic devises [Chalasani *et al*., 2007]; however, it has not been revealed what circumstance induces such sporadic $Ca^{2+}$ responses, and whether it correlates with behaviors or not. In this study, we measured neural activities of AIY in free-moving worms, and investigated the role of sporadic $Ca^{2+}$ responses and $Ca^{2+}$ peaks with high amplitudes.
To visualize neural activities, we used a $Ca^{2+}$ indicator, G-CaMP6 [Ohkura *et al*., 2012]. As previously reported, $Ca^{2+}$ changes in AIY were detected only in neurites, not in soma. To measure the $Ca^{2+}$ level in AIY and behaviors of worms at the same time, we used a home-made tracking system. The system detected AIY locations from binarized fluorescent images, and traced worms by controlling a x-y stage driven by stepping motors. In our experiment, we investigated two pre-conditioned worms; one condition was named ‘control’ - worms just transferred from on-food plates to off-food plates, and the other condition was ‘starving’ - worms left 30 minutes after transferred to off-food plates. In both conditions, some worms showed sporadic $Ca^{2+}$ responses and $Ca^{2+}$ peaks with high amplitudes, which exceed average + 5SD of the basal activities. We investigated differences between animals with and without $Ca^{2+}$ peaks in each condition. Without regard to the control and starving, AIY activities have positive correlation with the speed of forward run in worms with $Ca^{2+}$ peaks. However, worms without peaks in starving, AIY activities have no correlation with the forward speed. These results indicate that sporadic $Ca^{2+}$ responses are important for control of forward speed, especially in starved worms.

**Title:** Innate locomotor bias in larval zebrafish influences behavioral choice

**Authors: *E. J. HORSTICK**, Y. BAYLEYEN, H. A. BURGESS
Div. of Developmental Biol., NIH/NICHD, Bethesda, MD

**Abstract:** Throughout the animal kingdom, bilateral organisms respond to their environment using asymmetric yet consistent motor strategies. A prominent example is human handedness, a behavior apparent early in life that effects social and physical interactions. Despite the commonality and impact of locomotor biases, the underlying neural bases and function remains poorly understood. Using three independent assays we demonstrate that larval zebrafish exhibit a persistent and state-dependent locomotor bias. First, we show that after loss of illumination larva respond with persistent same-direction turns. Individual larva, repeatedly tested over minutes or days demonstrated a preference for same direction turn use. Second, after loss of illumination, individual long-latency startle direction was biased. Third, larva presented with two equal intensity light spots preferentially phototaxed to either left or right-ward over repeated trials. Surprisingly, direction preference in all three assays was correlated for individual larvae. Collectively these data demonstrate larval zebrafish possess an innate locomotor bias that influences how larvae respond to environmental challenges in the absence of clear directional cues. We have excluded genetic inheritance, developmental sensory instruction, and retinal circuitry as the source of the lateralized bias. To locate circuitry driving this behavior we performed a circuit breaking screen using Gal4 lines. Lines that fail to maintain same-direction turning will help identify the neural basis of the behavioral asymmetry. Our data show that we have identified a novel persistently biased locomotor behavior in larval zebrafish, influencing how these larval engage their environment. By using this novel model we can determine how functional behavioral asymmetries are established in the nervous system.

**Title:** Natural echolocation sequences evoke target range selectivity of neurons in the inferior colliculus of the big brown bat (Eptesicus fuscus)

**Authors: *S. MACIAS**, J. LUO, C. F. MOSS
Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Echolocating bats utilize precise auditory temporal computations in biosonar to estimate their distance to objects in the environment. Here, we report that response selectivity of neurons in the inferior colliculus (IC) of the big brown bat to pulse-echo delay, the neural representation of target distance, depends on the temporal patterning of sound elements in a natural echolocation sequence. Acoustic stimuli consisted of species-specific echolocation sound sequence of frequency-modulated (FM), containing both pulses and echoes from a moving target with dynamic spectro-temporal features. About 55 % (165/299) of IC neurons showed selective and facilitated responses to a subset of pulse-echo elements in the sequence, indicating selectivity to pulse-echo delay. This response selectivity was not evident when the same neurons were stimulated with isolated pulse-echoes presented randomly at 300 ms pulse intervals. In addition, the selectivity to specific pulse-echo delay appeared for pulse intervals below 50 ms in the natural sequence, but not when pulse intervals in the sequence were unnaturally expanded to 250 ms. Our data suggests that echo responses to objects at different distances are gated by the bat's active control over the temporal patterning of its sonar emissions.

**Title:** Midbrain responses to communication and echolocation sounds in big brown bats

**Authors: *A. SALLES**, S. MACIAS, M. WARNECKE, C. F. MOSS
Psychology and Brain Sci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Acoustic communication has been studied in many species, such as crickets, birds, amphibians and mammals, including humans. Yet our understanding of the neural mechanisms of sound communication is incomplete. Bats are auditory specialists that use sound to navigate the environment and to communicate with conspecifics. Important advances have been made in understanding the neural underpinnings of echolocation, but far less is known about the mechanisms of acoustic communication. In big brown bats (Eptesicus fuscus) call structure, along with behavioral context, appears to determine the function of acoustic signals. Past studies in other bat species have shown that neurons in the inferior colliculus (IC) encode specific spectrotemporal features of natural communication sounds through selectivity to FM features. This leads us to investigate the neural mechanisms that enable the big brown bat's discrimination of communication and echolocation calls, with FM components that differ largely in duration and sweep rate. Here we compare neural responses of single neurons in the IC to acoustic signals used by bats for spatial orientation and social communication. We recorded echolocation and communication signals of bats in flight and played back these sounds to awake, passively listening animals. IC recordings were taken with multichannel silicon probes, and single units were sorted off-line. Here we compare single unit responses to the bat's own echolocation and communication signals with neural activity evoked by the signals produced by conspecifics.

**Title:** Clutter modulates midbrain SC activity in bats tracking sonar targets along the range axis

**Authors: *M. J. WOHLGEMUTH, III**[1], N. B. KOTHARI[2], C. F. MOSS[2]
[2]Dept. of Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD

**Abstract:** Echolocating bats often forage in cluttered spaces, where they must detect and track moving prey surrounded by other competing objects. This task requires that the bat localize and separate sonar objects in azimuth, elevation and range. The bat measures the time delay between sonar pulse emission and echo return to determine target distance, and adaptations in vocal behavior can therefore be analyzed to provide a measure of the bat's orientation along the range axis. The midbrain superior colliculus (SC) has been implicated in sensorimotor integration for species-specific orienting behaviors, with sensory signals related to the spatial position of an object converted into pre-motor commands for orienting towards a stimulus. In the bat SC, sensory neurons respond selectively to the 3D location of auditory objects, and premotor neurons are implicated in the generation of commands for sonar vocalizations, ear and head movements. Early research on the visuomotor orienting system of primates has shown that competitive stimulus interactions reduce SC sensory responses to an attended stimulus, and saccadic eye movement trajectories curve towards the competitive stimulus. In this study, we investigated competitive stimulus interactions between a moving prey item and stationary clutter objects positioned along the target's trajectory. Using 16-channel silicon probes, we recorded neural activity in the SC of a bat tracking a moving prey item, with and without clutter placed along the target's trajectory. We analyzed extracellular potentials off-line and determined whether sensory and motor activity in the SC of the echolocating bat was modulated by the presence of clutter objects. Our results show that distracting objects evoke adjustments in the bat's sonar orienting behaviors and alter activity of single SC neurons. This study provides new data on the role of the SC in spatial orientation in complex 3D environments.

**Title:** Fast ripple in the inferior colliculus of big brown bat encodes precise timing of sonar vocalization

**Authors: *J. LUO**, S. MACIAS HERRERA, C. F. MOSS
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

**Abstract:** Echolocating big brown bats can discriminate echo delay differences in the microsecond range. Despite decades of research, the neural mechanisms mediating such remarkable behavioral performance are not well understood. Here we report that the first spike of multiunit activity in the inferior colliculus (IC) of awake big brown bat occurs as soon as four milliseconds after the onset of frequency-modulated sweeps stimuli and shows a sub-millisecond variability in response latency. The 1st spike of multiunit activity is topographically organized, with shorter response latency and lower latency variability in ventral regions of the IC. The 1st spike of some multiunit activity was frequency selective and/or shows amplitude-latency trading. We also recorded local field potentials to the same sound stimuli, and focused our analysis on the high frequency band (200-600 Hz), also known as fast ripple. The latency of the fast ripple onset depended on stimulus amplitude and frequency, showing parallels with multiunit response patterns at the same recording sites. It is noteworthy that the onset of the fast ripple showed shorter response latency and lower temporal jitter than single unit responses to the same sound stimuli. To test whether the observed fast ripple is an artifact of the electrostatic loudspeaker signal broadcast, we replaced the playback system with a vocalizing bat and again found fast ripple responses to sound stimuli. Further analysis revealed that the magnitude of fast ripple correlated positively with the number of neurons firing synchronously. Lastly, to better understand the contribution of single unit activity to the fast ripple, we developed a biophysical model. Through quantitative biophysical simulation, we show that the magnitude of the fast ripple depends directly on the number of neighboring neurons firing synchronously within a 5 ms window. Thus, we provide the first evidence that fast ripple can encode sound stimuli and could serve to register the precise timing of auditory events on a rapid time scale.

**Title:** Density of echo flow patterns guides navigation in echolocating big brown bats

**Authors: *M. WARNECKE**[1], B. FALK[2], S. MACIAS HERRERA[2], C. F. MOSS[2]
[1]Psychological and Brain Sci., [2]Johns Hopkins Univ., Baltimore, MD

**Abstract:** Navigation and orientation are fundamental to all living creatures, and organisms must adapt their locomotion in response to environmental stimuli received through different sensory modalities. For example, some visually-guided animals, such as bumble bees, adapt their flight paths and velocity with respect to optic flow patterns (Srinivasan et al., 1996; Baird et al., 2010). Similarly, recent studies have evaluated the navigation of echolocating bats guided by acoustic flow patterns (Warnecke et al., 2016). Echo flow, cascades of echoes arriving at the ears of the moving bat, varies with the animal's velocity, its head aim, and distance to objects in the environment. When echolocating big brown bats flew through a corridor whose walls were built from symmetrically spaced poles that returned equal echo flow patterns from opposite sides, they centered themselves within the corridor. An imbalance of echo flow patterns, created by manipulating the pole-spacing on opposite corridor walls, caused bats to veer away from the side of densely-spaced poles and toward the side of sparsely-spaced poles (Warnecke et al., 2016). However, it is unclear whether bats adjusted their flight paths to use echo flow information, or to steer away from the more echoic, densely spaced corridor side. In this study, we manipulated pole echo intensity in addition to pole spacing. To understand how the bat might process echo flow, we also recorded local field potentials (LFP) from the bat inferior colliculus (IC) while broadcasting acoustic stimuli mimicking dynamic echo cascades arriving at the bat's ears as it flew through the corridor. Our analysis compares expected and actual peak times of the LFPs in response to stimuli representing echoes from the experimental corridor walls and provides insight to the bat's flight adaptations under different echo flow conditions.

**Title:** Adaptive echolocation behavior modulates sensory, sensorimotor and premotor neural activity in free flying bats

**Authors: *N. B. KOTHARI**, M. J. WOHLGEMUTH, C. F. MOSS
Johns Hopkins Univ., Baltimore, MD

**Abstract:** The superior colliculus (SC) is a laminated midbrain structure implicated in species-specific orienting behaviors. The superficial layers of the SC receive retinal input, intermediate layers show multisensory and sensorimotor properties, and deep layers exhibit pre-motor activity. Sensory information from the superficial and intermediate layers is combined to generate motor commands for orienting behaviors. Most previous research on the functional classes of SC neurons in mammals and birds, however, has almost exclusively been conducted in head fixed or anesthetized preparations using artificial stimuli, which most animals would never encounter in their natural environments. Such artificial experimental paradigms allow the experimenter to separate sensory events from motor events, which facilitates the classification of neural activity into sensory, sensorimotor and pre-motor activity. However, in nature, animals are constantly moving, and differentiating between sensory, sensorimotor and premotor neural activity is a difficult and yet unsolved problem in freely behaving animals. Here we exploit the echolocating bat's active sonar system to characterize SC activity through a unique methodology that combines both empirical and theoretical approaches. With a lightweight telemetry device, we transmitted and recorded neural signals picked up by a 16-channel silicon probe implanted in the SC of the free-flying, echolocating bat. Using the physics of sound we constructed an echo model, which allowed us to reconstruct the instantaneous acoustic stimulus space as the bat flew in a large room equipped with 13 high-speed video cameras and a 16-channel microphone array placed along the four walls. Combining neural recording with the echo model revealed that sensory, sensorimotor and motor activity in the SC is modulated by adaptive echolocation and flight behaviors in bats engaged in an ethologically relevant task.

Psychology, Univ. of Toronto, Toronto, ON, Canada

**Abstract:** Several studies around the world show a high incidence of depression and stress during pregnancy. These emotional disturbances are associated with negative effects on the outcome of pregnancy and fetal development, such as pre term birth and low birth weight. Oxytocin (OXT) is a peptide involved in the mediation of stress responses and also recently related to depression. In the present study, we investigated which factors better predict prenatal depression and stress in a heterogeneous population of pregnant women in Uruguay. Two hundred pregnant women were randomly invited to participate in the study, provided blood samples and completed several questionnaires and scales that evaluated early experiences, demographic information, current family context, depression and stress symptoms, among other information. Several polymorphisms of the OXT and OXT (OXTR) receptors were also investigated. We found a high incidence of symptoms of depression (26%) and stress (30%) in the Uruguayan population. Emotional abuse of the pregnant woman in her family of origin, couple conflicts, and lack of social support during pregnancy were the best predictors of depression and stress during pregnancy. We will discuss the contribution of genetic variants for the OXT and the OXTR receptor. Our study suggests that screening of early experiences in pregnant women and their social and family context during pregnancy may contribute to the early detection of emotional disturbances and the mitigation of the adverse effects that depression and stress have on mothers and fetuses.

**Title:** Systematical investigation of plasma metabolomics alteration among experienced meditators of Tibet Buddhism monks

**Authors: T. XUE**, T. J. XU, H. LI, *D. H. CUI
Shanghai Mental Hlth. Ctr., Shanghai City, China

**Abstract: Abstract:** Based in Buddhism philosophy, the biological mechanism underlying the promising benefit of mindfulness mediation on physiological well-being has increased interest since its growing emphasis on clinical trials, yet is still unclear. To advance our knowledge on this traditional mediation, this study first systematically investigated the altered plasma metabolomics profile in Tibetan Buddhist monks from two sects of meditation (20 Nyingma monks and 20 Gelug monks), who have practiced the historic tradition from 5 to 35 years, compared to their local meditative naïve Tibetan (20 each). Plasma were collected at their mountain retreat in Tibet. A total of 63 and 72 differential metabolites were identified and annotated in Nyingma and Gelug meditative monks, respectively, compared to their local Tibetan, 13 of which were shared between two compared groups, which was primarily associated with glucose metabolism, indicating an overlapped character of the two meditative trainings. Principal component analysis (PCA) further revealed that, regardless of meditation types, a significant discrimination of metabolites between monks and its local Tibetan was observed, suggesting markedly altered metabolic activity triggered by long-term meditation. However, different types of meditation led to distinguishable pathway changes. In terms of Nyingma monks and its local Tibetan, the pathway of peroxisome proliferator regulation was primarily altered, suggesting an affected cell activity associated with immunity through Nyingma meditation. However, nicotine metabolism and circadian rhythm were more likely to be downregulated during Gelug meditation compared to its local Tibetan, indicating an altered neural activity, which could contributed the spiritual and peaceful mind of monks. Overall, our data revealed distinctive metabolomic features displayed in Tibet Buddhism meditators and controls as well as different meditation sects, offering an initial contribution towards increased understanding of the biological processes underlying meditation.

**Abstract:** Unpredictability and fragmentation of sensory signals (FRAG) during the perinatal period is emerging as a novel, important contributor to aberrant maturation of several neural circuits related to both cognition and emotional processing, with important emotional and cognitive consequences. It is possible that FRAG impacts synaptic growth and pruning, leading to compromised structural circuitry involved with cognition and emotional processing that then predisposes adolescents to increased risk for anhedonia. Evidence for this scenario is now found in rodent models, where pups subjected to FRAG developed unique functional changes including anhedonia and enhanced amygdala reactivity. In this study, we investigated differences in structural and functional connectivity in children (range 8-11 years old) as a result of differences in patterns of sensory signals from their mothers early in life, focusing on the fragmentation and unpredictability of these signals. Using diffusion tensor imaging, resting-state functional MRI, and a unique naturalistic observation paradigm, we characterized the interaction between fragmented care (quantified as entropy rate) and functional and structural changes in amygdala (AMY), medial prefrontal cortex (mPFC), nAcc, and anterior cingulate cortex (ACC). We found that axial diffusivity (a measure known to increase with brain maturation) **is negatively correlated with increases in entropy specifically in fiber tracts between the right nACC and right mPFC**. This suggests that high unpredictability in early-life sensory signals is associated with deficits in white matter in circuits associated with pleasure/reward processing. In addition, in a longitudinal analysis of functional connectivity in resting state fMRI data**, correlated activity in the AMY-ACC circuit increased significantly and this change (higher connectivity) correlated with entropy rate**. This result suggests that high FRAG is associated with functional changes in areas involved in emotional processing during childhood. Further study is needed to test if this early aberrant development in pleasure/ reward and emotional circuitries predicts adolescent risk for anhedonia.

**Title:** Differential epigenetic patterns in children with documented trauma

**Authors: *B. S. MULLIGAN**[1], E. L. BEARER[2]
[1]Pathology, Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Dept. of Pathology, UNM Sch. of Med., Albuquerque, NM

**Abstract:** Pediatric trauma is prevalent, a leading cause of death in children in the USA (accounting for 34-39% of all deaths in ages 1 to 14 years), and is associated with development of post-traumatic stress disorder (PTSD). Why adverse childhood experiences (ACEs), such as traumatic injury, have life long impact on both mental and physical health is not understood. Our hypothesis is that ACEs trigger alterations in stress hormones and epigenetic changes (DNA methylation, DNAme) that persist over the lifespan. To test this we investigated cortisol levels from hair samples and DNA methylation from saliva collected from children, ages 4-8, referred for trauma-focused cognitive behavior therapy (TF-CBT). These children were followed at four time points, over the 6 to 8 months of therapy. We measured cortisol levels in 3cm of hair and DNA methylation at 850,000 sites in saliva at entry and one month after therapy. All but one of the children displayed altered cortisol levels: some were elevated and dropped towards normal at conclusion; one child was normal and rose significantly during TF-CBT. We found a global DNAme difference between the child whose cortisol rose and the other children. Since anxiety is known to cause dry mouth in children, we explored whether this global change may be due to cell composition of the saliva by obtaining methylation patterns for keratinocytes and whole blood and performing a reference-based cell deconvolution in RnBeads. We found that the global DNAme patterns were attributable to cell type composition of the saliva: children with ACE-related changes had saliva samples composed of 68.653% (+/- 3.343%) keratinocytes (K), with the remaining being whole blood. Those that did not report trauma showed 36.452%(+/- 5.735%) K composition. This variation in saliva cell composition of traumatized children was replicated with children from a different study, who also displayed high K composition (69.854% +/- 6.534%). Significant epigenetic differences between children who recently had trauma and those that did not remained after cell composition correction. These changes were primarily in genes involved in immune response and regulation of DNA methylation, while some were altered for genes over-expressed in the brain. To what extent duration and intensity of trauma effect these

changes, or what mechanism may drive an individual's "resiliency" is unclear; we intend to explore these questions further by investigating the relative impact of injury on the methylome.

**Title:** Region-specific sensitivity to long-term effects of preterm birth with very low birth weight: Longitudinal structural MRI including the MoBa study

**Authors: *K. SRIPADA**[1], K. J. BJULAND[2], A. E. SØLSNES[1], A. K. HABERG[1,3], K. GRUNEWALDT[1,3], G. C. C. LØHAUGEN[2], L. M. RIMOL[1], J. SKRANES[1,2]
[1]Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Dept. of Pediatrics, Sørlandet Hosp., Arendal, Norway; [3]St Olavs Univ. Hosp., Trondheim, Norway

**Abstract: Background**: Preterm-born (gestational age ≤ 37 weeks) children with very low birth weight (VLBW, birth weight < 1500 g) face higher risks for periventricular white matter injury and lasting adverse effects on motor skills, cognitive performance, behavior, and quality of life. Longitudinal structural MRI assesses which brain structures appear most vulnerable to long-term effects and serves as a reference point for functional differences. We investigated possible changes in the cortex and subcortical structures longitudinally to assess whether and to what extent the neurodevelopmental trajectories differ in these groups, as well as development of executive function, in early school age. **Design/Methods**: Preterm-born VLBW subjects (n=46) born between 2003-2007 were recruited based on admittance to the St. Olav's University Hospital NICU in Trondheim, Norway. Term-born control subjects from the Trondheim region (n=134) were recruited from the Norwegian Mother and Child Cohort Study (MoBa). MRI and cognitive data were collected at mean age 8.0 years (range: 4.9-11.1) and 9.1 years (range: 6.1-12.0). 123 participants had two 1.5 T MRI scans; 52 with one scan were also included. FreeSurfer version 5.3.0 was used for morphometry. Cognitive skills were assessed with age-appropriate IQ tests, NEPSY, and Wechsler Memory Scale-III. **Results**: Cortical surface area in all 4 lobes, and to a lesser extent cortical thickness, were impacted in the VLBW population, yet no group x time effects in cortex were seen, indicating similar growth patterns between the groups. Subcortical structures were generally smaller in the VLBW group but with some catch-

up growth of hippocampus bilaterally, brainstem, left amygdala, left cerebellar white matter, and left thalamus over approximately 16 months. VLBW children had an average IQ 1 SD below term-born peers (95 vs 107) and lower scores on WMS-III Spatial Span, but statistically similar performance on the NEPSY Visual Attention and Statue tests. **Conclusion**: Pre-term born VLBW participants showed similar developmental trajectories to their term-born peers in this middle- to late-childhood window, with some catch-up development of hippocampus bilaterally, brainstem, left amygdala, left cerebellar white matter, and left thalamus visible in the VLBW group. While cortical surface area, and to a lesser extent cortical thickness, are impacted in the VLBW population, the growth curve for cortical development during this period appears more influenced by age rather than compounding effects of preterm birth with VLBW, which may owe to early childhood medical and educational interventions.

**Title:** Mechanisms underlying psilocybin-induced change in anxiety, depression, and spirituality in cancer patients

**Authors: *S. E. MENNENGA**, L. T. OWENS, T. MALONE, M. P. BOGENSCHUTZ, S. ROSS
Psychiatry Dept., New York Univ. Sch. of Med., New York, NY

**Abstract:** End-of-life distress, including clinically significant anxiety and depression, is common in patients diagnosed with cancer, and is associated with poor psychiatric and medical outcomes. A double-blind, placebo-controlled, crossover trial was conducted at the New York University School of Medicine to evaluate the therapeutic potential of psilocybin-assisted psychotherapy to treat cancer-related anxiety and depression. Twenty-nine patients with cancer-related anxiety and depression were randomly assigned to receive treatment with psilocybin (0.3 mg/kg) followed by niacin (control condition) separated by seven weeks, or niacin followed by psilocybin (0.3 mg/kg), both in conjunction with preparatory, supportive, and integrative

psychotherapy. Psilocybin treatment produced immediate, substantial, and sustained improvements in anxiety, depression, and spiritual wellbeing. At the 6.5-month follow- up, approximately 60–80% of participants continued with clinically significant reductions in depression or anxiety, and both treatment groups exhibited sustained benefits in spiritual wellbeing, existential distress, and quality of life. To understand the mechanism(s) underlying these immediate and lasting changes in anxiety, depression, and spirituality, we investigated relationships between subjective aspects of the mystical experience for each participant's active (psilocybin-induced) treatment session, and short-term and persisting changes in anxiety, depression, and spirituality. We found that short- and long-term increases in spiritual wellbeing were related to higher scores on the Mystical factor of the Mystical Experience Questionnaire (MEQ; r= 0.50-0.75), whereas anxiety and depression reductions were related to higher ratings of Transcendence of Time and Space, Ineffability, and Positive Mood (r= 0.40-0.50). The importance of these and other recent findings for understanding the neural networks and cellular mechanisms that likely contribute to psilocybin-induced experiences of transcendence of time and space, positive mood, ineffability, mystical states, and lasting cognitive and behavioral change will be presented.

**Abstract: Background.** Child abuse has devastating and long-lasting consequences on individuals, considerably increasing the lifetime risk of negative mental health outcomes such as depression and suicide. Yet, the neurobiological processes underlying this increase in vulnerability remain poorly understood. Here, we investigated the hypothesis that epigenetic, transcriptomic and cellular adaptations in the anterior cingulate cortex may associate with a history of child abuse. **Method.** Post-mortem brain samples from a total of N=78 human subjects and from a rodent model of the impact of early-life environment (N=24) were analysed. Groups were constituted of depressed individuals who died by suicide, with (N=27) or without (N=25) a history of severe child abuse, as well as of psychiatrically healthy controls (N=26). Genome-wide DNA methylation and gene expression were investigated using Reduced Representation Bisulfite Sequencing and RNA-Sequencing, respectively. Cell-type specific validation of differentially methylated loci was performed following fluorescence-activated cell sorting of oligodendrocyte and neuronal nuclei. Differential gene expression was validated using Nanostring technology. Finally, oligodendrocytes and myelinated axons were analysed using stereology and Coherent Anti-stokes Raman Scattering microscopy, allowing for high-throughput and high-resolution imaging of individual myelinated fibers in the cingulate cortex. **Results.** A history of child abuse associated with cell-type specific changes in DNA methylation of oligodendrocyte genes and a global impairment of the myelin-related transcriptional program. These effects specifically occurred as a function of child abuse, as they were absent in depressed suicides with no history of early life adversity, and strongly correlated with myelin gene expression changes observed in the animal model. Furthermore, a selective and significant reduction in the thickness of myelin sheaths around small-diameter axons was observed in individuals with history of child abuse. **Conclusion.** This study indicates that child abuse, in part through epigenetic reprogramming of oligodendrocytes, may lastingly disrupt cortical myelination, a fundamental feature of cerebral connectivity.

**Title:** Investigating the effects of violence exposure, physical abuse, and sexual abuse on brain activity following exposure to psychosocial stress

**Authors: *J. PURCELL**[1], A. M. GOODMAN[1], N. G. HARNETT[1], S. MRUG[1], M. N. ELLIOTT[2], S. TORTOLERO EMERY[3], M. A. SCHUSTER[4], D. C. KNIGHT[1]
[1]Psychology, Univ. of Alabama at Birmingham, Birmingham, AL; [2]RAND Corp., Santa Monica, CA; [3]Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [4]Boston Children's Hosp., Boston, MA

**Abstract:** Violence exposure (e.g., witnessing or experiencing an assault) is a prevalent issue that affects approximately 25% of adolescents in the United States (McLaughlin et al., 2016). In particular, physical and sexual abuse are associated with poor physical (Irish et al., 2010) and psychological (Chen et al., 2010) outcomes. Given the prevalence of childhood violence exposure and its deleterious effects, it is important to understand how these experiences affect neural activity in response to future stressful experiences. Therefore, the current study aimed to examine the effects of violence exposure, physical abuse, and sexual abuse on blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) signal in a community sample. Changes in BOLD signal associated with cumulative violence, physical abuse, and sexual abuse were expected in the hippocampus, amygdala, and prefrontal cortex. A community sample of adolescents and emerging adults were interviewed prospectively (ages 11, 13, 16, & 20 years) regarding their exposure to violence and experiences of physical abuse and sexual abuse. Following the last assessment, participants underwent a separate fMRI session during which they completed a psychosocial stress task (i.e. the Montreal Imaging Stress Task; Dedovic et al., 2005). Functional images were collected using a 3T Siemens Allegra MRI scanner and analyses were completed using the AFNI software package (Cox, 1996). Linear mixed effects models revealed differences in activation within the hippocampus and the prefrontal cortex in response to psychosocial stress for participants who had experienced either physical or sexual abuse. Cumulative violence exposure alone did not predict differences in activation in response to psychosocial stress in this study. Results suggest that physical or sexual abuse in childhood is associated with altered prefrontal cortex and hippocampal activation in response to future stressors. Understanding the relationships between these childhood stressors and future stressful experiences may offer new insights into the genesis and maintenance of psychopathology associated with childhood violence exposure.

**Abstract:** The white matter tracts of the cingulum bundle, uncinate fasciculus, and stria terminalis/fornix, provide communication pathways between brain structures that are important for emotion learning, expression, and regulation. Decreased white matter microstructure within these fiber tracts has been associated with emotional dysfunction including depression and anxiety. Exposure to neighborhood disadvantage during childhood and adolescence is a risk factor for depression and anxiety symptoms (Santiago, Wadsworth, & Stump, 2009). Although prior research has examined the relationship between household socioeconomic status (SES) and white matter structure, the effects of neighborhood influences on white matter microstructure has received limited attention. Determining the relationships between neighborhood disadvantage and white matter microstructure of the brain may offer new insight into mechanisms by which adverse life experiences impact developing neural systems. The current study investigated the effect of adolescent exposure to varying degrees of neighborhood disadvantage on white matter tracts of the cingulum bundle, uncinate fasciculus, and stria terminalis/fornix in young adults. Using geocoded addresses for each participant at age 11, multiple indicators of neighborhood disadvantage from the U.S. Census were combined. Diffusion tensor imaging (DTI) data were collected from these individuals in young adulthood (N=169; Mean age 19.6years; SD = 1.17). The results demonstrate that the white matter structure in the cingulum bundle, uncinate fasciculus, and stria terminalis/fornix varied with neighborhood disadvantage, such that greater neighborhood disadvantage was associated with reduced QA in each of these white matter tracts. These findings suggest that the neighborhood a child lives in may play an important role in the microstructure of white matter connections of the brain; these neural effects may explain the impact of neighborhood disadvantage on emotional and behavioral outcomes.

**Authors: *E. DAVIS**, A. GOODMAN, T. OREM, M. WHEELOCK, N. HARNETT, S. MRUG, D. KNIGHT
Univ. of Alabama At Birmingham, Birmingham, AL

**Abstract:** There is limited prior research on the effect of violence exposure on the neural function that underlies the emotional response to stress. However, violence exposure during adolescence can have an impact on stress reactivity later in life. Therefore, the present study investigated the relationship between prospectively measured adolescent violence exposure (average age 14) and the neural response to psychosocial stress as young adults (average age 19). In the present study, 224 participants that had been previously assessed for adolescent violence exposure completed the Montreal Imaging Stress Task (MIST). The MIST is a psychosocial stress task designed to investigate brain reactivity to stress. Our results showed that participants with higher rates of violence exposure, compared with participants with lower rates of violence exposure, rated the stress task as less stressful ($p < .01$). In addition, participants with high rates of violence exposure showed decreased differential neural activity in response to the MIST within the hippocampus and multiple regions of the prefrontal cortex ($p < .01$). The present findings suggest that violence exposure in adolescence reduces stress reactivity as young adults, which may be facilitated by decreased neural activity in the prefrontal cortex and hippocampus.

**Title:** Effects of childhood trauma experiences on cognitive ability and emotion processing in schizophrenia

**Authors: *S. WON**, S. LEE, H. YUN, S. WOO, B. JIN
Psychiatry, Kyungpook Natl. Univ. Hosp., Daegu, Korea, Republic of

**Abstract: Background:** Deficits in cognitive ability and emotion perception have been frequently reported in schizophrenia patients. However, it is still unclear the effects of childhood maltreatment experiences on cognitive ability and emotion perception in schizophrenia. **Methods:** In this study, 83 schizophrenia patients and 54 controls were recruited. Cognitive abilities were measured by several tasks including the Wisconsin Card Sorting Test (WCST), the Continuous Performance Test (CPT), and Auditory Verbal Learning Test (AVLT). Also, we developed affective Go/No-Go and emotion perception task using E-prime software. **Results:** Experiences of emotional neglect ($p = 0.01$), emotional abuse ($p < 0.001$), and sexual abuse ($p = 0.003$) are greater in schizophrenia than in control. In results of cognitive tasks and affective Go/No-Go task, control group showed greater performances in several tasks including AVLT, CPT, WCST, and affective Go/No-Go task (all ps $< 0.05$). In emotion perception task, schizophrenia group had lower accuracy rate on contempt and sad faces perception compared to control group (all ps $< 0.05$). Delayed response time on surprise and anger faces was related to childhood maltreatment experiences (all ps $< 0.05$). Also, interaction effect was significant in response time of sad face perception ($p < 0.001$). In addition, schizophrenia with high childhood maltreatment experiences showed greater depressive symptoms compared to schizophrenia with low childhood maltreatment experiences. **Discussion:** Childhood maltreatment experiences can modulate the ability of emotion perception in schizophrenia. These alterations in emotion processing can be linked to emotional distress, such as depressive symptoms, in schizophrenia patients.

**Title:** Adolescent development of social behavior and oxytocin receptor system following prenatal alcohol exposure and early life adversity

**Authors: *P. J. HOLMAN**, L. ELLIS, C. RAINEKI, J. WEINBERG
Cell. & Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

**Abstract:** Social behavior deficits associated with prenatal alcohol exposure (PAE) emerge early in development and persist across the lifespan, often becoming more pronounced as the individual approaches adolescence. Importantly, early-life adversity (ELA) can also dramatically shape social behavior development, and individuals with PAE are more likely to experience early-life adversity. The central oxytocinergic (OT) system has been implicated as a key regulator of social behavior, and its disruption of may underlie deficits in social behavior observed following PAE and/or ELA. Here, we combine animal models of PAE and early-life adversity to investigate the potential role of the OT system in mediating the unique and/or synergistic effects of PAE and ELA on social behavior function in adolescent male and female rats. Offspring of PAE, Pair-Fed, and *ad libitum* Control dams were evaluated first on a social motivation task followed by a social discrimination task in early (P28-35) or late (P39-P45) adolescence. In a separate cohort, we assessed both social (social discrimination) and non-social (object recognition) learning and memory using a well-established rat model of PAE in conjunction with a model of ELA to begin to dissect the unique and/or synergistic contributions of each insult. Specifically, from P8-12, half the dams were provided with insufficient nest bedding, which increased abusive-like maternal behaviors such as rough handling of and stepping on pups and reduced arch-backed nursing. Brains were removed and assayed using OT receptor binding and c-fos mRNA to measure neural activation (PFC, lateral septum, amygdala, hypothalamus). Results from social motivation testing showed that all animals spent significantly more time in the social chamber, suggesting that social motivation is not inhibited by PAE. Social discrimination data indicate sexually dimorphic effects of PAE, such that only males were unable to discriminate between a familiar and novel social stimulus. Data from our combined PAE and ELA models demonstrated that at P30, PAE impaired social discrimination in males regardless of rearing conditions, while ELA impaired social discrimination in PAE and control females. Analysis of brains revealed no differences in amygdala OT receptor binding in P30 females; however, early-life adversity decreased OT receptor binding in the lateral part of central amygdala in P30 control but not PAE males. Taken together, these results suggest that PAE alters social behavior development in a sexually dimorphic way, and that these behavioral changes, at least in males, are associated with altered development of the OT system during adolescence.

**Title:** Neonatal colonization with Bifidobacterium species elicits sex-specific effects on memory, sociability, and anxiety-like behaviors of adult gnotobiotic mice

**Authors: *B. K. LUK**[1], S. VEERARAGAVAN[2], M. ENGEVIK[1], A. MAJOR[3], J. VERSALOVIC[3]
[1]Baylor Col. of Medicine/Texas Children's Hospit, Houston, TX; [2]Mol. and Human Genet., Baylor Col. of Med., Houston, TX; [3]Pathology, Texas Children's Hosp., Houston, TX

**Abstract: Background**: Postnatal colonization of the human gastrointestinal tract with *Bifidobacterium* species overlaps in time with a critical period of neural circuit development and organization in the brain. Given that these bacterial species are predominant members of the human infant microbiota, CNS modulation by *Bifidobacterium* early in life may have pervasive and lasting effects on brain function and behavior. We hypothesized that neonatal colonization with a consortium of "infant-type" *Bifidobacterium* species would result in long-term effects on adult behavioral phenotypes. **Methods:** In order to examine the effects of early *Bifidobacterium* colonization, germ-free Swiss Webster mice were treated with a mixture of "infant-type" *Bifidobacterium* species, including *B. bifidum, B. longum* ss. *infantis, B. breve*, and *B. dentium* (~$1x10^9$ CFUs/treatment). The treatment began at postnatal day 1 (P1) and was repeated every other day from P1-P20. This treatment resulted in immediate and stable colonization of the pups over the course of the experiment. Control groups of mice received either sterile saline gavages (germ-free controls), or were colonized with a complex murine microbiota (conventionalized controls). All mice were raised in identical gnotobiotic isolator units and were handled in the same manner. At 6-7 weeks of age, the mice were removed from the isolators and underwent a battery of behavior testing to assess a variety of motor and non-motor behaviors. **Results:** Colonization of female mice with the consortium of *Bifidobacterium* mimicked the effects of colonization with a complex murine microbiota, restoring normal anxiety-like behaviors and improving recognition memory in adult mice. However, *Bifidobacterium* colonization was not sufficient to rescue the hyperactive phenotype, or the sociability deficit observed in female germ-free mice. Colonization of male mice with *Bifidobacterium* also normalized the anxiolytic phenotype of germ-free mice, and improved motor performance and recognition memory, though no differences were observed in locomotor activity or sociability between groups of males.

**Conclusion:** Together, these data indicate that postnatal colonization with a small consortium of select *Bifidobacterium* species is sufficient to recapitulate the results observed when mice are colonized with a complex microbiota in a sex- and behavior-dependent manner.

**Title:** Resilience or vulnerability? A sum of life experiences

**Authors: V. PIÑA-DIAZ**, E. HERNANDEZ-REYES, M. VALLE-NAVA, J. YAÑEZ-VARGAS, *C. J. MONTES RODRIGUEZ
Facultad de Psicologia,UNAM, CDMX, Mexico

**Abstract:** Resilience is the capability of coping behaviors under stressful/adverse situations that allows organisms to keep psychological and physiological health, while nonadaptive behaviors are related to vulnerable phenotypes. Most of the resilience studies consists in exposing animals to one stress model (i.e. Social Defeat, Unpredictable Chronic Mild Stress, UCMS) and, the evaluation of several behaviour tests (i.e. social interaction, anxiety, motivation) after the stressful experience. However, resilience in humans seems to be different, coping behaviors depends of several factors and early development play a crucial role (Dannlowski et al., 2012). We studied the effect of adverse early postnatal development (Maternal Separation (MS) from PD2-14), the effect of stressful conditions in the adult (UCMS vs Medium Social Stress, MSS) or the sum of these conditions (MS+stress) on the behavioural output. We observed that each stress model promotes a specific behavioral output, the MSS promotes high social interaction, decreases anxiety and motivation; UCMS also increase social interaction but promotes anxiety and decrease motivation; MS decrease social interaction, promotes anxiety and decrease motivation. The effects of UCMS are potentiated by MS on motivation but counterbalanced on social interaction and anxiety, while the MS on the MSS has an additive effect, increasing even more the social interaction and decreasing anxiety. Our results show that resilience or vulnerability is the result of experiences throughout lifespan more than of a unique aversive/traumatic experience. Also, we support that early life experience is crucial for developing coping behaviors.

**Title:** Acute and inflammatory neonatal pain disrupts later-life fear conditioning and sensory function: The role of CRF

**Authors:** ***M. A. BURMAN**[1], S. DAVIS[2], E. HOLMQVIST[2], E. HARRIS[1], V. EATON[1], A. STEINIS[1], M. RICE[1]
[1]Psychology, Univ. of New England, Biddeford, ME; [2]Univ. of New Engalnd, Biddeford, ME

**Abstract:** In humans, early-life trauma has been linked to an increased prevalence of psychological disorders, including anxiety and depression, as well as sensory disorders such as chronic pain. Time in the neonatal intensive care unit (NICU), often with repeated painful skin-breaking procedures without the benefit of analgesics, is correlated with increased risk for psychological and sensory dysfunction. Our lab has been using a rodent model of neonatal pain during postnatal days (PNDs) 1-7 to explore its effect on subsequent fear conditioning and sensory function at the equivalents of early childhood (PND 24), adolescence (PND 45) or adulthood (PND 66). Our previous data have shown that repeated hindpaw pricks during the neonatal period produce age-dependent changes in tactile sensitivity as well as alterations in fear conditioning. Our current studies have explored the neurobiological role of corticotropin releasing factor (CRF) and differing pain modalities. In *Experiment 1* rats were subjected to the neonatal pain manipulation, and on PND 6, tissue samples from the amygdala and hypothalamus were collected and analyzed using RT-qPCR to measure genetic markers for CRF. Early results suggest that neonatal pain produces increased CRF expression in the amygdala respective to their non-pain counterparts in a sex-dependent manner. In *Experiment 2*, rats were treated with the CRF-R1 antagonist, antalarmin hydrochloride or vehicle, and subjected to the neonatal manipulation. Preliminary results suggest that blockade of CRF can attenuate the subsequent alterations in fear response and sensory function. Finally, in *Experiment 3* rather than the hindpaw pricking procedure (an acute pain model), rats received an injection of either vehicle or λ-carrageenan into the hindpaw on PNDs 1 and 4 and subsequently tested using our fear conditioning and sensory testing protocol. Preliminary results suggest an impairment of fear conditioning that is sex and age dependent, as well as an apparent thermal hyposensitvity. These

data show lasting emotional and sensory consequences of neonatal pain and implicate the CRF system in modulating these effects.

**Title:** Early life adversity: Neuroplasticity and anxiety-related neuronal oscillations in the brain

**Authors:** ***S. MURTHY**, D. E. HERMAN, P. LARA-MEJIA, G. OBIOFUMA, E. GOULD
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

**Abstract:** Adverse experiences during early life lead to significant effects on brain function and behavior. Early adverse experiences produce not only neurobiological and behavioral changes, but also increase susceptibility to anxiety and mood disorders during adulthood (Heim C et al., 2001). Rodent models of early life adversity have been well-characterized in the rat, and have been used to study both the behavioral and neurobiological effects of early life stress. A rat model of early life adversity involving the maternal separation stress paradigm showed increased anxiety and decreased neurogenesis in the hippocampus in adulthood (Mirescu et al., 2004). In mice, maternal separation does not produce consistent increases in anxiety, numbers of new neurons or numbers of several inhibitory interneuron subtypes, so we used an alternate model of early life adversity, the maternal separation stress with early weaning model (MSEW) (George et al., 2010), to study and characterize changes in behavior and neuroplasticity. We found an increase in anxiety in MSEW mice in adulthood but no change in the numbers of new neurons in the hippocampus, suggesting other cellular processes likely underlie MSEW-induced anxiety increases. The ventral hippocampus and the medial prefrontal cortex have been associated with anxiety-like behaviors (Padilla-Coreano et al., 2016), and lesions of either area have shown to reduce anxiety-like behavior (Bannerman DM et al., 2003; Sullivan R et al., 2002). Theta frequency (4-12 Hz) range neuronal oscillations have been implicated in anxiety-like behavior, and increases in theta power in both regions as well as an increase in theta frequency synchrony between the two regions have been demonstrated during high anxiety (Adhikari et al., 2010). These findings raise the possibility that increased anxiety with early adversity may arise from changes in neuronal oscillations in these brain regions. However, the electrophysiological profile of adult rodents following early life adversity has been understudied. Here we have used the

MSEW model in mice, to study and characterize changes in neuroplasticity as well as theta range neuronal oscillations within the brain during anxiety-like behaviors in adulthood.

**Title:** Transcriptomic alterations across reward circuitry by early life stress in male and female mice

**Authors: *C. J. PENA**[1], I. PURUSHOTHAMAN[1], H. M. CATES[2], R. C. BAGOT[3], D. M. WALKER[1], C. PATEL[1], L. SHEN[1], E. J. NESTLER[1]
[1]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Pharmacol., Weill Cornell Med. Col., New York, NY; [3]Psychology, McGill Univ., Montreal, QC, Canada

**Abstract:** Abuse, neglect, and other forms of early life stress (ELS) significantly increase risk for psychiatric disorders including depression. Individuals with a history of ELS also have worse forms of depression including earlier onset and more frequent episodes, and are less responsive to traditional antidepressant medications. We recently developed an ELS paradigm in male and female C57/Bl6 mice wherein stress in a specific postnatal window from P10-17 increased the likelihood that additional stress in adulthood results in depression-like behavior, without altering behavior prior to additional stress. We performed RNA-sequencing in adult male and female ventral tegmental area (VTA), nucleus accumbens (NAc), prefrontal cortex (PFC), and ventral hippocampus (vHIP) to investigate transcriptomic changes that reflect long-lasting ELS-induced adaptations in the brain's reward circuitry central to depression-like behaviors. Here we present detailed analyses of the transcriptomic adaptations resulting from ELS, and after a "second hit" of stress in adulthood. Multifactor bioinformatic analysis reveals that ELS has a greater impact on NAc transcription among male mice, while recent adult stress dysregulates more genes in male VTA, PFC, and vHIP. Among females, ELS had a greater impact on transcription than sub-threshold adult stress in all brain regions examined. Using a threshold-free rank-rank hypergeometric overlap analysis, we show that ELS transcriptionally "primes" the brain in a

similar way as adult stress, even prior to presentation of depression-like behaviors. Finally, we are making comparisons with transcriptional profiles from mice responsive or non-responsive to antidepressant treatments to predict treatment efficacy in ELS-exposed mice, work suggesting that individuals with a history of ELS have unique transcriptional brain signatures that necessitate unique pharmacological treatment.

Col., New York, NY; [7]Neuroendocrinology, The Rockefeller Univ., New York, NY

**Abstract:** Development of diagnostics and more effective treatments for major depressive disorders (MDD) can be guided by mechanistic insights from animal studies. These are urgent medical and public health need given that MDD is projected to be the second leading cause worldwide to the medical and economic disease burden by 2020. There is a broad literature from our and other groups supporting rapid antidepressant effects of the epigenetic modulator of glutamatergic function with insulin-sensitizing properties, acetyl-L-carnitine (LAC), across animal models. A common trait of such animal models with depressive and metabolic-like dysfunction was an endogenous reduction in LAC levels in the plasma and in mood regulatory brain regions, such as the hippocampus and prefrontal cortex. Therefore, based upon several converging preclinical evidence, we started by investigating the association between LAC and MDD in humans with a targeted-oriented and mechanistic-driven approach. Plasma distribution

of LAC and the internal control free-carnitine were determined in samples from 45 healthy controls (HC) and 71 patients suffering with MDD using LC-MS/MS. HC and MDD patients did not differ on any demographic and clinical characteristics, except that, as expected, MDD patients had significantly higher depression severity scores as assessed with the two psychiatric scales, HAM-17 and MADRS (Ham-17: HC=0.6+/-1.1, MDD=20.2+/-3.3, $p<0.0001$; MADRS: HC=1.4+/-2.4, MDD=32.9+/-4.7, $p<0.0001$). Our recent data show that LAC is significantly lower in MDD patients compared to HC. Reduced LAC levels in MDD patients are associated with greater depression severity and earlier onset of depression, and a treatment resistant course of illness. Consistent with lower LAC in more severe forms of MDD, our data also show an association between reduced LAC levels and childhood trauma in patients with a treatment resistant course of illness. In all, while a growing literature on LAC supplementation provides converging evidence for its rapid antidepressant-like effects, our current human findings show that LAC can serve as a marker to delineate a novel biologically-defined MDD subtype that could benefit by treatment with LAC. Given our previously reported link between LAC and insulin resistance (IR) in animal models with depressive vulnerability, more work is warrant to test feasibility of utilizing LAC supplementation alone or in conjunction with therapies with other medications (e.g.: insulin-sensitizing agents, GLP agonists etc), in treatment of MDD.

**Abstract:** Early life experiences related to parental care as well as childhood trauma play a powerful role in later mental and physical health. Recent work showed that childhood abuse is associated with reduced levels of the epigenetic modulator of glutamatergic functions with insulin-sensitizing properties acetyl-L-carnitine (LAC) in patients with depression. Here, we implemented a novel mating model, using wild-type or heterozygous BDNF val66met (hets) dams and controlling for paternal care, to assess the effects of maternal care on the brain and the body in individuals at genetic risk for the development of the depression, diabetes, progressing to dementia (3D's). Our data show that wild-type and hets dams differ in the amount of maternal care provided to offspring assessed by in and out of the nest caring and self-maintenance behaviors. We then assessed the impact of such different maternal care on male hets offspring across two different adulthood ages. Behavioral, molecular and metabolic characterizations of adult offspring show that the 3D's manifests in individuals at genetic risk (i.e.: hets) that receive low nurturing only. Indeed, low nurtured hets, as opposed to high nurtured hets, show depressive-like traits, including abnormal social behaviors and psychomotor retardation-like symptoms. These behavioral differences are concomitant with a peripheral metabolic dysregulation, including insulin-resistance (IR), and reduced levels of LAC in low nurtured hets as opposed to high nurtured hets. Molecularly, these features of depressive- and IR-like states along with reduced levels of LAC, were found to be associated with striking different transcriptomic profiles in the hippocampal ventral dentate gyrus (vDG). Among the most significant differentially expressed genes, RNAseq analyses revealed the inhibitor of glutamate release mGlu2 that, as confirmed by qPCR and protein analyses, is reduced in the vDG of low vs high nurtured hets in line with previous work from our and other groups supporting a role for mGlu2 in stress responses. Finally, more aged hets that received low nurturing showed cognitive impairments in memory tasks at the Y-maze, suggestive of dementia-like symptoms, which were not apparent before. Such cognitive impairments were not observed in high nurtured hets at either age. Cross-fostering is ongoing to causally prove that high maternal care counteracts a genetic predisposition to development of the 3D's. In all, these findings suggest that maternal care has huge influences on brain and body health and point to positive early life experience as mean to "block" manifestation of the 3D's in individuals at genetic risk.

**Abstract:** Social behavior is a complex behavioral domain that is impaired in several psychiatric disorders, including depression (MDD) - a life-threatening disorder in urgent need of improved treatments and with occurrence by sex that is twice as high in women as in men. Although studies with pharmacological agents that unselectively modulate group-II metabotropic glutamate receptors, namely mGlu2 and mGlu3 receptors, have shown a role for group-II mGlu receptors in mood regulation, a circuit-level understanding of the specific activation of these receptors in mood regulation, including social interaction, is lacking. Therefore, we developed a herpex-simplex viral construct to selectively overexpress mGlu2 receptors (HSV-mGlu2-OE) in the hippocampal ventral dentate gyrus (vDG) and studied the effects of the specific HSV-mGlu2-OE on in vivo mammalian social interactions, and on structural plasticity of the vDG and a sexually dimorphic brain region, the medial amygdala, which is interconnected to the ventral hippocampus. We find that both male and female BDNF val66met mice (hets) that received low nurture[1] early in life - and are known to be resistant to common antidepressant SSRIs and yet are responsive to the novel rapid acting antidepressant, acetyl-L-carnitine (LAC) - show a sex-common reduction in mGlu2 expression in the vDG. Instead, low nurtured male and female hets show sex-dimorphic structural plasticity of MeA stellate neurons and social interactions that are impaired in male hets only. Specific HSV-mGlu2-OE in the vDG corrects social interactions and MeA structural plasticity in male hets with behavioral outcomes similar to those of wild-type males. Our circuit-level mechanistic findings reveal a previously unknown role for mGlu2 receptors in a highly integrated brain circuit underlying sex-differences in social behavior and are reminiscent of previous work showing a role for the MeA in social withdrawal in depressive-like illness and the ability of an epigenetic modulator of the glutamatergic system, LAC, to remediate retraction of dendrites of MeA stellate neurons and ameliorate dysfunctional social behavior that results from exposure to chronic restraint stress in males. Our findings also highlight the importance of early life experience in the development of depressive-like symptoms. More studies are needed to understand the role of sex hormones and to further characterize such vDG-MeA circuit underlying sex-differences and commonalities in response to

early life experiences. Identification of specific molecular targets at a circuit-level subserving complex behaviors, such as social interactions, can lead to improved treatment options

**Title:** Adolescent social isolation increases excitatory synaptic activity in the rat nucleus accumbens core

**Authors: *S. EWIN**, A. G. ALMONTE, E. S. CARTER, J. L. WEINER
Physiol. and Pharmacol., Wake Forest Sch. of Med., Winston Salem, NC

**Abstract:** Our lab has established a rodent model of adolescent social isolation (aSI) which engenders robust and enduring increases in behaviors linked to alcohol addiction vulnerability, including increases in anxiety-like behaviors, ethanol intake and preference. We have recently shown that the basolateral amygdala (BLA), a brain region heavily implicated in the pathophysiology of anxiety and addiction, is hyper-excitable following aSI. The BLA sends glutamatergic projections to other addiction-related brain regions including the ventral hippocampus (vHC) and nucleus accumbens (NAc). We have recently found that the vHC exhibits robust increases in excitatory synaptic activity following aSI, which supports the idea that aSI promotes increased excitability in downstream targets of the BLA. In these studies, we have started characterizing aSI-mediated neurobiological adaptations in the NAc. Despite the well-known role of the BLA-NAc projection in mediating motivational aspects of drug reinforcement, no studies to date have examined how aSI-associated adaptations within this circuit may contribute to the addiction vulnerable phenotype promoted by this model. Our first studies employed an unbiased approach, examining the overall effects of aSI on NAc excitability and plasticity. Initial findings suggest that, as observed in the vHC, aSI leads to an increase in

synaptic excitability in the NAc. Unexpectedly, aSI did not lead to alterations in long term depression in this brain region. Further work is being done, using optogenetic and chemogenetic approaches, to determine if the BLA-NAc projection is impacted by aSI and whether adaptative changes in this circuit contribute to the escalation in ethanol drinking associated with this model of alcohol addiction vulnerability.

**Abstract:** Major depressive disorder is classified by the World Health Organization as the leading cause of disability worldwide, with more women being affected than men. Women suffering from depression are frequently prescribed antidepressant medication. However, should a woman become pregnant she must choose whether or not to continue antidepressant treatment, as both maternal depression and antidepressant treatment are known to negatively impact fetal development. This study investigated this question using an animal model of depression to better understand the developmental implications of maternal depression, its treatment with sertraline, a frequently prescribed selective serotonin reuptake inhibitor (SSRI), and the discontinuation of treatment during pregnancy. For this, thirty-six female Sprague-Dawley rats were treated with either a vehicle (oil) or corticosterone (CORT; 40 mg/kg, s.c.) for 21 days to create a depressive-like phenotype. On the 16$^{th}$ day of CORT/oil treatment, rats were given either sertraline (SER; 20 mg/kg, p.o.) or a vehicle (water) daily and then mated with males at the end of the CORT treatment period. To investigate any differential effects of discontinuation of SER treatment, half of the SER-animals discontinued treatment at gestational day (GD) 16, and the other half continued receiving the medication through parturition. Once offspring reached adulthood, they underwent a variety of behavioral testing to determine the effects of each condition on anxiety-like and depressive-like behavior, and stress reactivity. Additionally, brains were collected after sacrifice to investigate levels of neurogenesis. Results indicate sex-dependent effects of both

CORT and SER treatment to the dams and its discontinuation in the behavior of the offspring. Currently, there is a critical need for more research on the effects of these exposures and the discontinuation of antidepressant medication during pregnancy in order to better advise pregnant women on whether or not to discontinue their medication.

**Abstract:** Brain development is a dynamic process beginning in prenatal life and extending throughout adolescence. Adversity and/or stress in any of these stages can alter the neurodevelopmental trajectory, putting the individual on a pathway to pathology. Alcohol is a teratogen that negatively alters brain development. However, how the early postnatal environment contributes to the pervasive effects of prenatal alcohol exposure (PAE) is poorly understood. Moreover, PAE often carries increased risk of exposure to adversity/stress during early life. Here, we examined whether PAE differentially increases vulnerability to immune dysregulation in response to early-life adversity, which may further alter brain development and lead to increased risk of psychopathologies. PAE and control litters were exposed either to limited bedding (postnatal day [PN] 8-12) to model early-life adversity or normal bedding, and maternal behavior and pup vocalizations were recorded. Peripheral (serum) and central (amygdala) immune (cytokine and CRP) responses of PAE animals to early-life adversity were evaluated in infancy (PN12). Male and female offspring were tested in early (PN30) and late

(PN45) adolescence using the open field (OF), elevated plus maze (EPM), and forced swim test (FST). Following FST, peripheral and central immune responses to stress (FST) were evaluated. Insufficient bedding increased abusive-like maternal behavior in both groups. Early-life adversity increased vocalization in all animals; however, PAE pups vocalized less than controls. In infancy, adversity reduced serum TNF-α, KC/GRO, and IL-10 levels in control but not PAE animals. PAE increased serum CRP, with even higher levels observed in PN12 pups exposed to adversity. PAE reduced KC/GRO and increased amygdala IL-10 levels. Our behavioral assessments indicated that, in females, PAE alone resulted in anxiety-like behaviors in the OF. This anxiogenic profile of PAE females emerged at PN30 and lasted until PN45. In males, PAE in association with early-life adversity increased anxiety-like behaviors in the EPM, and similar to females, this anxiogenic profile emerged at PN30 and lasted until PN45. The behavioral alterations in early and late adolescence were associated with changes in the peripheral and central immune system. Our results indicate that PAE alters immune system development and both behavioral and immune responses to early-life adversity, which could have subsequent consequences for brain development and later life health. Indeed, the alterations in the immune system could be one of the underlying mechanisms of the anxiogenic profile observed following PAE and/or early-life adversity.

**Abstract:** Several works have reported that social defeat promotes social stress, decreasing social interaction and motivation. Social defeat is a high social aversive model that promotes a depressive phenotype, we studied a medium social stress model (10 min/10 days) in Wistar male rats. In this model, animals were not defeated every day (0-5 in 10 days) and several social interaction events occurred. We called this model medium social stress (MSS) since they had

some aggressive encounters (45.5/10d) but almost none finished in social defeat. We observed that MSS increased resilient behaviors such as high social interaction scores and low anxiety evaluated by the open field test; interestingly, a decrease in motivated behaviors was also observed. The MSS model is closer to the bullying situation where the aggressor send positive and negative signs to the defender, we are reporting that this kind of interaction results in a high social interaction and low anxiety, both behaviors are considered resilient behaviors. It may be possible that low social stress promotes resilience as it is observed in humans (Cyrulnik, 2013) or in other protocols with low stress (Franklin et al, 2011). However, the high social interaction score after social aversive interaction can also be readed as non adaptative, this idea is also supported by the decrease in motivation; suggesting these animals cannot read the context correctly or they are complacent as a strategy to avoid social aggression. We believe that resilience should be read according to the context demands and personal experiences. More behavior evaluation need to be done to understanding the final behavioral outcome of MSS.

**Abstract:** Early life stress (ELS) in the form of child abuse/neglect is associated with an increased risk of developing social dysfunction in adulthood. However, little is known about the underlying specific neural substrate as well as neuromodulatory signaling that governs ELS-induced social dysfunction. Here, we show that ELS-induced downregulation of dopamine receptor 3 (Drd3) signaling and its corresponding effects on neural activity in the lateral septum (LS) are both necessary and sufficient to cause social abnormalities in adult mice. Drd3-expressing-LS (Drd3 LS) neurons show blunted neuronal activity in response to social stimuli in animals exposed to ELS, while the optogenetic activation of Drd3 LS neurons rescues ELS-induced social impairments. Furthermore, pharmacological treatment with the Drd3 agonist

normalizes the social dysfunctions of ELS mice. Thus, we identify Drd3 signaling in the LS as a critical mediator and potential therapeutic target of social abnormalities caused by ELS.

**Abstract:** Early life stress (ELS) predisposes a variety of psychiatric conditions, such as increased anxiety in females. A potential molecular basis for these lasting consequences remains unknown. Brain-derived neurotrophic factor (BDNF) is an activity-dependent growth factor regulated by experience that is important for timing brain development in sensory cortices. Here, we investigated if it also plays a role in the prefrontal cortex (PFC), a part of the limbic brain involved in the modulation of social behavior across species. We investigated a robust mouse model of fragmented care due to reduced availability of nesting material during the first postnatal week (P2-P9). Levels of BDNF and stress-related molecules were assessed by immunohistochemistry, in situ hybridization, RT-qPCR and HPLC. We found PFC levels of BDNF to be reduced in ELS females. Similar reduction of BDNF was observed in PFC of female rhesus monkeys raised for the first month of life without their mother. A sexually dimorphic BDNF reduction and elevated anxiety was replicated in the PFC of normally raised female knock-in mice carrying one allele of the common human BDNF Val66Met polymorphism. We

next explored the potential to rescue anxious outcomes in female ELS mice by a developmentally timed intervention. Environmental enrichment was confirmed to increase BDNF levels in the mouse PFC. Music exposure after ELS prevented the expected anxiety phenotype in adult female mice. Likewise, human female subjects who had experienced early adversity also exhibited strong anxiolytic response to childhood music when placed under acute stress as adults. Altering BDNF signaling by behavioral or drug therapies in the developing PFC might be a strategic target to mitigate the pre-destined psychiatric outcomes following early adversity.

**Title:** Maternal social regulation of infant's fear in the selectively-bred anxious rat phenotype

**Authors: *A. M. WHITE**[1,2,3], J. HIDER[1,3], J. BOULANGER BERTOLUS[1,3], D. CHANG[1,3], R. M. SULLIVAN[4], H. AKIL[1,2,3], J. DEBIEC[1,2,3]
[1]The Mol. and Behavioral Neurosci. Inst., [2]Neurosci. Grad. Program, [3]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI; [4]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY

**Abstract:** During the early stages of life in altricial species, the caregiver is a potent regulator of the infant's physiological and emotional state. While pups can learn to avoid an odor paired with a mild foot shock from the 10th day of life (postnatal day - PND - 10), this learning is abolished when the odor-shock pairing is performed in the presence of a non-fearful dam. This effect is supported by the maternal presence blocking the release of the stress hormone corticosterone (CORT), an effect termed maternal buffering of fear. Whereas social buffering of fear occurs throughout life, maternal fear buffering is its most powerful example, since maternal presence may totally suppress the stress response and prevent fear conditioning in preweaning pups until around PND 15. We have previously shown the early emergence of classical fear conditioning at PND 4 and elevated CORT responses in Sprague-Dawley (SD) rat pups from a selectively-bred

anxious rat phenotype (ANX) relative to outbred SD rats. Here, we examine the maternal buffering of fear in ANX and wild-type rat pups at early infancy (PND 4), weaning (PND 21), and one week after weaning (PND 28). Pups received 11 pairings of an odor conditioned stimulus (CS) and a 1s 0.4 mA tail shock in the presence of an anesthetized dam or in the absence of an anesthetized dam. Control groups included ANX pups which received 11 odor presentations in the absence of shock and age-matched wild-type SD rats. CORT levels were measured before and after fear conditioning. Pups were exposed to the CS 3 times during a freezing test at PND 11, 22, or 29 in order to assess fear memory. Behavior was video recorded and pups' freezing in response to the CS was scored. Maternal presence was able to block fear conditioning in ANX pups conditioned at PND 4 ($p = 0.68$), PND 21 ($p = 0.19$), and PND 28 ($p = 0.21$); the pups that received odor shock pairings did not freeze significantly more than pups that received odor in the absence of shock. Surprisingly, maternal presence did not block a rise in corticosterone in ANX pups that received odor-shock pairings at PND 4 relative to pups that received exposure to the odor alone ($p = 0.004$). These findings suggest that although ANX pups can acquire fear conditioning and CORT responses to stressors at an earlier age than wild-type SD rats, the presence of the dam continues to serve as a potent regulator of emotional state at older ages than expected. Additionally, it suggests that CORT may not be the sole mechanism through which maternal buffering operates, and opens new avenues for exploring the underlying neurobiology of this phenomenon.

**Title:** Epigenetic effects of prenatal and juvenile stressors on adult behaviors in rats

**Authors: L. B. STEELE**[1], *B. ZIMMERBERG[2]
[1]Neurosci., [2]Psychology, Williams Col., Williamstown, MA

**Abstract:** Stressors during gestation or the juvenile period of development can lead to enduring alterations in affective behaviors. This experiment asked whether there were any interactive effects of experiencing both stressors dependent on genetic variance. Subjects were selectively-bred High and Low Vocalizing lines with line differences in anxiety that persist into adulthood. We hypothesized that maternal and juvenile stress might interact with these line differences.

Maternal restraint stress occurred on gestational days 16-20 and juvenile isolation from postnatal days 35-60. Adults were tested on a social choice test wherein a rat could choose to have proximity to (without touching) a same sex conspecific, compared to proximity to a toy rodent. Anxiety and arousal behaviors were also assessed in this T-maze test. Results indicate that both stressors had gene X environment effects. Line X Prenatal Stress X Juvenile Isolation analyses were significant for social behavior (prenatal stress combined with juvenile isolation to increase social behavior in Lows while Highs only increased social behavior in response to isolation); anxiety behavior (prenatal stress increased risk aversion in double-housed Highs and isolated Lows), and arousal (double-housed Highs reared less than Lows, all prenatally stressed reared less than controls, but isolation increased rearing in Lows and decreased it in Highs). These results will be discussed in relation to the "Double-Hit" Hypothesis in neuroimmunology.

**Title:** Assessing long-term behavioral changes following seizures and stress in larval zebrafish

**Authors: *D. EXLER**[1], J. ANDREWS[1], D. FINORE[2], S. MCROBERT[2], J. J. LIPPMAN-BELL[1]
[1]Philadelphia Col. of Osteo. Med., Philadelphia, PA; [2]St. Joseph's Univ., Philadelphia, PA

**Abstract:** There is increasing recognition that novel methods are needed to investigate seizure-induced development of epilepsy and behavioral deficits, especially in early life. Early-life seizures may disrupt brain development and lead to deficits such as intellectual disability and autistic-like behaviors (Dodrill, 2002; Gant et al., 2009). Current therapies offer only symptomatic treatment and are not disease modifying, in part because how seizures lead to long-term deficits remains unclear. Though promising signaling pathways have been identified in rodents, many remain difficult to interpret. Thus, we aim to create a more simplified model. A larval zebrafish seizure model is established (Baraban et al., 2005), but long-term behavioral and cognitive consequences are not fully characterized, and thus how well the model aligns with early-life seizures in humans cannot yet be ascertained. To begin assessing behavioral changes after seizures in larval zebrafish, we exposed fish to the chemoconvulsant pentylenetetrazole (PTZ, 8mM) at day post fertilization (dpf) 7. At dpf 28, we assessed behavior after 1 min and 1 hour acclimation to the test tank. Our pilot data shows significant decreases after 1 min

acclimation in fish exposed to PTZ compared to control fish in social behavior (shoaling; p=0.015), total swim distance (p=0.028), and mean swim velocity (p=0.040), and increased freezing (p=0.007). After a 1 hour acclimation time, total swim distance (p=0.006) and mean swim velocity (p=0.002) remained significantly decreased in PTZ fish. Interestingly, zebrafish that experienced the same early-life handling stress as the PTZ group but no exposure to PTZ (and thus no seizures), did not display changes in swim distance, velocity, or freezing compared to unhandled controls. However, they showed hyperactivity and a longer lasting deficit in social behavior than the PTZ group, with significantly less shoaling than unhandled controls at both 1 min (p=0.02) and 1 hour (p=0.03). Taken together, these data imply that seizures alter zebrafish behavior for weeks, potentially with an increase in anxiety (freezing). Further, early life-stress alone may lead to long-lasting social and behavioral deficits that are separable from seizure-induced deficits. Additional experiments are required to determine the implications of the behavioral changes. We are optimistic that using zebrafish to study long-term effects of early-life seizures and early-life stress will allow us to overcome many of the constraints and complications that arise in rodent research, and will open a window for high-throughput molecular and cellular network analysis in a reduced, simplified model.

[1]Columbia Univ. Med. Ctr., New York, NY; [2]Pathology & Cell Biol., Columbia Univ. Col. of Physicians and Surgeons, New York, NY; [3]Columbia Univ., New York, NY; [4]EB Sci., Oakland, CA; [5]Pathology & Cell Biol., Columbia Univ. Col. of Physicians & Surgeons, New York, NY

**Abstract:** We previously showed that colostrum oxytocin (OT) modulates cellular stress response, inflammation, and autophagy markers in newborn rat gut villi. Little is known about whether there are analogous responses in the brain. Here, we tested whether brain regions rich in oxytocin receptors (OTR) mirror the effects previously observed in gut villi. As with previous experiments, we measured signaling protein markers associated with endoplasmic reticulum stress, including BiP (an ER chaperone), eIF2a (translation initiation factor), and pPKR (eIF2a kinase), as well as two inflammation-signaling proteins; NF-κB and its inhibitor IκB. We measured these markers in newborn brain nuclei presumably stressed by nutrient insufficiency (viz, after birth and 1-2 hours before the start of nursing) (unprimed), and 1-2 hours after the start of nursing (primed). Brain tissue from unprimed and primed animals was harvested from six brain regions: solitary tract nucleus (STN), paraventricular nucleus (PVN), supra-optic nucleus (SOP), cortex (CTX), striatum nuclei (STR), and medial preoptic nucleus (MPO). Expression of BiP/GRP78, and p-eIF2a were upregulated in unprimed and downregulated in primed NTS tissue, whereas NF-κB was high and stable in both conditions. Expression of BiP and NF-κB was the same in the other tested regions in the both unprimed and primed conditions. The integrated stress response factor eIf2a was phosphorylated by dsRNA dependent kinase (pPKR) in the SON, CTX, STR and MPO. However, eIf2a was phosphorylated by another kinase, general control nonsuppressed2 kinase (GCN2), in the NTS, and to a lessor extent in PVN. These results indicate that PVN and SON utilize a different phosphorylation mechanism from the other regions, one that may be immune to the impact of nutrient insufficiency. Collectively, our data shows that brain responses to nutrient insufficiency stress may be subsequently offset by signaling from colostrum-primed gut. Our data also suggest that the newborn gut stress modulating mechanism we previously observed in enterocytes is mirrored in brain regions rich in OTR.

**Abstract:** Depression and anxiety during pregnancy reach high prevalence of 20%. Stressful events experienced by pregnant women might negatively impact fetal development and cause mood and anxiety disorders later in life. Pre- and post-partum usage of antidepressants such as serotonin reuptake inhibitors (SSRI) has been recently increased, however their influence on newborn development is still unclear. Here, we aimed to investigate the effect of antidepressant treatment given to nursing mothers on the anxiety-like behavior and brain-derived neurotrophic factor (BDNF) of their prenatally stressed offspring. Two antidepressants, which also have anxiolytic features, used in this study are the SSRI escitalopram and the Shan-zha herb (also known as Hawthorn). The current study was designed to mimic the situation in which infants are nursed by mothers treated with antidepressants for post-partum depression/anxiety began at pregnancy. Pregnant mouse dams were randomly assigned to either control or restraint stress during the last week of pregnancy. Following parturition, dams were treated with either escitalopram, Shan-zha, saline or remained non-treated for 21 days while nursing. Offspring could receive treatment only via lactation. Subsequently, anxiety-like behavior of dams and offspring (postnatal day 21) was evaluated using the elevated plus maze. Escitalopram levels in the serum were assessed by radioactive binding assay of unoccupied serotonin transporter on the platelets. In addition, hippocampal BDNF levels in the dams and offspring were assessed using enzyme-linked immunosorbent assay. Our results indicate that prenatal stress induced anxiety-like behavior in the dams and their offspring which was normalized by both escitalopram and Shan-zha treatments. Escitalopram was evident in the serum of the dams but not in the serum of the offspring, implying it did not reach the brains of the offspring. Therefore, we suggest that the behavioral effect seen in the offspring was mediated by indirect effect of escitalopram on mothers' behavior rather than direct effect of escitalopram on the offspring brain. Since Shan-zha's mechanism of action is unknown, we could not determine whether it was transferred to the offspring blood via lactation. The results of the present study underscore the importance of preventing the deleterious effect of prenatal stress on newborn behavior by treating the mother with antidepressants.

**Abstract:** Stress is both a trigger and a symptom of many psychiatric diseases but little is known about the shared genetic and environmental influences that act on the hypothalamic pituitary adrenal (HPA) axis and increase the risk and severity of these devastating diseases. Animal models can be used to study the behavioral, physiological, circuit-based and molecular consequences resulting from an altered HPA axis and provide insights for translational studies in human patients.
We measured HPA axis activity in the recently established Collaborative Cross (CC). The CC combines the genomes of 8 inbred mouse strains that represent the three major subspecies of *Mus musculus*. This inbred population contains unique allele combinations that have not yet been studied in existing mouse resources. As such, the CC has the ability to extend phenotypic diversity in a way that has not been observed previously.
We examined basal corticosterone (CORT) and CORT following an acute restraint stress and two hours post restraint in male and female mice from 13 CC strains. We identified significant strain and sex differences in CORT levels at all time points. As expected, several strains showed vastly higher basal and stress-induced CORT levels than has been previously observed in other inbred mice and selected populations.
These data represent the first characterization of HPA axis activity in the CC. These initial studies will form the basis for examining the effects of a dysregulated HPA axis on behavior, physiology and brain circuitry and allow us to gain more insight, at the systems genetics level, into the underlying role of stress on affective disorders.

**Title:** Anhedonia following early-life stress involves aberrant interaction of pleasure/reward circuits and anxiety/fear circuits and is reversed by partial silencing of amygdala corticotropin-releasing hormone

**Authors: *J. L. BOLTON**[1,2], J. MOLET[1], L. REGEV[1], Y. CHEN[1], N. RISMANCHI[1], E. HADDAD[2], D. Z. YANG[1], A. OBENAUS[2], T. Z. BARAM[1,2]

**Abstract: Background:** Anhedonia, the diminished ability to experience pleasure, is an important biological entity associated with both depression and schizophrenia. Anhedonia often arises already in adolescence, but its origins and mechanisms are poorly understood. We have previously identified anhedonia, manifest as decreased sucrose preference and reduction in social play, in adolescent male rats that experienced early-life chronic stress. Here we probed the molecular, cellular and circuit mechanisms underlying this serious emotional problem.
**Methods:** We examined functional brain circuits and neuronal populations activated by social play in adolescent rats experiencing early-life stress (CES), compared with controls. Structural connectivity between stress- and reward-related networks was probed using high-resolution diffusion tensor imaging (DTI). We intervened with the aberrant activation patterns observed in CES rats via viral-directed reduction of corticotropin-releasing hormone (CRH) expression in the central nucleus of the amygdala (ACe), and tested for reversal of anhedonia in individual rats.
**Results:** Sucrose preference was reduced in adolescent CES rats, indicating anhedonia. Social play, an independent measure of anhedonia, activated brain regions involved in pleasure and reward in both control and CES groups. Notably, in CES rats, social play also provoked activation of CRH-expressing neurons in ACe, typically involved in anxiety and fear, indicating aberrant functional connectivity. DTI revealed aberrant structural connectivity of bilateral amygdalae to prefrontal cortex in CES rats. Administration of CRH-shRNA, but not control shRNA, into ACe reversed the CES-induced anhedonia in individual rats, without influencing

other emotional measures.
**Conclusions:** Together, these findings provide the first evidence for aberrant interactions of stress-related and reward networks after CES, and for a mechanistic role of CRH-expressing amygdala neurons in emotional deficits that portend major neuropsychiatric disorders.

**Abstract:** Adolescence is a developmental period characterized by neuronal growth. Environmental factors such as maternal neglect, social stress and drugs of abuse have a direct impact on future behavioral patterns. Because rats are highly social animals, we decided to investigate if isolation stress during adolescence increases conditioned place preference (CPP) to drugs of abuse. Since D2 receptors play a role in cocaine sensitization in adult animals and because adolescents and adults differ in dopaminergic connectivity and D2 receptor populations, we investigated if D2 receptors are altered during these conditions. Female rats were weaned at postnatal day 23 and housed in singly or in pairs. At day 38 rats were tested for open field behavior and elevated plus maze and at day 40 they tested for CPP to cocaine (15mg/kg). Rats were then euthanized, brains collected and stored at -80 C. Our data show that rats that were singly housed showed greater conditioning to cocaine compared to grouped housed rats. When studying the brains of these animals we found that single housed rats showed a decrease in the number of D2 immunoreactive cells in the nucleus accumbens, lateral septum and prefrontal cortex compared to grouped housed rats. However, cocaine treatment abolished the decrease in D2 immunoreactivity induced by isolation stress. These data show that isolation stress increases the rewarding properties of cocaine, and suggest that this effect may be mediated by altering D2

receptor population in brain areas associated with motivation and reward. It also shows that the social environment during adolescence exerts long-lasting effects on motivational and reward pathways.

**Title:** Effects of chronic corticosterone exposure on neuroendocrine function of adolescent and adult male mice

**Authors: Z. SHAHANOOR**, M. R. BAKER, R. SULTANA, *R. D. ROMEO
Psychology and Neurosci. and Behavior Program, Barnard Col. of Columbia Univ., New York, NY

**Abstract:** Adolescence is associated with the maturation of the hypothalamic-pituitary-adrenal (HPA) axis, the major neuroendocrine axis mediating the hormonal stress response. Adolescence is also a developmental stage marked by a variety of stress-related vulnerabilities, including psychological and physiological dysfunctions. Many of these vulnerabilities are accompanied by a disrupted HPA axis. A mouse model of disrupted HPA function has been developed using oral chronic corticosterone (CORT) adminstration, which result in various physiological and neurobehavioral abnormalities, including changes in stress reactivity and anxiety-like behaviors. However, this model has only been established in adults. In an effort to further compliment and extend this model, we tested how disrupting the HPA axis in adolescent and adult mice would influence hormonal and neurobiological stress reactivity. Specifically, we exposed adolescent and adult male C57BL/6 mice to 4 weeks of oral corticosterone exposure (25 μg/ml in 1% ethanol) or tap water vehicle (tap water with 1% ethanol) and tested their plasma corticosterone and neural activity patterns, as indexed by FOS immunohistochemistry, before, during, and after a 30 min session of restraint stress. Our data indicate that chronic CORT treatment during adolescence or adulthood leads to hormonal hypo-responsiveness, such that stress failed to elevate plasma CORT levels in treated mice. Despite this reduced hormonal response, we found significant neural activation in both adult- and adolescent-treated mice in the paraventricular nucleus of the hypothalamus (PVN), a brain region necessary for the initiation of the hormonal stress response. Therefore, these data indicate a dissociation between stress-induced peripheral and central stress responses following chronic CORT exposure during either adolescence or adulthood. Moreover, we found that stress-induced neural activation in the PVN was highest in

animals treated during adolescence, indicating an age-dependent effect of chronic CORT treatment on later PVN stress reactivity. Together these experiments extend this mouse model of chronic HPA disruption on neurobiological outcomes to include adolescent animals and highlight unique effects of HPA disruption during adolescence. Given the substantial vulnerabilities to HPA dysfunctions during adolescence this model may prove useful in better understanding these vulnerabilities.

**Title:** Adolescent Sprague-Dawley rats display a blunted neuroimmune response evoked by an acute stress challenge

**Authors: *D. LOVELOCK**, M. ORLOFSKY, T. DEAK
Behavioral Neurosci. Program, Dept. of Psychology, Binghamton Univ., Binghamton, NY

**Abstract:** Adolescence represents a critical developmental period during which CNS sites critical to emotion-regulation are impacted by major life experiences, including stress challenges. Studies using cross-sectional designs to compare adolescent and adult stress reactivity have revealed delayed recovery of the corticosterone (CORT) response to several stress challenges. Adolescents also display a blunted cytokine response in the CNS when challenged with acute alcohol exposure or lipopolysaccharide. Since acute stress challenges also increase expression of cytokines, the primary goal of the present experiment was to examine age-related differences in expression of several key pro-inflammatory cytokines in stress-sensitive CNS sites as well as in the spleen. We hypothesized that adolescents would show an impaired cytokine response relative to adults, as well as a delayed corticosterone recovery. To test this, adolescent (P29-31) and adult (P73-78) male Sprague-Dawley rats were exposed to acute footshock (1 mA, 90 second variable ITI, 5 sec each) for 1 hour (40 shocks), 2 hours (80 shocks), or for 2 hours with a 2-hour recovery period in order to establish the time course of cytokine and neuroendocrine changes evoked by acute footshock exposure. Expression of pro-inflammatory cytokines interleukin (IL)-1β, IL-6, TNF-α, as well as the immediate early gene c-Fos, were measured in the paraventricular nucleus of the hypothalamus (PVN), the medial amygdala (MeA), and the ventral hippocampus (vHPC) using real time RT-PCR. In addition, plasma concentrations of CORT and progesterone (PROG) were measured as humoral indices of the stress response. As predicted,

adolescents displayed a significantly reduced IL-1β response compared to adults in the PVN. In the vHPC, IL-1β expression levels peaked at 4 h in adults, and this effect was also blunted in adolescents. In adults, TNF-α levels tended to decrease during stress exposure and recovered by 4 h in all brain regions examined, whereas in adolescents recovery was not complete by 4 h in the PVN and TNF-α did not change at all in the MeA. Induction of c-Fos was also blunted across all brain regions in adolescents relative to adults. Acute stress led to increased plasma CORT and PROG in both adolescents and adults, yet delayed recovery was observed in PROG, but not CORT. Overall, these findings indicate that adolescents have a blunted neuroimmune response to acute stress challenges, and may have implications for developmental vulnerability to subsequent stress-related pathologies later in life.

**Title:** endocannabinoid modulators and PUFAs regulate decision-making and attention in adolescent stressed rats

**Authors: *A. DAGNINO-SUBIABRE**, M. OVANDO, P. CASTRO
Inst. of Physiol., Univ. De Valparaíso, Valparaiso, Chile

**Abstract:** Endocannabinoids and polyunsaturated fatty acids (PUFAs) play a key role in cognitive functions, for example learning and memory. However, their effects on complex cognitive functions such as decision-making and attention during adolescence remain unknown. The aim of this study was to determine whether both endocannabinoid modulators and PUFAs affect decision-making and auditory attention in adolescent stressed rats. Male Sprague-Dawley rats were trained in a two-alternative choice task (2-ACT), a behavioral paradigm to study complex cognitive functions in rats. Trained animals that reached a performance over 80% of correct trials in the 2-ACT were randomly assigned to control and stress experimental groups. To analyze the effects of restraint stress (3 h/d, PND: 42-48), trained rats of both experimental groups were subjected to 50 2-ACT trials one day before and one day after the stress period. A difference score was determined by subtracting the time spent in the inter-trial interval (decision-making) and the number of correct trials (auditory attention) after those before the stress

protocol. In the course of the stress period, animals were treated with endocannabinoid modulators [AM251 ($CB_1$ antagonist) or URB597 (FAAH inhibitor)] or supplemented with PUFAs [n-3 PUFAs (fish oil) or n-6 PUFAs (primrose oil)]. In the animals of the control experimental group, n-6 PUFAs supplementation itself impaired decision-making and auditory attention, while endocannabinoid modulators and n-3 PUFAs improved them. These results suggest that chronic stress and n-6 PUFA increases the endocannabinoid system activity, which in turn impairs decision-making and auditory attention. Conversely, endocannabinoid modulators and n-3 PUFAs would decline the effects of chronic stress on endocannabinoid system.

**Title:** Chronic adolescent stress impairs memory but not learning in adult female rats

**Authors: *M. M. HYER**[1], M. BEKHBAT[2], G. N. NEIGH[1]
[1]Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA; [2]Dept. of Physiology, Sch. of Med., Emory Univ., Atlanta, GA

**Abstract:** Chronic adolescent stress (CAS) has been implicated in increased incidence of cognitive and emotional deficits in adulthood. The hippocampus, a brain region that mediates learning, memory, and emotion, is rich in hormone receptors, providing a site of action for hormones to directly alter behavior. Adolescents are particularly vulnerable to perturbations as neural systems that regulate these behaviors are developing - including the hippocampus. While the effects of CAS on learning and memory in adult male rats are relatively well characterized, parallel effects in females are less clear. We tested the hypothesis that female Wistar rats exposed to CAS would show deficits in learning and memory performance in adulthood. Females exposed to CAS or control conditions were trained on the Barnes Maze task. Both groups showed parallel, improved performance on the task over 10 trials indicating that learning was not altered by CAS in female rats ($p>0.05$). When tested 48 hours after the final training trial, a significant effect of CAS on memory performance was evident. Females exposed to CAS showed an increased latency to initially locate the position of the goal box ($p<0.05$). Additionally, CAS females revisited the location of the goal box less often during the probe trial ($p<0.05$). Interestingly, CAS also resulted in differing search strategies. CAS females exhibited a more randomized search pattern while control females engaged in a serial search strategy

($p<0.05$). The memory deficit in the CAS females persisted throughout three probe trials across a 4 week period and was still evident following ovariectomy ($p<0.05$) - suggesting that ovarian steroids were not driving these effects. Taken together, these findings suggest that CAS has a significant and long lasting impact on memory performance in adult female rats. Additionally, CAS appears to alter their search strategy when females are engaged in a spatial memory task. The work from this study highlights the need to identify factors that may contribute to poor memory performance in women that may be related to overall cognitive deficits following CAS. Implications from these findings suggest that identifying early life stress in females may allow for intervention to attenuate poor cognitive performance and improve memory strategies in females. Further investigation into possible underlying neural and genetic correlates is ongoing.

**Title:** Adult effects of chronic adolescent stress on glucocorticoid receptor regulation

**Authors: *S. A. ROWSON**[1], M. BEKHBAT[2], S. D. KELLY[3], G. N. NEIGH[4,3]
[1]Mol. and Systems Pharmacol. Grad. Program, [2]Neurosci. Grad. Program, [3]Physiol., Emory Univ., Atlanta, GA; [4]Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA

**Abstract:** Women are more likely than men to develop stress-related mood disorders such as major depression. Furthermore, adolescents may be particularly susceptible to the harmful effects of chronic exposure to stressors. A rat model has been useful in studying the long-term effects of chronic adolescent stress exposure, and previous studies have found that female, but not male rats exposed to chronic adolescent stress exhibit enhanced depressive-like behaviors in adolescence that persist to adulthood. However, the molecular consequences of chronic adolescent stress exposure in adulthood are not known. These studies examine the impact of chronic adolescent stress on adult regulation of the glucocorticoid receptor. The glucocorticoid receptor mediates negative feedback on the hypothalamic pituitary adrenal (HPA) axis, a major component of the neuroendocrine system that mediates the response to stress. Male and female rats were exposed to a mixed-modality chronic adolescent stress paradigm consisting of isolation, restraint, and social defeat or non-stress control conditions during adolescence (PND

35-49). In adulthood (PND 94), rats were exposed to a novel acute forced-swim stressor, and brain tissue was collected 15, 30, or 120 minutes following acute stress exposure. A separate control group was collected at baseline without acute stress exposure. The hippocampus was dissected and quantitative PCR was used to assess gene expression of *Fkbp5*, the negative regulator of glucocorticoid receptor nuclear translocation. Glucocorticoid receptor localization was assessed by western blot in nuclear and cytoplasmic protein fractions. Adult female rats exposed to chronic adolescent stress exhibit increased *Fkbp5* gene expression in the hippocampus at baseline compared to non-stressed controls ($p < 0.05$). Additionally, female rats exposed to chronic adolescent stress exhibit reduced hippocampal nuclear GR 30-minutes following acute stress exposure, suggesting impaired nuclear translocation activity of the receptor. Adult males do not exhibit altered *Fkbp5* expression or GR localization in chronic adolescent stressed rats compared to non-stressed controls ($p > 0.05$). These studies provide novel evidence that chronic adolescent stress impacts the molecular regulation of the glucocorticoid receptor with long-term implications into adulthood. Furthermore, these studies highlight the sex-specific nature of the consequences of adolescent stress exposure on the molecular level and the potential for a role of the glucocorticoid receptor in mediating the sex-specific behavioral effects of chronic adolescent stress exposure.

**Title:** Adolescent stress leads to enduring enrichment of inflammatory pathways in the hippocampus without peripheral immune consequences

**Authors: *M. BEKHBAT**[1], S. A. ROWSON[1], S. D. KELLY[1], G. K. THARP[2], M. G. TANSEY[1], G. N. NEIGH[3]
[1]Dept. of Physiology, Sch. of Med., Emory Univ., Atlanta, GA; [2]Div. of Developmental & Cognitive Neurosci., Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [3]Dept. of Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA

**Abstract:** Chronic adolescent stress (CAS) has previously been shown to prime the hippocampal inflammatory response in adult male rats; however, the underlying mechanism and origin are undefined. Here we tested the hypothesis that CAS exaggerates induction of the pro-inflammatory NF-kappa-B pathway in adult rat hippocampus without compromising the

peripheral immune response. Male and female adolescent rats underwent a mixed-modality CAS paradigm or received no stress. Five weeks following the last stressor all rats received a single, systemic injection of either a low dose of lipopolysaccharide (LPS) or vehicle to unmask possible priming effects of CAS. Total RNA from the hippocampus was used to perform RNA-Seq and enriched transcriptional pathways were identified using gene set enrichment analysis. NF-kappa-B emerged as the most enriched pathway in CAS males and females compared to non-stressed controls following LPS. Targeted qPCR experiments further confirmed that CAS exaggerated the expression of I-kappa-B ($F(1,105)=4.209$, $p=0.043$), p65 ($F(1,105)=5.262$, $p=0.024$), and p52 ($F(1,105)=8.186$, $p=0.005$). To explore the underlying mechanisms of CAS-potentiated neuroinflammation, we tested whether CAS impaired glucocorticoid-mediated anti-inflammatory gene expression. Interestingly, CAS led to a marginal increase in the induction of the anti-inflammatory gene DUSP1 ($F(1,105)=3.253$, $p=0.074$), indicating partial anti-inflammatory compensation in CAS rats. CAS impacted neither LPS-induced NF-kappa-B activity in the spleen ($F(1,57)=0.256$, $p>0.05$) nor plasma IL-6 ($F(1,58)=1.083$, $p>0.05$) and TNF-alpha ($F(1,43)=0.60$, $p>0.05$), suggesting that the central effects of CAS on the NF-kappa-B pathway are independent of changes to the peripheral immune response. Collectively, our results indicate that chronic stress experienced during adolescence leads to long-lasting changes to the hippocampal genomic profile, and that the inflammatory consequences of CAS are specific to the brain.

**Title:** Adolescent social stress differentially impacts affect-related behaviors and nicotine responses in C57BL/6J and BALB/cJ mice

**Authors: *M. J. CARUSO**[1], D. E. REISS[1], J. L. THOMAS[1], J. I. CAULFIELD[1], N. A. CROWLEY[2], S. A. CAVIGELLI[1], H. M. KAMENS[1]

**Abstract:** Affective disorders and nicotine use are significant contributors to global morbidity and mortality as independent and comorbid diseases. Exposure to adolescent stress, potentially via stress-induced hypothalamic-pituitary-adrenal axis dysregulation, can exacerbate both. Little is known about the factors that promote susceptibility to comorbidity of these disorders. We examined the relationship between stress-induced changes to affect-related behaviors and nicotine responses. Male and female mice (BALB/cJ & C57BL/6J) were exposed to either chronic variable social stress (CVSS) or control conditions during adolescence (PND 25-59). In adulthood, anxiety/depression-related behaviors were measured using the elevated plus-maze (EPM) and social interaction test. Nicotine responses were assessed via acute effects on body temperature, corticosterone production, locomotor activity, and voluntary oral nicotine intake. We also characterized spontaneous inhibitory and excitatory postsynaptic currents (sIPSC/sEPSC) in the prefrontal cortex (PFC), basolateral amygdala, and nucleus accumbens core (NAc), because these stress-susceptible regions regulate affect- and drug-related behaviors. Relative to controls, CVSS males exhibited reduced EPM open arm activity and increased social avoidance (male C57BL/6J). Alternatively, CVSS increased nicotine-induced locomotion during late-adolescence and adult nicotine-induced corticosterone production in BALB/cJ males, relative to controls. CVSS decreased adult voluntary nicotine consumption in BALB/cJ males, relative to controls. In C57BL/6J males, CVSS increased sIPSC frequency in the mPFC, relative to controls. The amplitude and frequency of sEPSCs were also decreased by CVSS in the mPFC and NAc, respectively. Females were unaffected by CVSS. Results indicate that CVSS differentially impacts affect-related behavior/physiology or nicotine responses in C57BL/6J and BALB/cJ males. Thus, changes in affect-related behavior/physiology and nicotine responses following adolescent social stress are sex- and genotype-dependent.

**Title:** Peri-pubertal period is a sensitive time for stress exposure in wild-type and mice with a genetic redox dysregulation

**Authors: M. R. SCHNIDER**, P. STEULLET, *J. CABUNGCAL, K. Q. DO
Dept. of Psychiatry, Univ. Hosp. of Lausanne, Lausanne-Prilly, Switzerland

**Abstract:** Accumulating evidence suggests that combination of genetic and early-life risk factors favours development of pathologies associated with psychiatric disorders such as schizophrenia. Furthermore, the nature of pathological phenotypes could depend on the timing of the environmental insult during postnatal development and the specific genetic vulnerability. Here, we explored these issues using WT mice and mice with a genetic redox dysregulation due to low GSH levels (Gclm KO). Our results show that a mild sub-chronic stress during pre-weaning period (PND10-20) did not induce overall stress effects in adulthood whereas the same stress protocol applied during peri-puberty (PND 30-40) altered startle response to an acoustic stimulus and induced spatial short-term memory deficit. Further we found a spatial recognition memory deficit that was caused by both factors (stress, redox dysregulation). These suggested that the peri-pubertal period is a sensitive time period for psychosocial stress. When exposed during peri-puberty to a more severe stress protocol (social defeat stress), mice exhibited in adulthood anxiety-like behavior, reduced sociability, anomalies in sensory gating capacity (pre-pulse inhibition of acoustic startle) and increased sensitivity to NMDA-receptor antagonist dizocilpine. In contrast, social defeat stress during late adolescence (PND 50-60) led to a hyper-locomotor phenotype (open field) but did not affect any other behaviors. We found however that social defeat had for the most part similar effects in WT and KO mice with the exception of affective behavior. This suggests a modulatory role of the GSH system on anxiety-like behavior. We then investigated the effect of a peri-pubertal social defeat stress on antioxidant systems in the anterior cingulate cortex (ACC) and hippocampus. In both regions, the positive correlation between GSH peroxidase (GPx) and GSH reductase (GR) activities was disrupted in socially defeated mice. Interestingly, a loss of correlation between GPx and GR activities was also found in the blood of schizophrenic patients that suffered from early-life trauma. In the hippocampus only, social defeat also decreased thioredoxin levels but increased expression of Nrf2, a key transcription factor in the antioxidant defense. These stress-induced alterations were found in both genotypes. This suggests that peri-pubertal psychosocial stress affects redox systems particularly in the hippocampus. In summary, we found that the type of long-term stress-induced behavioral alterations depend on the intensity and exact timing of the stress, with the peri-pubertal period being a particularly vulnerable time.

**Abstract:** Women are susceptible to developing perinatal depression if they suffer from a history of depressive-episodes, anxiety, or prolonged stress. Selective serotonin reuptake inhibitors (SSRIs) are the most common antidepressant for perinatal maternal depression, with 10% of pregnant women being prescribed these medications. SSRIs cross the placental and blood-brain barrier, potentially affecting offspring neurodevelopment. While clinical work suggests an effect of prenatal SSRIs on infant neural development via peripheral biomarkers, it is unclear if there are long-term effects of perinatal SSRI exposure on the developing brain. The aim of this study was to determine how fluoxetine exposure, a popular SSRI used during the perinatal period, affects the serotonergic system and synaptic plasticity in the prefrontal cortex (PFC) of rat offspring. To model aspects of maternal depression, prior to breeding, Sprague-Dawley rat dams were subjected to chronic unpredictable stress. Perinatal treatment with fluoxetine (10mg/kg/day) or vehicle occurred from gestation day 10 to postnatal day 21. The following four groups of male and female offspring, in the juvenile or adult period, were used: 1. Control+Vehicle, 2. Control+Fluoxetine, 3. Pre-gestational Maternal Stress+Vehicle, 4. Pre-gestational Maternal Stress+Fluoxetine. Brains of offspring were used for monoamine analysis (juveniles) in the PFC and measures of synaptic plasticity (juveniles and adults) in the cingulate cortex (mPFC). Perinatal fluoxetine increased juvenile serotonin levels in the PFC. However, pre-gestational maternal stress, regardless of perinatal fluoxetine, reduced post-synaptic density, via PSD-95 immunoreactivity, in the mPFC of juvenile and adult male offspring, but had no effect on pre-synaptic density as measured by synaptophysin immunoreactivity. There were also no long-term effects of maternal stress or perinatal fluoxetine on synaptophysin or PDS-95

densities in the mPFC of female offspring. These results point to an enduring, sex-dependent effect of maternal stress on plasticity in the PFC. Investigating the impact of perinatal SSRIs and maternal stress on neurodevelopment will further our understanding of the benefits and risks of these medications to treat maternal affective disorders.

**Abstract:** Adolescence is the time period when individuals expose themselves to much more social communication, which in turn provides them higher level of stressors. Although spine change has been understood by intracellular mechanisms triggered by neural activation, it is still unclear whether stressors may also participate in the physiological and possibly pathophysiological synaptic pruning in adolescence. In the present study, we first identify that aberrant synaptic pruning in the layer 5 pyramidal neurons of the medial PFC during adolescent critical period using a DISC1 transgenic mouse, which showing depressive behavior phenotype. In this model, we demonstrate increased glucocorticoid levels during early adolescent period activates the expression of RhoU mediated by GR and/or MR signaling and affected PAK activation. Blocking the downstream effector of RhoU, *i.e.*, PAK with FRAX 486 prohibited the arousing of depressive behavior as well as synaptic pruning. The effect of RhoU-mediated PAK activation on E/I balance in the pyramidal neuron and *in vivo* γ-oscillation will be explored.

**Abstract:** Adolescence and early adulthood are the age period of highest drug abuse. Dopaminergic (DA) output from the ventral tegmental area (VTA) to the nucleus accumbens (NAc), prefrontal cortex (PFC) and lateral septum (LS) are essential components the reward circuitry and differ between adolescent and adult rats. In this study we investigated if isolation during adolescence alters the rewarding properties of cocaine in male rats. Since Dopamine D2-receptors (D2DR) are inhibitory receptors associated with decreased reinforcement to the rewarding effects of drugs of abuse, D2 receptors in the NAc, LS and PFC were assessed as well. Following weaning (day 23), male rats were single (isolation) or group-housed with siblings of the same sex. At day 34 they were tested in an open field (OF) and subsequently in an elevated plus maze (EPM). From days 35-48 they were tested for Conditioned Place Preference (CPP) to cocaine (15 mg/kg).
We found that isolated male rats spent more time in the margins of an open field and also in the closed arms of an EPM than grouped housed males, indicative of greater anxiety. They also showed greater conditioning to cocaine than their grouped-housed counterparts. We also observed that isolation decreased D2 immunoreactivity in the NAc, LS and PFC, a difference that was not observed in isolated rats that were treated with cocaine. These data indicate that a social stressor such as isolation during adolescence, can induce profound and long lasting changes in emotional and addictive behaviors. This work was partially supported by NSF PIRE program #1545803.

**Title:** Social isolation during adolescence induces sex-dependent differences on the activity of the hypothalamic-pituitary-thyroid axis, and its response to cold exposure

**Authors: D. RODRÍGUEZ-SARMIENTO**, *E. L. JAIMES, P. JOSEPH-BRAVO
Inst. De Biotecnología, UNAM, Cuernavaca, Morelos, Mexico

**Abstract:** Social stressors in rats such as perinatal maternal separation or social isolation can have long-lasting effects on their neuroendocrine development and response to environmental stressors later in life. Response to social isolation depends on the animal's age, sex, duration of the stressor, and to external factors (environmental events). As the hypothalamic-pituitary-thyroid (HPT) axis activity is susceptible to various forms of stress, we studied if post-weaning social isolation altered the HPT axis function and its response to an environmental stressor, such as cold, and if changes were dependent on the animal´s sex. The initial response to acute exposure to cold begins with the increased expression of *Trh* in the paraventricular nucleus (PVN) and its hypothalamic release. This, in turn, stimulates the release of TSH from the anterior pituitary gland and thyroid hormones from the thyroid gland into the circulation. Male and female Wistar rats were socially isolated at weaning on postnatal day (PND) 23 and through adolescence. Starting adulthood (PND 60), half of the male and female rats were left undisturbed at room temperature (RT) or exposed to a cold environment (4°C) for one hour, then immediately sacrificed. mRNA levels of *Trh* in the PVN, *Trh-r1*, *Tsh-β*, *Dio2* in adenohypophysis; and expression of genes associated with brown adipose tissue (BAT) thermogenesis (*β3-AR*, *Pgc1-α*, *Dio2* and *Ucp-1*) were semi-quantified by RT-PCR. Serum hormones were quantified by radioimmunoassay or ELISA. Social isolation induced a significant increase of serum corticosterone concentration in females but not male rats. Basal HPT axis activity was not affected by social isolation in female rats, and serum TSH concentration increased in response to cold exposure as expected, compared to animals kept at RT. In male rats, isolation induced a hypothyroidism, concentration of serum TSH increased and that of T4 decreased compared to naïve animals. In response to cold exposure, *Trh* mRNA levels increased in isolated male rats, but not that of serum TSH. No significant changes were found in gene expression on either anterior pituitary or BAT of isolated cold exposed male or female rats. In conclusion, social isolation induces differences in the HPT axis function depending on the

animal´s sex. Male isolated rats become hypothyroid, partially blunting the activation of the HPT axis in response to cold exposure.

**Abstract: 1. Purpose:** Prenatal environmental factors such as stress in pregnant rats exert a profound influence on development of nervous system and can affect susceptibility to epilepsy. On the other hand, environmental stimuli such as maternal physical exercise may favor brain development in the offspring. Thus, physical exercise contributes to reduce seizure susceptibility before brain insult and seizure frequency in the chronic epilepsy condition. Although studies have demonstrated the deleterious influence of stress during pregnancy on offspring behavioral and seizure susceptibility, very little is known about how to minimize these negative effects. This work aimed to verify whether physical exercise during pregnancy of mothers submitted to prenatal stress minimizes offspring seizure susceptibility in the beginning of postnatal development. **2. Methods:** Pregnant rats were divided into the following groups: control (n=4); forced exercise (treadmill) (n=3); stress (restraint) (n=3); forced exercise/stress (n=3); voluntary exercise (n=3); voluntary exercise/stress (n=3). Male pups were divided into the following groups: control (n=17); forced exercise (n=14); stress (n=14); forced exercise/stress (n=17); voluntary exercise (n=16); voluntary exercise/stress (n=17). The threshold for first motor manifestation after a unique dose of pentylenetetrazole (PTZ) (45mg/kg) was analyzed at 25 postnatal days. **3. Results:** A reduction in the threshold for first motor manifestation was observed in the stress group compared to control group ($p<0.001$). Both forced and voluntary exercise/stress groups increased the threshold for first motor manifestation compared to stress group ($p<0.005$). Increased threshold for first motor manifestation was also noted in physical exercise (forced and voluntary) groups compared to forced ($p<0.001$) and voluntary ($p<0.000$)

exercise/stress groups. **4. Conclusion:** Our results demonstrate that both forced and voluntary exercise during gestation attenuates the negative effects of PTZ-induced in offspring from mothers submitted to prenatal stress.

**Title:** Mouse strain differences in SSRI sensitivity correlates with serotonin transporter binding and function

**Authors: *Z. JIN**[1], Y. LI[2]
[1]pharmacology, capital medical Univ., Beijing, China; [2]beijing institurte of pharmacology and toxiology, beijing, China

**Abstract:** Selective serotonin reuptake inhibitors(SSRIs) bind 5-HT transporters, leading to the accumulation of 5-HT and amelioration of depression. Although different mouse strain showed different sensitivity to SSRIs in mouse models of depression, the reason for these strain differences remains unclear.Therefore, in the present study, we examined immobility time and locomotor activity in two mouse strains, namely, C57BL/6J and DBA/2J mice, and the effects of the SSRIs fluoxetine, paroxetine, and citalopram in these mice. Furthermore, we analysed 5-HT transporter binding and reuptake inhibition in both strains to explore their relationship to the immobility and locomotor activity effects of the three SSRIs in these two mouse strains.We found that the SSRI citalopram dose dependently reduced immobility time in both the FST and TST in DBA/2J but not C57BL/6J mouse strains, whereas fluoxetine showed opposite results. Paroxetine reduced immobility time similarly in both strains. The affinity of citalopram for the 5-HT transporter in DBA/2J mice was 700-fold higher than that for in C57BL/6J mice, whereas the affinity of fluoxetine in C57BL/6J mice was 100-fold higher than that in the DBA/2J mouse.Furthermore, High citalopram concentrations were required to [$^3$H]5-HT uptake in C57BL/6J but not DBA/2J mouse cortical synaptosomes, whereas fluoxetine also showed opposite results. The effects of paroxetine on 5-HT transporter binding and on the synaptosomal 5-HT uptakeParoxetine showed similarly in both strains. These results suggest that immobility duration depends on 5-HT transporter binding levels, leading to apparent strain differences in

immobility time in the FST and TST. Furthermore, differences in 5-HT transporter binding may cause variations in SSRI responses on behaviors.

**Abstract:** Numerous studies in recent years have shown that prenatal or postnatal stress could affect brain development and cause long term consequences on brain function. In developmental studies, pregnant mice are often injected with different substances to study their effects on developing fetuses. In the present study, we therefore investigated whether the prenatal sham injection of pregnant mice could affect the development of the fetal brain. Pregnant mice were divided into 4 groups. Three groups were sham injected (skin pierced with a 20G needle in the back region as for subcutaneous injections); the first group on days 13, 14 and 15 p.c., the second group on days 17 and 18 p.c. and the third group on days 13, 14, 15, 17 and 18 p.c. Control group was not injected. In male offspring of injected mice, intermale aggressive behavior was evaluated. Additionally, we followed the offspring bodyweight, and at sacrifice measured their testosterone levels in blood and processed their brain for immunocytochemistry. Male mice from the second and the third experimental groups (injections from E17-E18 and from E13-E18) had significantly reduced intermale aggressive behavior in comparison to the males from control group and the first group (injected on days E13-E15). Furthermore, testosterone levels in the second and the third groups were significantly reduced, although testis weights and seminal vesicle weights were not affected by prenatal injections. Body weight in male offspring was significantly higher in the first (E13-E15) and in the third (E13-E18) group in comparison to the second group and control mice. Immunocytochemical staining in two sexually dimorphic areas, calbindin positive group in the preoptic area and vasopressin expressing fibers in the lateral

septum did not differ between groups. These results suggest that prenatal injections of pregnant mice are serious enough stress that could cause behavioral consequences in adult offspring, and should be taken into account when planning and executing experiments with mice.

**Title:** Adolescent stress exposure impairs short-term synaptic plasticity in the Nucleus Accumbens

**Authors: *A. U. DEUTSCHMANN**, A. Q. FOSNOCHT, L. A. BRIAND
Temple Univ., Philadelphia, PA

**Abstract:** Adolescent social stress puts individuals at increased risk for multiple psychiatric diseases, including substance use disorders. However, little is known about how adolescent social isolation alters the brain to make an individual more vulnerable to addiction. The nucleus accumbens plays a central role in the development and expression of addictive behaviors and is influenced by stress exposure. The current study utilized an adolescent isolation stress model that we have shown to increase motivation for cocaine in adulthood in order to examine the effects of stress on accumbal physiology. Here we show that adolescent social isolation stress leads to a persistent disruption in short-term synaptic plasticity in the nucleus accumbens. As adults, animals that experienced adolescent social isolation exhibit a decrease in paired pulse facilitation and an increase in sEPSC amplitude and frequency. A disruption in paired pulse facilitation often indicates an increase release probability. However, adolescent isolation stress impairs paired pulse facilitation without altering initial release probability, suggesting alterations in the readily releasable pool. Future studies are underway to test this hypothesis. Taken together, we have demonstrated that adolescent isolation stress alters presynaptic function in the nucleus accumbens. The nucleus accumbens receives glutamatergic input from multiple brain regions including the amygdala, hippocampus, and prefrontal cortex. Work is underway to examine the individual contributions of these inputs to the effects of adolescent social stress on accumbal physiology.

**Title:** The role of glutamate receptor trafficking in vulnerability to a social defeat stress

**Authors: *K. E. LUCERNE**, A. Q. FOSNOCHT, L. A. BRIAND, J. LENZ, A. S. ELLIS
Psychology and Neurosci., Temple Univ., Philadelphia, PA

**Abstract:** Individuals who experience social stressors such as social rejection or isolation are more likely to develop psychiatric disorders such as substance use disorder, anxiety disorders, or depression. However, not all individuals who experience these social stressors go on to develop psychiatric disorders. Understanding the mechanisms by which individuals are more or less vulnerable to social stress could provide avenues for prevention. Exposure to stress leads to neuroadaptations in glutamatergic transmission and AMPA receptor trafficking. However, very little is known about the role that this trafficking plays in vulnerability to stress. The current studies utilized two different mutant mouse models with disruptions in AMPAR trafficking proteins. We first utilized a mouse with a point mutation in the GluA2 AMPA subunit that prevents PKC-dependent phosphorylation and internalization. We found that disrupting activity-dependent GluA2 internalization lead to an increased susceptibility to social defeat. Next, we examined whether mice with a constitutive knockout of PKMzeta, a protein involved in insertion of AMPARs, exhibited alterations in susceptibility to social defeat. Preventing the insertion of AMPARs into the membrane led to a decreased susceptibility to social defeat. Taken together this suggests that increased AMPAR expression leads to increased vulnerability to social defeat stress. Future work will examine how this affects the ability of social stress to potentiate cocaine-taking behavior.

**Title:** Spinal cord neurovascular coupling is not affected by isoflurane anesthesia: Evidence from decerebrated rats

**Authors:** *T. PAQUETTE[1], ***T. PAQUETTE**[1], *T. PAQUETTE[3], H. LEBLOND[1], M. PICHÉ[2]
[1]Dept. d'anatomie, [2]Chiropractic, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada; [3]CogNAC research Group (Cognition, Neurosciences, Affect et Comportement), Trois-Rivieres, QC, Canada

**Abstract:** Neurovascular coupling is a physiological process involving a local hemodynamic response associated with surrounding neuronal activity. Functional magnetic resonance imaging (fMRI) uses this relation to infer neuronal activity by measuring magnetic signals related to changes in deoxyhemoglobin concentration. In a previous study, isoflurane-anesthetized rats showed tight spinal cord neurovascular coupling that was unaffected by large fluctuations in systemic blood pressure. However, the influence of isoflurane on spinal neurovascular coupling is not established. The objective of this study is to examine the effect of anesthesia on spinal neurovascular coupling in anesthetized decerebrated and non-anesthetized decerebrated rats, during nociceptive processing.
All experimental procedures were approved by the Université du Québec à Trois-Rivières animal care committee, and were in accordance with the guidelines of the Canadian Council on Animal Care. Six male Wistar rats were anesthetized using isoflurane (1.2-1.5 %). After a craniectomy, rats were decerebrated mechanically. Local field potentials (LFP) and spinal cord blood flow were recorded simultaneously in the lumbosacral enlargement, where activity was evoked by electrical stimulation of the sciatic nerve. The mean arterial pressure was recorded continuously with a pressure transducer connected to a cannula inserted in the right carotid artery. Constant current electrical stimulation was applied on the sciatic nerve at 8 stimulus intensities ranging between 0.1 and 9.6 mA. Physiological responses to electrical stimulation were recorded in

decerebrated rats with or without isoflurane anesthesia.
In decerebrated rats under anesthesia, mean arterial pressure changes evoked by sciatic stimulation were not significantly different compared with those of decerebrated rats without anesthesia (p=0.064). Moreover, anesthesia has no effect on the LFP (p=0.53) and spinal cord blood flow responses evoked by electrical stimulation (p=0.57). The neurovascular coupling remained tight and comparable between rat with or without anesthesia (p=0.39). Furthermore, stimulus intensity did not alter neurovascular coupling, which remained comparable for all intensities between 0.15 and 9.6 mA compared with the 0.1 mA intensity.
These results support the use of isoflurane in neurovascular studies. Also, results suggest that fMRI is an adequate method to quantify the neuronal activity based on the spinal hemodynamic changes in anesthetized or non-anesthetized subject.

**Title:** Brainwide mapping of spontaneous network dynamics in the mouse brain

**Authors: D. GUTIERREZ BARRAGAN**[1], S. PANZERI[1], *A. GOZZI[2,1]
[2]VAT09198791007, [1]Inst. Italiano di Tecnologia, Rovereto, Italy

**Abstract:** Spontaneous brain activity is characterized by recurrent coupling and decoupling of local and remote neuronal substrates across different spatio-temporal scales. Resting-state functional magnetic resonance imaging (rsfMRI) has been recently employed in humans to non-invasively map brainwide network dynamics via recordings of spontaneous blood oxygen level-dependent (BOLD) signal.
Such investigations have shown that spontaneous network activity undergoes spatio-temporal reconfiguration recapitulating a finite number of brain functional states, which can be related to higher-order cognitive processes.
By mapping the repertoire of spontaneous BOLD co-activation among brain regions, here we show that analogous transitions occur in rsfMRI datasets of the mouse brain. We used clustering analysis to sort and selectively average rsfMRI activity timeframes into distinct and recurrent patterns of non-stationary co-activation and co-deactivation that can be mapped with voxel

resolution.
We describe a reduced number of reproducible brainwide patterns encompassing the co-occurrence of previously described intrinsic connectivity networks of the mouse brain, including integrative high-order cortical regions (default-mode, salience) as well as motor sensory, hippocampal and sub-cortical networks. Notably, inverse co-occurrence of default-mode and lateral cortical networks activity is a prominent feature of many of the identified states, suggesting a competing relationship between these two macroscale neural systems, recapitulating a cardinal feature of human network organization. We also show that the identified network states are characterized by smooth transitions from one state to another, as well as gradual assembly and disassembly.
Collectively, our findings corroborate the presence of dynamic reconfiguration of spontaneous network activity as a fundamental, evolutionary-conserved principle of mammalian cortical activity, and identify a set of recurrent brain states that characterize brainwide network dynamics in the mouse. This approach paves the way to targeted investigations of the elusive neural drivers of spontaneous network dynamics via interventional approaches in rodent models.

**Title:** Novel restraint device in awake rat imaging

**Authors: *S. R. CRAMER**[1], Y. MA[1], N. ZHANG[2,3]
[1]Biomed. Engin., [3]The Huck Inst. of Life Sci., [2]The Pennsylvania State Univ., State College, PA

**Abstract:** Functional imaging in awake animals has become an important tool for measuring whole-brain functional connectivity. Unfortunately, the imaging environment is stressful, and the loud noises emanating from the magnetic resonance imaging (MRI) gradients are not conducive to motionless subjects. To achieve better imaging performance, recent studies have focused on improving head restraint, but little attention has been given to the restraint of the body. In the absence of proper body restraint, motion artifacts arising from head movement persist. Moreover, appropriate design of the body restraint may significantly reduce pain, stress, and

fear. Otherwise, the over activity of brain regions responsible for these behavioral manifestations may cause incorrect interpretations of data. In this study, we developed an integrated full body restraint device that optimizes both head and body restraint. In addition to minimizing total subject motion, this device focused on reducing stress levels associated with imaging. Blood corticosterone levels were measured before, during, and after a novel acclimation procedure that involved the full body restraint device. Other physiological indexes were monitored and recorded during acclimation including respiration and heart rate. To further validate this new restraining setup, single and multi-echo fMRI data were acquired in awake rats during resting state and visual stimulations.

**Title:** Myelination covariance of human cerebral cortex

**Authors: *Z. MA**, N. ZHANG
Biomed. Engin., Penn State Univ., University Park, PA

**Abstract:** Brain morphometric covariance of gray matter density or cortical thickness has been widely used for studying brain connectivity. These structural covariance approaches were based on the morphometry of mixed brain compartments, whereas the covariance of any specific component such as cortical myelin has yet to be explored. In the present study, we extended this structural covariance concept by adopting T1w/T2w ratio myelin content for cross-population covariance measurement. Using T1w/T2w ratio myelin maps from the Human Connectome Project, we systematically investigated cross-subject myelination covariance of the human cerebral cortex and identified highly reproducible myelination covariance patterns. We constructed a whole-brain myelination covariance network and characterized its topological properties. We further evaluated the correspondence between myelination covariance and resting-state functional connectivity and revealed their unique network-specific relationship. This study has promoted the understanding of the brain organization from myelination covariance and also demonstrated the structural covariance-function relationship of the human cerebral cortex.

**Title:** Brain-derived neurotrophic factor (BDNF) as a potential biomarker for resting-state network remodeling after ketamine infusion

**Authors: *M. WOELFER**[1,2,3], M. LI[1,2], L. COLIC[1,2], V. LESSMANN[4], T. BRIGADSKI[4,5], M. WALTER[1,2,6]
[1]CANLAB, Magdeburg, Germany; [2]Leibniz Insitute for Neurobio., Magdeburg, Germany; [3]New Jersey Inst. of Technol., Newark, NJ; [4]Otto-von-Guericke Univ., Magdeburg, Germany; [5]Univ. of Applied Sci. Kaiserslautern, Zweibruecken, Germany; [6]Univ. Tuebingen, Tuebingen, Germany

**Abstract:** Introduction Ketamine, an NMDAR antagonist, produces fast antidepressant response with a maximum efficacy 24h after infusion [1]. Animal studies showed that ketamine generates higher synaptic plasticity via induction of Brain-derived neurotrophic factor (BDNF) [2]. Patients with depression have lower blood level of BDNF and show an increase after ketamine infusion [4]. Besides, depressed patients have hyperconnectivity within the Default mode network (DMN) [5]. Ketamine decreases the Functional Connectivity (FC) in healthy subjects between posterior cingulate cortex (PCC) and medial prefrontal cortex (mPFC), two main regions within DMN [6], revealing possible mechanisms of the antidepressant effect.
Methods In a double-blind study, 81 healthy subjects received infusion of either ketamine (0.5 mg/kg) or saline. In each subject, resting state fMR images (TR= 2.8s, voxel size= $2 \times 2 \times 2$ $mm^3$, 7T ) and plasma blood samples were acquired at baseline and 24h post-infusion. Ketamine (n=32) and placebo (n=30) groups were preprocessed using scripts developed in the functional connectome 1000 project. Dorsal PCC (dPCC) was chosen as a priori seed region [6] and FC maps were calculated. The mean FC value was extracted from clusters showing significant change after infusion. Extracted FC values were correlated with the plasma BDNF at 24h (n=45).
Results 24h after infusion, ketamine treated subjects showed higher BDNF level compared to placebo (p=0.015). A decrease in FC between the dPCC and both dorsolateral PFC (p=0.005 FWE) and two cluster in mPFC (p=0.001 & p=0.030 FWE) was observed 24h after infusion.

Subjects with higher BDNF level after ketamine show significantly higher FC disconnection between dorsal PCC and mPFC (r= 0.64, p=0.006).
Conclusions Ketamine decreases FC within the DMN and increases BDNF 24h after ketamine. Higher BDNF level correlates with stronger FC disconnection between anterior (mPFC) and posterior (dPCC) part of DMN. This finding highlights the role of BDNF as a potential biomarker for network remodeling in the brain.

**Abstract:** Serotonergic transmission affects behaviours and neuro-physiological functions via the orchestrated recruitment of distributed neural systems. It is however unclear whether serotonin's modulatory effect entails a global regulation of brainwide neural activity, or is relayed and encoded by a set of primary functional substrates. Here we combine DREADD-based chemogenetics and mouse fMRI, an approach we term "chemo-fMRI", to causally probe the brainwide substrates modulated by phasic serotonergic activity. We describe the generation of a conditional knock-in mouse line that, crossed with serotonin-specific cre-recombinase mice, allowed us to remotely stimulate serotonergic neurons during fMRI scans. We show that chemogenetic stimulation of the serotonin system does not affect global brain activity, but results in region-specific activation of a set of primary target regions encompassing parieto-cortical, hippocampal, and midbrain structures, as well as ventro-striatal components of the mesolimbic reward systems. Many of the activated regions also exhibit increased c-Fos immunostaining upon chemogenetic stimulation in freely-behaving mice, corroborating a neural origin for the observed functional signals. These results identify a set of regional substrates that act as primary functional targets of endogenous serotonergic stimulation, and establish causation between phasic activation of serotonergic neurons and regional fMRI signals. They further highlight a functional cross-talk between serotonin and mesolimbic dopamine systems hence providing a novel framework for understanding serotonin dependent functions and interpreting data obtained from human fMRI studies of serotonin modulating agents.

**Abstract:** Cortical capillary blood flow and oxygenation are highly heterogeneous. Mapping the absolute capillary blood flow and oxygenation along the capillary path is a key step towards understanding how oxygen is transported and delivered in a complex microvascular network to enable adequate tissue oxygenation. In this work, we applied two-photon microscopic imaging of intravascular oxygen partial pressure ($PO_2$) to measure both oxygen concentration and red blood cell (RBC) flux in cortical arterioles, capillaries, and venules. The $PO_2$ measurements with high signal-to-noise ratio were enabled by a novel oxygen-sensitive phosphorescence probe, PtG-2P. Imaging was performed in awake, head-restrained C57BL/6 mice (n=15), through a chronic sealed cranial window centered over the E1 whisker barrel.
We obtained a detailed mapping of the resting state cortical microvascular $PO_2$ in all arterioles and venules, and both $PO_2$ and RBC flux in most capillaries down to 600 μm depth from the cortical surface (n=6,544 capillaries across all mice). Capillary RBC speed and density were also extracted and all measurements were co-registered with the microvascular angiograms. We characterized the distributions of capillary $PO_2$ and flow as a function of branching order and cortical depth. The results show strong positive correlation between oxygenation and flow in the capillary segments, with an increased correlation in downstream capillaries. We have also observed homogenization of both oxygenation and flow in deeper cortical layers, which may imply a mechanism to improve oxygen delivery without increasing global blood flow in the area with increased metabolism.

**Abstract:** While understanding the neural correlates of schizophrenia represents a major challenge for neuroscientists, the quantification of functional network connectivity (FNC) measured from functional neuroimaging data obtained from schizophrenia patients is emerging as a promising approach towards a more complete understanding of the disorder. Despite these advances in research approaches, the interpretation of FNC data is complicated by the widespread history of exposure to antipsychotic medications in schizophrenia patients. As a result, the potential contributions of antipsychotics to FNC in schizophrenia patients remain to be fully explored. Because ethical considerations render the evaluation of the effects of chronic exposure to antipsychotics in healthy controls impossible, the present study evaluated the effects of chronic olanzapine exposure on FNC in an animal model. Adult male rats were given daily injections of olanzapine (2mg/kg) or vehicle for 30 days. Resting state BOLD signal data were obtained in separate 10 minute echoplanar imaging (EPI) sequences conducted prior to drug treatment and 24h following the completion of the drug treatment protocol utilizing a 4.7T Bruker Biospin magnetic resonance imaging scanner. Group independent component analysis (gICA) was then performed on the data to identify individual components or local connectivity networks. Finally, cross-correlations between individual component timecourses were calculated to estimate FNC and compared across time points and drug treatment conditions. Olanzapine exposure was associated with alterations in FNC for components localized to the hippocampus, striatum, retrosplenial cortex, cingulate cortex and cerebellum. Additionally, olanzapine decreased spectral power within the 0.08Hz-0.12Hz range in a broad set of components. Arterial spin labeling (ASL) data obtained during each session suggest a large, but non-significant, reduction in blood flow as a result of olanzapine exposure that may partially account for alterations in FNC and component time courses. Comparison of pre-treatment data with data obtained 30 days later also revealed widespread alterations in FNC as a function of the temporal delay between the first and second scanning session regardless of drug treatment condition. These observations indicate that chronic exposure to low-dose olanzapine in the rat results in altered FNC and component timecourses in a distributed set of brain regions implicated in schizophrenia.

**Abstract:** We characterized cortical microvascular $pO_2$ and blood flow changes in response to whisker and shoulder stimulation in awake mice. Measurements were performed by combining two photon microscopy (TPM) phosphorescence lifetime imaging of the cortical oxygenation, and optical coherence tomography (OCT) imaging of the cerebral blood flow. In order to perform fast spatio-temporally resolved measurements of $pO_2$, we used a newly-developed oxygen-sensitive probe PtG-2P, which has significantly higher brightness than the established two-photon-enhanced oxygen sensor PtP-C343. We characterized the performance of the new probe in vivo and mapped the amplitudes and shapes (e.g. initial dip, overshoot, and post stimulus undershoot) of the $pO_2$ changes as a function of the vessel type (e.g., arterioles, capillaries, and venules) and a distance from the activation center. Our measurements in the awake mice are not affected by the confounding factors of anesthesia on the animal physiology, including the level of cerebral metabolism and the amplitude and speed of neuronal and vascular responses. These results will help to understand changes in cortical oxygenation and blood flow at the microvascular scales, and will help us improving quantitative interpretation of fMRI signals.

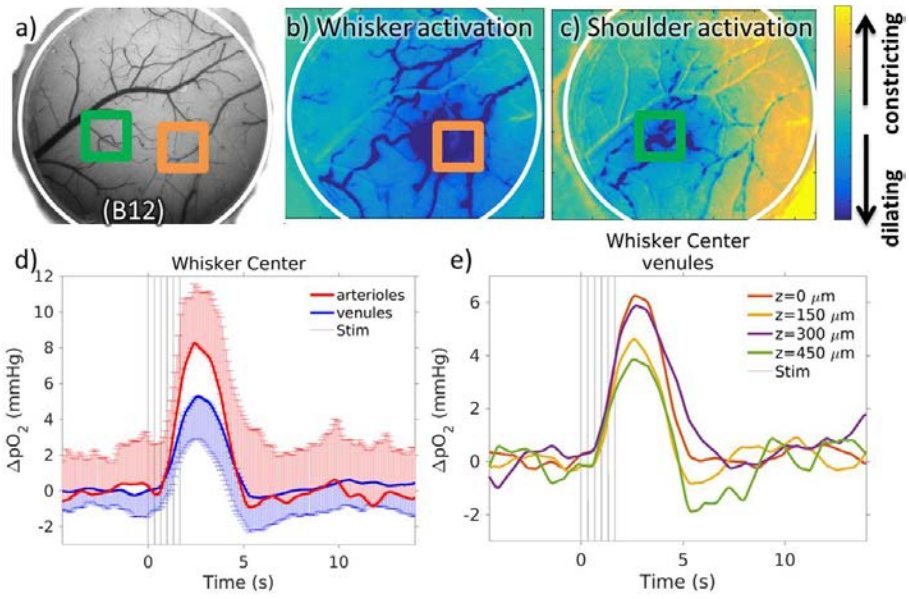

Figure 1. Optical Intrinsic Signal Imaging (OISI) and intravascular Two Photon Microscopy (TPM) measurements during functional activation with whisker and shoulder stimulation in awake mice; a) Single CCD frame over field of view (FOV) of 2.5x3.2 mm; Cortical activation center mapping using OISI with b) whisker and c) shoulder stimulation. Green and orange boxes mark FOVs for TPM (600x600 µm); d) Average $pO_2$ changes in arterioles (standard deviation plotted upward) and venules (standard deviation plotted downward) with whisker stimulation at the activation center from 11 animals; e) venous $pO_2$ responses at different depths from pial surface

**Title:** A high-resolution population MRI template and automated processing tools for standardized analysis and visualization of the macaque brain

**Authors: *C. SPONHEIM**[1], J. SEIDLITZ[2], B. JUNG[1], A. MESSINGER[1], L. G. UNGERLEIDER[1]
[1]Lab. of Brain and Cognition, [2]Developmental Neurogenomics Unit, Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract:** Anatomical MRI templates are commonly used in human neuroimaging to facilitate data analysis and comparison across subjects and studies. Template use is rare in non-human primate neuroimaging, in part because previous in vivo templates of the monkey brain were not detailed enough to reliably identify anatomical structures. To address this need, we made a high-resolution in vivo MRI template of the macaque brain by averaging T1-weighted scans from 31 adult subjects using linear and nonlinear registration methods. We call this anatomically representative template the National Institute of Mental Health Macaque Template, or NMT for short (Seidlitz et al., 2017).
The NMT is freely available and includes digitial maps to differentiate the brain from the rest of the head and to parcellate tissue into gray matter, white matter, cerebrospinal fluid, and - for the first time - the major arterial blood vessels. Cortical thickness and the volume of major structures have been characterized. We provide several cortical surface reconstructions for visualization of individual or group data (e.g. functional MRI maps). We supply nonlinear transformations to (and from) other templates (e.g. D99 and F99) so that digital atlases associated with these templates can be applied to the NMT. For example, one could determine what brain areas coincide with a functional activation or target a brain area for electrode placement, making a lesion, or pharmacological manipulation.
Finally, we provide a set of processing tools that use our characterization of the NMT as a starting point to automatically and objectively register and characterize the T1-weighted scans of individual subjects. These scripts replace the time-consuming manual processes of brain extraction, tissue segmentation, and morphometric feature estimation for each individual subjects. The NMT package thus establishes a common platform for data visualization, precise single-subject data analysis, comparing findings across subjects and studies, and combining data acquired using both different methodologies.

**Title:** An MRI anatomical atlas and resting state activity-based functional parcellation of the brain of the mouse lemur primate (Microcebus murinus)

**Authors: *N. A. NADKARNI**[1], S. BOUGACHA[1,2], C. GARIN[1], M. DHENAIN[1], J.-L. PICQ[1,3]
[1]Neurodegenerative Dis. Lab., MIRCen, CEA, Fontenay aux Roses Cedex, France; [2]U1077, INSERM, Caen, France; [3]Lab. de psychopathologie et de neuropsychologie, Univ. Paris 8, St Denis, France

**Abstract:** The gray mouse lemur (*Microcebus murinus*), a small non-human primate, is attracting increased attention as a model for studying aging and age-related diseases in the brain. Its rodent-like size (typical length 12cm, 60-120g weight), rapid maturity (puberty at 6-8 months) and decade-long lifespan brings rodent-like practicality to a primate model. MRI is now widely exploited in animal models for the unique longitudinal anatomical and functional information it provides. Automation and standardization of analysis require images to be registered to a standard space template. We have developed the first one for the mouse lemur brain, including an 80-region anatomical atlas, and also begun a functional delineation using data from resting state functional MRI (rsfMRI). Template data sets were acquired in 34 animals, 15-60 months old, at 7T using a T2-weighted sequence, resolution 115×115×230µm. Aided by brain identification using the IIBI RATS skull stripper, images were registered and averaged with AFNI through linear then non-linear stages to produce a final template. Segmentation of structures was carried out by hand. RsfMRI data was acquired in 15 other animals, 10-40 months old, at 11.7T using a T2*-weighted sequence, resolution 208×313×1000µm, 450 volumes at TR=1s, plus a 200µm isotropic anatomical scan to aid registration (carried out in AFNI to the above template). Regional intrinsic functional organization was characterized using Nilearn by applying a fast dictionary learning decomposition on the registered concatenated rsfMRI 4D

data. As shown in the figure, template image contrast was of high quality, allowing all major brain regions to be segmented, including small (fornix) and intricate (cerebellar white matter arborescence). Functional parcellation produced an aligned but differing set of regions, especially cortical subdivisions, demonstrating its complementarity. This original combination of anatomical and functional MRI delineation is a powerful new tool for brain-wide studies of morphology and function in the increasingly-important mouse lemur model.

**Title:** Dynamic functional-PET imaging of time-dependent brain activity change by optogenetic stimulation of the motor cortex

**Authors: *D.-H. KWON**, J. CHO, J.-Y. PARK, H.-I. KIM
Gwangju Inst. of Sci. & Technol. (GIST), Gwangju, Korea, Republic of

**Abstract:** Positron emission tomography (PET) is an excellent tool for providing metabolic information of the radiolabeled biomarkers. [18F]FDG PET allows quantitative measurement of changes in regional brain glucose metabolism following stimulation. However, the PET provides an amount of glucose consumption over the full-time course and lacks the temporal information to catch physiological alterations. We tried to track time-dependent brain activity after motor cortex stimulation to decipher the dynamic neural circuit activated by optogenentic stimulation. In this study, the dynamic PET data were obtained. Rats (n=18) received AAV5-CaMKIIα-ChR2(H134R)-eYFP (1μl) in the motor cortex and virus construct was expressed. Following implanting the optical ferrule in the same area, the 34-minute dynamic PET was performed simultaneously with injection of [18F]FDG (100mCi/100g). Next day, the similar PET scan was performed with 30-minute optogenentic motor cortex stimulation. The entire PET scan was divided into thirty-four 60s-frames. The difference of regional glucose metabolism was examined statistically by comparing each time frame of two separate scans. Furthermore, the statistical tests for static PET integrated with all time frames were also compared to metabolic map derived from the dynamic PET. The data were spatially normalized by using SPM8 with a toolbox, spmratIHEP, and intensity normalization and paired t-tests were done by using AFNI. The brain regions with significant FDG changes in a group with stimulation were yielded based on a P value of less than 0.05 and a cluster-size of greater than 12 contiguous voxels. Plotting the normalized mean activity of the significant regions over the whole time, we could observe the time-dependent fluctuation of long-range signaling. Motor cortex (M1) as higher in metabolism than sham group throughout stimulation time. The striatum responded actively at the beginning of the stimulus and gradually diminished. However, static PET analysis showed no statistical results in the striatum regions. The activities of internal capsule and thalamus were found to be significant in the early (<10min) and late (>20min) stimuli, while the middle frames showed little difference between two groups. Therefore, independent PET analysis at each time point may overcome the problems of general PET image analysis, where statistical significance can be lowered or ignored for a small number of brain regions where the change is small during the entire reaction time. It is possible to compare the signal pattern during a certain time interval with the continuous electrophysiological signal by acquiring more number of time points for analysis.

**Abstract:** BOLD fMRI signals detect changes in the concentration of deoxyhemoglobin, and as such depends in a complex manner on functional hyperemia, oxygen consumption and blood volume. Consequently, the extent to which these signals report specific cellular activity and local vascular changes remains unknown. Here, we use the mouse olfactory bulb (OB) as a neurovascular model and three imaging techniques- two-photon imaging (GCaMP6f and PO2), ultrafast ultrasound imaging (fUS) and 17T BOLD fMRI to link microscopic neuronal and vascular activation to mesoscopic vascular activation, i.e. changes in Power Doppler and BOLD signals, in response to odor stimulation. Transgenic mice expressing GCaMP6 under control of the Thy1 promoter were implemented with chronic windows compatible with the three imaging techniques and repetitively imaged under anesthesia. We first demonstrated that for each imaging technique, repetitive imaging sessions gave reproducible responses to odor stimulation. In each animal, we then imaged the same olfactory bulb region with the three imaging approaches. We report differences in the threshold and dynamic range of local changes in identified mitral cell activity, capillary red blood cell flow and oxygenation, Power Doppler and BOLD signals in response to odor. This work allows to discard some uncertainties regarding the relationship between local neuronal activation and both microscopic and mesoscopic vascular responses, and characterizes some of the limits inherent to mesoscopic imaging based on blood flow changes (fUS and BOLD fMRI).

**Abstract:** Blood oxygenation level dependent functional magnetic resonance imaging (BOLD fMRI) is an ideal non-invasive brain mapping technique. Acquisition and methods development make fMRI compelling to study cerebrovascular ageing, while acknowledging that non-neuronal nuisance sources, like increased cardiac-related effects, are more pronounced in older adults. Retrospective temporal and spatial filtering technique, RETROICOR, is effective at removing fMRI artifacts and rapid multiband fMRI also has promise for ageing research. These approaches, however, inadvertently limit the scope of corrections or increase the presence of structured noise. This study presents another approach that has yet to be applied to ageing, specifically multi-echo fMRI in which three consecutive echo acquisitions are combined per volume. This approach may yield added BOLD specificity (Posse et al., 1999). We hypothesized that multi-echo-weighted fMRI will enhance image quality compared to both an uncorrected single-echo, and RETROICOR. Our three participant groups were 16 younger adults, 29 healthy older adults, and 13 older adults with cerebral small vessel disease. In support of our first objective, we found task-related activation Z-statistics were significantly reduced using the weighted multi-echo fMRI compared to the uncorrected single-echo approach ($P<0.001$). Qualitative visual comparison revealed multi-echo-weighted fMRI was effective at reducing 'activation' from areas notorious for their non-neuronal contributions (Figure); however there was no difference in Z-statistics between RETROICOR and multi-echo-weighted approaches ($P=0.6$). Lastly, post-hoc, we observed a trend towards an ageing group effect for the multi-echo fMRI ($P=0.1$) but not RETROICOR ($P=0.8$). This multi-echo fMRI approach appears to improve activation quality akin to other data-scrubbing tools, which may improve spatial specificity of

neurovascular functional mapping. Therefore, multi-echo fMRI may have practical benefits in the study of brain ageing and vascular dysfunction.

**Title:** Noninvasive quantification of baseline oxygen extraction fraction (OEF) in the human brain using velocity-selective excitation and arterial nulling (VSEAN)

**Authors: *E. Y. LIU**[1,2], J. GUO[1,5], E. C. WONG[1,3,4], R. B. BUXTON[1,2,3]
[1]Ctr. for fMRI, [2]Neurosci. Grad. Program, [3]Radiology, [4]Psychiatry, UCSD, La Jolla, CA; [5]Radiology, Stanford Univ., Stanford, CA

**Abstract:** The local brain oxygen extraction fraction (OEF), the ratio of oxygen metabolized by the brain ($CMRO_2$) to oxygen delivered by cerebral blood flow (CBF), is a fundamentally important indicator of metabolism. With an additional measurement of CBF, absolute $CMRO_2$ can be calculated ($CMRO_2$ = CBF * arterial $O_2$ concentration $C_aO_2$). Quantification of $CMRO_2$ provides a measure of the brain's energy utilization and baseline levels of neuronal activity, and serves as a marker of brain function and viability. Accurate measurements of OEF and $CMRO_2$ are thus significant for defining and understanding brain physiology, especially as perturbations of these baseline markers can be seen in pathologies including stroke and Alzheimer's disease. Raichle et al. (2001) suggested that a baseline state of the brain can be described in terms of OEF, changes to which are also the origin of blood oxygenation level dependent (BOLD) signal changes. Although measuring OEF is challenging, in recent years several MRI methods have been developed based on inhalation of different gas mixtures, on the quantitative measurement of the susceptibility effect of the venous blood, or on the relaxation effects of altered hemoglobin $O_2$-saturation on the transverse relaxation rate ($T_2$) of venous blood (e.g., TRUST and QUIXOTIC). A newer method, velocity-selective excitation and arterial nulling, (VSEAN, Guo et al. 2012) was introduced to overcome some limitations of earlier techniques, providing a more sensitive and noninvasive approach to measure OEF. This method isolates the signal from venous blood which, taken along with a $T_2$-venous oxygen saturation ($Y_v$) calibration curve, yields estimates of venous oxygenation and consequently OEF. We report here a test of VSEAN in 19 subjects scanned during a baseline state: subjects performed a simple one-back memory task by viewing a white screen with single-digit numbers projected at the center. This was used to define the "baseline" to be consistent with other tasks in the session. A dual-echo arterial spin labeling (ASL, PICORE QUIPPS II) acquisition simultaneously recorded CBF and BOLD dynamics, also in the baseline state task. Preliminary results yield values of baseline OEF similar to previously reported measurements of extraction, validating the accuracy of the new methodology. Additionally, absolute $CMRO_2$ values were calculated from the OEF and CBF measurements, assuming typical $C_aO_2$, thus painting a complete picture of the brain's baseline energy state using a toolbox of noninvasive techniques. The tolerable nature of these methods make them good candidates for future application to patients in clinical environments.

**Abstract:** Epileptic seizures involve hyperexcitable and hypersynchronous neuronal activities resulting in high cerebral metabolic demands and hyperemia. Many studies utilized animal seizure models in order to study the dynamics of neurovascular coupling during seizure evolution. However, the neurovascular coupling has not been fully understood yet at a single neuronal cell type and a single vessel level. Here, we investigated the dynamics of the neurovascular coupling between principal neurons and adjacent vessels (arteriole & venule) with *in vivo* two-photon imaging in thy1-GCaMP6f mice. We induced focal ictal events by an intracortical injection of 4-aminopyridine and used fluorescent dextran to visualize cortical vessels during imaging. At ictal onset, calcium signals of excitatory neurons surged and maintained at a heightened level until seizure termination. Arterioles near the seizure focus dilated right after the ictal onset and maintained their maximum dilation until seizure termination. Unlike arterioles, venules did not change in response to the onset or termination, but seemed to maintain a dilated tone. During post-ictal periods, alongside with arteriole constrictions, calcium signals reduced below the baseline. In addition, the pattern of calcium activity seemed to be dependent upon the type of ictal events. In sum, the activities of calcium signal from excitatory neurons revealed a tight coupling with the dynamic of arterioles at ictal onset and termination.

**Abstract:** Given the growing understanding of the importance of healthy vasculature in the maintenance of healthy brain function, there has been increasing focus on measurement of vascular dynamics *in vivo* in animal models. Capillaries, the smallest vessels in the brain, make up about 85% of brain vasculature, yet reports of their dynamic functionality are widely varied. Historically, it has been difficult to measure small vascular changes using optical imaging, capillary diameter measurements in particular. Several common pitfalls likely contribute to these difficulties, including choice of imaging parameters including pixel size and acquisition speed, noise in the data, and post-processing. Similarly, accurate measurements of red blood cell (RBC) velocity from image sequences historically suffer from speed issues. To date, the most successful published techniques rely on high-speed line scans, precluding simultaneous diameter measurements in all but the most specialized multiphoton systems. Here we describe techniques to image and measure small changes in capillary diameter with sub-pixel resolution and to accurately track RBCs and record RBC velocity using a commercially available multiphoton microscope. Furthermore, we show that these two methods are compatible with each other and can be successfully used simultaneously to parse out diameter and velocity information from the same image acquisition.

**Title:** Caffeine caused a widespread increase of resting brain entropy

**Authors: *D. CHANG**, Q. GE, J. ZHANG, Z. WANG
Hangzhou Normal Univ., Zhejiang, China

**Abstract:** Entropy indicates the degree of irregularity of a system, and is an important trait of brain function. Entropy is often considered as a measure of complexity and high entropy suggests high information processing capacity. At rest, human brain is consistently shuffling between different intermediate states around a critical point. This restless effort is believed to facilitate brain function in order to be better prepared for upcoming unexpected events. Such a system-wise trait may also provide a unique window for probing brain both at healthy and diseased condition. We have previously developed a technique to map brain entropy (BEN) using fMRI and shown that BEN is stable across time and differs between controls and patients with various brain disorders. To further establish its usefulness in neuroscience and clinical research, a critical step is to examine its sensitivity and specificity under experimental modulations. To this end, we performed the first BEN variation study under pharmaceutical challenge using caffeine, which is the most widely used psychostimulant. Our hypothesis is that the beneficial effects of caffeine on the brain will induce higher resting BEN. Resting fMRI were collected from sixty caffeine-naïve healthy subjects (30/30 males and females, age: 23 ± 3 years) before and after taking a 200 mg caffeine pill with signed IRB consent forms. BEN and cerebral blood flow (CBF) maps were calculated using BENtbx and ASLtbx respectively. Statistically analysis through paired-t test showed that caffeine induced significant CBF reduction in the whole brain ($p<0.001$, corrected) and BEN increase in a large portion of the cerebral cortex ($p<0.001$ corrected) with the highest increase in lateral prefrontal cortex, the default mode network (DMN), visual cortex, and motor network. Increased BEN was not related to CBF reduction, suggesting a neuronal nature of the observed BEN effects. Increased BEN means increased brain activity irregularity and subsequently greater information processing capacity. Increased resting BEN in the sensorimotor system, DMN, and frontal area is consistent with the

enhanced facilitation effects (such as vigilance and attention) of caffeine. In conclusion, we revealed, for the first time, the neuronal effects of caffeine on BEN using a large sample size, proving truth of our hypothesis. These data also proved the sensitivity of BEN to pharmaceutical modulation, suggesting it as biomarker for monitoring longitudinal brain function variations.

**Abstract:** Neurons produce and release an array of vasoactive messengers, such as neuropeptides, which contribute to neurovascular coupling. We recently showed that

Neuropeptide Y (NPY), known to be released from NPY-positive (NPY+) inhibitory cortical neurons (INs), is responsible for the constriction phase of vascular response to neuronal activation [1]. NPY+ INs are a sparse neuronal population (Fig. 1A) co-expressing NPY with a number of vasodilators. In this work, we sought to identify the vascular and electrophysiological "signatures" of selective activation of NPY+ INs. We used mice expressing channelrhodopsin in NPY+ INs (NPY-CreER$^{T2}$/Ai32) and in all cortical INs (VGAT-ChR2). We imaged diameters of single penetrating arterioles using 2-photon microscopy and measured local field potentials (LFP) with a laminar electrode array. Optogenetic (OG) activation of NPY+ INs produced a clear biphasic vascular response but no measurable LFP (Fig. 1B). In contrast, both vascular and LFP signals were detected in response to OG stimulation of all INs (Fig. 1C). The lack of LFP during activation of NPY+ INs can be explained by their sparsity and modest hyperpolarization of their postsynaptic targets, contributing insignificantly to the extracellular potential. These results provide a demonstration that some types of neuronal activity may produce a readily detectable vascular/hemodynamic response in the absence of detectable electrical signals. This argues against a common notion of low sensitivity of fMRI to neuronal activity compared to "direct" electrophysiological measures. Instead, the sensitivity across different measurement modalities will depend on the exact composition of neuronal ensemble activity and cell-type-specific effects on dilation, $O_2$ consumption, and extracellular potential, underscoring the importance of multimodal integration for the inference of circuit activity [2].

**Title:** Charactering the rat brain's functional network during the awake and anesthetized states using the multi-echo fMRI

**Authors: *Y. MA**[1], Z. LIANG[3], T. NEUBERGER[1,2], N. ZHANG[1,2]
[1]Biomed. Engin., [2]The Huck Institues of Life Sci., Penn State Univ., University Park, PA;
[3]Neurosci., Chinese Acad. of Sci., Shanghai, China

**Abstract:** The brain's functional network in awake and anesthetized states has been extensively investigated using the whole-brain fMRI technique. However, an increasing number of recent studies have identified different types of artifacts in fMRI signals due to its high susceptibility to head motions and physiological fluctuations, undermining the fidelity and interpretability of fMRI data. Specifically, head motion is one of the major issues in awake animal imaging, and changes of physiological conditions are significant in anesthesia. Recently the multi-echo imaging technique has been developed and demonstrated to minimize the disruptive effects of those artifacts. In this study, we acquired the multi-echo fMRI data during wakefulness and graded anesthetic depths in rats using a newly designed setup that can further reduce head movement. And a novel preprocessing pipeline was used to achieve automatic alignment of rat's fMRI data, especially for large head motions during awake imaging. Then group-ICA method was used to investigate the major signal components within the optimally combined signals derived from the preprocessed data. All independent components were projected to individual multi-echo data for back reconstruction, and BOLD components and non-BOLD artifacts were identified based on the multi-echo signal model. Results show that BOLD components were dominant in our new awake rat imaging setups, and that spatial patterns of BOLD components showed high similarity to anatomically defined brain regions and intriguing consistency across the awake and different anesthetic depths.

**Title:** Characterization of gray matter hemodynamic response function in mild traumatic brain injury

**Authors: *A. TAYLOR**, D. RESS, J. KIM
Neurosci., Baylor Col. of Med., Houston, TX

**Abstract: Abstract:** The hemodynamic response function (HRF) measured by functional magnetic resonance imaging (fMRI) is the signature of neurovascular coupling in the brain. It is possible that this measured response can be used as a biomarker of diseases that lack structural abnormalities or damage. One such disease is traumatic brain injury (TBI), in which diagnosis is based on subjective behavior and symptoms. We hypothesize that measurement of the HRF can reveal changes in neurovascular coupling in TBI subjects with potential diagnostic utility. **Methods:** We evoke the HRF across most (~75%) of cerebral cortex with a 2-sec audiovisual stimulus with a complex finger-movement task. fMRI with high spatial (2-mm) and temporal (1.25-sec, SMS) resolution is used to measure the HRFs, which are parameterized to yield peak amplitude and time-to-peak (TTP). This procedure was performed on a pool of 8 healthy subjects and 3 patients with a history of severe TBI and unresolved cognitive symptoms (loss of taste, dizziness, etc.). **Results:** Healthy subjects yield a reliable spatial pattern of HRF amplitude (Fig A), while TTP is generally stable across cortex and subjects. For TBI subjects, preliminary data shows variable and different amplitude patterns for each subject. But, remarkably, compared with the healthy, the TBI subjects show a delay in their TTP (p=0.039). **Conclusion:** Functional MRI can be used to characterize neurovascular coupling in both healthy subjects and patients that may not express other structural markers of disease. There is potential clinical utility in HRF measurement including diagnosis and monitoring of mild TBI and other similar pathologies. **Figure:** HRF parameters. **A)** patterns of HRF amplitude for healthy subject; **B)** distribution of HRF time-to peak between healthy subjects; **C)** average (and standard deviation) HRF principal component for healthy subjects (N=8) and TBI patient.

**Title:** IoT for neuroscience: A communication infrastructure for experiments and clinical exams

**Authors: *S. T. FOLDES**[1,2], A. JACOBSON[1]
[1]Barrow Neurolog. Inst. Phoenix Children's Hosp, Phoenix, AZ; [2]Sbhse, Arizona State Univ., Tempe, AZ

**Abstract: Introduction:** Systems used for the research and clinical evaluations of neural activity are highly specialized and have limited customization beyond their specific purpose. A system that incorporates data from various sources and distributes processing in "real-time" would be more useful and could be used to determine when enough data are collected for clinical exams, provide data quality feedback during collection, and be used for brain-computer interfacing (BCI) to control devices.
**Methods:** A modular communication infrastructure was developed to stream data between computers and be easily customized for many projects. This infrastructure was built upon the well-defined and reliable message protocol MQ Telemetry Transport (MQTT). MQTT has been commonly used in Internet of Things (IoT) applications asynchronous communication between devices with minimal overhead in transmission and setup. In our system, modules use MQTT to “publish” data to the network and “subscribe” to data streams to receive the most recent data when it becomes available. This system is agnostic to data format allowing a variety of devices to communicate asynchronously and without regard to specifics such as sampling rates. Furthermore, the interface was developed for MATLAB to allow for easier prototyping; ideal for neuroscientists and biomedical engineers.
**Results:** The first iteration of the infrastructure was designed for BCI. Specifically, the system was evaluated with 1D control incorporating an acquisition module for EEG, processing module to compute event related desynchronization, and subject interface module to provide feedback of brain activity in real-time. The distributed design allowed this system to be run on various system configurations, including across multiple computers with wired or wireless connections. Transmission times for publishing and retrieving messages of different sizes were evaluated. We found the system required only 0.48±0.45 ms for wired and 3.10±1.20 ms for wireless to publish and retrieve 512 floating point values. This represented an extreme data size that might be seen from ECoG or uECoG recordings with 512 channels.
**Conclusions:** We developed a modular neural processing and stimulus control system that is capable of versatile experiments and exams and evaluated it in a BCI. **We uniquely combine the existing protocols from IoT with MATLAB to produce a system that is robust, generalizable, and can be adopted without specialized programing skill.** We are now applying this system to other applications such as more advanced BCI systems in a patient setting, and for remote, online data analysis of multimodal neurocritical care data.

**Title:** Further elaboration of the distribution of agouti-related peptide-immunoreactive axons using a canonical rat brain atlas in the adult male rat: High spatial resolution analysis of rostral forebrain regions

**Authors:** *B. E. PINALES[1], ***B. E. PINALES**[1], J. D. HAHN[2], A. M. KHAN[3]
[1]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [2]Biol. Sci., USC, Los Angeles, CA; [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

**Abstract:** Agouti-related peptide (AgRP) is a neuropeptide intensively studied for its role in feeding control; despite this, its brain expression is only partially determined. Here, we extend our earlier immunocytochemical investigation of AgRP chemoarchitecture in the rat forebrain (SFN 2016, San Diego, #453.13), with additional rostral forebrain analysis of AGRP axon distribution. We identified AgRP-immunoreactive (ir) axons and mapped their distribution digitally to sequential levels of a canonical rat brain atlas (L.W. Swanson, *Brain Maps*, 2004). This was accomplished with referenced Nissl cytoarchitecture, the use of camera lucida drawings, and careful determination of plane of section (Zséli G et al., (2016) *J Comp Neurol* 524:2803). Fixed frozen brain sections of an adult male Sprague-Dawley rat were incubated with a rabbit polyclonal antibody raised against the 83-132 amino acid sequence of human AgRP (Phoenix). Labelling was visualized with 3,3'-diaminobenzidine, and the data were mapped with the aid of darkfield microscopy. AGRP-ir axon distribution was enumerated for semi-quantitative analysis with the use of Axiome C software (created by JDH; SFN 2016, San Diego, #467.01).
The cerebral cortex displayed no AgRP-ir except for very sparse labeling in midline structures, notably the dorsal tenia tecta (TTd). In the striatum, there was low to moderate AgRP-ir in the nucleus accumbens (ACB) and the rostroventral part of the lateral septal nucleus (LSr); surrounding areas were devoid of axons. In the pallidum, there was sparse labelling in the substantia innominata (SI). In contrast, the bed nuclei of the stria terminalis (BST) had high expression of AgRP-ir axons, but low to moderate labeling in some BST subdivisions (oval, juxtacapsular). In the thalamus, the paraventricular thalamic- (PVT) and paratenial (PT) nuclei displayed a low (caudal) to high (rostral) AGRP-ir axon density. In the hypothalamus, dense AgRP-ir axons were observed in the paraventricular- (PVH), periventricular- (PV), arcuate- (ARH) and dorsomedial (DMH) hypothalamic nuclei. Moderately dense AgRP-ir was present in

the anterior hypothalamic- (AHA), medial preoptic- (MPO), and lateral hypothalamic (LHA) areas. Sparse AgRP-ir was found in the anterior hypothalamic- (AHN) and ventromedial hypothalamic (VMH) nuclei, and the retrochiasmatic area (RCH).
Collectively, our data provide high spatial resolution rat brain atlas maps of AgRP-ir distribution and will aid in comparing other chemoarchitecture mapped to the same reference atlas. These data may also allow the precise targeting of interventions in forebrain regions that receive inputs from AgRP-expressing neurons.

**Abstract:** The lateral hypothalamic (LHA) and the ventral tegmental areas (VTA) contain neural substrates that participate in the control of many motivated behaviors, but few studies have detailed their interconnections, and none have mapped precisely the distributions of neurons that project to the VTA from cytoarchitectonically defined LHA subdivisions. We identified retrogradely labeled neurons in specific LHA subdivisions and other portions of the fore-, mid- and rostral hindbrain projecting to the VTA by injecting FluoroGold (FG) into the VTA. For this report, we detail maps of two pairs: 1) FG injected into the rostral and caudal VTA and 2) FG injected into the VTA and rostromedial to the VTA. We also identified retrogradely labeled neurons in the diencephalon that were immunoreactive for the neuropeptides hypocretin 1/orexin A (H/O) or melanin-concentration hormone (MCH). FG+ cell counts in specific LHA subdivisions were compared between cases where FG was deposited directly into the VTA (hits;

n = 4) or adjacent to the VTA (misses; n = 4). There was robust FG signal in the bed nuclei of the stria terminalis, amygdala, habenular nuclei and dorsal raphe nucleus. There were select retrogradely labeled neurons in the LHA and zona incerta that were H/O and MCH positive. A three-way ANOVA [case (hit or miss) *vs* side (ipsilateral or contralateral) *vs* subregion (LHA subdivisions or rest of hypothalamus)] revealed greater numbers of FG+ neurons ipsilateral to the injection site as compared to contralateral ($F_{1, 2972}$=27.691, $p < 0.001$). An ANOVA for FG+ neurons on the ipsilateral side revealed: 1) the number of FG+ neurons that occupy the hit versus miss cases ($p < 0.001$); and 2) the LHA versus non-LHA regions in hypothalamus ($p < 0.001$). There is a significant interaction between the number of FG+ neurons that occupy the LHA sub-regions and the rest of the hypothalamus in both the hit versus miss cases ($p = 0.023$). FG+ neurons were distributed across the 25 LHA sub-regions on the side ipsilateral to the injection site in both groups. The most retrograde labeling was found in the LHA, posterior region in the misses (21%) versus the hits (11.2%). There is also robust labeling in the LHA, dorsal region in both the miss (19.3%) and hit (18.2%) cases. Retrogradely labeled neurons that occupy the LHA anterior group were abundant in both the hit (22.9%) and miss (17.8%) groups. Collectively, our results allow the identification of major neuronal populations within LHA subdivisions that project to the VTA. The mapped distributions of discrete neuronal populations may aid the development of a useful animal model for the treatment of eating and metabolic disorders which involve dysfunction of these areas.

**Abstract:** Hypothalamic functions, by engaging neuroendocrine and autonomic systems as well as behavioral responses, are necessary for homeostasis. Given its range of functions, it is unsurprising that the last half-century has revealed several complex fiber systems and a host of functionally diverse cell types nested within the hypothalamus. Our goal is to examine the chemoarchitecture of the lateral hypothalamic area (LHA) using standardized cytoarchitecture-based spatial framework. Here we build upon previous reports on LHA chemoarchitecture (SfN San Diego, 2016. Poster #453.07; SfN Chicago, 2016. Poster #616.08) generated from efforts of our HHMI-funded Brain Mapping & Connectomics laboratory course for freshman undergraduates. This year's cohort performed triple label immunohistochemistry to stain for hypocretin/orexin (H/O), melanin-concentrating hormone (MCH) and tyrosine hydroxylase (TH). Distributions of immunoreactive (ir) fibers and cell bodies were mapped to reference atlas plates from Swanson (L.W. Swanson, *Brain Maps: Structure of the Rat Brain, 3rd ed*) with the aid of adjacent Nissl-stained sections. Immunostained sections were imaged using wide-field epifluorescence microscopy. As in previous reports, immunodetected cell bodies for H/O and MCH were prominently found in dorsal and dorsolateral parts of the LHA. Additionally, TH-ir neurons and their fibers were visualized co-spatially with these labels. Specifically, TH-ir neurons were detected in the dopaminergic group and the medial tip of the zona incerta. Ventral to this, TH-ir cells were also found within a dorsal part of the arcuate hypothalamic nucleus. Although these cell populations do not co-localize, there is the possibility of interactions among them. This is being explored using confocal imaging at high-magnification. Collectively, these data contribute to our understanding of mesoscale connections within the LHA, and will greatly aid in determining stereotypical patterns of neuropeptidergic neurons and their axonal projections that are prevalent across multiple subjects.

**Abstract:** As part of a collaborative effort to examine the chemoarchitecture of GABAergic neurons within the mouse forebrain, we examined those GABAergic neurons that express the catecholamine-synthesizing enzyme, tyrosine hydroxylase (TH). We crossed the *vGAT-cre* mouse expressing cre recombinase under the vesicular GABA transporter (vGAT) promoter to a L10-EGFP reporter mouse to label the soma of vGAT neurons, then performed multi-label immunofluorescence cytochemistry against TH (mouse, 1:2000) and GFP (rabbit, 1:1000) using formalin-fixed vGAT-L10-EGFP brain tissue. Furthermore, we used Nissl-stained datasets and regional nomenclature from the Allen Brain Atlas online (P56, coronal) to perform Nissl-based parcellation and plane-of-section analysis in order to contextualize the observed TH/GFP expression patterns. Several hypothalamic regions contained neurons that co-localized GFP- and TH-immunoreactivity (ir). The zona incerta contained the most striking co-labeling of GFP/TH-ir neurons. This region corresponded closely to the A13 dopaminergic cell group (A13). There was also a dense grouping of co-labeled cells slightly ventral to A13, at the medial tip of the ZI, which may correspond to the rostral tip of the posterior hypothalamic nucleus (PH) within the *hypothalamic medial zone*. The *periventricular zone* also contained a moderate density of GFP/TH-ir neurons in the parvicellular division (anterior parvicellular part) of the paraventricular hypothalamic nucleus (PVHap); the intermediate (PVi) part of the periventricular hypothalamic nucleus; and at various rostrocaudal levels within the arcuate hypothalamic nucleus (ARH). In the *periventricular region*, there was a moderate density of EGFP/TH-ir neurons in the preoptic (PVpo) part of the periventricular hypothalamic nucleus, as well as some neurons in the dorsomedial hypothalamic nucleus (DMH) and the medial preoptic area (MPO) just ventral to the anterior commissure. Collectively, these results suggest the existence of novel hypothalamic populations that may signal through the co-release of GABA and catecholamines, such as dopamine. Further functional studies may confirm these structural findings and test the neurochemical signatures of these neurons.

**Title:** Towards automatic registration of histological data to canonical brain atlases

**Authors: *J. G. PEREZ**[1], O. FUENTES[2], A. M. KHAN[3]
[1]Computer Sci., The Univ. of Texas At El Paso, El Paso, TX; [2]Computer Sci., [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

**Abstract:** Since the early 1900s, the creation of brain atlases for model organisms (e.g., mouse, rat) has revolutionized neuroscience by allowing investigators to precisely target probes to identify structure-function relations in the brain, to localize neural systems elements at multiple scales, and to identify connections between neuronal cell populations. Although several brain atlases are now available online, few researchers map their spatial datasets to them. This is mainly due to the bottleneck of requiring trained domain experts to manually enter spatial data onto digital atlas plates, a very slow, laborious and error-prone process. This major rate-limiting step, i.e., the manual mapping of spatial data, has hampered the development of a unifying spatial model of the brain with registered, internally consistent datasets from diverse studies across multiple scales. We seek ultimately to circumvent the manual mapping step by developing high-throughput image analysis software that automates mapping of spatial datasets to brain atlases at cellular- and tissue-level scales. Such an infrastructure will allow neuroscientists to rapidly and accurately populate the atlases with their newly generated spatial datasets.
As a first step towards this long-term goal, we have developed an image analysis method that given an image of a Nissl-stained tissue section of a rat brain automatically finds the likely location of the region in a rat brain atlas. Our method works by first precomputing local descriptors of regions of interest in each plate of the target atlas. We use the scale-invariant feature transform (SIFT) to identify and characterize these regions; SIFT descriptors have been shown to be robust to changes in scale, orientation, noise, and illumination, which makes them well-suited for this application. Given the Nissl-stained image, we compute its SIFT descriptors and then use a stochastic search algorithm to find the best matching region in the atlas according to the similarity of their SIFT descriptors. As a proof of concept, we have used Nissl plates from the Paxinos & Watson atlas (*The Rat Brain in Stereotaxic Coordinates, 7th edition*, 2014) and have registered them to corresponding plates within the Swanson rat brain atlas (*Brain Maps, 3rd edition*, 2004; larrywswanson.com). Experimental results show the method is accurate and efficient, generating results that can be validated by comparing them to independently derived registration solutions obtained from craniometric data. This system will help facilitate the assignment of histological data sets within canonical reference spaces to accelerate the mapping efforts of trained domain experts.

**Abstract:** The arcuate hypothalamic nucleus (ARH) is a primary sensor of metabolic signals critical for regulating nutritive state and basal metabolism. Neural substrates within this region help control appetite through the actions of various neurotransmitters and neuropeptides. A deep midline structure, the ARH is approximately 2.5 mm-long rostrocaudally in the adult rat, an area that spans five levels within the Swanson reference atlas (*Brain Maps: Structure of the Rat Brain, 3rd Ed).* However, despite its vast expanse, its chemoarchitecture is poorly characterized and often treated as being uniformly homogenous. To characterize ARH chemoarchitecture across its 3-dimensional extent, here we analyzed the spatial organization of six major neuropeptides and signaling molecules within the ARH: hypocretin/orexin, melanin-concentrating hormone, phenylethanolamine-*N*-methyltransferase, tyrosine hydroxylase, neuronal nitric oxide synthase, and calbindin. Using multi-fluorescence immunohistochemistry, in conjunction with Nissl-based parcellation and mapping, we labeled these molecules in the ARH and obtained fluorescence images of them using high-resolution, wide-field microscopy. The spatial distributions of their expression within neuronal perikarya and axonal fibers were mapped to ARH-containing levels of the Swanson atlas with the aid of a camera lucida. To enhance peptide expression, a 48-hour food deprivation model was also used. Initial results indicate that for several peptides there exists a spatial restriction of expression to either dorsoventral or mediolateral sub-regions of the ARH. In the case of TH and calbindin, somata were densely distributed within the dorsomedial but not ventromedial ARH. In contrast, for PNMT, the opposite was observed, with fiber expression robustly appearing within the

ventrolateral ARH. We also observed parallel spatial distributions of certain molecules across the ARH. MCH and H/O were found to innervate ARH space in complementary patterns, possibly reflecting their redundant actions in fine-tuning physiological operations. Dramatic shifts in the densities and spatial distributions of peptidergic elements were also noted in the normal vs food - deprived animals. By mapping the distribution of distinct neuropeptides and signaling molecules across the ARH to a canonical rat brain atlas, our datasets can be contextualized with other types of data mapped in the same reference space. This data integration, in turn, may improve our understanding of how the ARH integrates signals as part of a node within larger control networks in the brain.

**Title:** Mapping the connections between the medial prefrontal cortex and the diencephalon: A combined anterograde and retrograde tract-tracing study in the adult male rat

**Authors: *K. NEGISHI**[1], *J. ALMERAZ[2], A. M. KHAN[3]
[2]Systems Neurosci. Lab., [1]UNIVERSITY OF TEXAS AT EL PASO, El Paso, TX; [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

**Abstract:** Adaptive changes to ongoing behaviors are supported by the cingulate region (CNG; alternatively, medial prefrontal cortex), a region often described topographically, with dorsal parts associated with adaptive actions and ventral parts with emotional and autonomic outcomes. However, CNG chemoarchitecture and connectivity also vary rostrocaudally; a feature that has received less attention. In order to examine CNG rostrocaudal topography in a standardized spatial framework, *P. vulgaris* leucoagglutinin and cholera toxin B subunit were co-injected into circumscribed CNG areas. Tracer immunoreactivities were plotted to the Swanson atlas (LW Swanson, *Brain Maps, 3rd ed.)* with the aid of an adjacent Nissl series. Here we report results following injections centered in mid-rostrocaudal (ILAm) and caudal (ILAc) parts of the infralimbic area and the dorsal part of the anterior cingulate area (ACAd).
Thalamic CNG connections were found mostly along midline structures. Dense bidirectional connectivity was observed throughout the mediodorsal thalamic nucleus (MD). Tracers from both ILA injections were concentrated in the medial part of the MD (MDm) along the border

with the paraventricular thalamic nucleus (PVT), while ACAd connections were concentrated in the lateral part (MDl) at its boundary with the central lateral nucleus. CNG connections with the nucleus reuniens (RE) were observed predominantly from the ILA, including bidirectional connections with ventrolateral RE sub-regions bordering the perireuniens nucleus (PR). Laterally, a similar clustering of ACAd connections was observed in the ventromedial tip of the ventral medial nucleus (VM). Hypothalamic connectivity with the CNG was restricted mainly to the ILA, although sparse ACAd axons and retrogradely labeled neurons were also observed. Notably, most of the observed CNG projections in the lateral hypothalamic area (LHA) originated from the ILAc and, to a lesser extent, the ILAm. Dense terminal fields from ILAc projections were seen in the dorsal (LHAd), suprafornical (LHAs) and posterior (LHAp) regions of the LHA. Within the tuberal nucleus, we characterized for the first time dense ILAc axonal terminals throughout the rostrocaudal extent of the terete nucleus (TUte).
The observations made here support and extend previous work done on CNG connections. Additionally, our atlas-based spatial framework co-extends with a larger body of anatomical studies in the rat. Together with tools for streamlining anatomical data (e.g., Axiome; Hahn & Swanson, 2016; SfN #467.01), these data will aid in the assembly of spatially precise connectomes.

**Title:** Efferent projections of thyrotropin-releasing hormone-synthesizing neurons from the tuberal region of the lateral hypothalamus impinge on histaminergic neurons of the tuberomammilary nuclei

**Authors: *E. SANCHEZ JARAMILLO**[1], G. WITTMANN[2], E. SÁNCHEZ-ISLAS[1], M. LEÓN-OLEA[1], R. M. LECHAN[2]
[1]Inst. Nacional De Psiquiatria, México, Mexico; [2]Dept. of Medicine, Div. of Endocrinology, Diabetes and Metabolism, Tufts Med. Ctr., Boston, MA

**Abstract:** Thyrotropin-releasing hormone (TRH) is a tripeptide widely distributed in the mammalian brain. Besides its critical role in the central regulation of the hypothalamic-pituitary-

thyroid axis, TRH has been proposed as a metabolic sensor that regulates appetite and energy homeostasis. Hypophysiotropic and non-hypophysiotropic TRH neurons originating from the hypothalamic paraventricular (PVN) nucleus, respond to highly demanding conditions as such food deprivation and cold exposure. However, little is known about other hypothalamic cells that synthetize TRH and may also be involved in eating behavior.
Central administration of TRH decreases food intake, but increases histamine in the tuberomammilary nucleus (TMN), where all the histaminergic neurons of the brain reside. As TMN histamine neurons are densely innervated by TRH fibers from an unknown origin (Sarvari et al., 2012), we mapped the TRH afferences using two complementary tracers.
The retrograde tracer, Cholera toxin B subunit (CTB, 0.5%) was injected by iontophoresis under stereotaxic guidance from a glass micropipette placed into the TMN E1-E2 and E4 subdivisions of 8 week old male Sprague Dawley rats (n=7). After 1 week of transport interval, animals were perfused and brain sections were prepared for double-labeling immunofluorescence using an antibody directed against pro-TRH(178-199) and CTB. The origin of CTB afferents to the TMN included the septum, medial, central and lateral preoptic area, bed nucleus of the stria terminals, perifornical area, anterior parvocellular PVN, lateral, anterior and ventromedial hypothalamus, peduncular part of the lateral hypothalamus, suprachiasmatic nucleus, medial amygdala and tuberal lateral hypothalamus (TuHL). However, Only double-labeled neurons were found in the TuLH suggesting that TRH neurons innervating histaminergic neurons in the TMN originate in the TuLH. To confirm the specificity of the retrograde tract-tracing result, we administered iontophoretically the anterograde tracer, Phaseolus vulgaris leucoagglutinin (PHAL, 2.5%) in the TuLH of 8 week old male Sprague Dawley rats (n=7). PHAL injections hit rostral, mid or caudal TuHL. After a 10 day transport interval, we identified double labeled PHAL- and pro-TRH-immunofluorescence cells on the TMN. We are currently determining the number of PHAH/pro-TRH-ir containing axon terminals and en-passant boutons in the E1-E5 subnuclei of the TMN. The data suggest, therefore, that TuLH TRH neurons may function as an important metabolic sensor in the brain to regulate the effects of neuronal histamine on energy homeostasis and thermogenesis.

**Title:** High-fat diet and aging interact to produce neuroinflammation and impair hippocampal- and amygdalar-dependent memory

**Authors: *R. M. BARRIENTOS**[1], H. M. D'ANGELO[1], A. SOCH[2], L. R. WATKINS[1], S. F. MAIER[1], S. J. SPENCER[2]
[1]Dept. of Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]RMIT Univ., Melbourne, Australia

**Abstract:** More Americans are consuming diets higher in saturated fats and refined sugars than ever before, and based on increasing obesity rates, this is a growing trend among older adults as well. While high saturated fat diet (HFD) consumption has been shown to sensitize the inflammatory response to a subsequent immune challenge in young adult rats, the inflammatory effect of HFD in the already-vulnerable aging brain has not yet been assessed. Here, we explored whether short-term (3 days) consumption of HFD would serve as a neuroinflammatory trigger in aging animals, leading to cognitive deficits. HFD impaired long-term contextual (hippocampal-dependent) and auditory-cued fear (amygdalar-dependent) memory in aged, but not young adult rats. Short-term memory performance for both tasks was intact, suggesting that HFD impairs memory consolidation processes. Microglial markers of activation (Iba1 and cd11b) were increased in the aged rats, but were not further amplified by HFD. However, these HFD-induced long-term memory impairments were accompanied by IL-1beta protein increases in both hippocampus and amygdala in aged rats. Central administration of IL-1RA in aged rats following conditioning mitigated both contextual and auditory-cued fear memory impairments caused by HFD, strongly suggesting that IL-1beta plays a critical role in these effects. Voluntary wheel running, known to have anti-inflammatory effects in the hippocampus, rescued hippocampal-dependent but not amygdalar-dependent memory impairments caused by HFD. Together, these data suggest that short-term consumption of HFD can lead to memory deficits and significant brain inflammation in the aged animal, and strongly suggest that appropriate diet is crucial for cognitive health.

**Abstract:** The ventral hippocampus (vHP) plays a central role in memory and affective processes such as anxiety and fear conditioning. Recent studies from our group show that vHP neurons also regulate learned aspects of feeding behavior via direct pathways to the lateral hypothalamic area (LHA) and medial prefrontal cortex (mPFC). The present study sought to deepen understanding of these feeding-relevant vHP signaling pathways by utilizing conditional dual viral-mediated pathway tracing strategies to identify collateral 1st-order and 2nd-order targets of LHA- and mPFC-projecting vHP neurons.
First-order outputs of vHP (field CA1; vCA1) neurons were investigated using viral (AAV1-hSyn-eGFP-WPRE-bGH) and nonviral (Phaseolus vulgaris-leucoagglutinin) anterograde pathway tracers. Analyses confirmed the LHA and mPFC as two principal vHP targets. To characterize these neural pathways further, collateral projections were investigated using a conditional dual viral approach: Cre-recombinase (CRE) was expressed in LHA- and mPFC-projecting vHP neurons following injection of a retrograde vector (AAV2retro-hSyn1-eGFP-2A-iCre-WPRE) into the LHA or mPFC, and a CRE-dependent anterograde vector (AAV1-CAG-Flex-eGFP-WPRE-bGH) was then injected into vCA1. Axon collaterals of vHP > LHA neurons were found in the nucleus accumbens (ACB), lateral septum (LS), and subfornical organ, whereas collaterals of the vHP > mPFC pathway were found in the ACB, LS, LHA, and lateral amygdala. Next, we examined 2nd-order outputs of these vHP pathways by injecting a transsynaptic anterograde vector (AAV2/1-hSyn-Cre-WPRE-hGH) into vCA1 that drives CRE expression in both 1$^{st}$-order (vCA1 injection site) and 2$^{nd}$-order neurons, and then a CRE-dependent anterograde vector (AAV1-CAG-Flex-eGFP-WPRE-bGH) was injected into the LHA or mPFC. Preliminary data indicate that many 2nd-order outputs of vCA1 > LHA and vCA1 > mPFC pathways converge on the same regions, including the medial and lateral septal nuclei. Interestingly, LHA neurons that receive direct input from vCA1 also project to mPFC, and mPFC neurons that receive input from the vCA1 project to LHA.
Collectively, these results reveal substantial convergence of the vHP > LHA and vHP > mPFC neural pathways with regards to both 1$^{st}$-order collateral and 2$^{nd}$-order projections. Considering our recent work identifying an important role for vHP signaling in learned and hedonic aspects of feeding behavior, future studies are needed to determine the functional implications of these newly identified signaling routes with regards to the control of food intake.

**Abstract:** Complex motivated behaviors must be prioritized and executed according to appraisal of internal drive states. When strong enough, these drives can suppress expression of other motivated behaviors. In mice, caloric starvation states can suppress normal self-preservation, social interaction, and water-seeking behaviors to favor foraging and food consumption behaviors. Starvation-sensitive Agouti-related peptide (AgRP) neurons expressed in the arcuate nucleus of the hypothalamus (ARC) may be integral to this process: stimulation of this population induces an artificial hunger-like state that also can suppress non-feeding-related behaviors. It is unclear, however, how different hunger states dynamically coordinate multiple types of motivated behaviors; $ARC^{AgRP}$ neurons' role in this process is also unclear. Here we sought to investigate the influence of natural hunger states, as well as an artificial hunger-like state through stimulation of $ARC^{AgRP}$ neurons, on an animal's drive to engage with a male or female conspecific.

**Abstract:** Trace amine-associated receptor 1 (TAAR1), a G protein-coupled receptor, is a modulator of monoaminergic neurotransmission. Selective TAAR1 agonists showed antipsychotic-like properties, antidepressant-like effects, and pro-cognitive properties. In addition, activation of TAAR1 inhibited the expression of drug and palatable food rewarding memories. However, few study investigated the role of TAAR1 in aversive learning and memory. Here, we examined the effects of TAAR1 partial agonist RO5263397 on lithium chloride (LiCl)-induced conditioned taste aversion (CTA). We showed that LiCl (0.075 or 0.15 M, 7.5 ml/kg, i.p.) significantly induced taste aversion to saccharin in rats. Pretreatment of RO5263397 (5.6 mg/kg, i.p.) significantly prevented the extinction of LiCl-induced CTA. Sub-chronic administration of RO5263397 delayed the extinction but had no effect on the extinction rates during later extinction. Further experiments should be conducted to confirm the effects of activation of TAAR1 on the expression and extinction of LiCl-induced CTA.

**Abstract:** Extinction-based procedures for eliminating fear-related memory have met with limited success in that fear memory often returns with the passage of time. Accordingly, more recent approaches have sought to prevent recovery of fear by targeting it directly, manipulating either a) the *lability* of newly retrieved fear memory prior to extinction training or b) *prediction error* during extinction training. In the present experiment, a modified extinction procedure was

used after training that incorporates features of both the lability and prediction error approaches, to determine the effectiveness of each approach in reducing retention of fear. In the modified procedure, animals were exposed to the conditioning apparatus for a brief period (30 sec) in the absence of shock, that is, they were removed from the apparatus before an opportunity to recall fear or equivalently to experience prediction error developed to a significant degree. Specifically, 24 hrs after contextual fear conditioning, rats were divided among 5 groups and received one of the following procedures: a single 30 sec exposure, a single 60 sec exposure, two 30 sec exposures separated by 10 min, two 30 sec exposures separated by 6 hrs; a control group was not exposed to the apparatus. Each of the 5 groups received two retention tests to determine the effectiveness of the extinction procedure in reducing retention of fear, the first test administered 24 hrs after the extinction procedure (short-term retention), the second test administered 11 days after the extinction procedure (long-term retention). If *prediction error* determines the effectiveness of the extinction procedure, then the second exposure in the 10-min and 6-hr conditions, accompanied by weak fear or equivalently weak prediction error, should not only limit retention of fear, it should do so *regardless of the inter-exposure interval*. In contrast, if *lability* determines the effectiveness of the extinction procedure, then the second exposure in the 10 min and 6 hr condition, introduced within or outside the window of lability, should not only limit retention of fear, it should do so *depending on the inter-exposure interval*. The results indicated that all exposure conditions reduced retention of fear both in the short term and long term, but only the 30 sec exposure administered within the window of lability (10 min condition) reduced retention in the long term to a level approaching the pre-training baseline. The results support the efficacy of the brief exposure procedure in attenuating long-term retention but suggest that its effectiveness may depend on lability rather than prediction error.

Nencki Inst. of Exptl. Biol. PAS, Warsaw, Poland

**Abstract:** With the passage of time after fear extinction an extinguished fear returns. Spontaneous recovery of fear is well described at the behavioral level; however the neuronal basis of the phenomenon is not well understood. The prelimbic region (PL) of the prefrontal cortex, which integrates signals from the basolateral part of the amygdala (BL) and the ventral hippocampus (vHIP), has been implicated in retrieval of both fear and fear extinction memories. Its involvement has been studied shortly after fear extinction; it is not known however how the BL and vHIP signals in the PL impact retrieval of fear extinction memory at later times after extinction. To investigate the role of the BL and vHIP inputs to the PL during extinction memory retrieval we used immediate early gene c-Fos mapping, functional anatomy tracing and optogenetic stimulation. We found two distinct subpopulations of neurons in the PL activated by successful extinction and relapse of fear; the fear neurons received predominantly the BL inputs, whereas the extinction neurons received mainly the vHIP projections. Consistently, optogenetic activations of the BL projections increased and the vHIP inputs decreased levels of freezing to the CS during retrieval of the recent but not remote memory. At the later times after extinction fear expression could be reduced by vHIP-PL pathway stimulation only after extensive extinction training, which is supposed to strengthen the vHIP-PL connectivity. The number of neurons activated by successful extinction and spontaneous fear recovery was similar. Thus, the results suggest that over time fear memory is no longer gated by the vHIP inputs to PL and the BL signals can play a dominant role, resulting in spontaneous recovery of fear.

**Title:** In the pursuit of the fear engram: Identification of neuronal circuits underlying the treatment of anxiety disorder

**Authors: *O. KHALAF**, L. DIXSAUT, V. GORDEN, L. GLAUSER, J. GRÄFF
Lab. of Neuroepigenetics (UPGRAEFF) - Brain Mind Inst., The Swiss Federal Inst. of Technol. (EPFL), Lausanne, Switzerland

**Abstract:** Fear and other anxiety disorders are extraordinarily robust and difficult to treat. Among the most effective treatments for anxiety disorders are exposure-based therapies, during which a patient is repeatedly confronted with the originally fear-eliciting stimulus in a safe environment so that the once fearful stimulus can be newly interpreted as neutral or safe. A fundamental element for successful exposure-based therapies is the reactivation/recall of the traumatic memory, which initiates a time-limited process called memory reconsolidation, during which a memory becomes susceptible to disruption.
Presently, the neuronal subpopulations and molecular mechanisms underlying successful fear memory attenuation remain completely unknown, which represents a big gap in memory research. Therefore, the first aim of this work is to identify the neuronal subpopulations that are causally implicated in effective attenuation of remote fear memories. This will help to determine whether the original traumatic memory trace has been permanently modified or a new memory trace of safety has been superimposed over the original one. The second aim is to develop a tool that allows for the isolation of the neuronal subpopulations causally implicated in remote memory attenuation, in order to be able to delineate the epigenetic and transcriptional mechanisms at play within these subpopulations. This will help to identify a molecular signature of effective remote fear memory attenuation.
The results of my research suggest for the first time that there is a small population of neurons in the dentate gyrus – that was active during the recall of fear – that needs to be reactivated during extinction to attain successful remote fear attenuation. While the inactivation of such population during extinction impairs fear attenuation, its activation ameliorates behavioral extinction. Furthermore, we have successfully established a method to isolate this neuronal subpopulation from the brain, namely by fluorescence-activated cell sorting. This tool will allow follow up studies to pursue the quest for the molecular signature of successful remote memory attenuation. Overall, these findings could help us to better understand the intricate principles of effective remote fear memory attenuation, and thus to develop new strategies that improve the treatment of anxiety disorder.

**Title:** Elucidating the mechanisms of fear extinction in developing animals: a special case of NMDAR-independent extinction in adolescent rats

**Authors: *M. A. BISBY**, K. D. BAKER, R. RICHARDSON
UNSW Sydney, Sydney, Australia

**Abstract:** NMDARs are considered critical for the consolidation of fear extinction. However, recent work has challenged this assumption. Namely, extinction retention is NMDAR-independent in infant rats and when extinction training occurs for the second time (i.e., re-extinction) in adult rats. In this study, a possible third instance of NMDAR-independent extinction was tested. Although adolescents typically exhibit impaired extinction retention, some recent work has shown that rats that are conditioned as juveniles and then given extinction training as adolescents (JuvCond-AdolesExt) have good retention of extinction (indicating successful extinction consolidation). However, this good extinction retention is observed in the absence of an upregulation of the synaptic plasticity marker phosphorylated mitogen activated protein kinase (pMAPK) in the medial prefrontal cortex, a region considered critical for extinction consolidation. In the current study, rats received either the non-competitive NMDAR antagonist MK801 (0.1mg/kg, s.c.) or saline 10 minutes prior to extinction training. Although juvenile rats exhibited impaired extinction retention after MK801 compared to saline, this effect was not observed in JuvCond-AdolesExt rats (*n*s = 11-12). Further experiments ruled out a number of alternative accounts for the lack of an effect of NMDAR antagonism on extinction retention in JuvCond-AdolesExt rats (e.g., that the animals were adolescents or had a delay between conditioning and extinction). These results provide evidence for yet another circumstance in which NMDARs are not required for successful extinction retention - that is, when rats learn fear as juveniles and undergo extinction as adolescents. Furthermore, our findings highlight the complexity of fear inhibition across development, particularly in adolescence.

**Abstract:** The medial prefrontal cortex (mPFC) has emerged as a brain region capable of gating the expression and extinction of fear memories. Subdivisions of the mPFC are proposed to exert orthogonal effects on the expression of fear. The prelimbic (PL) division is believed to enhance fear; whereas, the infralimbic (IL) is believed to diminish fear and thereby facilitate extinction. However, the dynamics of how mPFC neural activity in these brain regions can exert overall net enhancement or suppression of fear expression remains unclear. Moreover, synthesis of results from lesion, microstimulation and single-unit recordings of IL and PL have yielded somewhat paradoxical conclusions that do not support a straightforward division of labor between IL and PL. In part, this may be a consequence of the methodological difficulty in discerning unique vs. overlapping contributions of two closely positioned brain regions. To address this, we expand our previous work (Temme et al., 2014), along with work from the Holmes laboratory (i.e. Camp et al., 2009; Fitzgerald etl al., 2014) which has characterized *wild-type* inbred mouse strains that differ in their capability for fear extinction learning. Specifically, we have found that the 129 inbred mouse strain is significantly impaired in extinction learning and also shows greater fear generalization to novel environments relative to the C57BL/6. Our goal is to leverage this distinction between these strains to visualize differences in neural activation in IL and PL during extinction. To do this, we compare mice of each strain that have been fear conditioned and then received a varying number of presentations of the CS during extinction (0, 30, or 60 presentations). We use both *in situ* and *in vivo* measures for neural activation in IL and PL during and after this extinction learning. First, we compare fractions of neurons in mPFC that show immunoreactivity for expression of immediate early genes, which are upregulated in response to increases in neural activity (*cFos, Zif268*). Furthermore, we use miniaturized endoscopes together with a genetically encoded calcium sensor (GCaMP6) to visualize fluorescence changes associated with neuronal activation in single cells of IL or PL during presentations of a CS during extinction training. Using these approaches, we may elucidate distinct cellular and network mechanisms that confer different extinction learning capabilities.

**Title:** Sex differences in extinction of conditioned fear in adolescent rats: Estrus cycle effects

**Authors: *J. H. KIM**[1], D. L. D. NGUYEN[1], S. WHITTLE[2], D. E. GANELLA[1]
[1]The Florey Inst. of Neurosci. and Mental He, Parkville, Australia; [2]Melbourne Neuropsychiatry Ctr., Parkville, Australia

**Abstract:** Over 70% of those suffering from anxiety disorders are diagnosed during childhood or adolescence. Despite these findings, adequate treatments are lacking, with over 50% of young people with anxiety disorders not responding to first-line treatments (i.e. cognitive behavioural therapy involving exposure training). While female children, adolescents, and adults are more than twice as likely to suffer from anxiety disorders as compared to males, the biological mechanisms underlying sex differences in anxiety disorders, especially during puberty, are poorly understood. Therefore, we examined fear conditioning and extinction in female and male postnatal day 35 rats. Rats first received 6 tone-shock pairings and then 60 tone alone presentations the next day for 2 days. Following each behavioural session, all female rats received a vaginal swab to monitor the estrus cycle (metestrus, diestrus, proestrus, and estrus). We observed comparable conditioning between male and female adolescent rats, and the estrus cycle on conditioning day did not affect tone-elicited freezing during conditioning and subsequent extinction days. However, the estrus cycle on the first day of extinction had a significant effect. Specifically, proestrus females overall froze significantly more (main effect of group, significant Tukey post-hoc) and showed a significantly delayed extinction (group x tone trials interaction) compared to male rats. The delayed extinction was further supported by Tukey post-hoc tests that showed higher lever of freezing in proestrus female rats at the final 7-12$^{th}$ block of extinction. Interestingly, this effect of proestrus during extinction day 1 carried over to the next day, even though many of the proestrus rats were no longer in that stage during extinction day 2. No other estrus cycle had effects on both extinction days, indicating that metestrus, diestrus, and estrus female adolescent rats fear condition and extinguish similarly to adolescent male rats. These findings are contrary to previous reports on the dampening effects of high estrogen levels in adult female rats on conditioned fear, and provide a rat model to study

why adolescent females may be more susceptible to developing anxiety disorders compared to males.

**Title:** Reproductive experience alters the involvement of N-methyl-D-aspartate receptors in fear extinction, but not fear conditioning, in female Sprague Dawley rats

**Authors: *S. TANG**, B. M. GRAHAM
UNSW Sydney, Sydney, Australia

**Abstract:** Recently, evidence has emerged showing that the behavioural and hormonal features of fear extinction are altered as a result of reproductive experience (Milligan-Saville & Graham, 2016). The current set of experiments sought to determine whether reproductive experience also alters the molecular features of fear extinction. In adult male rats, it has been widely demonstrated that the activation of N-methyl-D-aspartate receptors (NMDAr) is essential for fear extinction. We therefore compared the involvement of NMDAr in fear extinction between nulliparous (virgin) and primiparous (reproductively experienced) female rats. Nulliparous and primiparous females received systemic administrations of either MK-801 (a non-competitive NMDAr antagonist) or saline prior to extinction training. MK-801 was found to impair extinction recall in nulliparous females, but not primiparous females. When the same dose of MK-801 was administered prior to conditioning, both groups of rats showed impaired recall of conditioning the following day. Although further research is necessary, the results of these experiments indicate that the extinction, but not the acquisition of fear, may become NMDAr-independent following reproductive experience.

**Title:** Improving extinction retention and reducing relapse in adolescent rats with a TrkB agonist

**Authors: *A. A. STYLIANAKIS**[1], R. RICHARDSON[2], K. D. BAKER[3]
[1]Sch. of Psychology, Univ. of New South Wales - Kensington Campus, Sydney, Australia; [2]Univ. of New South Wales, Sydney, Australia; [3]UNSW Australia, Sydney, Australia

**Abstract:** A number of preclinical studies have demonstrated that fear extinction is impaired during adolescence. Evidence from studies with adult rodents suggests that the neurotrophic factor BDNF, or brain-derived neurotrophic factor, is important for extinction retention. However, there is some evidence that BDNF signaling does not function effectively during adolescence, which could be a contributing factor to the poor extinction retention exhibited in rats in this developmental period. One of the receptors that BDNF binds to and activates is the TrkB receptor. Past work has reported that a TrkB agonist, 7,8-dihydroxyflavone (7,8-DHF), injected systemically before a sub-optimal extinction session facilitated retention of extinction and reduced fear relapse (renewal) in adult mice. Here we examined whether 7,8-DHF also improves extinction retention and reduces renewal in adolescent rats. Adolescent rats (33 days of age) were given 3 CS (white noise)-US (.45 mA shock) pairings in Context A. The next day, rats were injected (i.p.) with 7,8-DHF (5 mg/kg) or vehicle one hour before extinction training in a second context (B). Over the next two days, rats were tested for extinction retention (in Context B) and ABA renewal. Adolescent rats given the TrkB agonist before extinction training exhibited improved extinction retention and less renewal than those injected with vehicle. These results demonstrate that activating TrkB receptors can ameliorate the extinction retention deficit typically exhibited by adolescent rats, as well as reduce fear relapse (renewal) in these animals. Considering that the impaired extinction retention exhibited by adolescents can be ameliorated by activating TrkB receptors, the receptors through which BDNF functions, the results of this experiment provide support for the hypothesis that dysfunctional BDNF signaling could be contributing to the extinction retention deficit of adolescents.

**Authors: *B. A. SILVA**, M. KINTSCHER, R. SCHNEGGENBURGER, J. GRÄFF
École Polytechnique Fédérale De Lausanne (EPFL), Lausanne, Switzerland

**Abstract:** The experience of strong traumata can lead to the formation of over-enduring fear memories that risk to degenerate into a pathological state known as post traumatic stress disorder (PTSD). When recalled, previously acquired memories can enter a labile state where new information can be incorporated. This memory update process forms the basis of the most successful treatments for PTSD, where subjects are repeatedly exposed to the trauma-inducing stimulus in a safe environment, resulting in an attenuation of the fearful component of trauma-related memories. Traditionally, the recall of recently acquired fearful memories is thought to be dependent on the hippocampus, whereas remote memory storage is said to rely more on higher cortical areas such as the medial prefrontal cortex. Nevertheless, here we hypothesize that hippocampal reactivation is necessary for remote memory updating. In particular, we posit that a bisynaptic cortico-thalamic-hippocampal circuit, involving the anterior cingulate cortex, the nucleus reuniens of the thalamus, and hippocampal area CA1, is critically involved in this process. To test this hypothesis, we are combining virus-based tracing and inducible chemogenetic tools for the specific manipulation of the neural activity of the neuronal population constituting such bisynaptic system during remote fear memory attenuation.

**Title:** Chronic alcohol after fear extinction augments cued freezing

**Authors: *H. C. BERGSTROM**, J. DISHART, A. HILLER, G. MINTZ, Z. WANG
Dept. of Psychological Sci., Vassar Col., Poughkeepsie, NY

**Abstract:** Post-traumatic stress disorder (PTSD) and alcohol use disorder (AUD) often co-occur. Some evidence suggests that alcohol may augment PTSD symptomatology. An inability to extinguish traumatic fear has been linked with the development of PTSD. In all prior studies modeling the impact of alcohol on fear extinction, alcohol was administered prior to extinction, leaving open the question of how alcohol directly interacts with the retrieval of a previously extinguished fear memory. Adult male C57BL/6 mice underwent auditory fear conditioning, context fear extinction, and cued fear extinction (massed presentations) on subsequent days. The next day, mice were administered daily intraperitoneal injections of ethanol (EtOH; 2.5 g/kg in 0.9% saline) or vehicle control over 5 days. Four days following alcohol exposure, CS-evoked freezing behavior in the extinction context was tested. Adult mice in the EtOH group (n=14) exhibited more CS-evoked freezing behavior relative to controls (n=13). There were no differences in contextual fear (pre-CS), context renewal and the effect of alcohol diminished with time (16 days). These data suggest that chronic alcohol impairs the retrieval of a previously established fear extinction memory and/or enhances the expression of the original fear memory. Analysis of neurons expressing the activity-regulated cytoskeletal protein Arc/arg 3.1 following fear extinction retrieval is ongoing in the basolateral amygdala, infralimbic, and prelimbic cortices

**Title:** MAP Training the brain with meditation and aerobic exercise

**Authors: *T. J. SHORS**, E. M. MILLON, H. M. CHANG
Behavioral and Systems Neuroscience, Dept. of Psychology, Rutgers Univ., Piscataway, NJ

**Abstract:** MAP Training[SM] is a novel brain health program designed to enhance neurogenesis—the production and survival of new neurons in the adult brain (maptrainmybrain.com; Shors et al., 2014, Curlik and Shors, 2013; Alderman et al., 2016; DiFeo and Shors, 2017). MAP Training[SM] begins with 20 minutes of silent sitting meditation followed by 10 minutes of slow walking meditation and ends with 30 minutes of aerobic exercise. Individuals who complete 8 weeks of training (twice a week) experience significant increases in mental and brain health, as assessed by decreases in depression, anxiety along with fewer ruminations about the past and increases in synchronized brain activity (Shors et al., 2014; Alderman et al., 2016; Shors et al., 2017). In this set of studies, we provided MAP Training to young adult women with and without trauma related to sexual violence history. Before training, women with sexual violence history reported more symptoms of depression, anxiety and post-traumatic stress disorder (PTSD) than women without a history. Moreover, those symptoms were highly related to ruminative thoughts and autobiographical memories about a stressful life event in their past. We propose that the MAP Training intervention is effective because the meditation component reduces trauma symptoms through extinction learning for trauma-related thoughts and memories while the aerobic exercise component targets depressive symptoms. We present the combination of mental and physical activity during MAP Training as a compelling new approach for enhancing brain health in people from all walks of life, but especially those who suffer from trauma and depression associated with stressful life events.

**Title:** Activational differences in neurons from the paraventricular nucleus of the thalamus in binge eating prone and binge eating resistant rats

**Authors: *K. A. RICHARDSON**[1], A. D. KIMBLE[2]
[1]Dept of Pharmacol., [2]Howard Univ. Col. of Med., Washington, DC

**Abstract:** The paraventricular nucleus of the thalamus (PVT) functions as a communication center between the ventral and dorsal striatum and the lateral hypothalamus. It receives innervation from neuropeptides that affect feeding. However, it is not clear what influence the PVT has on binge eating behavior. The purpose of this study is to determine whether there are activational differences in the PVT of binge eating prone (BEP) and binge eating resistant (BER) rats. It is hypothesized that BEP rats have significantly more c-Fos-activated neurons versus BER rats. We used a rodent, binge eating protocol to identify female Sprague Dawley rats (250-300g, n=7/group) that display BEP or BER phenotype. After the completion of nine feeding tests, the animals were processed for c-Fos immunoreactivity. Rats classified as BEP consume significantly more palatable food (high fat, sugar) than BER rats. Quantification of c-Fos cells is still underway, but preliminary results indicate a trend in increased c-Fos in the PVT of BEP versus BER rats. The activation of PVT neurons after palatable food consumption may indicate an involvement of these neurons in mediating binge eating behavior.

**Title:** D2 receptor independent modulation of iMSN synaptic transmission by dopamine in the nucleus accumbens

**Authors: *D. A. BURKE**[1,2], V. A. ALVAREZ[1]
[1]Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD; [2]Dept. of Neurosci., Brown Univ., Providence, RI

**Abstract:** Medium spiny neurons (MSNs) in the nucleus accumbens express high levels of dopamine D1 or D2 receptors and receive dense innervation of dopamine fibers from the ventral tegmental area. Dopamine, acting on these receptors, modulates synaptic transmission and plasticity through a combination of pre- and postsynaptic effects. However, dissecting the specific function dopamine receptor activation has proven difficult due to the presence of

dopamine receptors on multiple interconnected cell types within the accumbens. In particular, D1 receptors are Gs/olf coupled receptors expressed on the half of the MSN population that forms the direct projection pathway (dMSNs), and D2 receptors are Gi/o coupled receptors expressed on the half of the projection MSNs that form the indirect pathway (iMSNs), as well as on interneurons, and presynaptic afferent terminals to this region. Understanding the specific synaptic consequences of dopamine receptor activation on MSNs in the accumbens has been difficult using conventional tools.
The goal of the current experiments is to determine how dopamine affects synaptic transmission between different combinations of MSN subtypes (i.e. iMSN->dMSN, iMSN->iMSN, etc.). Using Adora2a-cre/Drd1-tdTomato or Drd1-cre/Drd1-tdTomato mice, we expressed channelrhodopsin-2 in either subpopulation of MSN to allow selective optogenetic stimulation of either iMSN or dMSN terminals, while measuring GABA IPSCs onto red-fluorescent labeled dMSNs or negative (putative) iMSNs using whole cell voltage clamp recordings. When stimulating iMSNs, application of D2-like agonist quinpirole inhibits IPSCs onto dMSNs and iMSNs to a similar degree. Interestingly, the endogenous agonist, dopamine, inhibits iMSN->MSN IPSCs to a much greater degree than maximal doses of quinpirole. This differential effect is due to a component of the overall inhibition that is not blocked by D1 and D2 antagonists or genetic deletion of D2 receptors from iMSNs. Current experiments are aimed at determining the means by which dopamine is inhibiting iMSN synaptic transmission that does not involve D1 or D2 receptors. Understanding exactly how dopamine modulates MSN->MSN lateral inhibition is a critical step for gaining full knowledge of how dopamine ultimately shapes information flow through the accumbens.

**Title:** $\Delta^9$-tetrahydrocannabinol (THC) produces bi-phasic rewarding and aversive effects in the anterior vs. posterior nucleus accumbens shell through dissociable μ vs κ opiate receptor mechanisms and differential modulation of medium spiny neuron activity

**Authors: *C. NORRIS**, H. J. SZKUDLAREK, S. R. LAVIOLETTE
Neurosci., Univ. of Western Ontario, London, ON, Canada

**Abstract:** The phytochemical in cannabis primarily responsible for its psychoactive properties, $\Delta^9$-tetrahydrocannabinol (THC), produces seemingly contradictory effects of reward and aversion at different doses. In addition, previous studies demonstrate that cannabinoid receptor

transmission can strongly modulate opiate-related motivational processing. Emerging evidence suggests that there are anatomical and functional differences between the poles of the shell region of the nucleus accumbens (NASh). Stimulation of a so-called “hedonic hotspot” on the anterior pole produces reward while stimulation of the rest of the structure either has no effect or produces aversion. Using a combination of conditioned place preference, social interaction, and *in vivo* electrophysiology we sought to elucidate how the unique properties of the NASh could be responsible for the biphasic effects of THC. Targeted microinfusions of THC into the anterior shell (+2.5mm from bregma) produces reward but microinfusions into the posterior shell (+1.5mm from bregma) produces aversion. Both these effects were challenged by either κ-opioid or μ-opioid receptor blockade. Reward in the anterior NASh was selectively blocked by co-administration of a μ-opioid receptor antagonist whereas aversion in the posterior NASh was selectively blocked by a κ-opioid receptor antagonist. Next, we wanted to examine if the effects of THC in the NASh generalized beyond producing reward and aversion. Using a social interaction test we demonstrated that infusions into the posterior (but not anterior) NASh induces deficits in natural sociability and social recognition memory. Conversely, THC infused into the anterior (but not posterior) NASh potentiates the reward salience of a normally subthreshold dose of morphine. Neither infusions into the anterior or posterior NASh have any effect on sucrose consumption, indicating these effects are specific to drug-related reward processing. Finally, using *in vivo* neuronal recording in rats, we demonstrate inter-cranial ventricle (ICV) infusions of THC produce a predominate decrease in medium spiny neuron (MSN) activity in the anterior NASh but produce a predominate increase in MSN activity in the posterior NASh. Collectively, these data further categorize the functional differences present in the NASh and suggest that interaction with endorphin receptors in the area are important for the effects of THC on affective processing.

**Title:** Delta-9-tetrahydrocannabinol and cannabidiol exert differential effects on aversive and rewarding emotional memory formation and salience attribution through actions in the ventral hippocampus

**Authors: *R. M. HUDSON**[1], W. J. RUSHLOW[2], S. R. LAVIOLETTE[2]
[1]Neurosci., [2]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

**Abstract:** Disturbances in emotional processing and salience attribution are core features of schizophrenia and other neuropsychiatric disorders. The ventral hippocampus (VHipp) contains large distributions of cannabinoid CB1 receptors (CB1R) that regulate emotional memory formation by modulating signaling in mesocorticolimbic structures such as the ventral tegmental area (VTA) and medial prefrontal cortex (mPFC). Delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) are phytocannabinoids that differentially impact dopamine (DA) activity and emotional processing. We have shown previously that intra-VHipp CB1R activation strongly modulates both fear and reward-related associative memory formation through modulation of mesolimbic neuronal activity states. In addition, we demonstrated that CBD can prevent amphetamine-induced amplification of DA activity and psychotomimetic behaviours through control of the rapamycin (mTOR) signalling cascade. Nevertheless, the mechanisms through which intra-VHipp THC and CBD may modulate emotional memory remain unknown. We used a combination of behavioural pharmacology, molecular analyses and in-vivo electrophysiology in rats to examine whether intra-VHipp THC and CBD differentially control the salience of rewarding and aversive emotional associative memory using a morphine place conditioning procedure (CPP), social reward assays and associative fear conditioning. In addition, we characterized the effects of intra-VHipp THC and CBD on simultaneous VTA DAergic and mPFC pyramidal neuronal activity states using single unit, extracellular electrophysiological recordings under urethane anesthesia. Intra-VHipp THC induced deficits in social memory formation but enhanced memory for morphine CPP and aversive associative cues. CBD alone had no effect, but when combined with THC increased social memory and disrupted THC-induced effects on reward and aversion-related emotional memory formation. We further report that CBD alone and co-administered THC control downstream phosphorylation of the mTOR signalling cascade within the VHipp. Additionally, intra-VHipp THC altered firing patterns in VTA DA and mPFC neurons by reducing phasic bursting levels and inducing opposing actions on population activity. Collectively, our findings implicate the VHipp as a critical site of action for phytocannabinoid-induced modulation of both reward and aversion-related emotional processing and memory formation. In addition, our findings have important implications for understanding potential positive and negative effects of specific cannabis-derived phytochemicals in neuropsychiatric symptomology.

**Title:** Order effects alter work effort in rat model of free choice

**Authors: *Z. T. KNAUSS**[1], M. M. QUEENER[1], J. A. LUBERA[1], M. FILIPOVIC[1], N. M. BOLDEN-HALL[1], J. P. SMITH[1], R. S. GOLDSMITH[1], K. A. SMITH[1], J. E. BISCHOFF[1], A. PRICE[1], M. C. MILLER[1], H. C. CROMWELL[2]
[2]Dept. of Psychology, [1]Bowling Green State Univ., Bowling Green, OH

**Abstract:** Previous research on effort is sparse, mainly showing weak effects to obtain consistent work by animal subjects. Studies have obtained consistent preference for the higher effort option but only after extensive training with forced choice. Moreover, no studies that we are aware of have shown animals will persist choosing the higher effort option despite obtaining relatively fewer rewards by making this choice. The sequence of effort experience could have a major impact on the intensity of work emitted by the subjects and even lead to this form of 'suboptimal' persistence. One of the goals is to create a more effective method to embed effort in order to test the impact of drugs of abuse on motivation and choice behavior. The present study used a paradigm that couple's elements of reward order during free foraging choice with the goal of forming a more naturalistic model of how order effects relate to work motivation/output in the rat model of choice. Previous work using this model has been successful at delineating components of choice behavior and comparing different contexts of choice (Ricker et al., 2016). Animals choose between a high effort option (5 lever press) with shifting reward outcome value either magnitude descending (5,4,2,1) or magnitude ascending (1,2,4, 5). The opponent low effort option (one lever press) contained a constant reward (one pellet) for all weeks. Work motivation/output was determined through analysis of high effort reward discrimination, preference and incentive contrast between weeks. An order effect was observed with animals working harder and providing more effort when rewards were in descending order as compared to rewards in ascending order. Further analysis will focus on a set of dependent variables including place preference, approach and consumption measures. In addition, the results allow for an analysis of error rates when obtaining reward options in different choice contexts. These findings suggest that rats that experience higher levels of work first, will choose to work and

prefer working even when the food reward is decreased to a point where it is costly in comparison to the constant one lever press one pellet reward. The implications of developing a consistent method to induce preferences for effort and work include: 1) the ability to test the impact of drugs of abuse on effort and work output; 2) to enable an examination of the environmental factors involved in how organisms choose to work harder and persist in choice evaluation toward effort vs. reduced effort options and 3) examining the neural substrates for effort as a key parameter in motivation and the brain basis of decision-making and choice.

**Title:** Effects of anandamide administration on components of reward processing during free choice

**Authors: *B. R. FRY**, L. C. ZONA, J. A. LALONDE, H. C. CROMWELL
Psychology, Bowling Green State Univ., Bowling Green, OH

**Abstract:** Previous research has implicated the positive modulation of anandamide, an endocannabinoid neurotransmitter, on feeding behavior. Anandamide is particularly noteworthy as it shares a similar mechanism of action with tetrahydrocannabinol, the primary psychoactive component in Cannabis. Cannabis legalization in North America has presented with a need to study endocannabinoid agonists and their effects on behavior. Much has yet to be determined in terms of the role of the endocannabinoid system in decision-making scenarios. The research presented here tested the hypothesis that anandamide would augment motivation and reward processing via appetitive and consummatory measures during an operant, foraging task. A three-box design was used in order to provide the animals with a free choice, exploratory foraging environment. Discrimination, preference, and incentive contrast were analyzed as discrete measures of decision-making in the three-box paradigm. Anandamide administration (1mg/kg) was found to significantly increase motivation for the optimal foraging outcome and alter basic processing of reward information involved in discrimination and relative valuation. The positive effects of anandamide on eating behavior and motivation have implications toward possible treatment modalities for patient populations presenting with disorders of motivation. These

findings suggest the need for continued investigation of the endocannabinoid system as a central component of motivated behavior.

**Title:** Electrophysiological characterization of novel selective and reversible kappa opioid receptor antagonists in VTA neurons

**Authors: *E. B. MARGOLIS**[1], T. L. WALLACE[2], L. J. VAN ORDEN[2], W. J. MARTIN[2]
[1]Neurol., UCSF, San Francisco, CA; [2]BlackThorn Therapeutics, Inc., San Francisco, CA

**Abstract:** Kappa opioid receptors (KORs) modulate physiological conditions of stress, reward, and mood, and are localized within neuronal circuits connecting midbrain monoaminergic neurons with forebrain limbic structures. Because activation of KORs within the ventral tegmental area (VTA) inhibits VTA dopamine neuron activity (Margolis et al., 2003 & 2006), blockade of KOR may be a useful approach to treating a variety of neurobehavioral disorders in which dopamine neuronal function is suppressed. Here we used an acute midbrain slice preparation from rat and whole cell electrophysiology to evaluate the potency, selectivity, and reversibility of four different KOR antagonists: BTRX-335140, BTRX-395750, PF-04455242, and LY2456302/CERC-501. Each compound reduced the outward current induced by the KOR selective agonist, U69593, in a concentration-dependent manner. BTRX-335140 acted as a full antagonist with an $IC_{50}$ of 1.1 nM in DA neurons, consistent with the potency measurements observed in a recombinant cell line stably expressing rat KORs ($IC_{50}$ = 3.2 nM). Similarly, BTRX-395750 ($IC_{50}$ of 5.8 nM) exhibited potent, full antagonist properties. Interestingly, LY2456302 showed an absolute $IC_{50}$ = 0.3 nM in this preparation, yet also had an unusually shallow sloped concentration response curve. In contrast, we found PF-04455242 exhibited partial antagonist activity in this VTA preparation, with a maximum of 60% blockade of the U69593 effect. PF-04455242 also generated an outward current and a decrease in membrane resistance in a subset of neurons, consistent with a channel opening. BTRX-335140 had no effect on responses to saturating doses of the mu opioid receptor agonist DAMGO or the delta opioid receptor agonist DPDPE in VTA neurons at a concentration that fully blocked the U69593 responses. Compared to the KOR antagonist nor-BNI, which as expected did not show any washout during slice experiments, responses to U69593 at least partially recovered following

washout (20 min) of all tested antagonists except PF-04455242. In particular, BTRX-335140 showed complete washout within 10 min of the termination of bath application. Together these data provide electrophysiological evidence that BTRX-335140 is a potent, selective, and reversible KOR antagonist in neurons within a key circuit implicated in many neurobehavioral disorders.

**Title:** Pharmacological characterization of BTRX-335140, a potent, selective and reversible kappa opioid receptor antagonist

**Authors: *T. L. WALLACE**[1], L. J. VAN ORDEN[1], M. GUERRERO[2], S. RILEY[2], S. BROWN[2], F. PORRECA[3], H. ROSEN[2], E. ROBERTS[2], W. J. MARTIN[1]
[1]Blackthorn Therapeut., South San Francisco, CA; [2]The Scripps Res. Inst., La Jolla, CA; [3]Dept Pharmacol., Univ. of Arizona Col. of Pharm., Tucson, AZ

**Abstract:** Kappa opioid receptors (KORs) are expressed throughout the brain including within mesolimbic and mesocortical circuits and are involved in reward processing, mood and cognition. Under conditions of stress, activation of KORs by the endogenous peptide dynorphin negatively impacts cognitive and affective processing leading to the hypothesis that antagonizing

KORs could be a therapeutic approach for treating mood disorders. We have developed a novel series of potent and selective molecules that exhibit KOR antagonist properties and here within show the pharmacological characterization of BTRX-335140. In radioligand binding studies using [$^3$H]Diprenorphine, BTRX-335140 demonstrated potent inhibition at human KOR ($K_i$ = 1.5nM) and showed 300-fold selectivity over human opioid mu receptor (MOR; $K_i$ = 0.45μM). Subsequently, BTRX-335140 was assessed for functional activity in a recombinant cell line stably expressing human KORs in which it demonstrated potent antagonism ($IC_{50}$ = 0.8nM) in response to challenge with the synthetic KOR agonist, U-50,488, and was modestly less potent following challenge with the endogenous ligand, Dynorphin A ($IC_{50}$ =6.1nM). BTRX-335140 demonstrated an approximate 125-fold separation between the KOR and the MOR ($IC_{50}$=0.1μM), and >8000-fold separation between KOR and delta (DOR; $IC_{50}$=6.5μM). In addition, BTRX-335140 potently blocked dynorphin A-induced activation of the β-arrestin pathway ($IC_{50}$ =4.8nM) suggestive of balanced antagonist properties, and antagonized dynorphin A-induced receptor internalization ($IC_{50}$=8.8nM). BTRX-335140 was tested for in vivo KOR antagonist properties using an agonist-induced prolactin challenge test in mice and rats. In these studies, KOR-agonists significantly increased the plasma prolactin concentration, and this increase was blocked by the oral administration of BTRX-335140 (minimally effective dose □10 mg/kg). Additionally, BTRX-335140 (1 mg/kg, intraperitoneal) blocked U-50,488-induced analgesia in naïve ICR mice in the tail flick test at 0.5h, but not 24h following administration, demonstrating the reversible nature of this compound. BTRX-335140 has excellent brain penetration properties as shown in an in vivo microdialysis evaluation in rats with striatal exposures approximately 4-times those observed from jugular vein samples collected in the same animals. Collectively, these studies demonstrate BTRX-335140 is a novel, potent, and reversible KOR antagonist with in vivo properties suitable for investigation in neurobehavioral disorders.

**Title:** Impulsivity an hyperdopaminergic disorders in Parkinson's disease: From behavioral to cellular approaches in a rodent model

**Authors: *R. MAGNARD**[1], C. CARCENAC[1], Y. VACHEZ[1], S. BOULET[1], D. J. BELIN[2], S. CARNICELLA[1]
[1]INSERM U1216, La Tronche, France; [2]Univ. of Cambridge, Cambridge, United Kingdom

**Abstract:** Impulse control disorders (ICDs) are a complex group of behavioral addictions found in 10 to 14% of Parkinson’s disease (PD) patients under dopamine replacement therapies. Importantly, impulsivity appears as a core symptom of ICDs. In the present study, we wonder whether denervation of the dopaminergic (DA) nigrostriatal system would promotes the development of ICDs when combined with DA agonist treatments. To answer this question, we used a rodent model of non-motor symptoms of PD recently developed in our team (Drui et al., Mol Psychiatry, 2014; Magnard et al., Transl Psychiatry, 2016). Briefly, rats were injected bilaterally with the neurotoxin 6-OHDA into the SNc in order to induce a selective, and partial denervation of the dorsal striatum. We treated them with the DA $D_2/D_3$ receptors agonist pramipexole, a medication known to favor the development of ICDs in PD patients. Two different tasks were used to measure cognitive and motor impulsivity respectively: the delay discounting task (DDT) and the 5-choice serial reaction time task (5-CSRTT). In the former, rats have to press a lever and choose between a smaller, but immediate, reward or a larger, but delayed, reward. In the later, they have to inhibit a prepotent response until the stimulus light appear. In the DDT, chronic administration of pramipexole increases impulsive choices in non-lesioned rats. Interestingly, SNc DA lesion render rats indifferent to the delay, which may reflect a lack of behavioral flexibility or a problem of choice between the magnitude of the reward and the delay. In the 5-CSRTT, pramipexole increases progressively premature responses, reflecting a pro-impulsive effect when the inter trial interval (ITI) is constant. However, when the ITI

punctually increased, pramipexole reduces premature responses, therefore exhibiting here an anti-impulsive effect. Interestingly, this modulation of motor impulsivity by pramipexole is only observed in rats with a high level of impulsivity, suggesting that an impulsive endophenotype may be an important factor of vulnerability to the effects of pramipexole. Moreover, we showed that the mammalian target of rapamycin complex 1 (mTORC1) pathway is long lastingly overactivated in the nucleus accumbens, as already observed in drug addictions. Such mechanisms may potentially be responsible for synaptic dysfunctions related to impulsive behaviors. Taken together, these results suggest that impulsivity in PD may occur through an abnormal activation of the mTORC1 pathway induced by pramipexole.

**Title:** Cholinergic antagonists do not alter reinforcer devaluation in macaques

**Authors: *H. F. WAGUESPACK**[1], C. CASTANON[2], E. WICKER[3], L. MALKOVA[5], P. A. FORCELLI[4], J. N. TURCHI[6]
[1]Neurosci., [3]Pharmacol. and Physiol., [4]Dept of Pharmacol., [2]Georgetown Univ., Washington, DC; [5]Dept Pharmacol & Physiol and the Interdisciplinary Program in Neurosci., Georgetown Univ. Med. Ctr., Washington, DC; [6]LN, Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract:** Reinforcer devaluation is a measure of goal-directed behavior, reflecting an animal's ability to adapt behavioral responses to changes in reward value. The neuronal circuitry associated with reinforcer devaluation has been extensively studied in nonhuman primates. This circuitry includes the thalamus, nucleus accumbens, orbitofrontal cortex, and amygdala (Mitchell et al., 2007; Izquierdo & Murray, 2010; Malkova et al., 1997; Wellman et al., 2005; West et al., 2011). Because these regions receive dense cholinergic input, we asked whether systemic injection of either nicotinic or muscarinic acetylcholine receptor antagonists, mecamylamine and scopolamine, respectively, would impair performance on the reinforcer devaluation task. For this purpose, we tested four rhesus macaques (*Macaca mulatta*) on a reward devaluation task. In this task, one set of 20 objects was consistently rewarded with one food (e.g., a peanut) and another 20 objects were rewarded with an alternative food (e.g., a fruit snack). Reinforcers were devalued through selective satiation: i.e., *ad libitum* access to one of the two foods for 30 minutes. After satiation, the animal typically will shift selection preference towards objects associated with the non-sated food. Animals were tested on a baseline choice session prior to

each devaluation session, in which their preference for objects associated with one of two rewards was examined. We tested animals after intramuscular injection of vehicle (0.9% USP grade saline), mecamylamine hydrochloride (1 mg/kg), or scopolamine hydrobromide (13.8 µg/kg); in each case, injections occurred 20 minutes prior to the selective satiation and 50 minutes prior to reinforce devaluation task. Under all three conditions, a clear devaluation effect was observed; thus, in the presence of either a nicotinic or muscarinic antagonist, animals are able to shift their behavioral responses in an appropriate manner. These data are consistent with previous studies, including a rodent study showing that systemic injection of either mecamylamine or scopolamine had no effect on reinforcer devaluation (Ostlund et al., 2014). Furthermore, these results corroborate a previous primate study, which showed that selective depletion of acetylcholine in the prefrontal cortex had no effect on reinforcer devaluation (Baxter et al., 2009).

**Title:** Ketamine increases sexual motivation in female rats

**Authors: *F. A. GUARRACI**[1], H. ABDEL-RAHIM, 78626[1], J. DEVORE[1], C. M. F. GONZALEZ[1], M. N. KUNKEL[2], D. LUCERO[1], J. SMAT[1], M. STINNETT[1], P. D. WOMBLE[1], E. QUADLANDER[1], J. A. BOYETTE-DAVIS[2]
[1]Psychology, Southwestern Univ., Georgetown, TX; [2]Psychology, St. Edward's Univ., Austin, TX

**Abstract:** Antidepressant medication often produces a host of side-effects, including sexual dysfunction and changes in anxiety (Ferguson, 2001). Recent research indicates that ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, may be an alternative drug that can rapidly reduce the symptoms of depression in patients unresponsive to standard treatments (Serafini et al., 2014). However, the side-effect profile of ketamine needs to be more fully investigated. Our study investigated the effects of ketamine on sexual behavior and anxiety in female rats. In Experiment 1, adult female rats received either saline or ketamine (10 mg/kg) 30 min prior to a sexual partner preference test during which each female subject was given the opportunity to interact with a sexually vigorous male or female stimulus. Immediately afterwards, female subjects were tested for locomotion in an open field. Female subjects treated with ketamine spent significantly more time with the male stimulus than saline-treated subjects.

No other measures of mating behavior (i.e., paced mating behavior, lordosis) were affected by ketamine. Ketamine also had no effect on line crossings during the open field test. In Experiment 2, female subjects from Experiment 1 received saline or ketamine (10mg/kg), counterbalanced for previous drug exposure, and were tested for anxiety on an elevated plus maze (EPM). Ketamine had no significant effect on time spent in the open or closed arms of the EPM. Taken together the results from these two experiments indicate that ketamine does not have side-effects like other medications for depression, and may have beneficial effects on sexual motivation.

**Abstract:** Among the neuropsychiatric symptoms expressed by Parkinson’s disease patients, apathy, or decreased motivated behaviors, is the most disabling and one of the most frequently reported, especially in patients under Subthalamic Nucleus High Frequency Stimulation (STN-HFS). While the most accepted explanation for this deleterious effect is a maladaptive reduction of dopaminergic treatments, some studies report that STN- HFS, by itself, could induce apathetic behavior by activating non-motor territories of STN or surrounding structures. The aim of this study is to clinch the question of the deleterious motivational effects of STN-HFS and to determine the underlying neurobiological basis.
Innovative wireless microstimulators allow continuous stimulation of STN of freely moving rats during several weeks. Motivation and several other aspects of behavior such as motor skills have been evaluated with state- of-the-art specific tests. We have thus shown, for the first time, that STN-HFS induces a motivational deficit without altering either the sensitivity for the reward or the motor capacities of the animals.
In the clinic, post STN-HFS apathy is reversed by dopaminergic treatments, especially those targeting the D2 and D3 receptors (D2/3R) such as pramipexole. This therapeutic approach has

been translated to our model and we have found that pramipexole perfectly reversed the motivational deficit induced by STN-HFS. These results seem to confirm that apathy can be induced directly by STN-HFS alone. They bring evidence that this could be due to downregulation of D2/3R in specific brain structures, taking us one step closer to understanding the neuropsychiatric effects of STN-HFS.

**Abstract:** The serotonin (5-HT) system has been implicated in affective and adaptive behavior. Low 5-HT transmission is thought to increase susceptibility to negative mood and impulsive behavior. However, it remains unclear how 5-HT system modulates value-based decision processes. To address this, we manipulated 5-HT transmission in macaque monkeys by systemic treatment with a 5-HT synthetic inhibitor or receptor antagonists while they performed value-based goal-directed tasks. There were two rewarding conditions, either reward size only (1, 2, 4, or 8 drops) or delay duration to reward (0, 3.3, 6.9, or 10.2 s) was manipulated. Each rewarding condition was assigned by an associated visual cue at the beginning of each trial. When monkeys (N = 6) were treated with 5-HT synthetic inhibitor, 4-chloro-DL-phenylalanine methyl ester hydrochloride (150 mg/kg, day), 5-HIAA, a metabolite of 5-HT in CSF was decreased about 50%. The monkeys' task performance in reward size condition got worse (i.e., higher error rates) regardless of reward size. Positron emission tomography (PET) with specific radioligands for 5-$HT_{1A}$, 5-$HT_{1B}$, 5-$HT_{2A}$, or 5-$HT_4$ receptors visualized unique distribution of each subtypes in the brain; 5-$HT_{1A}$, medial prefrontal cortex, amygdala and hippocampus; 5-$HT_{1B}$, ventral palladium and globus pallidus; 5-$HT_{2A}$, prefrontal and orbitofrontal cortex; 5-$HT_4$, striatum. We treated

monkeys with systemic injection of each receptor antagonist (WAY100635, GR55562, MDL100907, or SB125487, respectively) and determined the antagonist doses that yielded about 50% occupancy by using PET. Blocking 5-$HT_{1A}$ receptor, but not other, increased error rates regardless of reward size (N = 4), as seen in 5-HT depletion. Blocking 5-$HT_4$ receptor facilitated the tendency of increase in error rates as delay duration increased. These results suggest distinct contributions of serotonergic receptor subtypes to value-based decision processes; attenuation of serotonin transmission via 5-$HT_{1A}$ receptor—probably in medial PFC and amygdala—induces value-independent alteration of decision, whereas reduced activation of 5-$HT_4$ receptor—presumably in the striatum—causes steep temporal discounting.

**Abstract:** Conditioned stimuli (CS) associated with both drugs and natural rewards can acquire not only predictive value, but also incentive motivational value. When a CS is attributed with incentive salience it acquires the ability to elicit complex emotional and motivational states that can gain control over one's behavior, potentially leading to maladaptive outcomes. However, individuals vary considerably in the extent to which they attribute incentive value to a CS. When rats are exposed to a Pavlovian conditioned approach (PCA) paradigm, two distinct behavioral phenotypes emerge: some rats preferentially approach the lever (sign-trackers, ST) while others approach the food cup (goal-trackers, GT). While the lever is a predictor for both ST and GT, only for ST does it become an incentive stimulus. Thus, the ST/GT model offers a way to study the neurobiological mechanisms underlying the attribution of predictive vs. incentive value to

reward cues. It has recently been discovered that the paraventricular nucleus of the thalamus (PVT), a small midline thalamic nucleus, is a key part in the neural circuitry underlying the attribution of incentive salience. Previous studies have shown that presentation of an incentive, but not a predictive stimulus is capable of eliciting robust c-fos expression in the PVT. In addition, lesions of the PVT have been shown to increase sign-tracking and decrease goal-tracking behavior. The PVT contains a high density of orexin receptors and several studies have found that orexin transmission plays a role in cue-dependent motivated behaviors. Furthermore, local delivery of orexin into the PVT increases dopamine release in the nucleus accumbens, and sign-tracking behavior is dependent on accumbens dopamine. Based on these data, we hypothesize that orexinergic activity in the PVT is critical for the attribution of incentive salience to reward cues. To test this hypothesis, we trained rats on a PCA task and then evaluated the effects of the intra-PVT infusions of either the orexin 1 receptor (OX-1) antagonist SB334867 or orexin 2 (OX-2) receptor antagonist TCSOX229 on the expression of sign-tracking behavior and on the conditioned reinforcing properties of the CS. We found that neither OX-1 nor OX-2 antagonism affected sign-tracking behavior, but both decreased the incentive motivational value of the CS during the conditioned reinforcement test. These results highlight a role for the orexin system, and specifically, that in the PVT, in mediating individual variation in the propensity to attribute incentive motivational value to cues associated with rewards.

**Title:** A history of cocaine alters prelimbic neuronal activity during learning and impairs subsequent reinforcer devaluation

**Authors: *E. A. WEST**, M. NIEDRINGHAUS, H. K. ORTEGA, R. M. HAAKE, R. M. CARELLI
Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

**Abstract:** A history of cocaine impairs the ability to adjust behavior away from reward-predictive cues following reward devaluation, a canonical test of flexible behavior. Here, we

used electrophysiology (multineuron) methods to record activity from prelimbic cortex (PrL), a key region necessary for flexible behavior, in cocaine-exposed rats (n=5; 14 days cocaine self-administration; 0.33 mg/inf) and controls (n=6, 14 days of saline/water self-administration) during pavlovian conditioning. Briefly, after 3 weeks of abstinence, rats were presented with two distinct cues as conditioned stimuli (CS+; one predicting a sugar pellet and one predicting a food pellet) and two cues that did not predict a reward (CS-); 10 trials each. After 10 sessions, rats underwent a devaluation procedure to induce a conditioned taste aversion to the sugar pellets. Rats were then tested on the same pavlovian task (under extinction) to evaluate their ability to avoid CS+ associated with the devalued outcome. On the last day of conditioning, control and cocaine-exposed rats spent significantly more time in the food cup during both CS+ compared to the CS- (day X cue interaction: controls, $F_{(3,15)}=11.4$, cocaine $F_{(3,12)}=11.3$, $p<0.05$), showing successful discrimination of rewarded vs unrewarded cues. Post-devaluation, controls successfully avoided the CS+ associated with the devalued reward; however, cocaine rats continued responding to both CS+ equally suggesting impaired behavioral flexibility (determined by a Devaluation Index, DI, DI=0.31 for controls vs. 0.009 for cocaine; t=2.4, *p <0.05). Recordings of PrL neurons on the last day of pavlovian conditioning revealed distinct populations of cells that were excited or inhibited during cues (classified as “phasic”). The percentages of phasic PrL neurons were similar in cocaine-exposed and controls; however phasic PrL neurons in the controls were predominately excited (15/22) whereas phasic Prl neurons in cocaine rats were predominately inhibited (9/15). We have previously shown phasic activity in the nucleus accumbens core (NAc), a predictor of flexible behavior (West and Carelli, 2016) and a primary target of PrL, is abolished in cocaine-exposed rats during pavlovian conditioning (Saddoris and Carelli 2014). We hypothesize the shift to an inhibition of PrL neurons following cocaine drives the loss of phasic activity in the NAc, leading to an inflexible phenotype. In support, pilot studies that inhibited the PrL to NAc pathway during cues using optogenetics during pavlovian conditioning resulted in impaired behavioral flexibility (control, n=3, DI=0.32; halo, n=4, DI=0.10), similar to that observed following cocaine.

**Title:** Effects of abstinence from cocaine self-administration on basal cell firing dynamics in prelimbic cortex and nucleus accumbens core

**Authors: *R. M. HAAKE**, M. NIEDRINGHAUS, E. A. WEST, R. M. CARELLI
Psychology and Neurosci., Univ. of North Carolina, Chapel Hill, NC

**Abstract:** Withdrawal and prolonged abstinence from cocaine is associated with numerous neuroadaptations within corticostriatal circuitry that mediate incubation of cocaine craving (Wolf, Nat Rev Neurosci, 2016). We have previously reported that 30 days of abstinence from cocaine self-administration is associated with robust increases in the number and strength of neurons that are responsive to cocaine-associated cues in the nucleus accumbens (NAc) core and prelimbic cortex (PrL), as well as an increase in drug seeking (Hollander and Carelli, J Neurosci, 2007; West et al., Eur J Neurosci, 2014). It is not clear, however, how basal (i.e., spontaneous, not task-related) activity in PrL and NAc core neurons changes as a function of cocaine abstinence. This is of crucial importance given the well-documented decrease in prefrontal cortical function (i.e., hypofrontality) in human cocaine addicts. In preliminary studies, adult male Sprague Dawley rats were trained to self-administer cocaine (n=3; 0.33 mg/inf, 2 h per session) or received yoked saline (n=2) during 14 daily sessions, before undergoing 30 days of experimenter-imposed abstinence (i.e., home cage, no drug). Using in vivo electrophysiological methods, we simultaneously recorded basal cell firing in the PrL and NAc core during 30 min sessions on the first (day 1) and final (day 29) days of abstinence. Our preliminary analysis revealed that abstinence from cocaine self-administration, but not yoked saline, was associated with a decrease in basal cell firing in PrL (mean firing rate: day 1, 5.5 ± 1.3 Hz; day 29, 3.3 ± 0.5 Hz), but no changes were observed in the NAc core (day 1 mean firing rate, 2.3 ± 0.6 Hz; day 29, 3.0 ± 1.0 Hz). Next, on day 30, cell firing was recorded during a test session consisting of three phases: 1) cocaine-associated cue probes, 2) extinction (i.e., lever press for cues only, no drug), and 3) cocaine self-administration. Preliminary data show that rats exhibited an abstinence-induced increase in cocaine seeking, i.e., ~5-fold increase in lever pressing under extinction on test day compared to last day of self-administration (day 14 mean lever presses = 23 ± 4.4; test day mean extinction presses = 107 ± 24.5), consistent with our previous work (Cameron et al., Neuropharmacology, 2016). Ongoing analyses are examining if abstinence-induced decreases in basal PrL cell firing are correlated with cell firing dynamics to cocaine-associated cues and during resumption of cocaine self-administration following abstinence, as well as increased cocaine seeking under extinction. Finally, future analyses will also examine whether abstinence leads to changes in PrL to NAc core connectivity.

**Title:** A distinct subpopulation of neurons in the anterior insula tracks cocaine-induced devaluation of natural rewards

**Authors: *T. M. MOSCHAK**, X. WANG, R. M. CARELLI
Psychology, Univ. of North Carolina, Chapel Hill, NC

**Abstract:** In individuals suffering from drug addiction, negative reinforcement can be a powerful motivator for repeated drug use. From this perspective, addicts continue to take drug not for the positive reinforcement, but to circumvent negative affective states such as dysphoria or anxiety typically associated with drug withdrawal. Our lab has developed a preclinical model to investigate drug-induced natural reward devaluation and associated negative affect in rats. On each day, rats receive 45 intraoral infusions of 0.15% saccharin (3.5 s/inf; ~1 inf/min), followed by access to self-administered cocaine for 2 hr. Rats initially exhibit appetitive responses to the saccharin. However, as the animals form the association between the tastant and delayed cocaine access, they come to exhibit aversive responses to the saccharin, suggesting a change in affective state. We previously showed that nucleus accumbens neural activity tracks this shift, but the involvement of other brain regions is unknown. One neural substrate that may play an important role in this process is the anterior insula (AI), which is well integrated with reward circuitry and has been implicated in craving, negative affect, and drug addiction. Thus, we sought to examine neural activity in the AI during our model of drug-induced natural reward devaluation. Over the course of 14 days, rats (n = 13) received infusions of saccharin paired with delayed cocaine access as mentioned above. On Day 1, 7, and 14 of the task, neural activity in the AI was recorded and orofacial behavior during saccharin delivery was measured and quantified as appetitive or aversive. Replicating previous work in our lab, our preliminary findings show that rats primarily exhibited appetitive behavior on Day 1 and aversive behavior on Days 7 and 14. Neural activity in the AI tracked this shift, but only in neurons that fired within the first 2 s of saccharin delivery. On Day 1, the majority of these “early-firing” neurons exhibited an excitatory response following saccharin infusion (26 of 37 neurons excitatory, 70%). However, by days 7 and 14, this shifted to a predominantly inhibitory response (day 7: 15/37 excitatory, 41%; day 14: 10/25 excitatory, 40%). Furthermore, infusion of an aversive tastant (quinine) resulted in a similar neuronal profile as Day 1 saccharin in “early-firing” neurons (27/36 excitatory, 75%), suggesting that these neurons may be tracking the devaluation of taste rather than aversive taste

per se. In total, these preliminary results show that the AI tracks cocaine-induced devaluation of natural rewards, and that it may be an important substrate in the negative affective state associated with drugs of abuse.

**Title:** Dynamics of prelimbic cortical neuron activity during delay discounting behavior

**Authors: *D. A. SACKETT**, R. M. CARELLI
Psychology and Neurosci. Dept., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

**Abstract:** Delay discounting is a form of decision making in which individuals discount the value of a reward based on the amount of delay to its receipt. As the delay to reward increases, the subjective value of the reward decreases. As such, delay discounting is a measure of impulsivity, since individuals will eventually “lose patience” and choose an immediate small reward over a larger, delayed reward. Delay discounting recruits many brain regions, including the dorsolateral prefrontal cortex in humans, which is the correlate of the rodent prelimbic cortex (PrL). While the PrL has been implicated in impulsivity, its specific contributions to delay discounting are unknown. Here, we utilized multineuron recording methods in male, Long-Evans rats (n=9) to characterize the firing dynamics of PrL neurons during discrete cues and lever press events in a delay discounting task that consisted of three trial types. On forced-choice delay trials, a cue light predicted the opportunity to press for a large reward (three sucrose pellets) delivered after a period of delay. During forced-choice immediate trials, another cue light predicted the opportunity to press for a small (one sucrose pellet) immediate reward. On Free Choice trials, rats were presented with both cue lights and were rewarded based on the contingency of the lever chosen. The task consisted of 20 forced choice and 10 free choice trials, each within three trial blocks: “no-delay” (large reward presented immediately), “short-delay” (10 s delay to large reward), and “long-delay” (20 s delay to large reward). Rats’ initial preference for the large reward decreased as delays for that outcome increased across blocks, reflecting classic discounting behavior. Preliminary electrophysiological findings indicate that the overall percentage of cue-evoked phasic vs. nonphasic cells (n = 178 cells, 77% nonphasic,

23% phasic) did not change across blocks. However, unique, excitatory PrL cell populations responded to discrete forced choice cues across each block, indicating a shift in cell firing dynamics across delays. Further, during the long-delay block, a greater percentage of phasic neurons tracked *both* forced-choice cues (40 cells, 52%) compared to the no-delay block (32 cells, 41%). Ongoing studies will confirm a role of the PrL during the delay for reward and reward receipt. Though preliminary, these data suggest that as the delay to reward increases, discrete neuronal populations in the PrL may track the predictive cue's discounted value. This cellular activity may serve to inform and update downstream structures, such as the nucleus accumbens, about the predicted value of rewards during delay discounting.

**Abstract:** Processing the hedonic valence of stimuli is integral for the performance of adaptive behavior. Many psychiatric disorders, including drug addiction, are associated with the emergence of negative affect and maladaptive hedonic processing (*e.g.*, anhedonia). The infralimbic cortex (IL) sends a robust glutamatergic projection to the nucleus accumbens shell (NAcSh) and both the IL and NAcSh have been implicated in the control of hedonic processing. Here, we began probing the role of the IL in hedonics using electrophysiological (multineuron) recording methods in behaving rats. Specifically, we recorded neuron activity and objective hedonic taste reactivity (TR) responses over the course of conditioned taste aversion (CTA) learning and its extinction. Naïve rats (n=4) that received intraoral (IO) infusions of sucrose predominantly exhibited appetitive TR (appetitive: 70.75 ±6.5; aversive: 0), but after a pairing with lithium chloride, rats displayed primarily aversive TR to the sweet (appetitive: 0.25 ±0.25; aversive: 65.25 ±19.61). During extinction (5 days of IO sucrose without a LiCl pairing), appetitive TR reemerged and aversive TR ceased (appetitive: 92.5 ±24.73; aversive: 0.75 ±0.48). Preliminary electrophysiology data suggests that IL neurons track the hedonic value of sucrose. Specifically, IL neurons exhibited 'phasic' responses (inhibitions or excitations in firing rate) in naïve rats (10 of 16 cells; 62.5% phasic), but the percentage of phasic neurons decreased during

CTA (3 of 18 cells; 16.6%), and then phasic activity reemerged during extinction (4 of 13 cells; 30.8%). Further, the excitatory and inhibitory response profile of phasic IL neurons changed over the course of CTA learning and its extinction. In the naïve state there was a mixed excitatory and inhibitory neural profile (58.33% excitatory, 41.66% inhibitory), while during CTA 100% of phasic neurons were excitatory. A mixed inhibitory and excitatory response profile reemerged during extinction (75% excitatory, 25% inhibitory). These preliminary data indicate that a subset of IL neurons track the rewarding value of sucrose in the naïve and extinction state, but not when it is devalued during CTA. Future experiments will employ optogenetic tools to determine whether the projection from the IL to the NAcSh plays a causal role in the regulation of hedonic processing in this task.

**Title:** White matter integrity is associated with individual difference in locus of control

**Authors: *S. IWAKI**[1,2], Z. DUO[1,2], T. KUMADA[3]
[1]Natl. Inst. Adv Indust Sci. & Tech., Tsukuba, Ibaraki, Japan; [2]Univ. of Tsukuba, Tsukuba, Japan; [3]Kyoto Univ., Kyoto, Japan

**Abstract:** The subjective sense to which extent people feel they have control on the outcome of events in their daily life is often referred to as Locus of Control (LoC). The LoC is considered to be an important aspect of personality especially in academic or health-related behavior (Rotter 1966). Persons with high internal LoC have belief that events that occur in their life are caused by their own action. Conversely, low internal LoC (i.e., high external LoC) corresponds to the individual tendency to associate the cause of events to external or uncontrollable factors. In this study, we test the hypothesis that the individual differences in LoC is correlated with the differences in brain structure, specifically, the white matter integrity in young adults. Fifteen male subjects (23.4 +- 2.6 years of age) participated in the study. Written informed consent was obtained from all subjects before the experiment complying with the policies of the internal review board of AIST. Subjects' locus of control was assessed by Japanese version of Locus of Control Questionnaire (Kamahara et al., 1982), which consists of 18 items with 4-point scales. The MRI data were acquired on a 3-T MR scanner (Philips Ingenia 3T). Fractional anisotropy (FA) maps were derived from diffusion tensor imaging (DTI) scans (TR=18,496 ms, TE=60 ms,

FA=90 deg, b-factor=1,000, 70 axial slices with 2 mm slice thickness) and used as a measure of white matter fibre integrity. Results of the correlation analysis between the internal LoC score and the FA maps show significant positive correlation in the bilateral posterior cingulate and the precuneus. The cortical areas adjacent to these regions are reported to be responsible for self-consciousness, self-related mental representation (Cavanna et al., 2006) and have dense connection to hippocampus where significant correlation between its volume and LoC have been observed (Pruessner 2005). These regions are also known as central nodes of the human default mode network which regulates internally-directed thought (Buckner et al., 2008). The current results indicate that the white matter integrity in the posterior cingulate and the precuneus might affect default mode network which explains individual difference in LoC.

**Title:** Lateral prefrontal neuronal activity during a 2 interval forced choice task

**Authors: *R. FALCONE**[1], D. WEINTRAUB[3], T. SETOGAWA[2], B. RICHMOND[2]
[1]NIMH, Bethesda, MD; [2]NIMH, BETHESDA, MD; [3]Functional Neurosurgery, North Shore Univ. Hosp., NEW YORK, NY

**Abstract:** Among its functions, lateral prefrontal cortex is involved in assessing rewards. It projects to the striatum that in turn, together with midbrain areas, projects back to the prefrontal cortex via medial dorsal nucleus of the thalamus. Monkeys with lesions in lateral prefrontal cortex (lPFC) lose the ability to integrate the reward value information across multiple domains. We recorded neuronal responses from lateral prefrontal cortex (probably 9/46v based on MRI) of two monkeys while they performed a task in which 9 combinations of reward were offered by mixing 3 sizes (2, 4 or 6 drops of water) and 3 delays (1, 5 or 10s). A visual cue predicting the combination being offered was presented throughout the trial. The monkeys were required to respond in one of two periods represented by the appearance of a yellow or a purple dot. On the appearance of yellow dot the monkeys could refuse the offer by releasing a bar immediately or accept by releasing when a purple dot appeared. If a purple dot appeared, the monkeys could accept by releasing immediately or refuse by waiting for the yellow dot. In the period immediately following the onset of the visual cue, before the dot appeared, i.e., before the monkey could plan when to make the motor response, we found that more than 50% of recorded neurons were modulated by the factors reward size and/or delay (factors in 2-way ANOVA). We asked whether this subpopulation of neurons modulated its activity according to the value that

the animal assigned to each offer (approximately subjective value) more than by strict measure of reward size and delay per se. For each monkey we estimated the subjective value of each offer from the observed behavioral data using the hyperbolic and the exponential discounting models. The estimated subjective value was used to correlate with the mean firing rate for each offer. We found that about one third of the neurons modulated their activity (either increasing or reducing linearly their firing rate) according to the subjective value. We think that the presence of neural representation of the reward value is important for making the desired choice action, such as accept or refuse. For this reason, we are trying to understand how the lPFC neurons convert the information of reward value in the non-motor planning of abstract choices.

**Abstract:** Signals of reward, punishment, and motivation have been recorded in a number of areas in the brain, including a reward signal in the primary motor cortex (M1). This work is continuing this investigation in the hand and arm regions of M1 and the primary somatosensory cortex (S1), as well as the dorsal premotor cortex (PMd). Two non-human primates (NHP) were trained to complete a gripping task on a virtual robotic arm, where the animal gripped and held a given level of force for a specified period of time. Prior to each trial, visual cues were displayed to inform the NHP if the trial would result in a juice reward if completed successfully, a punishment consisting of a five-second timeout if completed unsuccessfully, or no reward or punishment, where the task would move immediately to the next trial. Subsets of trials with no cues and with catch trials, where a cue was presented but no reward or punishment delivered, were included to investigate reward and punishment prediction and error. Multiple levels of reward and punishment were incorporated to investigate how the value of reward and punishment were represented in these regions, and how the interplay between the two was

represented as motivation. Neural data were recorded from the hand and arm regions of M1, S1, and PMd, and spike sorted to isolate individual units. We hypothesize that in addition to reward and punishment, motivation is represented by subpopulations of neurons in M1 and S1. Investigating the intricacies of these signals in M1 and S1 will allow future brain-machine interfaces (BMI) to capture the breadth of these signals in one or two brain regions that also contain sensorimotor information, rather than requiring multiple implants in multiple regions. These data will be useful in creating algorithms for more robust and nuanced BMI control, taking greater advantage of the range of information available in these regions for better neural control of robotic prostheses.

**Title:** The effects of the NOP-receptor antagonist BTRX-246040 on the sensitivity to losses during decision-making and on spatial working memory performance in non-human primates

**Authors: *H. SEO**[1], K. S. ABEDRABBO[2], M. N. BOUCHER[2], T. L. WALLACE[3], W. J. MARTIN[3], A. F. T. ARNSTEN[2], D. LEE[2]

**Abstract:** Nociceptin/orphanin FQ and its receptor (NOP-R) are widely distributed in cortical and subcortical brain regions associated with reward processes, anxiety, food intake and pain. Evidence from clinical and preclinical studies has suggested an antidepressant-like effect of the selective NOP-R antagonist BTRX-246040 (aka LY2940094; Post et al., 2016). However, the effect of antagonizing the NOP-R system on higher cortical functions relevant to depression has yet to be characterized in detail. In the present study, we evaluated the effects of BTRX-246040 in monkeys using a task that required representations of gains and losses, and compared it with those in a visuospatial working memory task that depends on neural representations by the dorsolateral prefrontal cortex. We trained rhesus monkeys (Macaca mulatta, n=2) in the token-based binary choice task where appetitive and aversive consequences of choice (e.g. gains and losses) were quantitatively manipulated in the identical stimulus modality, and tested the effect of BTRX-246040 on the animal's choice behavior. During the task, animals played a biased-

matching pennies game against a computerized opponent (Seo and Lee, 2009). Animals gained a token only when they matched the opponent's choice, and the number of tokens remained unchanged or decreased otherwise. A juice reward was delivered when the animal accumulated 6 tokens. The tokens owned by the animal at the beginning of a trial were displayed as small disks in a circular array at the center of the computer monitor. Empty circles served as placeholders indicating the number of tokens needed for the reward. Behavioral analysis using a logistic regression model showed that animals tended to repeat/switch their choice when it was followed by gain/loss of tokens, respectively, demonstrating the reinforcing and punishing effect of gains and losses in the task. Once animals were trained, they were tested approximately 1-hour after BTRX-246040 (0.001-1.5mg/kg, intramuscular) or saline (vehicle) administration. Compared to control sessions, animals switched their choice subsequent to losses significantly less frequently when they received BTRX-246040 (1.0 mg/kg). Animal's choice behavior following gains was not affected, suggesting that BTRX-246040 might selectively reduce the punishing effect of losses. In contrast, a lower dose of BTRX-246040 (0.01 mg/kg; n=8) significantly improved animals' performance in the spatial working memory test. These results suggest that NOP-R system might mediate adaptive behavioral choice subsequent to losses, via a pathway distinct from the one that mediates spatial working memory.

**Abstract:** Curbing the potential of superficially seductive environmental cues motivating behavioral tendencies with increased risk of long-term negative consequences has attracted great interest in addiction neuroscience. We investigated the effects of two transcranial magnetic stimulation (TMS) protocols on blood oxygen level-dependent (BOLD) signals while processing high-caloric (HC) and low caloric (LC) food images. Location of TMS application was over the right mid-ventrolateral prefrontal cortex (mid-VLPFC) which had been predetermined by seed-based resting-state fMRI with seed voxels located in the ventral tegmental area (VTA) which were differentially more active for HC than LC food stimuli. In a first sample of 15 healthy male participants, BOLD signals for both food categories were comparably modulated by continuous (cTBS) and intermittent theta-burst (iTBS) TMS in bilateral orbitofrontal cortex, mid-VLPFC, right amygdala, and the VTA. Effects of TMS protocols differed quantitatively in right basolateral amygdala, left dorsal caudate nucleus and left anterior insula. Compared to sham stimulation, iTBS, but not cTBS also affected subjective ratings of wanting HC food items in a second, separate sample of 24 participants. Results are discussed from the perspective of putative regional interactions for which neurostimulation of right mid-VLPFC is the entry point of downstream signal changes for HC and LC food cues, indicating a shift in valuation stimuli of initially different incentive salience.

**Title:** Hemisferic asymetry link between attachment styles

**Authors: *E. VARLIK ÖZSOY**[1], E. GÜLBETEKIN[2]
[1]Psychology Dept., [2]Dept. of Psychology, Akdeniz Univ., Antalya, Turkey

**Abstract:** Attachment is a very common issue that is suggested healthy childhood development on the basis of the phenomenon of attachment (Bowlby, 1979). It refers to the relationship between the child and caregiver. These early interactions with mother directly shape the architecture of the growing brain (Siegel, 2012). The two sides of the human brain are different in their processing abilities and preferences. According to approach-withdrawal model,

happiness, surprise, and anger are referred to as approach emotions and sadness, disgust, and fear are referred as withdrawal emotions. Davidson et al. (2000) proposed that there is cerebral asymmetry in the neural representation of approach and withdrawal emotions. Accordingly, approach emotions are related to left hemisphere activity while, withdrawal emotions are related to right hemisphere activity. For instance Davidson et al. (2000) found that infants with more dominant right-hemisphere activity at rest were more likely to cry and fuss when separated from their mothers in comparison to infants with more dominant left hemisphere. The main aim of this study is to find out if there is a link between hemispheric asymmetry and attachment styles of adults. 26 male and 38 female undergraduate students (totally 64) who had no psychological or neurological disorders participated the study.We presented 32 photos -which were selected according to a pilot study- showing positive and negative relationships with parents, partners and self in three viewing conditions: right visual field/left hemisphere (RVF/LH), left visual field/right hemisphere (LVF/RH) and inter-hemispheric/center. The participants were asked to rate the stimuli according to feeling of closeness. It was aimed to investigate whether the ratings and the reaction time of the participants change in respect to the attachment styles of the participants and viewing conditions. Participants also filled Attachment-Based Mental Representation Scale, Experiences in Close Relationships R, The Brief Symptom Inventory, Hand Use Test with an information form. In order to determine the effects of sex and visual half field/hemisphere (VHF/H) on subjects' responses, 2 x 3 (sex × VHF/H [RVF/LH, LVF/RH, center]) repeated measures ANOVA was conducted. We found a significant main effect of VHF/H, $F(1, 186) = 5{,}60$, $p = .001$, $\eta p^2 = .08$ and a significant interaction effect of sex and VHF/H $F(3, 186) = 3{,}28$, $p = .02$, $\eta p^2 = .05$. Following analysis for the interaction effect indicated that in LVF/RH condition men responded most negatively to negative mothers and women responded most negatively to negative fathers. We did not observe the same effect in RVF/LH and center conditions.

**Title:** Moral cognition and reasoning in relation with prosocial and aggressive behaviors for elementary students

**Authors: *L. UCHIYAMA**
Houai Res. Inst., Warabi-Shi, Japan

**Abstract:** In the recent education of elementary school, it has been important to grow a rich spirit in ruling oneself, and cooperation with others, but no clear solution has been made to aggressive behaviors amid growing concerns yet. This research shows which actions school kids choose, prosocial behaviors or offensive actions in cooperative playing scene like doing puzzle. Several studies have shown that prosocial moral reasoning is related positively to prosocial behaviors (Eisenberg, et al,1995; Eisenberg, et al, 2001, Calro, et al, 2010) but is negatively related to aggressive behaviors (Laible, et al, 2008; Calro, et al, 2010). Despite the previous evidences on the relationships between prosocial moral reasoning, prosocial behaviors, and aggressive behaviors, few studies have disclosed these links with real performance by kids due to choice questionnaires in the previous studies. In this research, normal elementary school kids, whose number included 8 people with an average of years in the present time, did puzzle over 2 trials with both disneys under the two way videos, pairing four children in a group. About seven days later, they had to answer several questions, which said what they did, whether they thought they helped and offended with their friends, and why they thought so, watching their videos. It was reported that means and standard deviations for each behavior variable were included in Table. Mean differences between prosocial behavior(physical help, linguistic help, and cooperation) and aggressive behavior(aggression and taking away) were shown. The values of prosocial behaviors were higher than those of aggressive behaviors. Also, mean differences for each behavior variable were examined using ANOVAS. There was a significant difference in five behavior variables ($F(4,35)=5.06$). For the third analysis, mean differences across behavior variables were examined using multiple comparison with ryan method. The values of linguistic help were higher than those of taking away and those of physical help. Concerning questionnaires for the cooperative reasons over their behaviors, what students said was that they wanted to complete their puzzle as quickly as possible, and their friends searched for the pieces and don’t know where to place the pieces. On the other hands, they regard the aggressive reason as their friends’ disturbances. If this study collects more data by the academic conference, it analyses correlations among variables at the scoring point with questionnaires and frequency of their behaviors during the puzzle, which will lead the research result.

**Title:** Jealousy is positively associated with fronto-striatal responses to angry faces

**Authors: *X. ZHENG**, B. BECKER, L. LUO, J. LI, K. KENDRICK
Key Lab. for NeuroInformation of Ministry of Educ., Univ. of Electronic Sci. and Technol., Sichuan, China

**Abstract:** Jealousy is a complex social emotion in close relationships and has been related to self-esteem and self-identification. Extreme jealousy in the pathological range (e.g. delusional jealousy) can promote aggression in terms of domestic violence, self-mutilation and even murder. Accumulating evidence has associated pathological jealousy with frontostriatal dopaminergic circuits (Marazziti et al., 2013). However, currently little is known about the underlying neuro-functional basis of non-pathological jealousy.

To identify the neuro-functional systems associated with trait jealousy, 85 healthy subjects (43 males, 18-27 years) underwent fMRI during an emotional face recognition paradigm. A total of 150 faces (happy, angry, fearful, sad and neutral, 30 faces each) were presented to subjects for 1500ms and after each one they were required to identify the emotion expression and rate its emotional intensity. Before the fMRI experiment, trait jealousy was assessed using the Multidimensional Jealousy Scale (MJS). To control for potential influences of trait aggression, all subjects were additionally administered the Buss-Perry aggression Questionnaire (AQ). Results of a correlation analysis showed that intensity ratings given by subjects for angry faces were positively associated with their MJS score ($p=0.043$, $r=0.220$). The fMRI results from a whole brain analysis demonstrated that higher trait jealousy was associated with increased activity in right hippocampus, bilateral inferior frontal gyrus, and the left dorsal striatum (putamen and caudate) ($p<0.05$, FWE-corrected) in response to angry emotional faces relative to neutral faces, controlling for participant gender and trait aggression as covariates. Further Psychophysiological Interaction analysis revealed an association between higher trait jealousy and increased functional connectivity between the right inferior frontal gyrus and left caudate ($p=0.034$, FWE-corrected) for angry versus neutral faces, again controlling for gender and trait aggression.

The present study provides the first evidence for an association between trait jealousy and the dorsal striatal-inferior frontal circuit specifically during processing of angry expression faces. The dorsal striatum and inferior frontal cortex share dense dopaminergic projections, suggesting a potential interaction between these dopaminergic pathways and trait jealousy during social-threat situations.

**Title:** Electroencephalographic evidence that mindfulness training dampens emotion sharing but increases approach orientation toward racial outgroup members' distress

**Authors: *D. R. BERRY**, D. BUSTAMANTE, K. W. BROWN
Dept. of Psychology, Virginia Commonwealth Univ., Richmond, VA

**Abstract:** Perceiving differences between oneself and others, which are often defined by racial and other social group divisions, can attenuate emotion sharing, a putative automatic response to others' distress (Gutsell & Inzlicht, 2012). Recent theory and research indicates that mindfulness training may decrease this perceived psychological distance between oneself and others, and can increase empathy and kindness toward outgroup members (Berry & Brown, 2017). This study asked whether brief mindfulness training would increase emotion sharing in interracial interactions. White female students ($N$=79) were shown video clips depicting racial ingroup and outgroup members expressing sadness. During these tasks 64-channel EEG was recorded, and self-report measures of empathic concern and empathic sadness felt for the sad individuals were taken after each video. Participants were then randomized to either a 4-day mindfulness training (MT), or sham mindfulness training (ST). The video viewing task, and EEG and self-report measures were completed again post-training. Homologous frontal EEG channel pairs (F1/2, F3/4, F5/6, F7/8) were created by subtracting log right alpha power from log left alpha power, and we expected that greater emotion sharing would be reflected in right frontal alpha suppression (cf., Gutsell & Inzlicht, 2012). Participants showed less post-training emotion sharing for racial outgroup members, relative to racial ingroup members ($p < 0.05$). MT, however, decreased emotion sharing toward both ingroup and outgroup members, indicated by greater alpha asymmetry scores on medial frontal channel pairs ($p < 0.05$). Yet MT increased self-reported empathic concern during interracial video observation ($p < 0.05$). To disambiguate approach and withdraw orientation in the alpha asymmetry measure, channel homologues were unpaired and analyzed separately. Relative to ST, MT decreased left frontal alpha asymmetry scores ($p < 0.01$), but did not change right frontal alpha scores. Importantly, decreases in post-training left frontal alpha scores predicted greater empathic concern ($p < 0.01$). These results indicate that mindfulness may increase empathy in interracial interactions not by increasing emotion sharing, but by increasing approach orientation to others' sadness.

**Title:** Neuroanatomical correlates of personal space preferences: A voxel-based morphometry study

**Authors: *J. VIEIRA**, T. P. TAVARES, D. G. V. MITCHELL
Univ. of Western Ontario, London, ON, Canada

**Abstract:** Keeping and appropriate distance from the surrounding world is a defensive mechanism that helps to prevent injuries (Graziano & Cooke, 2006) and ensures the preservation of personal space boundaries (Hayduk, 1983). Research has shown that atypical personal space preferences are characteristic of several psychiatric and personality disorders (e.g. autism, schizophrenia, psychopathy); yet, the neuroanatomical bases of personal space regulation remain poorly understood. In this study, we used voxel-based morphometry (VBM) to investigate the structural brain correlates of personal space preferences. Twenty-three healthy volunteers underwent Magnetic Resonance Imaging (MRI) scanning and high-resolution T1-weighted structural scans were acquired. Outside the scanner, participants performed a Stop-distance task, wherein they adjusted the distance between themselves and an experimenter walking towards them, across a series of trials. Preprocessing and analyses of anatomical data for VBM were performed using Statistical Parametric Mapping software (SPM12) and included visual inspection and realignment, segmentation, bias correction and spatial normalization (Ashburner and Friston, 2005). Images were registered using DARTEL to increase the accuracy of inter-subject alignment (Ashburner, 2015), smoothed using a 10 mm Gaussian FWHM, and normalized to Montreal Neurological Institute (MNI) space. To investigate the association between personal space preferences and regional grey matter volume, we performed voxel-wise regression analysis using average preferred distance in the Stop-Distance task as predictor and controlling for total intracranial volume. Results showed grey matter volume in the right premotor cortex (BA 6; xyz=57, 0, 29; 1513 voxels) was positively correlated with preferred distance (FWE-corrected $p < .05$). These results are consistent with neurophysiological data from non-human primates (Cléry et al., 2015) and functional MRI data from humans (e.g., Ferri et al. 2015) highlighting the role of the premotor cortex in responding to looming objects that enter one's personal space. Our results suggest the premotor cortex is also implicated in responding to personal space intrusions by social stimuli, and provide a structural correlate of personal space preferences in humans.

**Title:** BOLD correlates of endogenous oxytocin release during affective touch

**Authors: *I. MORRISON**[1,2], H. LINDHOLM[3], G. NOVEMBRE[2], L. HANDLIN[2,3]
[1]Linköping Univ., Linkoeping, Sweden; [2]Ctr. for Social and Affective Neurosci., Linkoeping Univ., Linkoeping, Sweden; [3]Sch. of Hlth. and Educ., Univ. of Skoevde, Skoevde, Sweden

**Abstract:** Touch in social relationships can have a strong affective and hedonic dimension, which may play a role in the formation and maintenance of social bonds. A candidate mediator of such a role is the neuropeptide oxytocin. Oxytocin has been implicated in numerous aspects of social interaction and bonding, and has been particularly associated with tactile stimulation. However, little is known about the contribution of endogenously-released oxytocin during social touch interactions in humans, and what cortical regions may be implicated in the context-dependent modulation of oxytocin release. To address this, we collected serial samples of plasma oxytocin while female participants were caressed on the arm and the palm, by either their romantic partner or by a stranger they had never met before. Peak oxytocin levels were higher for partner than for stranger touch, demonstrating that touch by familiar vs unfamiliar others has differential effects on oxytocin release. A larger group (n=36) underwent this paradigm in the fMRI scanner. To investigate any effects on stress- and autonomic-related hormones, plasma cortisol and catecholamine levels were serially sampled alongside oxytocin. Blood samples were collected during the scanning session via an indwelling, magnet-safe catheter. A total of nine samples per participant was gathered: baseline (1), during partner touch (3), intermediate (1), during stranger touch (3), and final. The order of partner/stranger touch was counterbalanced across participants. Partner touch was rated significantly more pleasant and relaxing than stranger touch. Consistent with previous findings, touch to the arm compared to palm elicited activation in operculoinsular and superior temporal cortex regardless of whether the participant was touched by partner or stranger. Specific effects of oxytocin and the other sampled hormones were investigated in these regions of interest, as well as in the whole brain. These findings elucidate the relationships between brain networks for affective touch, endogenous oxytocin levels, and stress-related variables.

**Title:** Flow: The application of psychophysiology to understand user experience in video games

**Authors:** ***M. M. NIEDZIELA**[1], M. ROSAZZA[2]
[1]HCD Res., Flemington, NJ; [2]Neurosci. Technol., HCD Res., Philadelphia, PA

**Abstract:** Usability research involves understanding human limits of perception, attention, and memory in ease of use and learnability of human-made objects such as websites or video games. Cognitive modeling involves creating a computational model to estimate usability based on psychological principles and experimental studies. Cognitive models can be used to improve user interfaces or predict problems, errors, and pitfalls during the design process. Flow is the mental state of operation in which a person performing an activity is fully immersed in a feeling of energized focus, full involvement, and enjoyment in the process of the activity, a theory pioneered by psychologist Csikszentmihalyi. The aim of our study was to use electrophysiology (fEMG, HRV, GSR) and eye tracking to identify flow events in physiological responses linked to in-game events. Twelve male participants (18-35 yrs) were measured with electrophysiology (fEMG, HRV, GSR), eye tracking while playing a novel video game, Darksiders 2, and given a post-game survey. Flow was calculated by amount greater than average arousal (GSR) generated and attention/motivation experienced (HRV) and then compared with performance in video game play at that time interval. On average, we found gamers entered a flow state 20.3% of the time coinciding with intense moments during the game with 24.6% of this time being a positive experience. Our study revealed that it is possible to predict the occurrence of flow during video game play. The ability to model flow using physiological measures may help game designers create better games and help researchers better understand game play.

Inst. of Standards and Sci., Daejeon, Korea, Republic of; [5]Dept. of Med. Physics, Univ. of Sci. and Technol., Daejeon, Korea, Republic of

**Abstract:** Listener often misinterprets speaker's intention during conversation, because the same words or sentences may deliver different meanings depending on speaker's voice tone, facial expression, and body language and so on. Different understanding of the same words comes from gender, culture, age, background. In this study, we focused different brain signal responses between male and female using magnetoencephalography (MEG) and electroencephalography (EEG) during affective auditory stimuli are given. Twenty-three native Korean speakers (11 females; age 23.8 ± 2.9) participated in this study; their brain signals were recorded while accordance or discordance affective stimuli between word and voice tone. The Korean words include five positive and five negative words; each words were spoken in positive, negative or reading tone. Subjects were given the stimuli, and they pressed one of three buttons depending on their feelings. The brain responses were measured simultaneously using MEG 152 sensors (KRISS) and EEG 21 electrodes (Biosemi), electrooculogram, and electrocardiogram with 1024 Hz sampling rate. The signals were filtered between 1 - 55 Hz, and some artifacts were removed. Boundary element method with three-spherical-shell head model was used for array-gain beamformer, one of well-known localizers. In accordance cases between words and tones yielded rather similar patterns, although female responses appeared in wider activation regions than male responses using MEG. Left posterior lobe was more activated on emotional stimuli than neutral stimuli. Right hemisphere and frontal area were activated on negative words, but right hemisphere was deactivated on positive words. In discordance cases, common patterns of male and female were more activation in wider areas on negative words with positive voice. Right hemisphere was more activated in male, while both hemispheres yielded bigger amplitude in female on negative words with positive tone. When positive words with negative tone were given, male results were similar to those of positive word and tone, however, female results were

similar to those of negative word and tone. On the other hand, EEG results showed that temporal lobes were activated regardless of conditions. From these results, it is inferred that the affective auditory stimuli may yield different brain responses depending on meaning of the words or voice tone, especially, the stimuli are more influenced to female than male, and negative stimuli are more impacted on the brain signal. In the mismatch of the emotion between words and voice tone, voice tone may be more effective to female, however, meaning of words may be more effective to male.

**Title:** Unique electrocortical responses associated with attentional bias to fearful facial expressions and auditory distress signals

**Authors: *J. STERR**[1], S. CONGER[2], B. DIMARIA[2], J. ANDRZEJEWSKI[2], J. M. CARLSON[2]
[1]Dept. of Psychology, [2]Psychology, Northern Michigan Univ., Marquette, MI

**Abstract:** Unimodal emotionally salient visual and auditory stimuli capture attention and have been found to do so cross-modally. However, little is known about the combined influences of auditory and visual threat cues on directing spatial attention. In particular, the neural mechanisms associated with the allocation of attention to multimodal fearful facial expressions accompanied by human auditory distress signals are unknown. Based on previous research indicating that fearful faces enhance attention by increasing the amplitude of the N170 event-related potential (ERP) in the contralateral visual cortex, it was hypothesized that visual cortical responses to fearful faces would be enhanced when co-presented with auditory signals of human distress. To test this hypothesis, we used a modified multimodal dot-probe task where fearful faces were paired with two sound categories: non-distressing human vocalizations and distressing human vocalizations. At a behavioral level, fearful faces captured attention across both sound conditions. In addition, distressing sounds resulted in faster reaction times than non-distressing sounds. These behavioral effects were mirrored in the ERP data. N170 amplitudes were enhanced in the hemisphere contralateral to the visual field of the fearful face. N170 amplitudes were also bilaterally enhanced by auditory distress signals. The results provide initial evidence suggesting that emotional attention is facilitated through unique mechanisms for auditory and visual signals in multimodal audiovisual distress signals.

**Title:** Resting state functional connectivity associated with alexithymic personality type

**Authors: *S. TUKAIEV**[1], M. CHERNYKH[1], I. ZYMA[1], Y. HAVRYLETS[3], V. RIZUN[3], M. MAKARCHUK[2]
[1]Dept. of Physiol. of Brain and Psychophysiology, [2]Dept. of Human and Animals Physiol., Natl. Taras Shevchenko Univ. of Kyiv, Inst. of Biol., Kyiv, Ukraine; [3]Dept. of Social Communication, Natl. Taras Shevchenko Univ. of Kyiv, Inst. of Journalism, Kyiv, Ukraine

**Abstract:** The alexithymia construct is characterized by impairment of emotional processing and reduced interaction between different brain areas during various experimental conditions. Yet little known about permanent alteration of functional connectivity associated with alexithymia in resting state. The aim of current study was to detect the psychological determinants of alexithymia and investigate the resting state cortical networks of alexithymic personality type. 232 volunteers, first-third year students from the Taras Shevchenko National University of Kyiv aged 18 to 24 years participated in this study. EEG was registered during the rest state (3 min). We estimated the interhemispheric and intrahemispheric average coherence across all EEG segments in all frequencies from 0.2-45 Hz. To determine the level of alexithymia we used 26-item Toronto Alexithymia Scale (TAS-26). Alexithymic personality type was found in 43 volunteers (TAS-26 total score ≥74, alexithymia group, AG). A control group consisted 113 subjects with low alexithymia (TAS-26 total score ≤62, non-alexithymia group, NAG). 85 participants formed borderline group (BG, TAS-26 total score 62> and <74). The main factors related to alexithymia were marked extraversion, high level of trait anxiety and outward euphoric activity. The emotional exhaustion and reduction of personal achievements (Maslach Burnout Inventory), the Resistance Phase (Boyko's Syndrome of Emotional Burnout Inventory) were the most pronounced within the alexithymia group. The alexithymic personality type demonstrated less developed spatial anticipation. In background EEG activity during the development of the alexithymia variations in EEG spatial synchronization were observed in low- and high-frequency EEG components. Alexithymic personality type includes breaking of interhemispheric anterior frontal-frontal (alpha1,2-subbands) and formation central-temporal links (alpha1-subband) (awareness and cognitive processing of incoming information). We demonstrated left lateralization of intrahemispheric links in alpha3 (occipital-parietal area) and beta (central area)

subbands (inner image formation, external attention). Inter and intrahemispheric coherence in low-frequency EEG components (theta2-subband) indicates the influence of alexithymia on attention focusing, working memory, and emotional processes. As such, topographical reorganization of functional connectivity under alexithymia had specific features reflecting information and emotion-activating processes.

**Abstract:** Many researchers believe that humans learn to recognize facial expressions by mimicking the expressions of others, thereby experiencing the emotion themselves. But what happens when one cannot generate or mimic facial expressions due to congenital facial palsy, such as that seen in Moebius Syndrome (MoS)? MoS, a rare congenital neurological disorder, is characterized by abnormality of the VI$^{th}$ and VII$^{th}$ cranial nerves, resulting in paralysis of the face and diminished skeletal muscle feedback. Thus, it is possible that individuals with MoS have trouble identifying or processing emotion. To investigate this question, we used a set of computer-based behavioral tasks to characterize the ability of MoS patients to detect and label emotional facial expressions.
Individuals with MoS and a group of healthy controls were shown morphs of neutral to fearful and neutral to happy faces, and were instructed to distinguish between fearful and neutral, and happy and neutral faces, with a button press. A one-up, three-down staircase procedure was used to determine each participant's threshold for 79% accuracy. The same morph stimuli and staircase procedure were used in a feature-detection control task, where participants were instructed to indicate with a button press whether the face depicted an open or closed mouth. For the emotion-labeling task, participants were shown faces depicting each of 7 emotions (happy,

sad, anger, disgust, fear, surprise, neutral) and instructed to press a button corresponding to each emotion, with “other” and “don't know” as additional response options.
Analysis of threshold levels for the emotion-detection task revealed that individuals with MoS, compared to controls, showed a deficit in detecting fearful faces, but not happy faces. Individuals with MoS performed similar to controls for labeling of angry, happy, neutral, sad and surprised faces, but worse than controls for labeling disgusted and fearful faces, often confusing the former with sadness and the latter with surprise. MoS individuals also performed similar to controls on the feature-detection control task. These results suggest that an emotion-detection deficit may be present in MoS, but further testing with additional patients is needed. Further, to test if the neurocircuitry underlying emotion processing is different in MoS compared to controls, we plan to use fMRI while subjects perform these tasks in the scanner. Results from these experiments will shed light on whether the paralysis of, and lack of feedback from, the facial muscles in MoS impairs emotion perception and its underlying neurocircuitry.

**Title:** Autonomic and central correlates of empathic response and sub-clinical psychopathy as reflected in heart rate variability and cerebral activity

**Authors: M. J. SCHUMACHER**, R. HJELLE, *R. L. LLOYD
Dept. of Psychology, Univ. of Minnesota, Duluth, MN

**Abstract:** Finding out the cause of conduct disorder has been a growing concern for researchers, and there is now evidence to support that it may be related to lack of empathic response. Humans are social creatures, and empathy is normally classified as a social emotion, therefore those who lack the ability to be empathic have trouble associating with others. The purpose of this study is to examine elevated sympathetic tone (relative to parasympathetic output) as reflected by HRV (heart rate variability) and to examine power and hemispheric distribution of frontal and temporal lobe activity as reflected by EEG in participants viewing an empathy-inducing video clip. The hypotheses of this study are: (1) that a diminished parasympathetic contribution to cardiac tone would be negatively associated with higher scores on the Levenson Self-Report Psychopathy scale (LSRP); (2) lower frontal lobe neurological activity (higher alpha activity in

EEG) would be associated with higher scores on the LSRP; (3) less lateralization of cerebral activity to the right temporal and frontal lobes will be associated with higher scores on the LSRP. Support of these hypotheses may indicate that these procedures could be used to help predict psychopathological traits based upon empathic responses as reflected by HRV and frontal/temporal lobe activity.

**Title:** Electrical stimulation of human orbitofrontal cortex engages limbic circuits and acutely improves negative mood

**Authors: *K. K. SELLERS**[1], V. R. RAO[2], D. L. WALLACE[1], M. B. LEE[1], K. M. JORDAN[3], L. B. BEDERSON[1], N. GOLDBERG-BOLTZ[1], R. G. HENRY[3], H. E. DAWES[1], E. F. CHANG[1]
[1]Neurolog. Surgery, [2]Neurol., [3]Radiology and Biomed. Imaging, Univ. of California, San Francisco, San Francisco, CA

**Abstract:** Mood disorders characterized by depression and anxiety are highly prevalent causes of morbidity and mortality worldwide. In 20-30% of patients, mood symptoms do not respond to medications or cognitive therapy, underscoring the need for new treatments. Deep brain stimulation (DBS), the direct electrical stimulation of specific brain regions, is a promising therapeutic strategy for mood disorders refractory to medical therapy[1], but the efficacy of DBS hinges on identification of optimal stimulation targets and parameters. Converging lines of evidence implicate frontostriatal and limbic circuits in emotion regulation[2,3], but DBS at sites within these networks shows variable efficacy for treatment-resistant depression. Prefrontal cortical regions, including orbitofrontal cortex (OFC), are thought to regulate emotion by exerting 'top-down' influence on reward pathways[4], but it is unclear whether electrical stimulation in OFC can elicit therapeutic relief of mood symptoms. Furthermore, how stimulation at a given site modulates circuit physiology remains poorly understood.

Here, we assess the effects of direct electrical stimulation in OFC on mood in 12 human participants with epilepsy implanted with intracranial electrodes for seizure localization. We demonstrate that unilateral stimulation of OFC acutely improves mood[5] in participants who have moderate to severe anxiety or depression symptoms at baseline. We found a stimulation-amplitude dose-dependent improvement in mood. Stimulated regions of the OFC were anatomically and functionally connected to distributed brain networks implicated in emotion processing, demonstrated using probabilistic tractography based on diffusion imaging and measuring electrically evoked potentials, respectively. Finally, we demonstrate the feasibility of using neural-based control signals to develop circuit-based closed-loop stimulation paradigms. These results suggest OFC as a promising target for neuromodulatory treatment of mood disorders.

**Title:** Evaluation of unpleasant emotions during cursor control from fMRI brain activity signals

**Authors: *Y. OGATA**, Y. KATSUI, N. YOSHIMURA, Y. KOIKE
Inst. of Innovative Res., Tokyo Inst. of Technol., Yokohama, Japan

**Abstract:** Recently, decoding emotions from brain activity signals has been drawn attentions to develop better communication tools based on computer devices. However, most existing studies focus on emotions elicited by passively viewing of emotional images or recollection of autobiographical memory, hence possibility of evaluating or decoding emotions elicited in daily-

life situation such as using devices was remain unclear. In this study, we aimed to identify brain regions related to emotions, especially frustration in daily-life situation by functional magnetic resonance imaging (fMRI).Fourteen healthy volunteers participants were asked to perform a target-reaching task within an MRI scanner and their brain activity was measured during the task. They moved a computer cursor to a target randomly appearing on one of eight positions. The task was consisted of three conditions: normal condition (NC), normal-small condition (NSC), and rotation and acceleration condition (RAC). NC was a control task that participants could control the cursor as they usually use. In NSC and RAC the cursor was not controlled as the subject was expected. After the task, participants answered a questionnaire relating emotions they had during the task. We separated participants into 2 groups (NSC and RAC) according to their answer which condition they felt more frustration and analyzed the fMRI data set for each group separately. The analysis revealed activation in supramarginal gyrus, insular cortex and middle frontal gyrus within NSC group and in dorsolateral prefrontal cortex within RAC group ($p<.001$, uncorrected). Additionally, we found that activation in the middle frontal gyrus was significantly correlated with evaluation score of irritation ($p<.05$), and that in supramarginal gyrus and insular cortex had marginally significant correlation ($p<.10$). In addition, amygdala and anterior cingulate cortex, that are known as emotion-related area, showed correlation with irritation score in NSC group ($p<.05$). These brain areas, especially middle prefrontal cortex and dorsolateral prefrontal cortex, seemed to relate to regulation of frustration. Our results suggested that unpleasant emotion in daily-life situation such as usage of devices could be evaluated by measuring brain activity from these emotional-related areas.

**Title:** Familiarity effects on musical appraisal

**Authors:** ***N. H. SPILKA**[1], S. J. PHILIBOTTE[2], S. SPIVACK[1], I. PASSMAN[1], P. WALLISCH[3]
[2]Dept. of Psychology, [3]Ctr. Neural Sci., [1]New York Univ., New York, NY

**Abstract:** We are interested in the mere-exposure effect in music. Previous research, (Zajonc, 1968; Hunter & Schellenberg, 2011), suggests thatthere is a mere-exposure as well as an over-exposure effect for a variety of stimulus materials, including music. However, most of thisprior research is underpowered, thus making it difficult to ascertain for any given study, whether any or both of these effects (whichcombined would create an “inverted-U” trajectory) are present. In

thisexperiment, 600 participants provided familiarity and musical appraisal ratings for entire songs as well as 12 repeats of musicclips from any given song. Using this high powered sample - and musicthat was not disliked, on average - we can show that there is noevidence for a mere exposure effect in music. Instead, repeatedexposure to musical stimuli results in an immediate and near-lineardrop in preference on the order of 1.3% per exposure. This researchsupports the prevalence of over-exposure effects for musical stimuli and puts the generality of the mere-exposure effect in question.

**Title:** Sex differences in alterations in the mood states of university athletes with a history of concussion

**Authors: *W. SAUVE**[1], D. ELLEMBERG[2], R. D. MOORE[3]
[1]Kinesiology, Neurodevlab, Montreal, QC, Canada; [2]Kinesiologie, Univ. De Montréal, Montreal, QC, Canada; [3]Univ. of Montreal, Montreal, QC, Canada

**Abstract:** Concussion or mild traumatic brain injuries are known to cause alterations in mood states (Mainwaring, 2004). Females comprise an increasing percentage of the athlete population and relative to males, they are thought to be at greater risk for concussion, as well as for reporting more intense symptoms following concussion (Covassin, 2007). Despite the results of these research, few studies comprehensively evaluated mood states and even fewer evaluated mood states between males and females beyond the acute phase of injury (Barnes, 1998; Covassin, 2007). This study aim to examine whether sex influences the alterations in the mood states following concussion in a longitudinal manner. To reach this goal, 31 collegiate athletes (15 females, age = 20.79 ± 1.37; 16 males, age = 20.93 ±1.12) completed the Beck Depression Inventory-II (BDI-II) and the Profile of Mood States (POMS) at 7 and 30 days following concussive injury. On the POMS subscales, all athletes, irrespective of sex, reported greater anger ($p$=0.05), vigor ($p$=0.03), fatigue ($p$=0.01), confusion ($p$=0.01) and the total mood disturbances ($p$=0.03) at day 7 compared to day 30. Analyses failed to reveal any sex differences for any of the POMS subscales or for total mood disturbance at either time point. All athletes, irrespective of sex, also exhibited greater intensity of depressive symptoms on the BDI-II ($p$<0.01) at day 7 compared to day 30. However, at day 7, female athletes reported significantly greater scores on the BDI-II than male athletes ($p$=0.05). The current results suggest that sex

differences in mood states alterations following concussion are selective to depressive symptoms. Further this difference appears relegated to the acute phase of injury. Thus time since injury, not sex, appears to be the most important factor moderating the intensity of mood states alterations following concussion.

**Title:** The neural basis of emotion induced by real playing in sports games

**Authors: *M. OTOMO**[1], J. SHINOZAKI[1], H. NAGAHAMA[2], Y. SAKURAI[2], T. NAGAMINE[1]
[1]Sapporo Med. Univ., Sapporo, Japan; [2]Sapporo Med. Univ. Hosp., Sapporo, Japan

**Abstract:** The neural basis of emotions caused by participating real sports games(Gms) was not fully understood. We aimed to clarify the neural basis of emotion such as disappointment and pleasantness by watching real sports matches where subjects participated themselves.
Participants are 9 karate players and 1 dancer. Four types of video clips of 14 seconds including the following moments were prepared from two-person competing Gms: Three video clips when the subject got (1) or lost (2) a point each taken from Gms in which the subject participated. Other three clips when a teammate of the subject got (3) or lost (4) a point taken from the teammate's Gms. Three video clips of got and lost each from the subject were interleaved and repeated three times to construct a set of 18 moments for one fMRI run. Another set of 18 moments of video clips from the teammate was also similarly prepared. Eight out of 10 subjects joined two fMRI runs watching sets of the subject and the teammate one by one, resulting perceiving 4 different kinds of moments. The remaining two subjects participated only one scan watching the set of subject oneself including 2 kinds of moments. After each fMRI run, subjects rated their memory confidence, disappointment and pleasantness for six moments each by 5-point Likert scales. Scanned functional images were checked by individual and group analyses, using Statistic Parametric Mapping (SPM) 12.
The activities in the bilateral anterior insular cortices (AI) were significantly stronger in lost than got moments during own Gms. However, these activities were not detected during teammate's Gms. We found significant activity in the left nucleus accumbens (NAcc) in got moments compared to lost moments during own Gms. However, these activities were not found during

teammate's Gms. Rating results showed that there was no significant difference in memory confidence between got and lost ($p = 0.203$). Pleasantness was significantly higher in got than lost moments ($p = 0.005$), and disappointment was vice versa ($p = 0.005$).
Although memory confidence was comparable between got and lost moments, the subjects experienced different degree of disappointment and pleasantness depending on the emotional moments. These results indicated that these emotions were not produced by memory confidence, but successfully evoked by moments of emotion during fMRI. Previous reports have provided the evidence of AI activation by disappointment in decision making task and NAcc activation in pleasant visual stimuli. Therefore, activities in the bilateral AI and left NAcc in the present study may be related to emotions of disappointment and pleasantness, respectively, in real sporting circumstances.

**Title:** Young adult neural responses to viewing gun violence videos

**Authors: *A. ADEBIMPE**[1], D. S. BASSETT[2,3], D. ROMER[1]
[1]Annenberg Publ. Policy Ctr., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Bioengineering, Univ. of Pennsylvania, Bioengineering, PA; [3]Dept. of Electrical & Systems Engin., Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Many popular movies feature high levels of gun violence in which characters use firearms to repel and destroy adversaries. The excessive gun violence in PG-13 movies is often acceptable to the general public if the violence appears justified. Justified gun violence involves shooters who are responding to the actions of characters who have harmed them; whereas, unjustified gun violence involves shooters who are inflicting harm on other characters for sinister purposes. Neural responses to viewing violent movies are largely unknown, and it is possible that viewing justified gun violence creates greater identification and empathy with the shooter. To investigate neural activity while viewing violent movies, we obtained fMRI data of 26 young adults (mean age: 20.08 years, std: 1.08 years, 13 females) while watching 4 justified and unjustified video clips for 12 minutes each. General linear model analysis was performed with FSL. The results show that middle temporal gyrus, a known sensory input to the auditory cortex which plays an important role in memory and encoding, was activated for both justified and unjustified video clips. The precuneus - known for its role in visual-spatial imagery and episodic

memory retrieval-was activated while watching justified but not unjustified clips. High activation at the precuneus suggests that participants identified with the justified violence with self-consciousness. Watching unjustified clips produced brain activation in the superior frontal gyrus and inferior parietal lobules, implicating attention and emotion-processing networks. Dorsal striatum was activated while watching unjustified clips, a finding that is particularly interesting in light their crucial role in decision making, especially in regard to action selection. The differences between justified and unjustified clips were found in primary visual cortex and inferior temporal gyrus, areas essential for conscious processing of visual stimuli and perception. The cuneus, dorsal prefrontal cortex and anterior cingulate gyrus were activated while watching unjustified clips in comparison to justified clips. This suggests that unjustified violence elicited more cognitive and emotional conflict than justified violence. Our results indicate that neural responses to justified and unjustified violence differ in young people and exist in high level cortical areas where information is abstracted beyond sensory constraints. Our results support the notion that justified violence elicits a greater identification with the shooter that can override constraints to violent action against particular opponents

**Title:** Anger increases dominance seeking in young male

**Authors: *R. M. DE ALMEIDA**, J. C. CENTURION CABRAL
UFRGS, Porto Alegre, Brazil

**Abstract:** Dominance is an agonistic behavior that have a direct impact on the organization of social groups and on interpersonal relationships. Although the association between emotions and dominance has a strong empirical basis, most studies on the subject are restricted to effects on perception, overlooking other possible implications of this relationship. Thus, we tested the hypothesis that anger increases dominance seeking in those who feel it, and fear decreases this agonistic behavior pattern. One hundred and eighty-four male students voluntarily completed the experiment; they were randomly selected and individually contacted at Federal University of Rio Grande (FURG) and Federal University of Rio Grande do Sul (UFRGS), Brazil. Volunteers were automatically and randomly assigned to one of the four groups: anger (n = 38), sadness (n = 41), fear (n = 36) or control (n = 47). After watching the film clip, the participants filled out the emotional assessment, and then, BIS/BAS scales and dominance measurement. The anger group showed the highest scores for 3 out of 4 dominance measures used, differing significantly from

the fear group (ps < 0.043), which had the lowest levels of dominance for all scores. These findings reinforce the notion that feelings of anger can cause an increase, and fear a decrease, in dominance motivation and agonistic behaviors, leading possibly to action tendencies for the establishment and maintenance of dominance hierarchy.

**Title:** Amygdala-medial prefrontal functional connectivity relates to stress exposure and mental health in early childhood

**Authors: *A. T. PARK**[1], P. SAXLER[2], A. B. CYR[2], J. A. LEONARD[2], J. D. E. GABRIELI[2], A. P. MACKEY[1]
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

**Abstract:** Functional connectivity between the amygdala and medial prefrontal cortex (mPFC) has been previously shown to be important for emotion regulation. Early life stress has been shown to disrupt this neural circuitry in older children, adolescents, and adults, thereby increasing later vulnerability to psychopathology. Critically, it is unknown how early in development stress-induced differences in amygdala-mPFC connectivity emerge, and whether such differences are linked to latent changes in mental health. In a resting-state functional connectivity analysis with 4- to 7-year-olds, we found significant negative correlations between two measures of stress–parent perceived stress and stressful life events experienced by the child–and amygdala functional connectivity with medial and orbital frontal regions. Further, decreased amygdala connectivity with orbitofrontal cortex (OFC) was associated with more behavioral problems, even within a subclinical range. Amygdala-OFC connectivity mediated the relationship between stressful life events and behavioral problems. These results suggest that the impact of stress on emotional circuitry is detectable in young children, and therefore could be used as a marker for the efficacy of interventions for preschool-aged children.

Ctr., U.S. Army Natick Res., Natick, MA; [5]Ctr. for Applied Brain & Cognitive Sci., Medford, MA; [6]Univ. of California, Santa Barbara, Santa Barbara, CA

**Abstract:** The capacity to control and regulate our emotions is essential for our ability to adapt to the environment and circumstances surrounding us. We recruited 25 male participants with marksmanship training and asked them to participate in two sessions: 1) an emotion regulation task while measuring EEG and 2) a target detection task with two stress conditions during which we measured ECG. Our analysis then examines the relationship between neural responses during the emotion regulation task and the participant's stress response, indexed by heartrate variability, during the target detection task in a 300-degree immersive simulator. During the emotion regulation task, participants were instructed to either passively attend or reinterpret 60 high arousal negative images from the Military Affective Picture System (Goodman et al., 2015). The continuous EEG data was then preprocessed using EEGLAB (Delorme & Makeig, 2004), and functional connectivity was computed between channel pairs by fitting multivariate autoregressive models and calculating the short-time direct directed transfer function (sdDTF). During the target detection task, participants were instructed to distinguish presentations of friendly and foes presented on a 300-degree immersive simulator. Participants wore a ThreatFire belt and completed two stress conditions, one where task errors were penalized by a vibration and another where errors resulted in shock. Throughout the target task, electrocardiogram was collected via the LifeMonitor vest and used to calculate heart rate variability. To examine the relationship between brain activity and stress response, we employed a Lasso regression analysis method to reduce the number of features and identify any EEG connections during the emotion regulation task that predicted heart rate variability (HRV) during the target detection task. Results demonstrated that the theta band connectivity detected during the emotion regulation

task, specifically during the “attend” and “reinterpret” phases occurring within the parietal lobe, successfully predicted low frequency HRV (LFHRV) during the shock condition. Connectivity was negatively correlated with LFHRV, such that stronger connections predicted lower LFHRV on average. These results have important implications towards understanding individual variability and trait based information regarding predicting a physiological response during a task from brain connectivity.

**Title:** Acute mental fatigue modulates cognitive processing of negative emotion

**Authors: *K. WATANABE**[1,2], A. T. SASAKI[1,4], K. TAJIMA[1,4], K. MIZUNO[1,4,3], Y. WATANABE[1,4]
[1]RIKEN Ctr. for Life Sci. Technologies, Kobe, Japan; [2]Dept. of Physiol., [3]Med. Sci. on Fatigue, Osaka City Univ. Grad. Sch. of Med., Osaka, Japan; [4]RIKEN Compass to Healthy Life Res. Complex Program, Kobe, Japan

**Abstract:** Chronic fatigue syndrome (CFS) is frequently accompanied by depression or anxiety disorders. Although there might be some relationship between such emotional disorders and fatigue, the details are still unclear. A number of reports revealed that depressive or anxiety patients exhibit biased attention to negative emotional stimuli such as sad or threat. In our previous behavioral study with healthy adults, we found that participants, fatigued by long lasting working memory task, exhibited opposite biased attention: they avoided paying attention to sad facial stimuli at acute mental fatigue state. Based on the finding, we hypothesized that cognitive processing of negative emotional stimuli is selectively suppressed at acute mental fatigue state. To verify the hypothesis, we conducted functional magnetic resonance imaging (fMRI) during an emotional attention task.
During fMRI scans, 31 healthy adults performed face dot probe (FDP) task as an emotional attention task before and after 2-back task, lasted for 45 minutes, as a fatigue-inducing mental task. In FDP task, participants were asked to view a pair of faces, out of which one was a neutral and the other was an emotional (angry, happy or sad) or neutral, and to press one of the two buttons corresponding to the side the dot appeared immediately after the face presentation, as

quickly as possible.
As a result of fMRI analysis for FDP task, we found that activations of the bilateral inferior occipital gyrus (IOG) and the right fusiform gyrus (FuG) were significantly different between before and after fatigue-inducing mental task. On parameter estimates (PEs) extracted from these three regions, we conducted a repeated measures analyses of variance. After the fatigue-inducing mental task, PEs of the bilateral IOG increased regardless of emotional conditions, and PEs of the right FuG decreased only under sad and angry conditions. Further, whole brain voxel-wise comparison with each emotional condition revealed that activations of the right thalamus, left superior parietal lobule (SPL) and right FuG significantly decreased under sad condition, and that of the left SPL significantly decreased under angry condition after fatigue-inducing mental task. In contrast, under happy and neutral conditions, there is no significant difference. It has been reported that the IOG contributes to early visual processing and the FuG includes fusiform face area. Taken together, the present results may indicate that, at acute mental fatigue state, much more resources are recruited for early visual processing, whereas the processing of negative emotional face perception is selectively suppressed.

**Title:** Measuring fatigue in a mouse model of radiation therapy

**Authors: B. S. WOLFF**[1], S. RAHEEM[1], *K. FUKUHARA[3], L. SALIGAN[2]
[1]Natl. Inst. of Nursing Res., [2]NINR/IR, NIH, Bethesda, MD; [3]Intramural Res., Natl. Inst. of Nursing Res., Bethesda, MD

**Abstract:** Fatigue is a common and distressing symptom following radiation therapy for cancer, and it can be frequently undertreated in clinical practice. It is commonly defined as a subjective feeling of exhaustion that is not alleviated by rest or sleep, and it is likely a symptom with very complex underlying biology. Consequently, it has proven difficult to study objectively. Our understanding of causes and potential therapies for fatigue may benefit from the systematic study of an animal model. To develop such a model, we have investigated in mice several quantitative behavioral methods to measure fatigue that develops after irradiation. Mice received irradiation targeted to the lower abdomen at a dosage of 8 Gy once per day for three days. We recorded

voluntary wheel running in their home cages, and used video cameras to monitor activity in their home cages and in the open field test. We found that irradiation caused a large and long-lasting reduction of activity in their home cages, measured in distance by wheel-running or video tracking. Irradiation also produced a shift in circadian activity patterns, with activity levels more heavily effected in the latter half of the dark (waking) hours. Video monitoring appeared to be the most sensitive measure of fatigue, with changes in behavior consistently seen in individual mice without averaging the results. In contrast, the open field test showed only modest effects of irradiation on distance travelled; center-time and other measurements were more heavily affected by irradiation, but they also may be more difficult to interpret. Overall, these results show that irradiation produces a fatigue-like reduction in mouse home cage activity that in important ways can mimic the fatigue symptoms experienced by cancer patients after radiation therapy. Future studies using this model may investigate causes of and treatments for cancer-related fatigue.

**Title:** Metabotropic glutamate receptor 5 mediates post-radiotherapy fatigue development in cancer patients

**Authors: L. FENG**[1], *S. D. DETERA-WADLEIGH[2], L. SALIGAN[3]
[2]Human Genet. Branch, NIMH, [3]NINR/IR, [1]NIH, Bethesda, MD

**Abstract:** Background Cancer-related fatigue is a common source of cognitive burden in cancer patients and little is known about its underlying mechanism. The aim of this study is to identify gene signatures predictive of post-radiotherapy fatigue in prostate cancer patients. Method Fisher Linear Discriminant analysis (LDA) was performed using whole genome microarray data from 36 men with prostate cancer, yielding a reduced base of the most discriminatory genes. Ingenuity Pathway Analysis was performed to identify the predictive network of genes. In vitro testing was performed using a T lymphocyte cell line, Jurkat E6.1. Cells were pretreated with mGluR5 agonist (DHPG), antagonist (MPEP), or control (PBS) for 20min before irradiation at 8Gy in a Precision X-Ray Irradiator. Cell death was accessed using the MTT assay. Confocal microscopy and IncuCyte quantitative analysis were used to assess mGluR5 receptor distribution post-radiation. Inflammatory cytokines released into the medium were measured using ELISA. Results The LDA model achieved 83.3% accuracy in predicting fatigue phenotype post-

radiotherapy. “Glutamate receptor signaling” was the most statistically significant (p = 0.0002) pathway among all the predictive genes as revealed by pathway analysis. The predictive gene, metabotropic glutamate receptor 5 (mGluR5) was found in Jurkat cells. Pretreatment with mGluR5 agonist resulted in mGluR5 receptor clustering after radiation, as well as increased inflammatory cytokine RANTES production, whereas inhibition of mGluR5 activity decreased RANTES concentration after radiation. Conclusions These results suggest that mGluR5 signaling in T cells may play an important role in the development of chronic inflammation resulting in fatigue, and it may also contribute to the individual differences in immune responses to radiation. Moreover, modulating mGluR5 provide a novel therapeutic option for treating this debilitating disorder.

**Title:** Ketamine effects on temporal discrimination in a rodent model of depression

**Authors: *M. A. FRIAR**, P. JANER, A. ROMERO, M. NASH, M. GOMEZ
Psychology, American Univ., Washington, DC

**Abstract:** Depression and subjective slowing of temporal perception has been linked by many studies since the 1960s (Thones and Oberfeld, 2015). Depressed patients will often report, “every hour seems like a year to me” or that “things seem to take forever”. While the debate continues as to whether individuals who suffer from depression perceive time objectively different, trends in recent studies indicate a distinct over-production of "short" and an under-production of "long" time production tasks by depressive patients. Ketamine has been found to produce a rapid and robust antidepressant effects in treatment-resistant patients. It has also has been known to affect time perception when used recreationally. Clinical studies have shown that a sub-anesthetic dose of ketamine can have effects within an hour, which can last up to a week without a subsequent dose (aan het Rot, Zarate, Charney, & Mathew, 2012; Ibrahim et al., 2012). In the current experiment, we studied if sub-anesthetic ketamine (10mg/kg i.p.) had any effects on time perception in depressed rodents. Specifically, female rats were trained on a fixed interval procedure (MacInnis and Guilhardi , 2006). Following the temporal training, we induced depression by a daily injection reserpine (.2mg/kg i.p.) for two weeks. Depressed state was confirmed by a forced swim test 24 h after the last reserpine injection. Subsequently, to establish

ketamine's antidepressant effects, rodents were injected with ketamine and retested in the fixed interval and forced swim procedure. This study confirmed that both drugs exerted its prescribed effects in rodents. Notably, reserpine induces depression and the single injection of ketamine significantly reduced depressive symptoms as shown by an increased escaping behavior in the forced swim test. Interestingly, although reserpine induced depression in forced swim test it did not cause distortion in time perception.

**Abstract:** Major depression afflicts approximately 16% of the world population and has become one of the leading causes of disability and economic burden. A number of monoamine-based antidepressants are available today; however, the delayed onset time and low remission rate of these treatments are still a major challenge. Thus, there have been efforts to find rapid-acting and effective antidepressants. The discovery of ketamine producing rapid and potent antidepressant effects paved the way for a new generation of glutamate-based antidepressants. Methoxetamine (MXE) is an N-methyl-D-aspartate (NMDA) receptor antagonist and has been shown to have pharmacodynamic similarities with its analogue ketamine. Furthermore, it was found that MXE also acts as a serotonin reuptake inhibitor. However, no studies have evaluated whether MXE can produce antidepressant effects. In the present study, we assessed whether MXE produces rapid-onset and sustained antidepressant effects in mice. We also investigated the probable mechanisms underlying such effects. ICR mice were acutely treated with intraperitoneal MXE (2.5, 5, or 10 mg/kg) and animal behavior was evaluated in the forced-swimming test (FST), tail-suspension test (TST), novelty-suppressed feeding (NSF), and elevated plus-maze (EPM). A separate group of mice were pretreated with NBQX, an AMPA receptor antagonist, or

ketanserin, a 5HT2 receptor antagonist, during the FST. Parallel experiments were also performed in mice treated with ketamine. MXE reduced the immobility time of mice during the FST and TST, and this effect lasted for 24 hours. MXE also decreased the latency to eat during the NSF and increased the time spent in the open arms of the EPM. These MXE-induced behavioral effects were comparable to that produced by ketamine. NBQX pretreatment significantly blocked the effects of MXE and ketamine in the FST. Interestingly, ketanserin only blocked the effects of MXE and not that of ketamine. Altogether, the results of the present study indicate that the ketamine analogue, MXE, has rapid-onset and sustained antidepressant effects and that its antidepressant effects might be mediated through glutamatergic and serotonergic mechanisms.

**Title:** Endogenous kynurenic acid mediates ketamine- and (2R,6R)-hydroxynorketamine-induced increases in extracellular glutamate and antidepressant actions

**Authors: *H.-Q. WU**[1,2], P. ZANOS[2], T. D. GOULD[2,3,4], R. SCHWARCZ[1,2,3]
[1]Maryland Psychiatric Res. Ctr., Baltimore, MD; [2]Psychiatry, [3]Pharmacol., [4]Anat. and Neurobio., Univ. of Maryland Sch. Med., Baltimore, MD

**Abstract:** (*R,S*)-ketamine (ketamine), a non-competitive NMDA receptor (NMDAR) antagonist, manifests rapid and sustained antidepressant effects in treatment-resistant patients. Production of ketamine's metabolite (*2S,6S*; *2R,6R*)-hydroxynorketamine (HNK) is essential in this regard, and (*2R,6R*)-HNK itself is sufficient to reproduce the antidepressant effects of ketamine in rodent models. These antidepressant actions of (*2R,6R*)-HNK are independent of NMDAR inhibition. Therefore, the mechanism underlying the rapid antidepressant actions of ketamine and (*2R,6R*)-HNK remain unclear. By *in vivo* microdialysis in rats, we show that an acute, systemic administration of either ketamine or (*2R,6R*)-HNK (both at 20 mg/kg) significantly reduces the extracellular levels of the astrocyte-derived tryptophan metabolite kynurenic acid (KYNA; maximal effect of -30% after 2 hours), concomitant with an increase in extracellular glutamate

levels (maximal effect of +179% after 3 hours), in the medial prefrontal cortex (mPFC). Pre-treatment with KYNA's bioprecursor L-kynurenine (5 mg/kg, ip), or the kynurenine 3-monooxygenasease inhibitor Ro 61-8048 (20 mg/kg, ip) prevented both of these acute effects of ketamine and (*2R,6R*)-HNK. Similarly, pre-treatment with L-kynurenine prevented ketamine- and (*2R,6R*)-HNK-induced decreases in forced swim test immobility time, and the effect of (*2R,6R*)-HNK to reverse learned helplessness, in mice. Reverse dialysis of the sodium channel blocker tetrodotoxin (TTX; 5 μM), used to prevent neuron excitability, did not modify ketamine- or (*2R,6R*)-HNK-induced effects on either KYNA or glutamate in the rat mPFC, suggesting a central role of astrocytes in the phenomena described here. Together, these data indicate that the antidepressant actions of ketamine, via the production of (*2R,6R*)-HNK, are mediated by KYNA-induced modulation of glutamate neurotransmission.

**Title:** Antidepressant and prophylactic ketamine administration differentially impact adult hippocampal neurogenesis

**Authors: *C. T. LAGAMMA**[1], W. TANG[2], A. MORGAN[3], J. C. MCGOWAN[3], R. A. BRACHMAN[4], C. A. DENNY[1,4]
[1]Integrative Neurosci., Res. Fndn. For Mental Hyg., New York City, NY; [2]Columbia Univ., New York, NY; [3]Doctoral Program in Neurobio. and Behavior, Columbia Univ., New York, NY; [4]Dept. of Psychiatry, Columbia Univ., New York, NY

**Abstract:** Ketamine, an N-methyl-D-aspartic acid receptor (NMDAR) antagonist, has been shown to have rapid, long-lasting antidepressant effects in treatment-resistant patients with major depressive disorder (MDD). We have recently shown that ketamine acts as a prophylactic and protects against the development of stress-induced depressive-like behavior in mice, indicating that preventative treatment for mental illness is possible. While there is significant investigation into ketamine's' antidepressant mechanism of action, little research has been done to elucidate ketamine's underlying prophylactic mechanism. More specifically, whether the prophylactic actions of ketamine are similar or divergent from its antidepressant actions are entirely unknown. Therefore, the goal of the current study is to determine age-dependent molecular signatures of cell-populations governing ketamine's antidepressant and prophylactic effects. Mice were administered a number of behavioral paradigms as described in Brachman et al., 2016. Post-fixed brains underwent an immunohistochemistry protocol for age-dependent neuronal markers including doublecortin (DCX), a marker of proliferating neurons; calretinin (CR), a marker for immature granule cells; and calbindin (CB), a marker for mature granule cells. The number of $DCX^+$ neurons in the DG, including those with tertiary dendrites, were not affected by prophylactic or antidepressant ketamine treatment, nor were they altered by SD. While prophylactic ketamine had no effect on the number of CR+ cells in the hilus, antidepressant ketamine treatment increased the number of $CR^+$ cells in SD mice to that of control levels. Lastly, antidepressant, but not prophylactic ketamine administration altered CR and CB expression in the HPC. These data suggest that prophylactic and antidepressant ketamine treatment differentially mediate the expression of age-dependent markers of adult hippocampal neurogenesis. The findings further elucidate the neurogenesis based changes associated with MDD pathology and can be used to develop a more targeted therapeutic approach when using ketamine to treat MDD.

**Abstract:** Stress exposure is a major risk factor for mood disorders, such as major depressive disorder (MDD) and post-traumatic stress disorder (PTSD). However, some individuals can successfully adapt to stress and do not develop mood disorders. This ability is known as stress resilience. We previously reported that a single injection ketamine, an NMDA receptor antagonist, prior to stress protects against the development of depressive-like behavior and buffers against a deleterious fear response in mice. However, the cellular and molecular pathways underlying ketamine-induced stress resilience are still largely unknown. Here, we seek to identify the contribution of the deltaFosB transcription factor in mediating ketamine-induced stress resilience. 129S6/SvEv mice were injected with saline or ketamine (30 mg/kg) 1 week before a social defeat (SD) paradigm. Following SD, the animals were sacrificed and the brains were processed to visualize deltaFosB expression. We found that prophylactic ketamine administration increases deltaFosB expression in the prefrontal cortex (PFC), specifically the infralimbic cortex (IL), prelimbic cortex (PrL), and anterior cingulate (Cgl). There was no effect of SD on deltaFosB expression in the PFC. Conversely, we found no effect of Group (Ctrl or SD) or Drug (saline or ketamine) in the dorsal hippocampus. However, interestingly, there was a significant effect of ketamine only in the SD group on deltaFosB expression in the ventral hippocampus. In a second set of experiments, mice were stereotaxically injected into ventral CA3 (vCA3) with viral vectors in order to upregulate or downregulate deltaFosB expression before prophylactic ketamine administration. Inhibition of deltaFosB only in vCA3 prevented ketamine's prophylactic effect on fear responses. Overall, these data indicate that prophylactic ketamine may induce protective effects by altering deltaFosB expression in the ventral hippocampus. Understanding how deltaFosB expression alterations influence depressive-like behavior, and how prophylactic ketamine may prevent these alterations, can elucidate both the pathophysiology of depression and provide insights into potential new treatment targets.

**Abstract:** Depression affects around 10% of the population. Current treatments including SSRIs and SNRIs have a delayed onset of several weeks to reach effectiveness, if at all effective. Within this timespan there is an increased suicidal risk. Ketamine, a potent anaesthetic, is considered a promising antidepressant with a very rapid onset. Although relatively safe, there are side effects such as induction of a dissociative state as well as addiction. Hydroxynorketamine (HNK), a metabolite of ketamine, could potentially be of clinical value with similar antidepressant actions ridding the side effects. However, knowledge about the mechanism of action is limited. Several recent studies demonstrate effects related to NMDA receptor inhibition, but also unrelated mechanisms, most of which lead to an increased glutamatergic signalling and BDNF-dependent synaptogenesis in the hippocampus and prefrontal cortex.
To investigate the effects of Ketamine and HNK in the hippocampus of juvenile (p30) and adult (p60) Wistar rats we injected pregnant dams with either dexamethasone (150ug/kg) or saline during the last trimester to create a depressive-like phenotype. We then used electrophysiology, behaviour, proteomics, neurogenesis markers to study the effects of ketamine and HNK in vivo, in slices as well as in dissociated subcortical cerebral stem cells. Recordings were also conducted in acute hippocampal sliced exposed to ketamine at different time points.
We observed no effects of ketamine or HNK on hippocampal synaptic transmission and plasticity in juvenile animals, irrespective of treatment (dexamethasone vs saline). This holds true also for AMPA and NMDA receptor expression and differentiation of dissociated subcortical cerebral stem cells. Results were corroborated by no behavioural recovery in the dexamethasone treated animals. There was, however, a decreased proliferation in the dentate gyrus in the depression model. This was reversed after ketamine treatment and proliferation even surpassed the control proliferation.
In general, there seems to be a limited response to ketamine in young humans as well as in juvenile rodents, both with regard to the negative side effects as well as to the antidepressant action. We are currently conducting experiments in adult animals to examine if the effectiveness of ketamine and HNK follow a developmental profile. In conclusion, ketamine and its metabolite HNK have no effect on hippocampal synaptic transmission and plasticity while influencing dentate gyrus proliferation in depressive-like and phenotypically normal juvenile Wistar rats.

**Abstract:** Long lag times for efficacy and high non-response rates of currently approved antidepressants necessitate the need for better drugs to treat mood disorders. In this regard, ketamine is a fast-acting, long-lasting NMDAR antagonist and has gained much traction over the past several years for alleviating depressive symptoms such as anhedonia and suicidal thoughts in treatment-refractory depression and bipolar patients. Despite its rapid and robust efficacy, use of ketamine is limited in large part due to its potential for abuse and capacity to produce dissociative effects even when administered at subanesthetic doses. Further, the precise mechanism of action of ketamine is unknown, as its human therapeutic effect via NMDAR inhibition cannot be fully recapitulated using alternative NMDAR antagonists.
We sought to identify ketamine's effects on gene transcription in affect-regulating brain regions, which are likely related to its sustained antidepressant actions. CD-1 male mice were treated with ketamine (i.p., 10mg/kg, N=12) or saline (N=12) and tissue collected 24 hours later. Messenger RNA was extracted from the hippocampus and was used to generate cDNA libraries for RNA-Seq. Several biologically relevant and q-value significant transcripts predicted to be differentially expressed between ketamine vs. saline-treated samples were validated by quantitative real-time PCR (e.g. *Mtor*: 19.7% increase, p=0.022; *Shank2*: 42.3% increase, p=0.021; *Shank3*: 42.0% increase, p=0.010; and *Cdr1*: 48% decrease, p=0.036). In addition, these transcripts were assessed in the HT-22 mouse hippocampal cell line treated with 20 μM ketamine for 24 hours (e.g. *Mtor*: 118% increase, p=0.014; *Shank2*: 335% increase, p=0.070; *Shank3*: 197% increase, p=0.048; and *Cdr1*: 46% decrease, p=0.004). KEGG pathway analysis of q-value significant transcripts identified pathways involved in Axon Guidance, Synaptic Vesicle Cycle, Glutamatergic Synapse, and neurological disorders (Alzheimer's, Parkinson's, and Huntington's Disease).
Our RNA-Seq results have implicated genes and pathways that may be relevant to the antidepressant action of ketamine. We are currently investigating the underlying epigenetic mechanism of ketamine action on these transcripts, and seeking to identify whether ketamine

shares transcriptional and epigenetic targets with (2R,6R)-hydroxynorketamine, a metabolite of ketamine demonstrated to exert antidepressant effects in rodents.

**Abstract:** Twenty percent of adults are diagnosed with major depressive disorder, which is typically treated with selective serotonin reuptake inhibitors. However, this type of medication takes approximately six weeks to produce therapeutic effects. Recently, low doses of ketamine, a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist, have been shown to produce rapid and long-lasting antidepressant effects. Studies that have begun to examine the mechanisms underlying these effects have focused on intracellular changes mediated by NMDA and/or AMPA receptors. However, the traditional view of the etiology of depression involves the need for an increase in extracellular serotonin to regulate mood. Surprisingly, there appears to be little research into the effects of ketamine on serotonin. One study found an increase in extracellular serotonin while another found an inhibition of serotonin uptake following ketamine treatment. Together, these studies suggest a role for serotonin in the antidepressant-like effects of ketamine, and putatively one involving uptake-1 and uptake-2 transporters for serotonin. A few studies have examined whether ketamine has affinity for the serotonin transporter (SERT; uptake-1) or organic cation transporter 3 (OCT3, uptake-2). In order to investigate this *in vivo*, we performed *in vivo* chronoamperometry. A nafion coated carbon fiber electrode and four barrel micropipette was inserted into the CA3 region of the hippocampus and serotonin, ketamine, or vehicle was applied exogenously. Our results showed a decrease in clearance rate of serotonin

after application of ketamine as well as an increase in signal amplitude. To further elucidate this effect, we examined antidepressant-like effects of ketamine in SERT knockout mice and OCT3 knockout mice bred on a C57BL/6J background. SERT knockout adult mice, OCT3 knockout adult mice, and wildtype adult mice were treated with vehicle or 3.2, 10.0, or 32 mg/kg ketamine and tested in the forced swim test. Ketamine did not produce antidepressant-like effects in the SERT knockout mice or the OCT3 knockout mice indicating that blockade of SERT and OCT3 may be necessary for the antidepressant-like effects of ketamine. Ongoing studies are continuing to examine the relationship between SERT and OCT3 in the antidepressant-like effects of ketamine.

Medicine, Translational Neuropsychiatry Unit, Aarhus Univ., Aarhus, Denmark; [5]Stereology and Electron Microscopy Laboratory, Ctr. for Stochastic Geometry and Advanced Bioimagi, Aarhus Univ. Hosp., Aarhus, Denmark

**Abstract:** Dysfunction of the glutamate system has been associated to stress-related neuropsychiatric disorders. Clinical studies on depressed patients found volumetric and functional changes in glutamatergic brain areas, including hippocampus (HPC) and prefrontal/frontal cortex, while preclinical studies on stress-based animal models of depression reported impaired glutamate neurotransmission and dendritic arborisation in the same regions.

Intriguingly, consistent evidence reported that the NMDA-receptor antagonist ketamine (KET) induces a rapid and sustained antidepressant effect, both in patients and rodent models of depression. However, the mechanisms underlying KET therapeutic effect are still not completely understood.
Using a chronic mild stress (CMS) rat model of depression, we aimed at studying the effect of CMS and KET on glutamate presynaptic release, dendritic trafficking of BDNF transcripts and dendritic morphology.
Rats were subjected to CMS for 5 weeks. Sucrose Preference Test was used to distinguish stress-resilient (CMS-R) from vulnerable (CMS-V) rats. 10 mg/kg KET, acutely administered to CMS-V 24 h before sacrifice, was able to restore sucrose preference. Although significant changes in body weight gain, adrenal glands/body weight and serum corticosterone levels were found in all CMS rats, the increase of corticosterone levels and adrenal glands/body weight was higher in CMS-V. A decrease in basal and depolarization-evoked glutamate release from purified HPC synaptosomes in superfusion was measured in the CMS-V group. KET restored basal, but not evoked, glutamate release in CMS-V. A significant reduction in total-BDNF, BDNF-2 and BDNF-6 splice variant mRNAs was found in HPC of all CMS rats. Moreover, in situ hybridization studies found reduced dendritic trafficking of these transcripts in CA1 and CA3 of CMS-V. KET treatment, although not reversing changes in BDNF mRNA levels, completely rescued dendritic trafficking in CA3 of CMS-V. Morphological analysis of CA3 pyramidal neurons showed a reduction in total length and branching of apical (but not basal) dendrites; KET restored these changes to control levels.
Our results show that chronic exposure to mild stress induces alterations in the hippocampus of vulnerable rats. Interestingly, a single administration of KET was able to reverse most of these deficits. Further investigation of the mechanisms underlying individual resilience or vulnerability to stress and fast KET antidepressant action could help to clarify the neurobiological underpinnings of depression and to identify new pharmacological targets for faster, more efficient antidepressant drugs.

**Title:** Glutamatergic-GABAergic synaptic plasticity within the prefrontal cortex associated with chronic stress and ketamine treatment

**Authors: *C. H. DUMAN**[1], S. GHOSAL[1], R.-J. LIU[1], M. WU[1], M. J. GIRGENTI[1], E. S. WOHLEB[2], R. TERWILLIGER[1,2], M. ALREJA[1], R. S. DUMAN[1]
[1]Dept. of Psychiatry, Yale Univ., New Haven, CT; [2]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

**Abstract:** The prefrontal cortex (PFC) plays a central role in stress adaptation, and structural and functional impairments of PFC have been implicated in the pathophysiology of major depression. Exposure to uncontrollable stress causes persistent changes in the synaptic integrity of the principal glutamatergic neurons in the PFC, characterized by neuronal atrophy and loss of synaptic connections (Duman et al., 2016, Nature Medicine). Glutamate N-methyl-D-aspartate (NMDA) receptor antagonists, such as ketamine, completely reverse chronic unpredictable stress (CUS) induced depressive behavior and synaptic deficits in layer V pyramidal cells in the PFC. An emerging clinical and preclinical literature indicates that an imbalance in excitatory and inhibitory neurotransmission characterized by deficient GABAergic inhibitory signaling in the PFC could lead to dysfunction of the PFC circuitry after stress exposure. The present study investigates synaptic mechanisms related to inhibitory function in the effects of chronic stress, and if ketamine rapidly reverses these deficits. Reporter mouse lines with specific labeling of pyramidal cells or GABA interneurons, were subjected to a 21-day CUS model to test the actions of ketamine on depression-like behaviors (forced swim and novelty suppressed feeding tests), GABA neurochemistry using western blots and mRNA analyses, and synaptic function of PFC neurons. Our results demonstrate that CUS exposure leads to depression-like behaviors accompanied by reductions in GABA markers at both the mRNA and protein levels. Whole-cell patch recordings of layer V pyramidal cells indicate that CUS decreased frequency of spontaneous inhibitory postsynaptic currents (IPSCs) in PFC pyramidal neurons. Additionally, whole cell voltage clamp recordings in layer II/III somatostatin (SST) positive interneurons show that CUS significantly decreased IPSCs, suggesting that chronic stress causes a reduction in the overall inhibitory tone within the PFC. Moreover, our preliminary anatomical analyses indicate that ketamine administration drives synaptic remodeling in a circuit specific manner in the PFC. Currently, studies are underway to confirm these effects of CUS and reversal by ketamine. Collectively, our findings suggest that impairments of GABA interneurons and inhibitory neurotransmission are key features in a depression-like state induced by stress, and therapeutic approaches that facilitate restoration of impaired inhibitory circuits could provide a novel therapeutic strategy for restoring function and treating depression.

**Abstract:** One third of major depressive disorder (MDD) patients exhibit resistance to antidepressant drugs, an identified MDD subpopulation known as treatment-resistant depression (TRD). The NMDA antagonist ketamine is the only clinically efficacious drug in TRD but delusional and cognitive side effects limit its clinical utilisation. Alterations in microtubule dynamics have been associated with the pathogenesis and treatment of MDD. Here, the Wistar Kyoto (WKY) rat model of TRD was used to investigate the temporal antidepressant and cognitive effects of a clinically relevant dose of ketamine and the feasibility of acetylated alpha-tubulin (Acet-Tub; marker of decreased microtubule dynamics) as a plasma biomarker of ketamine efficacy. Adult male WKY rats (n=20 per group) received a single administration of ketamine (5mg/kg, s.c.) or saline (1ml/kg, s.c.). Immobility in the forced swim test (FST), a measure of depressive-like behaviour, was tested 30min, 24h and 48h post-administration in separate groups of animals. Plasma was isolated immediately after the FST for analysis of Acet-Tub by Infrared Western Blot. The cognitive effects of ketamine (5mg/kg, s.c.) in WKY rats (n=10) was investigated in the working memory delayed non-matching to sample (DNMS) task 30min and 24h post-administration and compared to Sprague Dawley (SD) rats (n=9) representative of a ‘healthy’ control strain. At 30min post-administration ketamine significantly reduced immobility in the FST while no significant change in plasma Acet-Tub expression was observed. WKY rats showed impaired DNMS performance compared to SD rats and further impairment was observed 30min after ketamine administration. Noteworthy, 40% of ketamine treated WKY rats did not complete the task at this time point. Ketamine significantly decreased immobility in the FST 24h post-administration accompanied by decreased plasma Acet-Tub. A pro-cognitive effect of ketamine was observed in DNMS 24h post-administration. No significant effects of ketamine were observed at 48h. Ketamine produced rapid (30min) and long-lasting (24h) effects in the FST in the WKY rat model of TRD. The rapid effect of ketamine was associated with adverse cognitive side effects while the long-lasting effect was accompanied by pro-cognitive efficacy. Plasma Acet-Tub, previously shown to be overexpressed in WKY rats

(Prenderville et al., 2015 Journal of Psychopharmacology Supplement 29 (8): A19), was decreased only when long-lasting antidepressant and pro-cognitive effects of ketamine were observed. Thus plasma Acet-Tub may represent a biomarker of ketamine antidepressant efficacy and a potential indicator of treatment responsiveness.

**Title:** Comparison of selective NR2B antagonism with non-selective NMDA receptor antagonism by quantitative electroencephalography (EEG) recordings in freely moving rats

**Authors: *B. FERGER**, P. VOEHRINGER, H. RAITH, C. DORNER-CIOSSEK
CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany

**Abstract:** Quantitative Electroencephalography (EEG) and vigilance states analysis have been proposed as useful diagnostic biomarkers of mental disorders and an important unit of analysis in the context of the Research Domain Criteria (RDoC) project. Here, we compare a selective NR2B receptor antagonist Traxoprodil with a non-selective NMDA receptor antagonist Ketamine on EEG brain activity and vigilance states. Wireless telemetric transmitters (F40-EET, Data Sciences International (DSI), USA) were implanted into the intraperitoneal cavity of male Wistar rats. EEG electrodes were placed supradurally above the cortex and EMG electrodes were sutured into the neck muscle. Effects of Ketamine (10,30 mg/kg, i.p.) and Traxoprodil (6,18 mg/kg, i.p.) were determined on EEG brain activity, EMG, body temperature and motor activity using the EEG analysis software NeuroScore (DSI, USA). Ketamine but not Traxoprodil increased motor activity whereas body temperature was significantly reduced by Ketamine only. Additionally, Ketamine enhanced the time spent in active and quiet wake and almost completely suppressed REM and NREM states, whereas Traxoprodil did not show any alteration in vigilance states. Power spectra analysis of Ketamine revealed a significant increase in gamma power, whereas Traxoprodil induced an overall decrease in most of the power spectra bands with the major effects on alpha and beta bands. In conclusion, Ketamine and Traxoprodil showed a high

level of central target engagement and different alterations in EEG parameters and changes in vigilance states. The data can be used to differentiate selective NR2B antagonism and non-selective Ketamine-like drugs which is useful for compound profiling in drug discovery projects.

**Abstract:** Recent evidence has suggested that the *N*-methyl-D-aspartate receptor antagonist ketamine shows significant therapeutic effects in major depression including treatment-resistant depression. Until recently, clinically available ketamine was a racemic mixture containing equal amounts of two enantiomers, *R*- and *S*-ketamine. Although some preclinical studies report that *R*-ketamine appears to be a potent antidepressant relative to *S*-ketamine, comparative studies on the individual effects of *R*- and *S*-ketamine are limited. Here we aimed to compare the antidepressant potency of *R*- and *S*-ketamine by using two different mouse models of depression: chronic corticosterone and isolation rearing paradigms. Either chronic administration of corticosterone or post-weaning social isolation in male C57BL6/J mice increased the immobility time in the forced swim test. For acute effects of ketamine, *R*-ketamine at doses of 10 and 20 mg/kg reduced

immobility time of isolation-reared, corticosterone-treated, and vehicle-treated control mice at 30 min after the administration, while *S*-ketamine at dose of 20 mg/kg, but not 10 mg/kg, reduced immobility time of these mice. In addition to the acute effects, *R*-ketamine showed sustained antidepressant effects in both isolation-reared and corticosterone-treated mice at 48 h and/or 7 days after the administration. *S*-ketamine at 20 mg/kg also showed sustained antidepressant effects in isolation-reared mice at 7 days after the administration, but it did not affect the immobility time of corticosterone-treated mice at even 48 h after the administration. These results suggest that *R*-ketamine show acute antidepressant effects at lower doses than *S*-ketamine in mouse models of depression used here. Furthermore, we found that both *R*- and *S*-ketamine exerted sustained antidepressant effects in isolation-reared model, but there was a difference between *R*- and *S*-ketamine in corticosterone-treated model. Further analysis on these models might contribute to clarify the common and distinct neural mechanisms for antidepressant effects of ketamine enantiomers.

**Title:** The ketamine metabolite hydroxynorketamine impacts downstream signaling via NMDA receptor inhibition

**Authors: *K. SUZUKI**[1], E. NOSYREVA[1], K. W. HUNT[2], E. T. KAVALALI[1], L. M. MONTEGGIA[1]
[1]Neurosci., [2]Biopharmaceutical Product Develop., UT Southwestern Med. Ctr., Dallas, TX

**Abstract:** Clinical data have demonstrated rapid and sustained antidepressant effects of ketamine, a noncompetitive N-methyl-D-aspartate receptor (NMDAR) antagonist. We previously showed that (R,S)-ketamine and other NMDAR antagonists produced fast-acting behavior antidepressant-like effects in mouse models. In addition, we found that ketamine blocked NMDARs at rest, which deactivates eukaryotic elongation factor 2 kinase (eEF2K), dephosphorylating eukaryotic elongation factor 2 (eEF2), resulting in a subsequent desuppression of brain-derived neurotrophic factor (BDNF) protein translation. This signaling

pathway then potentiates synaptic AMPAR responses in the hippocampus via insertion of GluA1 and GluA2 subunits. A recent study suggested that the ketamine metabolite, (2R,6R)-hydroxynorketamine (HNK) is essential for the antidepressant effects of ketamine in mice in an NMDA-independent manner. We assessed (2R,6R)-HNK on NMDAR-mediated miniature excitatory postsynaptic currents (mEPSCs) in hippocampal neurons. We find that (2R,6R)-HNK significantly inhibits NMDAR currents at rest in a manner consistent with open channel block of the NMDARs similar to ketamine. Congruent with the electrophysiology data, the treatment of (2R,6R)-HNK on hippocampal neurons resulted in a significant decrease in phosphorylated eEF2 levels demonstrating that the block of synaptic NMDAR extended to intracellular signaling. Collectively, these data reveal that (2R,6R)-HNK blocks synaptic NMDARs similar to the parent compound, ketamine. We propose that the ketamine metabolite (2R,6R)-HNK acts through direct inhibition of NMDARs and this continued inhibition of NMDARs may explain why ketamine has long lasting antidepressant effects that are not observed by other NMDAR blockers.

**Title:** Connectivity-phenotype associations with depressive symptom improvement after ketamine administration

**Authors: *J. W. EVANS**, E. D. BALLARD, C. FARMER, A. NUGENT, C. ZARATE, Jr.
NIH, Bethesda, MD

**Abstract:** Major Depressive Disorder (MDD) is associated with a heavy burden of disability and can also lead to suicidal thoughts, attempts and deaths. The heterogeneity of symptoms associated with MDD has been an obstacle to identifying specific neural correlates of the presence of depression as well as response to treatment. Ketamine, a glutamate modulator, with a rapid antidepressant response, and is therefore an ideal model to assess rapid changes across depressive symptoms. Subscale scores from a previous exploratory factor analysis of several clinical and self-reported depression rating scales (MADRS, HAMD, BDI and SHAPS) were used as measures of unidimensional constructs of depression. Four of the subscales, depressed mood, tension, suicidal thoughts and negative cognitions, were evaluated in resting state scans (8 minutes with eyes closed at 3T) across a clinical trial of ketamine. The aim of the analysis was to

investigate the connectivity-phenotype associations with depressive symptom improvement after ketamine in a sample of patients with treatment-resistant depression. For this study, a cohort of 29 MDD subjects (ages 20-65, 17 female) received resting state fMRI scans over the course of a double blind randomized placebo controlled cross-over ketamine infusion study: once at baseline, and before and after both placebo and drug infusions. We used multivariate distance matrix regression (MDMR) implemented in the Connectir package in R (http://czarrar.github.io/connectir) to compare voxelwise functional connectivity profiles in relation to our variables of interest. The MDMR models tested were overall MADRS score and as well as the individual subscale scores. From these results, we find that there are distinct maps corresponding to each of the latent factors and the MADRS scale. Regions of overlap included the insula, anterior and posterior cingulate and thalamus. Tension and Negative Cognition were associated with the hippocampus and suicidal thoughts being associated with more frontal regions. Depressive mood had significant association with the somatosensory regions. The intrinsic connectivity findings affirming existing regions associated with MDD which suggests neurobiological validity of this analysis.In conclusion, these results may help provide a more data driven approach to understanding the heterogeneity of depression and potential neural underpinnings of symptom profiles both before and after rapid-acting treatment with ketamine.

**Title:** Oleoylethanolamide modulates depressive like and stress related responses by recruiting histaminergic neurotransmission

**Authors: *A. COSTA**, S. D. SCHMIDT, B. RANI, P. BLANDINA, M. PASSANI, G. PROVENSI
Univ. of Florence, Firenze, Italy

**Abstract:** Oleoylethanolamide (OEA) is a fat sensing molecule that conveys signals from the intestine to the brain by engaging afferent vagal fibers. Recently we provided evidence that the

endogenous histamine is required for OEA to fully exerts some of its anorexic effect[1]. In the present work, we studied the influence of OEA on stress responses and its potential as an antidepressive-like agent, and if central histaminergic system plays a role in such effects. To this end, mice unable to synthesize histamine due to either disruption of the histidine decarboxylase gene (HDC) or injection of alpha-fluoromethylhistidine (a-FMH, an inhibitor of this enzyme, 5µg/5µL, i.c.v.) and WT littermates were tested in two different paradigms: Tail Suspension Test (TST), a predictive model of antidepressant-like effect, and the Social Defeat Stress (SDS) a risk factor for common psychopathologies such as depression. Mice were treated with either OEA (5 or 10 mg/kg, i.p.) or vehicle. In the TST, OEA significantly reduced the immobility time in WT and control mice, but this effect was not observed in HDC-KO or a-FMH-treated mice. Furthermore, to understand the molecular mechanisms responsible for these effects, cortical and hippocampal CREB phosphorylation was measured by Western Blot analysis. OEA-induced increase in cortical and hippocampal CREB phosphorylation was impaired in histamine-deficient mice. To investigate if OEA affects stress reactivity and cognition we examined the behavioral effects of the SDS in WT. Mice treated with OEA (10mg/kg,i.p.) or vehicle were exposed to an aggressive congener until the first attack and then it was separated by a transparent, perforated Plexiglas for 1 hour. The protocol was repeated for 21 consecutive days. Mice were then tested for Social Interaction Test with the aggressor and in the Novel Object Recognition Test (NOR). Preliminary data indicate that OEA reverts the social defeat-induced depressive-like behavioral profile. OEA decreases stress-induced social avoidance, when compared to stressed animals treated with vehicle and ameliorates cognitive performances in the NOR. The same protocol is underway with histamine-deprived mice to evaluate whether histamine plays a role in the cognitive effects of OEA . Collectively, our data provide novel insight into the role of central histaminergic system in OEA induced favorable effect in depressive-like and stress- related responses.

**Title:** Rapid antidepressant action of ketamine: Increase in cAMP independent of NMDA receptor antagonism in glial cells

**Authors: *N. WRAY**[1], J. SCHAPPI[2], M. M. RASENICK[3]
[1]physiology and biophysics, Univ. of Illinois at Chicago Dept. of Physiol. and Biophysics, Chicago, IL; [2]Physiol. & Biophysics, Univ. of Illinois At Chicago, Chicago, IL; [3]Dept Physiol, Biophysics, Univ. of Illinois at Chicago Col. of Med., Chicago, IL

**Abstract:** Ketamine produces robust antidepressant effects in depressed subjects within hours of administration, often when traditional antidepressant compounds have failed to alleviate symptoms even after 2 months of treatment. We hypothesized that ketamine would translocate $G\alpha_s$ from lipid rafts to non-raft microdomains, similarly to other antidepressants but with a distinct, abbreviated treatment duration. C6 glioma and primary glia stably transfected with $G\alpha_s$-GFP were treated with 10uM ketamine for 15 minutes, which translocated $G\alpha_s$ from lipid raft domains to non-raft domains. Similar to the loss of clinical efficacy seen about a week after ketamine infusion, localization of Gas to lipid rafts returns 24 hours after the withdrawal of ketamine. Other NMDA antagonists did not translocate $G\alpha_s$ from lipid raft to non-raft domains and knockdown of NR1 (loss of NMDA receptors) was without effect. However, the ketamine metabolite, 6 OH norketamine, which does not antagonize NMDA receptors, was effective in translocating Gas. The ketamine induced $G\alpha_s$ plasma membrane redistribution allows increased functional coupling of $G\alpha_s$ and adenylyl cyclase, increasing cyclic adenosine monophosphate (cAMP) production. Furthermore, increased intracellular cAMP increased phosphorylation of cAMP response element-binding protein (CREB), resulting in elevated BDNF expression. These actions were reversed in the presence of the cAMP antagonist, Rp-cAMPs. These results reveal a novel antidepressant mechanism mediated by acute ketamine treatment in glial cells that may contribute to ketamine's powerful and rapid antidepressant effect.

**Title:** Metformin enhances antidepressant response rate to ketamine in a rodent model of antidepressant treatment resistance

**Authors: *J. B. PRICE**[1], C. HE[3], S. K. ERHARDT[4], L. SCHWIELER[3], W. BOBO[1], M. A. FRYE[1], S. J. TYE[2]
[2]Psychiatry & Psychology, [1]Mayo Clin., Rochester, MN; [3]Karolinska Institutet, Stockholm, Sweden; [4]Karolinska Inst., Stockholm, Sweden

**Abstract:** Background: The mechanisms mediating the response rate for ketamine's antidepressant effect in treatment-resistant depression are not well understood. However, emerging evidence is pointing towards a neuroendocrine link between stress, depression, and metabolic dysfunction. In depression, chronic HPA-axis activation and allostatic overload ultimately impacts cellular energy regulation through impairment of insulin sensitivity, glucose homeostasis, mitochondrial function, and downstream cellular metabolic pathways. As a consequence, an individual's capacity to function and respond to challenges at the cellular level is impaired. We have previously shown that activation of the insulin signaling pathway directly correlates with antidepressant response to ketamine in antidepressant-resistant rats. The main aim of this project was to determine the synergistic therapeutic effect of metformin, a common treatment for type 2 diabetes, on ketamine's antidepressant response rate in these animals' behavioral responses and peripheral levels of glucose and insulin.
Methods: Rats were administered ACTH (100ug/day, 14 days) to establish a treatment resistant phenotype. Rats were administered control vehicle saline or ketamine (10mg/kg) and/or metformin (200mg/kg). Rats were then subjected to forced swim testing. Before and after behavioral testing, blood was collected for measurement of glucose levels.
Results: Results demonstrate that metformin+ketamine significantly reduced immobility during the forced swim test in rats pretreated with ACTH ($p<0.001$). This reduction matched the antidepressant effect of solo-ketamine treatment. However, the response rate for metformin with ketamine was significantly higher than for ketamine alone ($p<0.05$). These animals also had significantly higher glucose levels relative to ketamine responders ($p<0.01$), ACTH controls ($p<0.05$), and naïve controls ($p<0.001$). Regressional analyses revealed a significant negative relationship between glucose and insulin following metformin and ketamine administration ($p<0.01$).
Conclusions: These results suggest an important relationship between stress, insulin, and glucose homeostasis, which may be a critical mediator of ketamine's antidepressant action. This presents the possibility that metformin may be a useful co-treatment to improve response rates to ketamine.

**Abstract:** Although the pathology of psychiatric disorders such as depression is unclear, recent studies demonstrate a role for the involvement of intracerebral inflammation, including evidence that the inflammatory cytokine interleukin-1β (IL-1β) reduces neurogenesis in adult rodent hippocampus and causes depressive behavior. Previously we had reported that stress increases ATP, which activates the Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3) inflammasome, which in turn increases IL-1β in the rat hippocampus. Thus, we propose a hypothesis that the inhibition of the NLRP3 inflammasome will produce an antidepressant effect by preventing IL-1β production caused by stress. Recently it has been reported that beta hydroxybutyrate (BHB), a ketone body that supports mammalian cell metabolism during states of energy deficits, such as fasting or exercise, reduces NLRP3 inflammasome-mediated production of IL-1β. We have found that peripheral BHB administration reduced inflammatory cytokines such as IL-1β and tumor necrosis factor α, and improved depressive and anxiolytic behaviors in the chronic unpredictable stress (CUS), a rodent model of depression. Also, BHB suppressed the activation of NLRP3 inflammasome. Although BHB has antidepressant effects, we don't know whether it acts in directly on brain or on peripheral inflammatory NLRP3 responses. Here, we evaluated the direct influence of BHB in brain by intracerebral administration of BHB into the lateral ventricle. The results demonstrate that direct i.c.v. infusions of BHB prevented depressive and anxiolytic behaviors caused by chronic unpredictable stress, indicating that BHB is capable of producing antidepressant effects by direct actions on the central nervous system. Further studies will be needed to test the contribution of peripheral blockade of NLRP3 on stress-induced antidepressant responses. Nevertheless, these findings are consistent with the hypothesis that inhibiting NLRP3 inflammasome in brain is a novel effective approach for the treatment of depression.

**Abstract:** Pro-inflammatory cytokines such as interleukin-1β (IL-1β) and tumor necrosis factor α (TNFα) are known to play a critical role in the development of depression via disruption of synaptic signaling and decreased neurogenesis in the adult rodent hippocampus. The key molecule that senses stress and controls the processing and release of pro-inflammatory cytokines is the Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3), a cytosolic pattern recognition receptor (PRR). We have demonstrated that psychological stress releases ATP, which activates the NLRP3 inflammasome and release of IL-1β and TNFα in the rat hippocampus, which produces anhedonic and anxiety behaviors in rats. Thus, inhibiting NLRP3 is a novel strategy for the treatment of stress-related depression. Beta-hydroxybutyrate (BHB), which is a ketone body that supports mammalian cell metabolism during states of energy deficits, has recently been reported to reduce NLRP3 inflammasome-mediated production of IL-1β. We have confirmed that peripheral BHB administration suppresses the activation of the NLRP3 inflammasome and reduces inflammatory cytokines such as IL-1β and TNFα, and improves depressive and anxiety behaviors in the chronic unpredictable stress (CUS) model of depression. However, administrating BHB orally is inefficient due to its rapid metabolism. Medium chain triglycerides (MCT), which make up a ketogenic diet, are known to cause rapid and sustained elevation of blood BHB levels, thus we administered MCT orally to rats and evaluated behaviors. Here we show that MCT treated animals showed anxiolytic effects in the elevated plus maze test and the open field test as previously reported, but also showed antidepressant effects in the forced swim test. Also, the MCT group showed reduced pro-inflammatory cytokines. Taking MCT orally is easy to apply in a clinical setting, and based

on the current findings would be expected to produce antidepressant effects. These results indicate that oral administration of MCT may be an easy and effective treatment strategy for stress-related depression.

**Abstract:** Stress is known to decrease neurogenesis and synaptogenesis in the rodent hippocampus and induces depressive-like behavior, however the mechanisms by which stress causes such neuroplasticity is still unclear. Previously, we had reported that a proinflammatory cytokine such as interleukin-1β (IL-1β) is an essential mediator of the anti-neurogenic effects of stress. Recently we have focused on the Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3), a cytosolic pattern recognition receptor (PRR), which is considered a key molecule for the stress reaction. NLRP3 recognizes various materials such as Damage Associated Molecular Patterns (DAMPs) and Pathogen Associated Molecular Patterns (PAMPs), and activated NLRP3 inflammasome cleaves immature IL-1β to the active form. Thus, we hypothesized that NLRP3 is a novel target for inhibiting stress-related neuroinflammation, which provides anti-depressive effects. To inhibit NLRP3, we applied beta-hydroxybutyrate (BHB), which has recently been reported to reduce the NLRP3 inflammasome-mediated production of IL-1β. We had confirmed that peripheral BHB administration suppressed the activation of the NLRP3 inflammasome, and reduced inflammatory cytokines such as IL-1β and tumor necrosis factor α (TNFα), and improved depressive and anxiety behaviors in the chronic unpredictable stress (CUS), a rodent model of depression. Interestingly, we also found that acute immobilization stress increased the number of astrocyte in the hilus and CA1 of the hippocampus, however the peripheral BHB administration suppresses the increase. Astrocyte is one of the key players which regulates neuroplasticity in the brain. Astrocyte is thought to play

two different roles; neuroprotective actions such as providing trophic support for neurons, and neuropathic actions such as promoting inflammatory processes. In this study, the number of astrocytes might be increased in response to the neural inflammation, or to inhibit neuroinflammation. However, the exact mechanism of this change is still unknown, and further studies will be needed, because depression is related to neuroplasticity including the interaction between astrocytes and neurons, astrocyte mediated by BHB might be implicated in the pathology of depression.

**Title:** The Rho-kinase inhibitor, fasudil, has antidepressant-like efficacy in adolescent mice

**Authors: *L. P. SHAPIRO**[1], S. L. GOURLEY[2]
[2]Pediatrics, Neurosci. Program, [1]Emory Univ., Atlanta, GA

**Abstract:** Adolescence represents a critical period of neurodevelopment, defined by structural reorganization and synaptic maturation within the prefrontal cortex. Although these processes are critical for the transition to adulthood, structural instability may open a window of vulnerability to neuropsychiatric disorders including depression. Interventions that facilitate activity-dependent neural remodeling, as occurs during adolescence, may be advantageous. Here we evaluated the structural and behavioral effects of Rho-kinase (ROCK) inhibition, which can expedite activity-dependent dendritic spine plasticity. Within the adolescent ventromedial prefrontal cortex (vmPFC), the brain-penetrant ROCK inhibitor, fasudil, increased levels of the post-synaptic marker PSD-95, while pruning dendritic spines, resulting in adult-like spine densities. Further, fasudil had antidepressant-like effects in the forced swim test in adolescent mice and was comparable to ketamine and fluoxetine. Fasudil also decreased the latency to approach a palatable food in the novelty suppressed feeding task, a rapid antidepressant-like effect. Fasudil did not alter prefrontal-dependent cognition as measured by a reversal learning task. Immunoblotting revealed that fasudil stimulated several neurotrophin-related signaling

factors in the vmPFC, including increasing the ratio of full-length:truncated tyrosine kinase receptor B (TrkB). Nevertheless, experiments utilizing viral vectors indicated that the antidepressant-like effects of fasudil in the forced swim test are dependent on the neuronal ROCK2 isoform and not TrkB signaling. Together these findings suggest that inhibition of ROCK2 in the vmPFC may have therapeutic potential for the treatment of adolescent-onset depression.

**Title:** The effects of TNF-alpha inhibition on $GABA_A$ and GluA1-ir cells across the rodent hippocampus and cingulate cortex in an animal model of depression

**Authors: *K. BRYMER**[1], H. J. KIM[2], H. J. CARUNCHO[3], L. E. KALYNCHUK[4]
[2]Physiol. and Pharmacol., [3]Col. of Pharm. and Nutr., [4]Col. of Med., [1]Univ. of Saskatchewan, Saskatoon, SK, Canada

**Abstract:** Chronic stress produces morphological changes to the rodent hippocampus and prefrontal cortex and impairs memory dependent on these areas. Importantly, chronic stress disrupts GABAergic and glutamatergic activity within these same regions. Furthermore, chronic exposure to stress promotes the release of cytokines, which in turn exacerbate the stress response and disrupt cognition. Prominent among these is the cytokine TNF-alpha, which is preferentially expressed in the hippocampus and prefrontal cortex. TNF-alpha is also known to influence the activity of both GABA and glutamate. We hypothesized that treating chronically-stressed rats with the TNF-alpha inhibitor etanercept could have antidepressant effects, and could reverse stress-induced deficits in cognition. We further hypothesized that etanercept would modulate the stress-induced alterations in GABAergic and glutamatergic activity. To test this hypothesis, we examined the effect of repeated corticosterone (CORT) treatment and concurrent TNF-alpha inhibition (i.e., with etanercept) on forced-swim test (FST) behavior. Additionally, we examined object-location and object-in-place memory--tasks that are dependent on the hippocampus and pre-frontal cortex, respectively. Finally, we examined $GABA_A$ –ir neurons within the hippocampus and GluA1-ir neurons within the hippocampus and prefrontal cortex using immunohistochemistry. Rats received either 21 days of daily CORT injections (40 mg/kg) or vehicle injections. Rats also received semi-weekly injections of etanercept (0.8 mg/kg).

Behavioral testing began on day 22. CORT increased depression-like behavior and impaired both object-location and object-in-place memory. Importantly, CORT rats treated with etanercept behaved like vehicle rats. CORT decreased the number of $GABA_A$-ir neurons within the subgranular zone (SGZ), and etanercept restored this to control levels. CORT also decreased the number of GluA1-ir neurons within both the SGZ and the cingulate cortex, but etanercept restored both to control levels. These novel results clearly demonstrate that etanercept has antidepressant effects, which are accompanied by a normalization of GABA and glutamate and a restoration of hippocampal-dependent and prefrontal-cortex-dependent memory. These results highlight an important role for the immune system in the pathogenesis of depression.

**Title:** Cannabidiol treatment induces antidepressant-like effect in streptozotocin-induced diabetic rats

**Authors: A. P. F. WALTRICK**[1], H. MORAIS[1], K. GENARO[2], J. A. CRIPPA[2], J. M. CUNHA[1], *J. M. ZANOVELI[1]
[1]Federal Univ. of Parana, Curitiba, Brazil; [2]Univ. Sao Paulo, Ribeirao Preto, Brazil

**Abstract:** Depression is highly incident in the diabetic patients. It is known that several antidepressant drugs used to treat depression may alter the blood glucose or even interact with hypoglycemic drugs. Thus, the search for a more effective treatment for the treatment of depression associated with diabetes is of utmost importance. In that way, the endocannabinoid system has been pointed as a promising system for the treatment of several diseases, among them depression and diabetes. The aim of this study was to evaluate the behavioral response of acute and sub-chronic treatment with cannabidiol (CBD) in diabetic animals (DBT) submitted to the modified forced swimming test (mFST). Accordingly, male *Wistar* rats (180-250 g; n=7-12) were treated with citrate buffer (10mM, pH 4.5, i.p.; normoglycemic group-NGL) or streptozotocin (60 mg/kg; i.p; diabetic group-DBT). Four weeks after, a group of animals was treated with an acute injection of CBD (0, 0.3, 3, 30 mg/Kg i.p.) 1 hour before the mFST.

Another independent group of animals was submitted to the regimen of 3 injections of CBD (0, 0.3, 3, 30 mg/Kg i.p.), 24, 5 and 1 hour before the mFST. The procedures were approved by the UFPR's Committee for the Ethical Use of Animals (#749). When compared to the NGL rats, DBT animals showed hyperglycemia, reduced weight gain and a pronounced depression-like behavior (increased frequency of immobility and reduced frequency of swimming and climbing). The acute treatment with CBD was not able to change the depressive-like behavior of these DBT animals and did not affect blood glucose or the reduced weight gain of these animals. However, the sub-chronic treatment with CBD (30 mg/kg i.p.) was able to reduce the increased frequency of immobility and to improve the reduced frequency of swimming of DBT animals, demonstrating an antidepressant-like effect. This same treatment did not affect blood glucose or reduced weight gain of DBT animals. In conclusion, our data indicate that CBD may represent a promising drug for the treatment of depression associated with diabetes.

**Title:** Analgesic and antidepressant-like effects of rutin in the reserpine-induced fibromyalgia in ovariectomized rats

**Authors: *A. HERNÁNDEZ LEÓN**[1,2], A. FERNANDEZ-GUASTI[1], M. GONZÁLEZ-TRUJANO[2]
[1]Ctr. De Investigacion Y De Estudios Avanzados De, D.F, Mexico; [2]Inst. Nacional de Psiquiatría "Ramón de la Fuente", Mexico city, Mexico

**Abstract:** Fibromyalgia (FM) is a musculoskeletal syndrome characterized by chronic widespread pain, tenderness to palpation, and various concomitant symptoms, including affective disorders like depression. The prevalence of FM in women is much higher than in men and it has been reported that FM symptoms are aggravated during sex hormone-related events, such as the menopause period. There are several pharmacological treatments for FM, such as pregabalin, fluoxetine, and duloxetine; however, in the majority of patients their adverse effects and relatively poor response to treatment have promoted its discontinuation. Therefore, it is necessary to search for new therapeutic alternatives. The antinociceptive and anti-inflammatory effects of flavonoids are well known. In this study, we investigated the analgesic and

antidepressant-like effect of rutin (RUT) (quercetin-3-O-rutinoside, a glycoside of the aglycon quercetin) by using the reserpine-induced myalgia in rats, a model of FM. Ten groups (n=8) of female Wistar rats (200-250 g) were ovariectomized (OVX) and divided in two block (5 groups per block), the first block was built to evaluate analgesic effect of RUT and the second block was used to analyze antidepressant-like response. Each block consisted in OVX group (negative control group of FM), reserpine group (positive control group of FM) and three groups of reserpinized rats receiving vehicle (solution saline/tween 80), RUT (562 mg/Kg i.p.) or reference drug Fluoxetine (FLX, 10 mg/Kg s.c.). All drugs were evaluated on the $5^{th}$ day after the last reserpine injection. The muscle pressure, tactile response, and cold allodynia thresholds were measured before drug administration, as well as at 30, 60,120, 150, 180, 210 and 240 min after treatments. Depressive-like behaviors were evaluated during 5 minutes in forced swim test (FST). Reserpine produce significant diminution in the muscle pressure and tactile response thresholds in 48% and 70%, respectively. Whereas, in the cold allodynia test, reserpine increased 8-folds the time response in acetone spray test and increased 1.5-folds the number of counts of immobility in FST. RUT produced a recovery partial in the three nociceptive thresholds resembling the effect of FLX. The number of counts of immobility was decreased in presence of RUT or FLX showing antidepressant-like effect in FST, this effect was not related to motor alteration as measured in an actimeter and in the rotarod test. In conclusion, these results give evidence that RUT produces analgesic and antidepressive-like effects in an experimental model of FM supporting its potential for the FM therapy.

**Title:** SUVN-911(nAChR $\alpha_4\beta_2$ ) antagonist addresses most of the limitations of current antidepressant therapies

**Authors: *R. ABRAHAM**, R. KALLEPALLI, V. GOURA, J. THENTU, V. KAMUJU, S. M. IRUPANNANAVAR, R. C. PALACHARLA, V. GOYAL, S. PANDEY, B. NARASIMHA, S. RAVELLA, A. SHINDE, A. MOHAMMED, R. NIROGI
Suven Life Sci., Hyderabad, India

**Abstract:** Depression is a major contributor to the overall global burden of disease and also the leading cause of disability worldwide. Globally, more than 300 million people of all ages suffer from depression. The currently available antidepressants have a number of limitations. Some of

these include low response and remission rates, delayed onset of action, sleep disturbances, cognitive dulling and sexual dysfunction. SUVN-911 is a potent and selective $\alpha_4\beta_2$ antagonist. It showed good brain penetration and receptor occupancy following oral administration. SUVN-911 showed good oral bioavailability in all preclinical species. It demonstrated antidepressant like effects in animal models of depression like the DRL-72s and forced swim assay. SUVN-911 showed faster onset of action and also procognition property. SUVN-911 did not cause sexual dysfunction in animal models. At behaviorally effective doses, SUVN-911 produced a significant increase in cortical serotonin and norepinephrine levels. SUVN-911 showed good margin of safety in toxicity studies and is non-mutagenic. The pharmacology, pharmacokinetic, metabolic, biopharmaceutical and toxicity profiles provide strong support to develop SUVN-911 for the management of major depressive disorders. Currently, a single-center, double-blind, placebo-controlled, randomized, phase 1 study to evaluate the safety, tolerability, and pharmacokinetics of SUVN-911 after single ascending doses and multiple ascending doses in healthy male subjects, under US IND is in progress.

**Title:** The differential effects of monophasic and biphasic repetitive transcranial magnetic stimulation on attentional processing in major depressive disorder

**Authors: *M. HYDE**[1,2], P. BLIER[1,2], L. MCMURRAY[3], A. ROSTOM[4], A. KHAN[3], V. KNOTT[1,2]
[1]CMM Program, Univ. of Ottawa, Ottawa, ON, Canada; [2]Univ. of Ottawa Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [3]Royal Ottawa Mental Hlth. Ctr., Ottawa, ON, Canada; [4]Queensway-Carleton Hosp., Ottawa, ON, Canada

**Abstract:** In addition to mood dysfunction, patients with major depressive disorder (MDD) exhibit cognitive impairments that interfere with daily functioning and resist improvement with conventional pharmacotherapies. Repetitive transcranial magnetic stimulation (rTMS) holds promise as an MDD intervention strategy; it involves the induction of a transient magnetic field and neuronal current flow. Presently, rTMS practice involves sinusoidal biphasic pulses; however, monophasic magnetic pulses may be more effective as they are associated with more homogenous neuronal activation. MDD has been associated with attenuated P300 event-related potential (ERP) amplitudes and prolonged P300 latencies, indexing decreased attention-related cortical resource allocation and slower cortical processing speed, respectively. This study aims to investigate the impact of monophasic and biphasic rTMS treatment on clinical outcomes (MADRS-assessed), as well as the P300 ERP. This randomized, double-blind trial involves 40 treatment-resistant MDD patients stratified equally to receive either monophasic or biphasic stimulation for six weeks (daily, 30 sessions total). P300 measurements are obtained pre- and post-rTMS treatment during an auditory task whereby infrequent, low-pitched target tones and distractor sounds (e.g., baby crying) are embedded among frequently presented high-pitched tones. Distractor sounds elicit a P300a, reflective of involuntary attention to novelty, while the target tones elicit a P300b indicative of voluntary attention. Preliminary analyses ($N$=11) revealed a reduction in MADRS symptoms ($p$<.001) following rTMS, though, no treatment-specific effects were found ($p$>.05). Interestingly, while greater P300a amplitudes were observed following monophasic treatment vs. baseline ($p$=.01), this was not observed with biphasic treatment ($p$>.05). These preliminary analyses suggest that the two rTMS treatments may differentially affect auditory novelty processing, though this effect will be verified with a larger sample as data collection is ongoing. Regardless, these data are encouraging with respect to the identification of cognitive changes associated with rTMS response and targeted MDD treatment.

**Title:** Selective positive allosteric modulators of α7 nicotinic receptors have antidepressant-like activity

**Authors: *M. CRADDOCK**[1], H. ARIAS[2], K. TARGOWSKA-DUDA[3], B. BUDZYńSKA[4], A. MICHALAK[4], C. J. LØLAND[5], K. JOZWIAK[4], G. BIALA[4]

**Abstract:** α7 Nicotinic acetylcholine receptors (AChRs) are widespread in the brain and involved in sensory response, memory, cognition, and mood regulation. The enhancement in activity of these receptors by positive allosteric mediators (PAMs) is of therapeutic importance in a number of cognitive deficits. Until recently, no research had considered the potential of α7-PAMs as treatments for depression. Recent results demonstrated that one of these compounds, PAM-2, has antidepressant-like activity in mice (Targowska-Duda et al., 2014, Neurosci. Lett. 569:126). To demonstrate whether other α7-PAMs have similar antidepressant-like activity, type I (NS-1738) and type II (PNU-120596 and PAM-2) PAMs were assessed using both the forced swim test (FST) and tail suspension test (TST). The FST results showed antidepressant-like activity in all α7-PAMs after subchronic treatment, and particularly in PAM-2 after chronic treatment. In general, the TST results confirmed the FST results, except for NS1738. Methyllycaconitine, an α7-antagonist, inhibited the observed antidepressant-like activity, demonstrating that α7 AChRs are involved in this activity. PAM-2, -3, -and -4 do not inhibit the human serotonin (hSERT), dopamine (hDAT), and norepinephrine (hNET) transporters at clinical concentrations, ruling out involvement of these neurotransmitter systems in the observed activity. Synergistic effects were shown when PAM-2 was co-administrated with the antidepressant bupropion, but not with the α7-agonist DMXBA. This enhancement elicited by α7-PAMs could pave the way for new adjunctive therapies in existing antidepressants since the clinical activity of many antidepressants is only around 10% better than the placebo effect. The

results show that PAM-induced α7 AChR potentiation produces antidepressant-like activity, which opens the door to a new area of therapeutic possibilities for PAMs in mood disorders.

**Title:** CXCR4 and CXCR7 agonists are present in plant species used for treatment of mental disorders in Peruvian traditional medicine

**Authors: *C. GALLO**, G. POLETTI, R. ROJAS, A. VAISBERG
Univ. Peruana Cayetano Heredia, Lima, Peru

**Abstract:** Rescuing traditional medicine practices is one of the possible avenues to discover novel pharmacological approaches for clinical conditions like mental disorders, for which pharmacotherapies with better adherence, long-term outcome and patient functionality are strongly needed. Previous studies have led us to collect information on the traditional use of plants for the treatment of mental disorders in several Peruvian localities and geographical regions. The species of interest were sampled, dried, grinded and extracted with ethanol. A total of 477 extracts from plant collections corresponding to 265 species from 87 different plant families were tested at CXCR4 and CXCR7 receptors for agonists by beta-arrestin/Tango assays in the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill (UNC). We identified 10 species with greater than 1.3 fold of average basal (basal with medium alone) for the two receptors. These extracts belong to 7 different plant families.The involvement of the chemokine receptors CXCR4 and CXCR7 in mental disorders has been reported and started to be discussed only in the past few years. Our data support this possible role.

**Title:** BU10119, a buprenorphine analog, produces robust antidepressant-like effects in mice

**Authors:** ***C. A. BROWNE**[1,2], S. A. ROBINSON[2], E. FALCON[2], S. M. HUSBANDS[3], I. LUCKI[1]
[1]Pharmacol. & Mol. Therapeut., Uniformed Services Univ. of the Hlth. Scienc, Bethesda, MD; [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Bath, Bath, United Kingdom

**Abstract:** Buprenorphine is a potent kappa opioid receptor (KOR) antagonist and mu opioid receptor (MOR) partial agonist with equimolar affinity, that is FDA approved for the treatment of opioid addiction and chronic pain. Accumulating evidence from clinical studies highlights the antidepressant potential of buprenorphine following only one week of administration, a timepoint at which conventional antidepressants are ineffective. Moreover, buprenorphine produces rapid and effective alleviation of depressive symptoms in treatment-resistant major depressed patients. Previously, our laboratory demonstrated that low-dose buprenorphine reversed behavioral deficits induced in two rodent models of depression, chronic mild stress and chronic social defeat. Furthermore, we determined that KOR antagonism mediated buprenorphine's antidepressant effects, whereas blockade of MORs facilitated buprenorphine's anxiolytic action. However, potential abuse liability associated with MOR agonist activity may impede the development of buprenorphine as a novel treatment for major depression. We show that mice exposed to chronic mild stress exhibit conditioned place preference for buprenorphine, but that this response was blunted in comparison he preference displayed by non-stressed controls. Reducing efficacy of buprenorphine at MORs without altering affinity and efficacy at other receptors, can enhance the therapeutic profile of buprenorphine. Here we evaluated the behavioral effects of a novel buprenorphine analog, BU10119 in male C57BL/6J mice using the forced swimming test (FST) at 1 and 24 h post administration and in novelty induced hypophagia (NIH) 24 h post treatment. The effects of BU10119 were compared with those of buprenorphine, the selective KOR antagonist CERC-501 and the selective MOR antagonist cyprodime.

BU10119 produced a similar inverted U-shape dose response curve to that of buprenorphine, reducing immobility in the FST and latency scores in the NIH, in the absence of MOR agonist induced hyperactivity, 1 and 24 h post treatment. Cyprodime was only effective at 1 h. CERC-501 reduced immobility at both timepoints, but reduced latency scores only at the highest dose 24 h post injection. Overall, these data show that BU10119 retains the beneficial behavioral profile of buprenorphine.

**Title:** SXC-2023: Preclinical characterization of a novel activator of the cystine glutamate antiporter (System $x_c^-$) and potential therapeutic for CNS disorders

**Authors: *C. E. BEYER**[1], M. P. NEARY[1], D. G. LAWTON[1], M. PREIGH[1], N. J. RADDATZ[2], D. C. LOBNER[2], J. R. MANTSCH[2], D. A. BAKER[2]
[1]Promentis Pharmaceuticals, Milwaukee, WI; [2]Marquette Univ., Milwaukee, WI

**Abstract:** Alterations in glutamate neurotransmission represent a common phenotype of several central nervous system (CNS) disorders. Effective targets for the development of novel treatment approaches can be discovered by evaluating molecular mechanisms that modulate glutamatergic neurotransmission in key circuits within the brain. We have designed SXC-2023 to activate the cystine-glutamate antiporter (also known as System $x_c^-$), a primarily astrocytic target described as an effective means to modulate extrasynaptic glutamate signaling as well as increase the synthesis of glutathione, an important intracellular antioxidant. In addition to possessing a favorable nonclinical profile, SXC-2023 was found to be active in a variety of rodent models. SXC-2023, with a minimal effective dose of 10 mg/kg, PO, was found to improve measures of anxiety and sensorimotor gating as measured using elevated plus maze and prepulse inhibition (PPI), respectively. To validate the mechanism of action of SXC-2023, we utilized a novel transgenic rat in which the gene encoding the primary protein for System $x_c^-$ was mutated, which eliminated cystine-glutamate exchange by this transporter. In wild-type rats, SXC-2023 (10

mg/kg, PO) significantly reversed sensorimotor deficits in the PPI model. However, this response of SXC-2023 was completely abolished in transgenic rats lacking a functional cystine-glutamate antiporter. Collectively, this nonclinical profile suggests that SXC-2023 is well tolerated and that targeting System $x_c^-$ with SXC-2023 may represent a novel treatment approach to reverse CNS symptoms routinely associated with glutamatergic dysfunction and/or oxidative stress.

**Title:** Noradrenergic signaling enhances MMP release from cultured hippocampal neurons; relevance to antidepressant efficacy

**Authors: S. ALAIYED**[1], M. S. MCCANN[2], E. KIM[3], K. J. KELLAR[1], *K. CONANT[4]
[1]Pharmacol., [2]Georgetown Univ., Washington, DC; [3]Georgetown Univ., Washinton, DC; [4]Neurosci., Georgetown Univ., Washington, DC

**Abstract:** Drugs that target monoaminergic neurotransmission represent a first line treatment for major depressive disorder, a debilitating condition affecting approximately 12-17 % of the U.S. population at some point during an individual’s lifetime. Though a full understanding of the mechanisms that underlie antidepressant efficacy in responsive individuals is not yet fully appreciated, responsiveness correlates with increased volume of select brain regions, particularly the hippocampus. Animal models suggest that regional increases in cortical volume reflect the ability of antidepressants to enhance dendritic branching, dendritic spine formation and neurogenesis. Indeed, increased dendritic branching occurs in adult animals and, along with formation of new dendritic spines, it can positively influence excitatory neurotransmission.

Mechanisms by which antidepressant monoamine reuptake inhibitors enhance brain volume-related endpoints are unknown but likely involve indirect and slowly evolving effects of increased monoamine levels. Herein we show that the monoamine norepinephrine can significantly increase the release of matrix metalloproteinase (MMP)-3 and -9 from cultured murine hippocampal neurons. These MMPs have been previously shown to enhance long-term potentiation and/or dendritic spine formation. In related experiments we observe that MMP inhibition reduces dendritic arborization of DIV 14 hippocampal cultures. We also show that the non-selective β-adrenergic agonist isoproterenol stimulates enhanced release of MMP-3 and -9, while the β-antagonist sotalol substantially reduces norepinephrine-stimulated release of these MMPs. Ongoing experiments are focused on the potential for norepinephrine to stimulate MMP-dependent changes in dendritic complexity and spine number. In terms of related *in vivo* work, we observe that desipramine reduces norepinephrine reuptake in C57/Bl6J mice. Ongoing *in vivo* studies are evaluating the effects of norepinephrine modulators, including desipramine and venlaflaxine, and the MMP dependence of each on hippocampal structure (spine number/dendritic arbor) and function (behavior and neurophysiology).

**Title:** Antidepressant effects of C-terminal fragment of tetanus toxin in a rat model of depression

**Authors: *Y. TIZABI**[1], B. GETACHEW[1], I. LIMON PEREZ DE LEON[2], J. AGUILERA[3], J. CASTRILLON[2], L. MENDIETA[2]
[1]Dept. of Pharmacol., Howard Univ. Col. of Med., Washington, DC; [2]Benemerita Univ. Autonoma De Puebla FCQ Lab. Neurofarma, Puebla, Mexico; [3]Inst. de Neurociències, Univ. Autònoma de Barcelona, Cerdanyola del Vallès (Barcelona), Spain

**Abstract:** The C-terminal domain of the heavy chain of tetanus toxin (Hc-TeTx) is a peptide fragment with demonstrated in-vitro and in-vivo neuroprotective effects against nigrostriatal dopaminergic damage, suggesting its possible therapeutic potential in Parkinson disease (PD).

Since depression is a common co-morbid condition with PD, and recently it has been suggested that neuroprotectants are likely to have antidepressant effects, we undertook this study to determine whether Hc-TeTx might also show antidepressant-like properties. For this purpose, Wistar-Kyoto rats, a putative and non-induced animal model of depression, were treated with a single injection of Hc-TeTx (40 µg/kg) administered intramuscularly. Controls received saline. The open field locomotor activity (OFLA) as well as performance in the forced swim test (FST) of these rats was evaluated 24 h after the injection. OFLA was measured in an automated monitoring cage for 5 min and immediately following this, the FST was performed for 5 min where the animals were videotaped and their immobility score, reflective of helplessness, was counted. Animals treated with Hc-TeTx showed significant decrease (about 2.5 fold) in their immobility score compared to control. The OFLA was not significantly affected. Interestingly, when the rats were tested in the same paradigms after one week of rest, the immobility score in Hc-TeTx treated rats was still significantly lower than the control (about 2 fold), whereas the OFLA score was approximately 60% higher than the control. Following 2 weeks of rest the immobility score in Hc-TeTx treated rats was approximately 25% lower than control, which was not statistically significant. The OFLA score was also not significantly different between the 2 groups. These results indicate a fast and long lasting antidepressant effect, at least for one week, of a single Hc-TeTx injection in WKY rats. Taken together, it may be suggested that Hc-TeTx may be of therapeutic potential in both PD and depression and particularly of benefit in PD-depression co-morbidity. **Abstract:** The low-affinity, high-capacity uptake-2 transporter family includes plasma membrane monoamine transporter (PMAT) and organic cation transporter isoforms (OCT2 & OCT3) that take up neurotransmitters from the extracellular space in the brain. We have shown uptake-2 transporters limit the effectiveness of the selective serotonin reuptake inhibitor (SSRI) fluvoxamine. Discerning the uptake-2 transporter type(s) involved is restricted by the unavailability of highly selective ligands. This project examines the pharmacological characteristics of seven novel uptake-2 compounds to block low-affinity/high-capacity (PMAT, OCT2, & OCT3) versus the high-affinity/low capacity monoamine transporters (dopamine (DAT), norepinephrine (NET), & serotonin (SERT) transporters). We tested the activity of ANSTO analogs, structurally based on the non-selective inhibitor decynium-22 (D22), in HEK cell lines expressing human OCT2, OCT3, or PMAT. Ligand competitions of [$^3$H]MPP$^+$ uptake were measured in whole, attached cells. Compared to OCT2 and PMAT, dose-responses of ANSTO compounds shifted 1-log leftward, indicating they are more potent inhibitors of [$^3$H]MPP$^+$ uptake through OCT3. ANSTO analogs displayed similar potencies to corticosterone, a potent blocker of OCT3. Binding displacement of selective radioligands in mouse brain preparations from striatum ([$^3$H]WIN35428, DAT) or hippocampus ([$^3$H]Nisoxetine, NET & [$^3$H]Citalopram, SERT) revealed most ANSTO analogs to have similar inhibition potencies as D22. However, two of the compounds were significantly more potent inhibitors at the SERT. Analyses of analogs and SSRI competitions measured in brain preparations from SERT, OCT3 & PMAT knockout mice are ongoing to further develop the specificity of the new compounds. These studies will reveal more about the pharmacological profile of these novel compounds for their potential therapeutic application to treat disorders with neurotransmitter dysregulation, such as depression and drug abuse.

**Title:** Chronic unpredictable stress modifies the quantity and morphology of microglia and neuronal health in cortico-limbic circuitry

**Authors: C. QUAILEY**[1], C. FLYNN[1], C. WHITELOCK[1], B. DALENA[2], K. JONES[1], K. RONALTER[1], M. M. MIRRIONE[3], *A. J. BETZ[2]

**Abstract:** Chronic unpredictable stress (CUS) is an animal model of major depressive disorder (MDD) The hippocampus has been shown to be a neuroanatomical substrate altered in MDD models. Microglia are essential CNS immune cells that undergo morphological modifications in response to stimuli and have been found to regulate hippocampal neurogenesis and neurodegeneration via inflammatory pathways. The main objective of this study was to dissociate the role of microglia activation, neuronal dysfunction and neurogenesis in regions of the hippocampus (HIPP) and prefrontal cortex (PFC) in adult male rats exposed to CUS (n= 5) versus control (n=5). Using immunofluorescence HIPP tissue was stained for Iba-1, NeuN, 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 (PFKFB3) and Ki67 and quantified using MATLAB and ImageJ. We found a significant increase in ameboid microglia ($p<0.020$) in the CUS molecular dentate gyrus and CA1. PFKFB3 is present in the molecular layer of the DG and may indicate neuronal excitotoxicity for stress exposure. This data suggests that modifications in microglia of the hippocampus and PFC may differentially regulate depressive-like behavior. Overall, our results may provide insight to the molecular mechanisms responsible for atrophy and neuronal dysfunction in cortico-limbic circuits related to MDD.

**Abstract:** Major depressive disorder (MDD) is among the most frequently diagnosed psychiatric disorders in the United States and adversely affects children, adolescents and adults. Evidence suggests a close relationship between emotional stress and vulnerability to MDD. MDD is characterized by behavioral and neurochemical adaptations, such as dysfunctional cognitive-affective processes and elevated hypothalamic-pituitary-adrenaocortical (HPA) activity. The hippocampus has been shown to be a neuroanatomical substrate altered in MDD models. Two regions of the hippocampus, the dorsal and the ventral regions, are suggested to be functionally different while the dorsal hippocampus is involved in cognitive function and the ventral hippocampus is involved in emotion and stress. Animal studies examining how treatments might ameliorate MDD have shown increased neurogenesis in the hippocampus after antidepressant treatments but less is known about the role of glutamate and antidepressant activity. Chronic unpredictable stress (CUS) has been used as a rodent model of MDD. We aimed to examine the expression of dorsal and ventral hippocampal glutamate activity in rats that experienced CUS and CUS + riluzole. Riluzole is a glutamate antagonist that modulates glutamate release and uptake. In the present study, male Sprague Dawley rats were exposed to CUS for 22 days or CUS + riluzole and control conditions were maintained. First, we examined behavioral tasks to demonstrate the antidepressant actions of oral riluzole. We found glutamatergic markers correlating with behavior. Second, we found altered protein levels of CD11b, GFAP, EAAT3, EAAT2, EAAT1 and VGLUT1 suggesting that chronic stress has effects on neuronal and glial metabolism and function. Further, riluzole may modulate glutamate through these mechanisms. Our data may provide insight as to the molecular mechanisms responsible for MDD vulnerability, pathogenesis and possible therapeutic remedies.

**Title:** The non-selective opioid diprenorphine produces delta-opioid receptor-mediated rapid antidepressant-like effects in the mouse

**Authors: *T. M. HILLHOUSE**[1], J. E. HALLAHAN[2], N. GRIGGS[2], E. SCHRAMM[2], J. R. TRAYNOR[2]
[1]Psychology & Neurosci., Weber State Univ., Ogden, UT; [2]Pharmacol., Univ. of Michigan, Ann Arbor, MI

**Abstract:** Major depressive disorder (MDD) is the most common mood disorder worldwide with a lifetime prevalence of ~15% (Kessler et al., 2012). Although patients suffering from MDD have access to a number of FDA approved medications including typical and atypical antidepressant drugs, there are two major issues with these drugs. First, there is a delay of 4-12 weeks from the start of treatment until symptom remission is attained. Second, there is a subpopulation of treatment-resistant patients that do not achieve adequate symptom remission following chronic antidepressant drug treatment. There is preclinical and clinical evidence that opioid receptors, particularly the delta-opioid receptors (DOPR) and kappa-opioid receptors (KOPR), play a role in the neurobiology of MDD. As such DOPR agonists and KOPR antagonists are viable targets for rapid-acting antidepressant drugs. The present study sought to extend findings on the opioid system and depressive-like behaviors using the non-selective opioid ligand diprenorphine which has been described as a mu-opioid receptor antagonist, but a DOPR and KOPR partial agonist. In the mouse, diprenorphine over the range 1 to 10 mg/kg produced a dose-dependent antidepressant-like effect in the tail suspension test and an anxiolytic-like effect in the novelty-induced hypophagia assay. The effects of diprenorphine in these two behaviors were completely prevented by treatment with 3.2 mg/kg of the selective DOPR antagonist naltrindole confirming that diprenorphine was functioning as a DOPR agonist rather than a KOPr antagonist. Functional ([35S]GTPgammaS) *in vitro* assays confirmed the partial DOPR agonist nature of diprenorphine. A major concern with DOPR agonists is the induction of convulsions. Importantly, diprenorphine up to 32 mg/kg did not produce convulsions in mice, and blocked convulsions caused by the full DOPR agonist SNC80. Taken together, these results provide further evidence that the DOPR system is a target for rapid antidepressant-like effects. Moreover, partial agonism of DOPR may provide a safer profile as compared to full DOPR agonists.

**Title:** CX614, a cognitive enhancing AMPAkine, as fast onset antidepressant

**Authors: *H. JOURDI**[1,2], M. KABBAJ[2]
[1]Biol. Departmet, Univ. of Balamand, Souk El Gharb, Lebanon; [2]Biomed. Sci., Florida State Univ., Tallahassee, FL

**Abstract:** Although fast-onset antidepressants, such as ketamine, an antagonist of NMDA-type glutamate receptors (NMDAR) and psilocybin, a partial agonist of various serotonergic receptors, provide important benefits in treating major depressive disorder (MDD), they produce multiple undesirable physical and mental side effects. Recent evidence indicates that blockade of AMPA-type glutamate receptors (AMPAR) abrogates the antidepressant effects of ketamine, that a ketamine metabolite [(*2R,6R*)-HNK; (*2R, 6R*)-hydroxynorketamine] interacts directly with AMPAR, and that the antidepressant effects of (*2R,6R*)-HNK are independent of NMDAR inhibition. Here, we provide strong evidence that a single dose of CX614 (4 and 6 mg/kg b.w.), elicits fast onset antidepressant effects that are at least as potent and long lasting as those elicited by a single ketamine dose (10 mg/kg b.w.) in the forced swim and sucrose preference tests (FST and SPT, respectively). Both CX614 doses and ketamine produced a statistically significant reduction in immobility in the FST and counteracted the reduction in sucrose consumption in the SPT. In vivo CX614 and ketamine treatments activate/phosphorylate TrkB, mTOR, ERK and AKT/PKB with CX614's effects on the phosphorylation of these molecules being dose-dependent. In addition, hippocampal tissue collected from ketamine- and CX614-treated rats and ketamine- and CX614-treated acute hippocampal slices were used to further elucidate the signaling pathways activated by these drugs. Our results indicate that both ketamine and CX614 treatments increased activation/phosphorylation of mTOR, ERK, AKT/PKB, and phosphorylation of 4EBP1. These results imply activation of the protein translation machinery, as was confirmed with increased expression of ARC. CX614 treatment of acute hippocampal slices increases the phosphorylation of TrkB, SSH1, cofilin, LIMK and GluR1. Taken together, our results infer coupling between protein synthesis, actin polymerization and GluR1 trafficking following CX614 treatment. Our results have implications for the use of CX614 as a new fast-onset antidepressant. Considering the highly significant correlation between depression and

cognitive impairment, our results afford added value in the treatment of cognitively impaired and/or depressed patients.

**Title:** Antidepressant effect of transcranial direct current stimulation of the rat medial prefrontal cortex

**Authors: *J. CONWAY**[1,2], L. WALTERS[1], R. J. RAYMOND[2], J. NOBREGA[2], F. R. BAMBICO[1,2]
[1]Psychology, Mem. Univ. of Newfoundland, St John's, NL, Canada; [2]Behavioural Neurobio. Lab, Res. Imaging Ctr., Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

**Abstract:** Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation procedure hypothesized to influence neuronal excitability and plasticity in a region-targeted manner. Recent investigations have highlighted its benefits in improving cognitive performance and psychiatric symptoms (Mondino et al., *BP* 2014), although its precise therapeutic mechanisms remain largely unclarified. We developed a rat model of tDCS and tested its antidepressant/anxiolytic activity using the forced swim (FST), novelty-suppressed feeding (NSFT) and elevated plus maze (EPMT) tests. We also examined its effects in rats that have undergone olfactory bulbectomy (OBX), a well-established animal model of depression. We targeted the medial prefrontal cortex (mPFC) because electrical stimulation of this region has been previously shown to result in an antidepressant response (Hamani and Nobrega, *EJN* 2010). Animals were given sham or tDCS current twice on day 1 and once on day 2 (30 min before testing). The current generator delivered low power current (0.05 to 0.1 mA) onto a conducting metal plate (1.5±0.25 x 2.5±0.25mm) fixed on the skull surface over the mPFC (AP+4.7 to +2.2mm; Paxinos and Watson, 2005). In the non-OBX group, stimulated animals receiving 0.1 mA exhibited significantly lower immobility episodes ($p<0.05$) in the FST. Locomotor activity was increased by stimulation but reverted to normal levels upon cessation of the current delivery. At 0.1 mA, animals also exhibited a non-significant increase in anxiety-like behaviour in the NSFT and EPMT. Post-mortem brain analyses using in situ hybridization imaging of the immediate early gene *zif268*, a marker of cell activation, revealed significant activation patterns in target regions, including the cingulate, prelimbic and orbital cortices. Behavioural analyses in OBX animals are underway. These data suggest that tDCS can be effectively modeled in the rat,

yielding highly selective patterns of brain activation, and could therefore serve to elucidate potential antidepressant mechanisms.

Sch., Boston, MA; [4]Physiol. and Physics, Univ. of Illinois at Chicago,Jesse Brown VA Med. Center,, Chicago, IL

**Abstract:** Major depressive disorder affects nearly 7% of adults in the US in any given 12 month period, and is predicted to be the number two cause of disability worldwide by the year 2020. While effective interventions exist, at least 1/3 of individuals do not achieve symptomatic remission despite treatment. The evidence from epidemiological, laboratory, and randomized placebo-controlled trials suggests deficiency of dietary n-3 poly-unsaturated fatty acids (n-3 PUFAs) may contribute to development of mood disorders, and supplementation with n-3 PUFAs (alone or in conjunction with SSRIs) may provide a new treatment option. The mechanisms of the antidepressant effects of n-3 PUFAs are unknown. Recent studies found that the density and number of glial cells are reduced in fronto-limbic brain regions in major depression. The purpose of the present investigation was to evaluate the impact of n-3 PUFA on the differentiation of neural progenitor cells. Neural progenitor cells (NPCs) were generated from iPSCs from fibroblasts of subjects with depression that were either sensitive or resistant to SSRI therapy, as well as from healthy control subjects. NPCs were treated with n-3 PUFAs (eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)), omega-6 PUFAs (arachidonic acid (AA) and linoleic acid (LA) and saturated fatty acid (steric acid (SA)) in glial cell-induction

medium. After 3 days treatment the GFAP positive cells were increased from 8% in control to ~35% in DHA and EPA group ($\tau$ test $p<0.05$). AA and LA group showed a trend of increasing GFAP positive cells without reaching statistical significance. SA treated cells were no different from control. Furthermore, real time quantitative PCR showed a twofold increase of GFAP mRNA expression with DHA and EPA treatment ($\tau$ test $p<0.05$), but not with SA treatment. Expression of neural (MAP2a) and oligodendrocyte (OLIG2) markers were not affected by any fatty acid treatment, These data suggest that n-3 PUFAs may alter downstream cell types differentiated from the NPCs, and may be one of mechanisms underlying n-3 PUFAs anti-depressant effect in the generation of new astrocytes.

**Title:** Methanandamide stimulates release of TRH and TRH-like peptides throughout male rat brain

**Authors: *A. E. PEKARY**, A. SATTIN
Res., VA Greater Los Angeles Hlthcare Syst, Los Angeles, CA

**Abstract:** There are currently no effective treatments for traumatic brain injury (TBI) or posttraumatic Stress Disorder (PTSD). As a result, many combat veterans resort to self-treatment with cannabis. The principal components of cannabis include delta1-tetrahydro-cannabinol (THC) which binds to both of the endocannabinoid receptors, CB1 and CB2. CB1 receptors predominate in the central nervous system (CNS) while CB2 receptors are concentrated in immune cells. CB1 receptors are part of the endocannabinoid system which in the CNS provides feedback regulation of the glutamatergic neurons which are the predominant excitatory nerves. These neurons require retrograde feedback inhibition of electrical activity by the endocannabinoid, anandamide, and co-release of TRH and TRH-like peptides to protect against the neurotoxicity of glutamate.
We wish to know whether endogenous TRH and TRH-like peptides, which have potent antidepressant, anti-epileptic, anxiolytic, analeptic, neuroprotective and anti-aging properties, and lack undesirable psychotropic side effects, are downstream mediators of the therapeutic

actions of the exogenous cannabinoids, including THC, and endocannabinoids, such as anandamide. Male Sprague-Dawley rats were given methanandamide(MA) ip and decapitated at 0, 2, 4 and 6 h later. TRH and TRH-like peptides were then measured in 12 brain regions: Medulla oblongata (MED), cerebellum (CBL), piriform cortex (PIR), hippocampus (HC), nucleus accumbens (NA), striatum (STR), amygdala (AY), entorhinal cortex (ENT), frontal cortex (FCX), hypothalamus (HY), anterior cingulate (ACNG), posterior cingulate (PCNG) by a combination of HPLC and RIA. The predominant effect observed was a sustain decrease (↓) in TRH and/or TRH-like peptide levels throughout the brain during the 2-6 h interval following ip MA. For example, TRH and 5 TRH-like peptide levels in PIR fell by 2 h consistent with MA-induced release of these peptides. We abbreviate this result as PIR(6↓,2h). The corresponding changes at 4 and 6 h were PIR(8↓,4h) and PIR(8↓,6h). Result for the 2-6 h interval we summarize as PIR(22↓). The cumulative result for the other brain regions were CBL(17↓), STR(14↓,2↑), MED(13↓,2↑), HC(13↓,2↑), HY(7↓,8↑), AY(6↓,5↑), NA(10↓), ENT(9↓,1↑), FCX(1↓,5↑), ACNG(2↓,3↑), PCNG(3↓). MA can release TRH and TRH-like peptides throughout the endocannabinoid-responsive regions of rat brain. We conclude that these peptides may have therapeutic potential for the treatment of traumatic brain injury and posttraumatic stress disorder.

**Title:** A single administration of agmatine, similar to ketamine, reverses depressive-like behavior induced by chronic administration of corticosterone in mice

**Authors: *V. B. NEIS**[1], L. E. B. BETTIO[2,1], M. MORETTI[1], P. B. ROSA[1], G. OLESCOWICZ[1], D. B. FRAGA[1], F. M. GONÇALVES[1], A. E. FREITAS[1], I. A. HEINRICH[1], M. W. LOPES[1], R. B. LEAL[1], A. L. S. RODRIGUES[1]
[1]Federal Univ. of Santa Catarina, Florianopolis, Brazil; [2]Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

**Abstract:** Agmatine has been shown to exert antidepressant-like properties in several clinical and preclinical studies, and recent evidence has indicated that at least some of the mechanisms underlying its antidepressant effect are similar to ketamine. Therefore, the present study investigated the effects of a single administration of agmatine on the depressive-like behavior induced by chronic administration of corticosterone in mice, comparing its effects with those presented by fluoxetine and ketamine in the tail suspension test (TST) in mice. For this purpose, adult female Swiss mice were submitted to administration of corticosterone (20 mg/kg, p.o.) for 21 days. In the 21$^{st}$ day, mice received a single administration of agmatine (0.1 mg/kg, p.o.), fluoxetine (10 mg/kg, p.o.) or ketamine (1 mg/kg, i.p.), and were submitted to the tail suspension test (TST) and open-field test after 24 h. Mice were immediately euthanized after behavioral tests and the hippocampi dissected for Western blot analysis of synaptic proteins (i.e. GluA1, PSD-95 and synapsin I). It was demonstrated that chronic administration of corticosterone induced an increase in the immobility time in the TST, an effect reversed by a single administration of agmatine or ketamine, but not fluoxetine. None of the drugs, alone or in combination, produced significant effects in the locomotor activity of mice. Western blot analysis demonstrated a corticosterone-induced decrease in the immunocontent of synapsin I, an effect that was reversed only by fluoxetine. In addition, an increased immunocontent of GluA1 was observed in vehicle-treated mice that received a single administration of agmatine, ketamine or fluoxetine, but not in animals submitted to chronic corticosterone treatment. However, no alterations in GluA1 phosphorylation (at both Ser831 and Ser845 phosphorylation sites) and in the immunocontent of PSD-95 were observed in any experimental group. Altogether our results reinforce the hypothesis that agmatine may be a novel therapeutic strategy for the treatment of depression and suggest that this compound may have fast-acting antidepressant properties. Further studies are warranted to elucidate whether this compound is able to induce an increase in the levels of synaptic proteins at different time points.

**Title:** Impact of low-frequency repetitive transcranial magnetic stimulation (rTMS) to the lower part of the medial frontal cortex on behavioral activity, sociability and motivation in monkeys

**Authors: *S. NAKAMURA**, T. IIJIMA, K.-I. TSUTSUI
Div. Sys Neurosci, Grad Schl Life Sci, Tohoku Univ., Sendai, Japan

**Abstract:** The medial frontal cortex (MFC) has long been considered to be involved in emotional, social and motivational behavior. Particularly, the lower part of the ACC is of special interest because the abnormal functioning of this brain region has consistently been reported in patients with major depressive disorder. In this study, we examined how the change of activity in this part of the MFC affects monkey behavior by applying low-frequency repetitive transcranial magnetic stimulation (LF-rTMS). Two Japanese monkeys were used in this study. In order to evaluate their mood and emotional state, we measured their within-cage spontaneous activity. Furthermore, we introduced a modified version of the Brinkman board test, which is originally developed to test manual dexterity, to quantify their motivational level. The test required monkeys to grasp pieces of food placed in vertically and horizontally oriented slots on the board. The food pieces were randomly placed in 12 out of 50 slots per session. Two types of boards were used to change the difficulty of the test: one had narrow (difficult) and the other had wide (easy) slots. We let the monkeys perform multiple sessions until it spontaneously stopped performing. We quantified two parameters before and after the LF-rTMS treatment: the number of sessions the monkey performed and the average time the monkey spent to finish a single session. As the LF-rTMS, TMS pulses were continuously given for 20 min at 1 Hz (1200 pulses in total), which is considered to have an inhibitory effect on the stimulated brain region. The LF-rTMS targeting the anterior region of the MFC including the lower part of the ACC induced significant decrease in the within-cage spontaneous activity, which is accompanied by a drastic decrease in sociability and an increase in cortisol level. Moreover, we observed significant reduction of the number of sessions in the difficult condition, but not in the easy condition. In contrast, we did not observe those effects following sham stimulation, the LF-rTMS to the posterior region of the MFC, or the LF-rTMS to the superficial region of the anterior MFC. The average time consumption per session in the behavioral test did not change before and after the treatment in both difficulties in any target regions. These results indicate that the lower part of the ACC and the surrounding MFC may be critically involved in the emotional, social and motivational control.

**Abstract:** The extracellular matrix protein reelin is highly expressed in the adult hippocampus and is known to participate in the regulation of synaptogenesis, dendritic spine plasticity, learning and memory, and glutamatergic and GABAergic transmission. Previous work in our lab has demonstrated that repeated corticosterone (CORT) injections reduce hippocampal reelin levels, increase depression-like behavior, impair objection-location memory, and disrupts the balance between glutamatergic and GABAergic signaling. Here, we hypothesized that infusing reelin into the hippocampus of CORT-treated rats could reverse the behavioral deficits through a restoration of the balance between glutamate and GABA. To test this hypothesis, we examined the effect of repeated CORT injections and concurrent hippocampal infusions of reelin on object-location memory, forced-swim test (FST) behavior, GluA1, GluN2B, and $GABA_A$ immunohistochemistry. Rats underwent stereotaxic surgery to implant an indwelling cannula into the dorsal hippocampus, and received either 21 days of daily CORT injections (40 mg/kg) or vehicle injections. Rats also received infusions of reelin (1µl/ µg) on days 7, 14, and 21 (repeated reelin) or only on day 21 (acute reelin) of the CORT injections. Behavioral testing began on day 22. As expected, CORT increased depression-like behavior and impaired object-location memory. Importantly, these effects were reversed in rats treated with reelin either once or three times. CORT upregulated GluN2B immunoreactivity, and reelin infusions brought this down to control levels, whereas CORT decreased GluA1-ir cells, and infusions of reelin increased this to control levels. Finally, CORT decreased the number of $GABA_A$-ir cells, and infusions of reelin restored this to control levels. These novel results demonstrate that a single infusion of reelin into the dorsal hippocampus has fast acting antidepressant effects, which are accompanied by restoration of the balance between glutamate and GABA.

**Title:** Novel mechanisms contributing to the antidepressant-like effect of pharmacological hippocampal activation

**Authors: *F. R. CARRENO**[1,2], L. D. ARROYO[1], D. J. LODGE[1,2], A. FRAZER[1,3,2]
[1]Pharmacol., UT Hlth. San Antonio, San Antonio, TX; [2]Ctr. for Biomed. Neurosci., San Antonio, TX; [3]South Texas Veterans Hlth. Care Syst., San Antonio, TX

**Abstract:** We recently demonstrated that selective modulation of hippocampal transmission by systemic administration of an α5-containing-GABAA receptor negative allosteric modulator, namely L-655,708, is capable of producing a hippocampal-dependent sustained antidepressant (AD)-like effect in the absence of any psychotomimetic or abuse-related effects as seen with ketamine. Although the AD-like effect of ketamine is dependent on BDNF-TrkB signaling in the hippocampus, that of L-655,708 does not seem to be. L-655,708 did not cause an increase in the phosphorylation of TrkB in the ventral hippocampus (vHipp) 30 or 60 min after its administration nor did intra-hippocampal administration of TrkB inhibitor, K252a, block the sustained antidepressant-like effect of L-655,708. To begin to examine alternative molecular mechanisms associated with the effects of L-655,708, we took advantage of a PathScan approach, which consists of an array kit that allows for the simultaneous detection of proteins, including 28 receptor tyrosine kinases and 11 important signaling nodes when phosphorylated. Using such an approach, in rats given L-655,708 one hour prior to tissue collection, we not only confirmed that TrKB was not involved, but that other receptor tyrosine kinases were not either. Of all the downstream markers analyzed, only ERK activation was increased in the vHipp, as measured by its phosphorylation. We confirmed this result using western blot analysis from vHipp total lysate collected after L-655,708 administration. We hypothesized that the CamKII pathway could be involved in the ERK activation via voltage gated calcium channels activating CamKII in the vHipp. Using western blot analysis, CamKII phosphorylation in the vHipp was found to be increased following L-655,708 administration. By identifying the mechanisms by which systemic administration of α5-GABAA receptor negative allosteric modulators recapitulate the therapeutic effects of ketamine without its psychotomimetic and abuse-related

effects, it should be possible to provide novel, safe, and effective approaches for treating patients suffering from refractory depression.

**Abstract:** Depression is a high prevalent psychiatric disorder with severe socioeconomic consequences. Adult hippocampal neurogenesis has been shown to be reduced in depressive patients, and the behavioral responses to antidepressant drugs are associated with pro-neurogenic effects. However, current available antidepressants have serious limitations and efforts have been done to find some new strategies as alternative antidepressant therapy. In this context, emerges agmatine, an endogenous polyamine, that has been shown to exhibit antidepressant effects in preclinical and clinical studies. The present study investigated the antidepressant-like effect of chronic treatment with agmatine in an animal model of stress induced by chronic administration of corticosterone to mice, as well as its effects on hippocampal cell proliferation in the ventral and dorsal subregions of the subgranular zone (SGZ) of the dentate gyrus. Moreover, the dendritic complexity (length and arborization in the dentate gyrus of the hippocampus) in mice exposed to corticosterone and/or agmatine or fluoxetine was investigated by Sholl analysis. Chronic administration of corticosterone (20 mg/kg, p.o., 21 days) increased the immobility time in the tail suspension test (TST), an effect reversed by the co-administration of agmatine (0.1 mg/kg, p.o., 21 days) or fluoxetine (10 mg/kg, p.o., 21 days, positive control). Moreover, corticosterone administration induced a decreased hippocampal cell proliferation in the whole dentate gyrus as shown by the decreased number of Ki-67 and PCNA positive cells, as well as in

the ventral and dorsal aspects of the hippocampus (as shown by Ki-67 staining). Treatments with agmatine or fluoxetine were able to reverse these corticosterone-induced alterations on cell proliferation parameters. Agmatine and fluoxetine also enhanced both the dendritic length and arborization in the dentate gyrus of the hippocampus. Altogether, our results show that the increase in hippocampal proliferation induced by agmatine may contribute, at least in part, to the antidepressant-like response of this compound in this mouse model of stress induced by chronic exposure to corticosterone.

**Abstract:** Decrease in the activity of dorsal raphe nucleus (DRN) serotonergic neurons is implicated in various mental disorders. One of the main strategies for treating psychiatric disorders is to activate serotonergic system, while the precise action mechanisms of clinically used drugs, such as selective serotonin reuptake inhibitors (SSRIs), remain to be elucidated. It is widely accepted that raphe serotonergic neurons show tonic firing, while little is known how serotonergic neurons control their firing activity. In this study, we examined control mechanisms for serotonergic activity and effects of chronic treatment with an SSRI on serotonergic firing activity. By using modified *ex vivo* electrophysiological recording methods, DRN serotonergic neurons showed spontaneous tonic firing in drug-free condition. Furthermore, even in the absence of excitatory and inhibitory ionotropic inputs, serotonergic neurons still generate spontaneous action potentials. The spontaneous firing activity was positively and negatively modulated by bath application of activator and blocker, respectively, for L-type voltage-dependent $Ca^{2+}$ channel (VDCC). Blockage of $GABA_B$ receptor increased both VDCC current

and spontaneous activity of serotonergic neurons through PKA-dependent mechanism. Additionally, chronic administration of an SSRI, citalopram increased both VDCC current and spontaneous firing activity of serotonergic neurons. Either bath application of L-type VDCC blocker, $GABA_B$ receptor antagonist or PKA inhibitor blocked the increasing effects of citalopram on VDCC current and spontaneous firing activity. Taken together, these results suggest that the serotonergic spontaneous firing activity is maintained by L-type VDCC, which is continuously inhibited by $GABA_B$ receptor-mediated signaling, and that chronic citalopram disinhibits serotonergic neuronal activity by weakening the continuous GABA inhibition.

**Abstract:** Glycosylation, the addition of a carbohydrate moiety to a protein during biosynthesis, is a common post-translational modification involved in several disease states. Specific protein-glycan structures have been reported to be useful as biomarkers for cancer and some neuropsychiatric disorders; however, the relationship between glycosylation of plasma proteins

and major depressive disorder (MDD) has not been studied. This study aimed to determine whether the plasma protein-glycan structure would differ in MDD from typical values, using both a stress-based mouse model and samples from patients with MDD. As a mouse model of depression and remission, we used chronically ultra-mildly stressed mice that were not treated or treated with imipramine, respectively. We also made comparisons between samples from patients with MDD who were actively depressed and those who were remitted. Protein glycosylation was analyzed using a lectin microarray that included 45 lectins with binding affinities for various glycan structures. The glycan structure profile of plasma proteins might represent candidate biomarkers for MDD.

**Abstract:** Introduction: Bilateral dorsomedial prefrontal cortex (DMPFC) rTMS has previously been used in open-label settings for a variety of psychiatric disorders, including treatment-resistant depression (TRD). However, its clinical efficacy is heterogeneous, and requires testing under placebo-controlled conditions. The aim of this study is to assess the efficacy of two protocols for DMPFC-rTMS in TRD against sham stimulation, and identify neuroimaging, psychometric or behavioral predictors of treatment response. Here we report preliminary results of the first 30 subjects enrolled. Methods: rTMS-naive TRD patients between 18-65 years were enrolled and randomized to one of three treatment arms: 1 Hz active, 20 Hz active, or sham rTMS to the bilateral DMPFC. All treatments were performed with a custom MagStim active-placebo coil to allow blinding of both patients and technicians. Treatments occurred twice daily for a total of 30 sessions. Patients completed the Beck Depression Inventory (BDI), at baseline, weekly throughout treatment, and at follow-up. A repeated-measures ANOVA was performed to

determine the effects of treatment group on severity. Patients also undergo an anatomical T1 and 10-minute resting-state fMRI, as well as a suite of psychometric scales (NEO Personality Inventory; impulsivity scales [BIS/BAS; BIS-11; UPPS-P; Monetary Choice Questionnaire]; emotion regulation scales [DERS]; and the Rumination Responses Scale), and a behavioral measure (Probabilistic Reward Task). Neuroimaging, psychometric and behavioral measures will be used to identify predictors of clinical response to dmPFC-rTMS. Results: To date, 30 participants (n=20 females, range 19-58 years) have completed treatment. We found a trend in the interaction between BDI severity and treatment arm (F=1.516, p=0.164), and a significant main effect of time on BDI (F=9.105, p=0.007). Both Group A (n=11) (p=0.021) and Group B (n=11) improved significantly (p=0.026). Group C (n=8), however, had a non-significant reduction on BDI (p=0.421). Discussion: Although preliminary, it appears that two treatment arms (treatment arms A and B) achieve a significant reduction of depressive symptoms relative to treatment arm C. Further work will enrol more patients in this study to confirm the effects of DMPFC-rTMS in TRD. As indicated above, we are collecting a battery of psychometric, behavioural and neuroimaging measures to identify predictors of treatment response and measures that change in association with treatment response. Additionally, we are also collecting a cohort of healthy individuals to use as a comparator group for our TRD patients.

**Title:** Reduced serum and cerebrospinal fluid levels of autotaxin in major depressive disorder

**Authors: K. ITAGAKI**[1], H. ABE[1], C. SHIBASAKI[2], W. OMORI[1], N. KAJITANI[1], M. OKADA-TSUCHIOKA[1], K. HATTORI[3], S. YOSHIDA[3], H. KUNUGI[3], *M. TAKEBAYASHI[1]
[1]Natl. Hosp Org Kure Med. Centr, Kure, Hiroshima, Japan; [2]Hiroshima Univ., Hiroshima, Japan; [3]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

**Abstract:** [Background] Autotaxin (ATX) is a major enzyme that is secreted to generate lysophosphatidic acid (LPA) which has diverse biological effects on neurodevelopment, the immune system, and inflammation. We previously reported the possible involvement of LPA1

receptor in the action of antidepressants (Kajitani et al., JBC 2016). However, the possible association between the ATX/LPA axis and the pathophysiology of major depressive disorder (MDD) remains to be elucidated. [Methods] Serum levels of ATX were measured in patients with MDD (N = 37) who underwent electroconvulsive therapy (ECT), and compared with those of healthy controls (N = 53). Serum levels of ATX before and after a course of ECT were then compared in the patients. In another sample set without ECT treatment, cerebrospinal fluid (CSF) levels of ATX were examined between patients with MDD (N = 26) and healthy controls (N = 27). An analysis was also conducted to determine whether there was an association between serum and CSF levels of ATX and clinical symptoms using the Hamilton Depression Rating Scale score. Serum and CSF ATX concentrations were measured by ELISA. Effects of antidepressants on ATX expression were investigated using rat brain samples. The ethics committees of NHO Kure Medical Center and the National Center of Neurology and Psychiatry approved the study protocol. All participants provided written consent. [Results] In the total subjects, both serum and CSF ATX levels for females were significantly higher than those of males ($P < .001$, $P = .006$, respectively), which indicates a gender difference for ATX. Prior to ECT, both serum and CSF ATX levels with MDD were significantly lower than those of healthy controls ($P = .001$, $P = .028$, respectively). After ECT, serum ATX levels in MDD were significantly increased ($P = .001$). There was a significant negative correlation between depressive symptoms and serum ATX levels in MDD at Pre-ECT and Post-ECT. Chronic antidepressant treatment did not change any mRNA and protein levels of ATX in rat hippocampus. [Conclusion] Both serum and CSF levels of ATX were significantly decreased in MDD patients, and serum ATX levels were increased following a course of ECT, which indicates a state-dependent manner. Antidepressants appear not to be directly associated with ATX expression. Our findings suggest that alteration of lysophospholipids such as the ATX/LPA axis could be related to the pathophysiology of MDD.

**Title:** Dynamic relationship between α-tubulin acetylation and $G\alpha_s$ localization in lipid-rafts: Potential basis of depression and antidepressant mechanism of HDAC6 inhibitors

**Authors:** *H. SINGH[1], ***H. SINGH**[1], J. SCHAPPI[1], *G. PANDEY[2], M. M. RASENICK[3]
[1]Physiol. and Biophysics, [2]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [3]Physiol. and Biophysics, Univ. of Illinois at Chicago Col. of Med., Chicago, IL

**Abstract:** Major depressive disorder (MDD) is a debilitating illness lacking clear molecular and cellular correlates as well as consistently effective treatments. Several studies have demonstrated that sustained antidepressant treatment moves $G\alpha_s$ out of lipid rafts, where it appears associated with tubulin. Histone deacetylase-6 (HDAC-6) enzymes deacetylate α-tubulin and are upregulated in neuropsychiatric disorders. HDAC6 knockout or HDAC6 inhibitors also displayed an antidepressant profile in animal models. While, a possible role for HDAC6 inhibitors in treatment of depression exists, the potential mechanism for this remains elusive. Previously, we demonstrated that treatment of rats or C6 glioma cells with several classes of antidepressants translocates $G\alpha_s$, from lipid-rafts, inducing a sustained elevation in cAMP production. Once freed from lipid-raft domains, $G\alpha_s$, couples more effectively with adenylyl cyclase-6 (AC6). Although $G\alpha_s$ interacts directly with tubulin to modify microtubule dynamics, tubulin also acts as an anchor for $G\alpha_s$ in lipid-rafts. Based on HDAC-6 roles in tubulin deacetylation and our data showing $G\alpha_s$ complexes with tubulin in lipid-rafts, we hypothesized that acetylation of α-tubulin disrupts tubulin-$G\alpha_s$ anchoring, rendering $G\alpha_s$ free to activate AC6. To test this, C6 glial cells were treated with the HDAC-6 inhibitor, tubastatin-A. Three-day treatment not only increased acetylation of α-tubulin but also caused translocation of $G\alpha_s$ out of lipid-rafts. Reciprocally, depletion of α-tubulin acetyl transferase-1 (ATAT-1), ablated this phenomenon. Fluorescence Recovery After Photobleaching (FRAP) on C6 cells stably expressing GFP-$G\alpha_s$, after tubastatin-A treatment showed an “antidepressant signature”. Finally, tubastatin-induced sustained elevation of cAMP was revealed by increased cAMP response element binding protein (CREB) phosphorylation and increased expression of brain derived neurotrophic factor (BDNF). Also, an increase in acetylated α-tubulin prevented the formation of tubulin-$G\alpha_s$-complexes in lipid rafts. Although other classes of antidepressants also reduced the association between tubulin and $G\alpha_s$, they had no effect on the acetylation of tubulin. Postmortem human brain tissue analysis revealed decreased membrane tubulin acetylation in subjects with depression even as the total acetylated tubulin content was comparable in depressed and control subjects. Thus, it is possible that compounds that decrease tubulin-$G\alpha_s$ interactions by increasing acetylation of α-tubulin may show promise for antidepressant therapy.

**Title:** Several antidepressants increase expression and activity of fatty acid desaturases

**Authors: N. WRAY**[1], *M. M. RASENICK[2]
[1]Physiol. and Biophysics, U. Illinois Chicago Col. of Med., Chicago, IL; [2]Dept Physiol, Biophysics, Univ. of Illinois at Chicago Col. of Med., Chicago, IL

**Abstract:** We have demonstrated that all classes of antidepressants translocate $G\alpha_s$ from plasma membrane lipid raft domains to non-raft domains, where $G\alpha_s$ is more likely to couple with its second effector adenylyl cyclase. This phenomenon has been demonstrated in both rats and cultured neural or glial cells, and cells respond to drug treatment within 3 days (15 minutes for ketamine). These drugs also accumulate, slowly, in lipid rafts. We have also shown that in post-mortem brain tissue from depressed subjects $G\alpha_s$ is localized in lipid rafts. These data are consistent with a clinically relevant /non-canonical action of antidepressants. One extant question concerns the possibility that some genetic program is elicited as a response of antidepressant treatment. To test this, we carried out an RNA sequencing study analyzing changes in mRNA expression. After three days escitalopram or imipramine treatment of primary rat astrocytes, fatty acid desaturase 1 (FADS1), fatty acid desaturase 2 (FADS2) and Stearoyl-CoA desaturase-1 (SCD1), showed significant increases. Western blotting confirmed increased protein expression levels of all desaturating enzymes in C6 glioma cells after three days treatment of escitalopram, imipramine, and phenelzine. Matrix-assisted laser desorption/ionization (MALDI) mass spec analysis of the plasma membrane derived from C6 cells revealed an antidepressant-induced increase in wide array of polyunsaturated fatty acids (PUFAs). Furthermore, probing for membrane fluidity using laurdan indicates an overall increase in membrane fluidity reflecting an increase in PUFAs present in the plasma membrane of antidepressant treated C6 cells. These changes in the plasma membrane may be responsible for the redistribution of $G\alpha_s$ to non-raft

micro-domains after antidepressant treatment and are consistent with antidepressant effects of n-3 PUFA.

**Title:** Adenylyl cyclase VI is required for SERT-independent antidepressant effects in glial cells: A potential screen for novel antidepressants

**Authors: *J. SCHAPPI**[1], A. H. CZYSZ[2], S. J. ERB[3], M. M. RASENICK[4]
[1]Physiol. & Biophysics, Univ. of Illinois At Chicago, Chicago, IL; [2]Psychiatry, Univ. of Texas, Dallas, Dallas, TX; [3]Pharmacol., Univ. of Minnesota Twin Cities, Minneapolis, MN; [4]Dept Physiol, Biophysics, Univ. of Illinois at Chicago Col. of Med., Chicago, IL

**Abstract:** Depression is a major public health problem and antidepressants are in widespread use throughout the world. Despite decades of investigation, the molecular mechanism for their action is unknown. Especially confusing is the long lag period (6-8 weeks) between the initiation of therapy and clinical effect. Antidepressants of different chemical classes promote sustained increases in cAMP, due, at least in part to the redistribution of $G_{\alpha}s$ from lipid rafts into non-raft membrane fractions resulting in increased $G\alpha_s$ functional coupling with adenylyl cyclase (AC). This has been demonstrated in both rats and cultured neural and glial cells by a number of techniques, including cell fractionation, functional assays, and imaging studies such as Fluorescence Recovery After Photobleaching (FRAP). Although monoamine transporters have been assumed to be a target for many antidepressants, C6 cells lack these, yet still show a "signature" antidepressant response. Furthermore, while these neural and glial cells showed an "antidepressant response", kidney epithelial cells like COS7 and HEK293 (or kidney and liver from rat) were unchanged by antidepressant treatment. In this study we sought to determine whether cellular antidepressant response, with respect to increased cAMP signaling and $G\alpha_s$ localization, is dependent on the type of AC isoform expression. Cell lines "insensitive" to

antidepressant treatment, such as HEK293, become responsive after transfection with AC6 (but not AC2 or AC3), showing translocation of $G\alpha_s$ from lipid rafts, both by cell fractionation and by FRAP. Thus, it is suggested that AC6 performs an anchoring function for $G\alpha_s$ outside of rafts, affixing the translocated $G\alpha_s$ into the non-raft domain, or perhaps even creates an antidepressant binding site, facilitating an antidepressant-induced increase in adenylyl cyclase activity.

**Title:** Antidepressant drug signalling through $LPA_1$ in human fibroblasts

**Authors: *P. ONALI**, S. DEDONI, M. C. OLIANAS
Univ. of Cagliari, Dept.Biomedical Sci., Monserrato, Italy

**Abstract:** Lysophosphatidic acid (LPA) is a major regulator of fibroblast function and drugs that block LPA receptors have been proposed to be effective agents in controlling abnormal fibroblast activity in distinct fibrotic diseases. We have recently reported that in Chinese hamster ovary fibroblasts different classes of antidepressants stimulate intracellular signalling by activating endogenous $LPA_1$, thus providing the first evidence that this receptor is a molecular target of certain antidepressants. We have also shown that these drugs activate the human $LPA_1$ over-expressed in HEK-293 cells. However, whether antidepressants are capable to signal through the human $LPA_1$ expressed and operative under native conditions remains unknown. In the present study we examined the effects of tricyclic and tetracyclic antidepressants on ERK1/2 signalling and DNA synthesis in cultured human dermal fibroblasts. We found that in these cells LPA potently induced ERK1/2 phosphorylation and stimulated [$^3$H]-thymidine incorporation into DNA. These effects were mimicked by the antidepressants amitriptyline, clomipramine and

mianserin. AM966, a selective $LPA_1$ antagonist, and Ki16425, a $LPA_{1/3}$ blocker, antagonized LPA stimulation of ERK1/2 phosphorylation in a concentration-dependent manner with nanomolar potencies. Blockade of $LPA_1$ also prevented the stimulatory effects of amitriptyline and mianserin on ERK1/2 phosphorylation and DNA synthesis. These data demonstrate for the first time that different antidepressants can act through the human $LPA_1$ expressed in fibroblasts to induce ERK1/2 activation and mitogenesis.

**Abstract:** Identifying reliable neural biomarkers that are predictive of mood dynamics in an individual is important both for personalized treatment of mood disorders and for understanding the neural processes underlying mood regulation. Here, based on semi-chronic, high-resolution, multi-site ECoG recordings obtained from epilepsy patients and simultaneous self-reports of mood (Immediate Mood Scaler), we identify network-level neural biomarkers that are predictive of mood dynamics over time in individual patients. To identify the biomarker, we first use a data-driven linear state-space modelling framework to describe neural network dynamics. Fitting the state-space model using neural features extracted from ECoG recordings, we find that a low-dimensional neural state is sufficient to describe the dynamics of large-scale ECoG. We estimate this low-dimensional neural state in real time using a Kalman filter. We then build a regression model that predicts mood variations over time from the estimated low-dimensional neural state. We find that using network ECoG activity and our modelling framework, we can decode mood variations over time in individual subjects. We further use the identified dynamical models to characterize the spatial and temporal characteristics of the mood biomarkers. Our analyses reveal subnetworks in the limbic system that are highly predictive of an individual's mood variations over time. We also identify the time-scales of these mood biomarkers. These dynamical mood biomarkers and mood decoding algorithms can provide insight into brain processes underlying

mood regulation and also enable the development of personalized stimulation therapies for depression based on feedback of the estimated mood.

**Abstract:** Modeling the effects of electrical stimulation on brain network dynamics plays a key role in developing automatic closed-loop stimulation therapies for neurological disorders such as depression. Our prior work has proposed to use a multivariate linear state-space model (LSSM) to describe brain network dynamics in response to stimulation input (input-output model). In addition, we have designed a binary noise (BN) modulated electrical stimulation pattern---a pulse train modulated by stochastic BN parameters such as pulse frequency and amplitude---to collect optimal input-output datasets for model identification. Here, we develop and validate the input-output brain network model by performing stimulation experiments in epilepsy patients. In these experiments, we apply the BN-modulated electrical stimulation pattern and concurrently record the high-dimensional electrocorticography (ECoG) response. As the input in our models, we use the pulse frequency and amplitude. As the output in our models, we use ECoG power features. We use a template-subtraction artifact removal algorithm to remove stimulation artifacts from ECoG activity during stimulation. Based on the collected input BN stimulation and output ECoG datasets, we fit a LSSM. We first evaluate how well the fitted model predicts the dynamic response of ECoG features. To do this, we use the fitted model to feed-forward predict the evolution of neural features in response to BN stimulation. We compare the predicted evolution to the observed evolution. Further, we evaluate how well the model predicts the steady-state neural response by performing a separate continuous stimulation experiment on the same patient. In this continuous stimulation experiment, we stimulate from the same location with pulse trains of fixed amplitudes. We then compare the observed continuous stimulation response to the steady-state response predicted by the LSSM. We find that the identified LSSM from BN stimulation experiments 1) achieved good prediction of the neural dynamics in cross

validation and 2) was significantly predictive of the steady-state responses measured in the continuous stimulation experiments. We also find that both stimulation pulse frequency and amplitude play important roles in regulating the output neural responses. Our results provide insight into the effect of electrical stimulation on human ECoG dynamics, and have important implications for devising novel model-based closed-loop therapies for treatment of various neuropsychiatric disorders.

**Title:** CA1 and dentate gyrus synaptic transmission and plasticity after physical exercise in an animal model for depression

**Authors: E. DAHLIN**, E. HANSE, *H. SETH
Univ. of Gothenburg, Gothenburg, Sweden

**Abstract:** Physical exercise has long been regarded as beneficial for wellbeing, physical as well as mental. However, it is not until more recently that detailed studies on the effects of physical exercise has been conducted. Among the beneficial effects, physical exercise has proven to be anti-depressant and is now prescribed by medical doctors in several countries. The mechanisms behind the anti-depressive effect are, however, not well known.
Several reports indicate an altered hippocampal function in depressed humans as well as in animal models. For example, depression is associated with a decreased synaptogenesis and neurogenesis in hippocampus leading to reductions in synaptic transmission and plasticity, most strikingly CA3-CA1 and dentate gyrus long-term potentiation (LTP).
Importantly, it is also known that running increases neurogenesis and facilitates LTP in the dentate gyrus. Therefore, it is not surprising that cognitive functions associated with hippocampus-dependent tasks are restored when some patients with depression are exercising. However, a detailed study of the events that leads to a restored cognitive function after physical exercise in an animal model for depression is lacking. We examine this by extracellular field recordings to study baseline synaptic transmission and plasticity at Schaffer collateral CA3 to radiatum CA1 synapses as well as medial perforant path to dentate gyrus synapses in an animal model for depression.
We used two age groups of male Wistar rats, P30-P40 or P60-P70, from either dexamethasone or saline treated dams. Dexamethasone (150ug/kg) or saline was injected daily for five consecutive days during the last trimester to create offspring with a depressive-like phenotype. Animals at

P30 or P60 were then allowed to run voluntarily for 10 days prior to electrophysiological recordings. Hippocampal samples are also stored to allowed analysis of proliferation and neurogenesis in the dentate gyrus. Later experiments will include patch-clamp recordings of evoked current in immature as well as mature neurons.
Experiments are ongoing but preliminary data show a limited effect of running on synaptic transmission and plasticity in exercising young P30 control anoimals. Whether this holds true also in older or depressed rats are under investigation. A longer running regime might also be needed in order to reveal the true effects of exercise on cognition.

**Title:** Altered expression of long, noncoding RNAs in patients with major depression

**Authors: *T. SEKI**, H. YAMAGATA, S. UCHIDA, K. HARADA, K. MATSUO, Y. WATANABE
Yamaguchi Univ. Sch. of Med., Ube Yamaguchi, Japan

**Abstract:** Although depression is the leading cause of disability worldwide, its pathophysiology is poorly understood. There is growing evidence suggesting that aberrant transcription regulation play an important role in the pathophysiology of depression. Although long noncoding RNAs (lncRNAs) have important functions in chromatin structure, gene expression, and the subsequent manifestation of various biological processes in the central nervous system, it is still unclear whether the aberrant expression of lncRNAs is associated with the pathophysiology of major depressive disorder (MDD). We therefore examined the expression of lncRNAs in peripheral blood leukocytes as predictive biomarkers for MDD. The study sample included 39 patients with MDD under a current depressive state and 40 healthy subjects, who were matched for age and sex. This study was approved by the Institutional Review Board of Yamaguchi University Hospital. Written informed consent was obtained from all participants after providing them with a complete description of the study. We measured the expression levels of 84 lncRNAs in the peripheral blood leukocytes of patients with MDD and healthy subjects using a quantitative real-time PCR analysis. We found that patients with MDD exhibited distinct expression signatures.

Several lncRNAs were differentially expressed in patients with MDD versus healthy subjects. Thus our data suggest that peripheral lncRNAs may serve as potential biomarkers for MDD. The study also suggests the contribution of lncRNAs in the pathophysiology of MDD. Further study would be necessary to clarify the role of lncRNAs in an animal model of depression.

Genome Ctr., [7]Dept. of Psychiatry, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

**Abstract:** Although inflammatory cytokines are established biomarkers of mood disorders, their molecular mechanism is not known. We hypothesized that circulating mitochondrial DNA (mtDNA) contributes to inflammation and could be used as biomarkers. We investigated if circulating mtDNA level is associated with inflammatory cytokines and can be used as a biomarker of mood disorders. This study was approved by the ethics committees of Hannan Hospital, Osaka City University, Kansai Medical University, RIKEN, and National Center of Neurology and Psychiatry and conducted in accordance with the Declaration of Helsinki. Plasma mtDNA level was measured with real-time quantitative PCR targeting two regions of the mtDNA and plasma level of four cytokines (GM-CSF, IL-2, IL-4, and IL-6) were measured with a multiplex immunoassay method in 109 patients with major depressive disorder (MDD). The most significantly correlated cytokine was verified with an enzyme-linked immunosorbent assay

(ELISA). The data from 28 patients with bipolar disorder (BD), 17 patients with schizophrenia, and 29 healthy controls were compared. MtDNA levels showed a nominal positive correlation with GM-CSF, IL-2, and IL-4 in patients with MDD. The most significant correlation with IL-4 ($\rho$ = 0.38, $P$ < 0.00005) was verified with an ELISA ($\rho$ = 0.19, $P$ = 0.0049). Unexpectedly, patients with MDD and BD showed significantly lower plasma mtDNA levels than controls. MtDNA levels were lower in the depressive state than in the remitted state in patients with MDD. Plasma mtDNA is reportedly affected by exercise (Lim *el al*., 2000) possibly due to the release from muscles. Thus, decreased physical activity during the depressive state could decrease the circulating mtDNA. In this regard, plasma mtDNA might be a candidate biomarker reflecting psychomotor retardation.

**Title:** Alterations in the amino acids in the mouse brain regions after adjunctive treatment of brexpiprazole with fluoxetine: Comparison with (R)-ketamine

**Authors: *Q. REN**[1], M. MA[1], Y. FUJITA[1], C. YANG[1], C. DONG[1], Y. OHGI[2], T. FUTAMURA[2], K. HASHIMOTO[1]
[1]Chiba Univ. Ctr. Forensic Mental Hlth., Chiba, Japan; [2]Otsuka Pharmaceut. Co., Ltd., Tokushima, Japan

**Abstract:** Brexpiprazole, a serotonin-dopamine activity modulator, is approved in the USA as an adjunctive therapy to antidepressants for the treatment of major depressive disorder (MDD). Similar to the *N*-methyl-D-aspartate receptor (NMDAR) antagonist ketamine, the combination of brexipiprazole and fluoxetine has shown antidepressant-like effects in animal models of depression. The present study was undertaken to examine whether the combination of brexpiprazole and fluoxetine could affect tissue levels of amino acids (glutamate, glutamine, GABA, D-serine, L-serine, glycine) related with NMDAR neurotransmission. A single injection of the combination of fluoxetine and brexpiprazole significantly increased GABA levels in the

striatum, and it significantly increased the D-serine/L-serine ratio in the frontal cortex and glycine/L-serine ratio in the hippocampus. Repeated administration of combination of two drugs significantly altered tissue levels of amino acids in the all regions. Interestingly, repeated administration of combination of two drugs significantly decreased D-serine/L-serine ratio in the frontal cortex striatum and hippocampus. In contrast, a single administration of (*R*)-ketamine significantly increased D-serine/L-serine ratio in the frontal cortex. In conclusion, these results suggest that alterations in these amino acids may be involved in the antidepressant-like effects of the combination of brexpiprazole and fluoxetine.

**Abstract:** Brexpiprazole, a serotonin-dopamine activity modulator, is approved in the USA as an adjunctive therapy to antidepressants for the treatment of major depressive disorder (MDD). Addition of low doses of the atypical antipsychotic drug brexpiprazole with selective serotonin reuptake inhibitors (SSRIs) could promote antidepressant effect in patients with MDD although

the precise mechanisms underlying the action of the combination are unknown. Combination of low dose of brexpiprazole (0.1 mg/kg) and SSRI fluoxetine (10 mg/kg) could promote a rapid antidepressant effect in social defeat stress model although brexpiprazole or fluoxetine alone did not show antidepressant effect. Furthermore, the combination of brexpiprazole and fluoxetine significantly improved alterations in the brain-derived neurotrophic factor (BDNF) - TrkB signaling and dendritic spine density in the prefrontal cortex, hippocampus, and nucleus accumbens in the susceptible mice after social defeat stress. Interestingly, TrkB antagonist ANA-12 significantly blocked beneficial effects of combination of brexpiprazole and fluoxetine on depression-like phenotype. These results suggest that BDNF-TrkB signaling plays a role in the rapid antidepressant action of the combination of brexpiprazole and fluoxetine.

**Title:** Identification of lysophosphatidic acid receptor 1 in astrocytes as a target for glial cell line-derived neurotrophic factor expression induced by antidepressants

**Authors: *N. KAJITANI**[1], K. MIYANO[3], M. OKADA-TSUCHIOKA[1], H. ABE[1], W. OMORI[1,2], K. ITAGAKI[1,2], Y. UEZONO[3,4], M. TAKEBAYASHI[1,2]
[1]Div. of Psychiatry and Neuroscience, Inst. for Clin. Res., [2]Dept. of Psychiatry, NHO Kure Med. Ctr. and Chugoku Cancer Ctr., Hiroshima, Japan; [3]Div. of Cancer Pathophysiology, Natl. Cancer Ctr. Res. Inst., Tokyo, Japan; [4]Div. of Supportive Care Research, Exploratory Oncology Res. & Clin. Trial Ctr., Natl. Cancer Ctr., Tokyo, Japan

**Abstract:** [Background] Preclinical and clinical evidence suggests that glial cell line-derived neurotrophic factor (GDNF) is important in the therapeutic effect of antidepressants. A previous study demonstrated that the tricyclic antidepressant amitriptyline induces Gi/o activation, which leads to GDNF expression in astrocytes. However, the specific target expressed in astrocytes that mediates the antidepressant-evoked Gi/o activation has yet to be identified. Thus, the current study examined the possibility that antidepressant-induced Gi/o activation depends on

lysophosphatidic acid receptor 1 (LPAR1), a Gi/o-coupled receptor. [Method] Rat C6 astroglial cells (C6 cells), primary cultured astrocytes, and primary cultured neurons were used in the following experiments. GDNF mRNA expression was examined using real-time PCR, Gi/o activation was examined using the cell-based receptor assay system CellKey™, and intracellular signaling cascades were examined using immunoblotting. [Results] AM966 (a selective LPAR1 antagonist) and Ki16425 (a selective LPAR1/3 antagonist), but not H2L5186303 (a selective LPAR2 antagonist), blocked GDNF mRNA expression and Gi/o activation evoked by various classes of antidepressants (amitriptyline, nortriptyline, mianserin, and fluoxetine) in C6 cells. In addition, deletion of LPAR1 by RNAi suppressed amitriptyline-evoked GDNF mRNA expression. Treatment of astroglial cells with the endogenous LPAR agonist LPA increased GDNF mRNA expression and GDNF protein release through LPAR1, whereas treatment of primary cultured neurons with LPA failed to affect the GDNF mRNA expression. The potential involvement of the transactivation cascade (FGFR, FRS2α and ERK1/2) related to GDNF expression in LPAR1-mediated signaling was examined. Pertussis toxin (a specific Gi/o inhibitor), SU5402 (an FGFR inhibitor), or U0126 (a MEK/ERK inhibitor) completely blocked LPA-evoked GDNF mRNA expression in C6 cells. Amitriptyline-induced phosphorylation of ERK1/2 and phosphorylation of FRS2α, a surrogate of FGFR activation, were significantly inhibited by AM966 and Ki16425, but not H2L5186303. LPA-induced phosphorylation of both ERK1/2 and FRS2α were also significantly inhibited by AM966 and Ki16425. [Conclusion] The current data are the first to clearly demonstrate that Gi/o-coupled LPAR1 in astrocytes mediates GDNF expression evoked by various antidepressants. It is suggested that LPAR1 is a novel, specific target of antidepressants which leads to GDNF expression in astrocytes.

**Title:** Inhibition of cytokine-induced intracellular signalling and neuronal cell death by antidepressants acting through $LPA_1$

**Authors: *M. C. OLIANAS**, S. DEDONI, P. ONALI
Biomed. Sciences, Sect. Neurosci., Univ. of Cagliari, Monserrato, Italy

**Abstract:** Pre-clinical and clinical studies have suggested that pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1a, IL-6 and interferons (IFN), play a role in the pathogenesis of major depression. A cellular mechanism by which these cytokines may exert a depressogenic effect is the impairment of hippocampal neural progenitor cell development and survival. However, how antidepressants can counteract the neurotoxic effects of pro-inflammatory cytokines is still not completely understood. We have recently discovered that distinct classes of antidepressants act through the lysophosphatidic acid (LPA) receptor $LPA_1$ to trigger growth factor receptor transactivation, cell proliferation and protection of glial cells from oxidative stress. In the present study we report that in mouse HT22 immortalized hippocampal cells, a neuroblast-like cell line, TNF-α-induced apoptotic cell death is inhibited by the tetracyclic antidepressants mianserin and mirtazapine and that this protection is mediated by $LPA_1$. TNF-α (10 ng/ml) enhanced the activity of caspases 8, 7 and 3, induced the cleavage of poly ADP-ribose polymerase (PARP) and increased DNA fragmentation. Cell exposure to either mouse IL-1a, IFN-β, IFN-γ or IL-6 failed to affect per se PARP cleavage, but enhanced the stimulatory effect of TNF-α, indicating the occurrence of a synergistic interaction between the cytokines in inducing apoptosis. Pre-treatment with the antidepressants failed to affect the stimulation of caspase 8 by TNF-α but markedly inhibited the induction of cytochrome c release from mitochondria, the activation of caspases 9 and 3, the stimulation of PARP cleavage, and the increase of DNA fragmentation elicited by the cytokine. Mianserin also counteracted the enhanced apoptotic response triggered by TNFα in association with either IL-1a or IFN-β. Pharmacological blockade of $LPA_1$ with the selective antagonist AM966 inhibited the anti-apoptotic effects of the antidepressants. These data show for the first time that certain antidepressants protect neuronal cells from cytokine-induced apoptotic cell death through activation of $LPA_1$.

**Abstract:** Deep Brain Stimulation (DBS) of the subgenual cingulated cortex (SCC) is an innovative therapeutic approach that has reported promising results in resistant major depressive patients. Preclinical studies using DBS of the ventromedial prefrontal cortex (vmPFC), the rodent correlate to human SCC, demonstrated its antidepressant effect along with consistent changes in the activity of locus coeruleus (LC)-noradrenergic system and in the rhythm of pontine-cortical network oscillations. Given LC-noradrenergic system is modified after stressful conditions and by antidepressants treatment, the aim of this study was to evaluate the effect of vmPFC DBS on stress-induced changes in electrical activity of LC neurons in unanaesthetized rats. For this purpose, the tonic and auditory-evoked activity of LC neurons were recorded before and after acute social stress exposition in control and vmPFC DBS treated rats.The results showed a robust inhibitory effect of DBS on tonic discharge rate of LC neurons after social stress, in contrast to the increased firing rate observed in control animals. Auditory stimulation generated an evoked response that was reduced after social stress in control and DBS rats, measured as lower number of evoked spikes discharged. However, the duration of the evoked response was significantly shorter in control animals after social stress than before stress exposition. By contrast, the duration of the evoked response in DBS animals remained similar after and before social stress exposure. Interestingly, stress tended to reduce the signal to noise ratio but DBS enhanced it.These results suggest that DBS promotes an inhibitory mechanism on LC induced by stress, inhibiting the tonic activity of LC neurons that might represent the more rapid LC-noradrenergic system recovery after stress. Furthermore, the modifications of vmPFC DBS on stress-induced changes on LC activity pattern might be to lead an optimal behavioral state as a strategy to combat stress. **Abstract:** Ketamine at sub-anesthetic doses has shown promising results as a potent and fast-acting antidepressant. Evidence from animal model studies suggests that the functional restoration by ketamine is associated with activation of MAPK and mTOR signaling cascades in the prefrontal cortex (PFC) within a few hours of ketamine administration, followed by a second wave of synaptic protein upregulation. Together, these molecular events lead to rapid synaptogenesis and reversal of neural atrophy. Furthermore, (2*R*, 6*R*)-hydroxynorketamine (HNK) has recently been identified as the main active component of ketamine metabolism. HNK is believed to be responsible for the antidepressant actions of ketamine, but with minimal side effects, and potentially through NMDAR-independent mechanism of action. However, critical gaps exist in understanding the exact molecular mechanisms of ketamine actions. Thus, it would be of great importance and interest to delineate the molecular mechanisms that translate mTOR activation into synaptogenesis-based structural remodeling. Cofilin and its upstream pathways, ideally positioned to bridge the gap between mTOR activation and spine formation, have emerged from an unbiased kinome/phosphoproteome screening for targets of ketamine treatment. As the major cytoskeletal component of dendritic spines, actin controls spine morphology and formation through changes in its polymerization state. Actin polymerization is negatively regulated by activation of cofilin protein. Further studies are currently underway to address the significance of cofilin phosphorylation and actin polymerization in synaptic potentiation induced by ketamine and HNK.

**Title:** Methylome profiling of young adults with depression supports link with immune response

**Authors: *C. R. LAPSLEY**[1], R. IRWIN[2], M. MCLAFFERTY[3], S.-J. THURSBY[2], S. O'NEILL[3], A. BJOURSON[1], C. WALSH[2], E. MURRAY[1]
[1]Northern Ireland Ctr. for Stratified Med., Ulster Univ., Derry, United Kingdom; [2]Biomed. Sci., Ulster Univ., Coleraine, United Kingdom; [3]Sch. of Psychology, Ulster Univ., Derry, United Kingdom

**Abstract:** Depression is the leading cause of global disability, affecting over 300 million people of all ages worldwide, with alarming rates of psychopathology recently identified among young people. Mental health problems typically develop in adolescence, and suicide is the second leading cause of death in young people aged 5-24. Despite its prevalence, the biology of depression and risk factors for suicide are poorly understood, hence there is a critical need to develop biomarkers that can be used to assist in diagnosis and identify individuals at risk. Genetic and environmental factors have been linked to increased risk for depression and suicide and their interaction may lead to development of mental illness. The aim of this study was to compare the DNA methylome of individuals with depression and matched controls to determine differences in methylation associated with the disorder. Participants recruited to the Ulster University student wellbeing study provided a saliva sample and completed a clinically validated online mental health survey (DSM-IV criteria). Cases of severe depression with comorbid 12 month and life-time self-harm and suicide attempt and age and gender matched controls were selected (n=32; 16 cases and 16 controls). DNA was prepared and quantified using the Illumina Infinium Methylation EPIC Kit, and validated with pyrosequencing. Raw data from the scanner (idat files) were processed using the RnBeads pipeline in the R statistical and programming environment. Samples separate out by gender, confirming the known difference in methylation between the sexes. There is a separation of depressed and healthy individuals in the female group, suggesting that there are differences in methylation between participants with depression and those without. Smoking status and age cofounders did not significantly contribute to the clustering associated with depression. Analysis of the top 1000 ranked sites shows that many of these are CpG gaining methylation in the depression group, and gene ontology analysis of the promoters showing largest change in methylation from this group indicated highly significant enrichment for immune response. Depression is associated with significant effects on DNA methylation, and the genes most affected are related to immune function in females. This data suggests an immune component to the aetiology of depression, consistent with the accumulating evidence supporting a relationship between inflammation and depression

**Title:** Nucleus accumbens deep brain stimulation increases mammalian target of rapamycin and glycogen synthase kinase 3 phosphorylation in ventral hippocampus

**Authors: *T. L. NGUYEN**[1], R. P. KALE[2], S. J. TYE[3]
[1]Mol. Pharmacol. & Exptl. Therapeut., [3]Psychiatry & Psychology, [2]Mayo Clin., Rochester, MN

**Abstract: Background:** While antidepressant effects of deep brain stimulation (DBS) are associated with progressive neuroadaptations within the mood network, their underlying molecular mechanisms are poorly understood. Glycogen synthase kinase 3 (GSK3) and mammalian target of rapamycin (mTOR) are important regulators of neuroplasticity. In this study, we investigated the effect of chronic nucleus accumbens (NAc) DBS on GSK3 and mTOR protein expressions within the dorsal (dHIP) and ventral hippocampus (vHIP) in an antidepressant-resistant rat model.
**Method:** Antidepressant-resistance was induced by daily injection of adrenocorticotropic-hormone (ACTH; 100 μg/day; 15 days). Portable microdevices provided continuous bilateral NAc DBS (130Hz, 100μA, 90μs) for 7 days. Four conditions were set up: ACTH (n=10), saline control (n=10), ACTH DBS (n=15), and ACTH sham control (n=11). Antidepressant efficacy was assessed using the forced swim test. Total and phosphorylated levels of GSK3 and mTOR within the dHIP and vHIP were quantified via Western Blot.
**Results:** Within the vHIP, we detected increased level of phospho-GSK3β in DBS compared to ACTH animals ($p<0.01$), and increased level of phospho-mTOR in DBS and sham compared to ACTH animals ($p<0.05$). No significant differences were detected within the dHIP. These vHIP increases of phospho-GSK3β and phospho-mTOR occurred concurrent with DBS antidepressant efficacy ($p<0.001$ relative to ACTH).
**Conclusion:** In an antidepressant-resistant rat model, chronic NAc DBS upregulated phospho-GSK3β and phospho-mTOR within the vHIP of the mood network and elicited antidepressant-like behavior.

**Title:** Which Lateral Habenula output pathway mediates the antidepressant effect of inhibitory DREADDs?

**Authors: *K. COFFEY**, J. NEUMAIER, P. BARTLETT
Univ. of Washington, Seattle, WA

**Abstract:** The lateral habenula (LHb) is small epithalamic region that acts as a key gateway between limbic forebrain neurons and the midbrain monoaminergic systems. Over the past decade there has been resurgence of interest in the LHb as evidence has emerged that it plays a central role in encoding rewarding and aversive stimuli and in neuropsychiatric diseases, including mood disorders. Recently, we found that expressing an inhibitory DREADD (hM4Di) in the LHb of rats and administering the otherwise inert ligand, clozapine-N-oxide (CNO) produced an antidepressant-like effect in the modified forced swim test (mFST) but the downstream target of LHb neurons mediating this effect is not known. There are three important targets of glutamatergic outputs from LHb: ventral tegmental area (VTA), rostral medial tegmental nucleus (RMTG), and dorsal raphe nucleus (DRN). Isolating the pathway responsible for this effect could provide an excellent target for developing novel antidepressant treatments with fewer off-target effects. In order to study the effect of inhibiting these pathways in isolation we utilized an intersectional viral vector strategy: AAV-EF1 α-DIO-$HM_4Di$ injected into LHb, and CAV2-Cre (a retrograde viral vector) injected into one of the three target areas in 16 rats per pathway. We utilized the mFST in a 3x2 design to determine if inhibiting any (or all) of the three pathways are sufficient to confer an antidepressant-like effect. We developed a novel automated activity scoring algorithm to provide unbiased behavioral output which compared well to conventional time sampling analysis of the mSFT. A small number of “anatomical misses”, that showed no LHb DREADD expression, generated a useful negative control group. The only treatment difference between groups was injection of either vehicle or CNO. Our results suggest that inhibiting the LHb to DRN pathway provides an anti-depressant effect, while inhibition of the other pathways does not. Animals with $hM_4Di$ in the LHb to DRN pathway that were treated with CNO showed less inactivity during the mFST, as well as increased swimming and climbing. These results supports the idea that inhibiting the LHb to DRN pathway provides animals with resilience to the behavioral despair normally induced by the mFST, and also opens up the LHb to DRN pathway to manipulation by highly specific therapeutics for the treatment of depression.

**Title:** Identification of genes under the transcriptional regulation of CREB or CREM in the hippocampus

**Authors: *M. T. MANNERS**[1], J. K. BRYNILDSEN[2], J. A. BLENDY[2]
[2]Systems Pharmacol. and Translational Therapeut., [1]Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Major Depressive Disorder (MDD) is a serious medical issue in the United States with over 16 million adults suffering from one or more major depressive episodes at any given time. Current antidepressant therapy is inadequate; with delayed efficacy and undesirable side effects, there is a clear unmet medical need for those requiring fast acting and continuous antidepressant therapy. The transcription factor cAMP response element-binding protein (CREB) regulates expression of many downstream genes that have been implicated in depression and the response to antidepressant treatment. Our lab has previously shown that reductions of CREB throughout the brain results in an antidepressant phenotype[1] as well as a rapid response to antidepressant treatment[2]. Further, localized deletion of CREB in the hippocampus is associated with an accelerated response to antidepressants[3]. However, in both constitutive and conditional CREB deletion models, the related Cre-binding protein CREM is upregulated. Overexpression of CREM activator isoform, $CREM_T$ in the hippocampus also resulted in an accelerated response to antidepressants[3]. While CREB and CREMτ can both bind to and activate CRE-target genes, it is not known if there are distinct genes that are differentially regulated by these proteins.
To further understand the individual roles of hippocampal CREB and CREM in depression, we constructed a mouse line with $Creb^{loxP/loxP}$ +/- Crem and an inducible enhanced GFP fused ribosomal L10a subunit (EGFP-L10a). Injection of adeno-associated virus expressing Cre recombinase into the hippocampus localized deletion of Creb and expression of EGFP-L10a to hippocampal neurons. Translating ribosome affinity purification (TRAP) was conducted by immunoprecipitation of the ribosomal subunit, and isolation of the actively translating mRNA. Comparative analysis of mRNA from wildtype and $Creb^{loxP/loxP;}$ +/- Crem enabled us to identify a unique population of CREB or CREM target mRNAs in the hippocampus. Identification of genes under the transcriptional regulation of CREB or CREM in the hippocampus will allow us to

better understand the role of CRE- binding proteins in depression and may ultimately result in identifying targets for future pharmacological therapy in the treatment of depression.

**Title:** Excess significance bias in basic antidepressant research: The case of the forced swimming test

**Authors: *C. LINO DE OLIVEIRA**[1], M. R. MACLEOD[2]
[1]CFS-CCB-UFSC, Florianopolis, Brazil; [2]Univ. Edinburgh, Edinburgh, United Kingdom

**Abstract:** Our studies aim to apply the principles of 3R (reducing, refining and replacing) to animal models used in the basic antidepressant. Currently, our main strategy is to modify the experimental design and analysis of existent animal models, mainly the forced swimming test (FST). Regardless of the efforts to follow protocols previously published, the FST provided negative results in our laboratory [1] [2]. A systematic review of the literature revealed that quality of our work was similar to other publications and suggested the unlikely possibility that our negative results were the first of a kind in the literature. Alternatively, we may be facing consequences of excess significance which may inflate the expectation of positive results leading to unexpected, underpowered studies and negative results [3]. Therefore, the main objective in this work is to investigate the prevalence of positive results or, excess significance, in the studies using FST. For that, a comprehensive systematic review of the literature was performed retrieving 4355 publications organized in a database [4]. Sixty two studies randomly selected from the database were analyzed using quality scale [3]. Quality evaluation revealed that sex, strains and ages of animals, type of drug and via of administration, treatment schedule and protocols of FST seemed source of heterogeneity. Additionally, actions to avoid bias such as “random allocation to a treatment”, “concealment of treatment allocation” and “sample size calculation” were neglected for most of the publications evaluated. Independent of the quality score of the publication, 88% of the experiments rejected the null hypothesis for the primary outcome while 92% of the studies reported non-significant results for secondary outcomes. Moreover, 100% percent of the studies reported results agreeing with the primary hypothesis.

These data suggest that FST studies may excess significance bias to the field of basic antidepressant research. Further analyses are necessary to identify the origin and the impact of the excess significance in the field of basic antidepressant research. Indeed, the abundance of "positive results" in the basics contrasts with the partial success of antidepressant treatments in clinical trials or in therapeutics [5]. [1]Domingues, K. **Title:** Imaging fluoxetine modulation of dentate gyrus function

**Authors: *E. CARAZO**[1], C. ANACKER[1], R. HEN[2]
[1]Integrative Neurosci., [2]Neurosci. and Psychiatry, Columbia Univ., New York, NY

**Abstract:** The molecular effects of Selective Serotonin Reuptake Inhibitor (SSRI) antidepressants, such as fluoxetine, have been studied extensively. However, despite being widely used in the clinic, only one-third of patients experience remission after up to four months of treatment with SSRIs. The lack of efficacy and delayed onset of action emphasizes the need to develop a more comprehensive understanding of the underlying mechanisms and neural circuits involved in anxiety regulation and antidepressant action. At the neural circuit level, it remains elusive how SSRIs modulate cellular networks implicated in mood- and anxiety-like behavior. We have previously shown that granule neurons of the dentate gyrus are crucial mediators of antidepressant effects on behavior. Here, we used miniature microscopes to perform in vivo $Ca^{2+}$ imaging in the ventral dentate gyrus of freely-moving mice, to investigate granule cell activity

during anxiogenic behavioral tasks before and after chronic fluoxetine treatment. We find that $Ca^{2+}$ activity of granule cells in the ventral dentate gyrus is increased during exploration of anxiogenic environments. Granule cell activity in the open arms of the elevated plus maze is increased by ~20% as compared to activity in the closed arms ($p<0.05$). These activity response patterns are modulated by chronic treatment with fluoxetine. Our data suggest that activity changes of granule cells in the ventral dentate gyrus may mediate anxiety-like behavioral responses.

**Title:** Use of a novel degradable biocomposite material as a delivery system for brain cell treatment and cell growth modification in 2D and 3D spheroid cultures

**Authors: *N. H. NGUYEN**, Z. NORCROSS, U. KANSAKAR, M. A. DECOSTER
Biomed. Engin., Louisiana Tech. Univ., Ruston, LA

**Abstract:** The three-dimensional (3D) cell spheroid model has emerged in recent years as a new approach in cell sciences in contrast to traditional 2D model with several advantages. Cell proliferation and morphology in 3D model better mimics the tissue micro-environment with potentially three layers of cells (proliferating, quiescent and necrotic), growing at different rates, instead of more even rate in 2D model. Furthermore, *in vitro* 3D model can give a more accurate response for drug treatment compared to 2D monolayers due to diffusion considerations. However, 3D model takes longer time to form and for the drug to take effect due to diffusion rate differences between the two models. Also, 3D spheroids data needs to be normalized (area and volume) to interpret the results. We here investigated the use of a novel degradable biocomposite material developed by our group called Copper High Aspect Ratio Structure (CuHARS), combined with 2D cells and 3D cell spheroid models as potential delivery system for cancer drug and cell growth modification. Two types of brain cells, brain tumor cells (CRL-2303 - American Type Culture Collection) and primary astrocytes (derived from rat cortical brain cells) were successfully grown in suspension with a density of 200,000 cells per well and transformed into 3D cell spheroids using a matrix-free system (Nanogaia: Ruston, LA). After developing for 7

days in vitro (DIV), biomaterials were added to the fully formed spheroids at 5, 10, and 25 ug per mL. Three types of materials were used for comparison: copper nanoparticles (CuNP), halloysite nanotubes (HNTs), and Cu-HARS. Spheroid area was measured every two days with microscopy and Image Pro Plus 7.0 and Matlab 2015b software, and viability measured using resazurin assay with fluorescent plate reader, at 3,5,7 and 9 DIV, post-treatment (n=96 total spheroids). Biomaterials were also added to 2D model to study the effect versus 3D model. Compared to the same brain tumor cell density, astrocyte spheroids compacted faster and grew slowly. Results showed that in both brain tumor cells and primary astrocytes, CuHARS material was internalized by the outer layer of the spheroid and caused less toxicity compared to the CuNP at the same concentrations. Viability of brain tumor cells with CuNP dropped initially to 36% at 3 DIV and then stabilized to 47% (5-9 DIV). In contrast, with CuHARS, viability was initially 80% and then stabilized to 74% at the same timepoints. These data for a copper biocomposite material indicate that the CuHARS may be functionalized by coating with anticancer drug or growth factor to use as a drug delivery system for cancer treatment as well as cell growth modification in normal brain cells.

**Title:** Clathrin nanoparticles efficiently deliver brain-derived neurotrophic factor to the hippocampus, reverse BDNF deficits and enhance neurogenesis and memory in a HIV-tat mouse model

**Authors: *J. K. KIM**[1,2], C. W. ADAM[1], D. ANCHALIYA[1], J. P. MCLAUGHLIN[3], M. J. KAUFMAN[1,2], F. VITALIANO[4], G. D. VITALIANO[1,2]
[1]McLean Hosp., Belmont, MA; [2]Harvard Med. Sch., Boston, MA; [3]Univ. of Florida, Gainesville, FL; [4]ExQor Technologies Inc., Boston, MA

**Abstract: Background:** Advances in treatment of neurodegenerative disorders have been made by administering brain derived neurotrophic factor (BDNF) directly to the brain, or by using drugs that increase BDNF indirectly. BDNF promotes neuroregeneration and restores brain functions, but cannot easily cross an intact blood brain barrier (BBB) or diffuse within the brain. Our goal was to produce BDNF-clathrin nanoparticles (NPs) that can efficiently target brain TrkB receptors, and reverse neurotoxic effects of HIV transactivator of transcription (tat) protein. **Methods:** GT-tg bigenic mice were treated daily for 7 days with saline (tat-) or doxycycline (100mg/kg/d i.p.) that induces tat expression (tat+). Concurrently, animals received daily intranasally either NPs (0.3mg/kg of BDNF with 2.4mg/kg of clathrin); BDNF; clathrin; or saline (40µl). Subsequently, NP/saline treated tat+ mice were tested with Barnes maze and Novel Object Recognition tests. For immunohistochemistry, mice also received Bromodeoxyuridine (BrdU 50mg/kg, Q12h i.p.) on days 1 and 2, and were sacrificed on days 7 or 14 of dox/saline administration. Neurogenesis and newborn cell proliferation and survival were determined with Doublecortin (DCX), Ki67 and BrdU antibodies respectively. For Western Blot analyses, hippocampi were removed and processed on the 4th day of dox/saline administration, and BDNF concentrations and signaling were analyzed. **Results:** BDNF-clathrin NPs significantly improved cell survival and proliferation, and doubled the density of young neurons in the hippocampus. BrdU+ ($p<0.0002$), Ki67+ ($p<0.002$) and DCX+ ($p<0.001$) cell densities significantly increased in the granule cell layer of dentate gyrus in NP treated tat+ mice, compared to saline treated tat+ or tat- mice. Hippocampal-based memory acquisition ($p<0.04$) and flexibility ($p<0.004$), and novel object recognition ($p<0.016$) significantly improved in NP vs. saline treated tat+ mice. NPs reversed BDNF signaling deficits in tat + animals by significantly increasing hippocampal levels of mature-BDNF ($p<0.007$), pro-BDNF ($p<0.01$), pAKT ($p<0.01$) and Akt ($p<0.002$) in NP treated mice, compared to mice that didn't receive NPs. **Conclusions:** NPs bypassed the BBB, doubled BDNF levels, enhanced hippocampal cell proliferation, survival and neurogenesis, improved memory and reversed neurodegenerative effects of tat protein in GT-tg mice. Hence, clathrin provides a highly efficient nanoplatform for delivery of BDNF to the brain. This noninvasive nanotechnology may be able to enhance neuronal regeneration and plasticity, and restore brain functions more quickly and completely than existing treatment methods.

**Title:** The effect of blood-brain barrier (BBB)-specific laminin isoforms for barrier function with the new *In vitro* BBB model incorporating multi-culturing system of BBB components

**Authors: *Y. TAKESHITA**, S. FUJIKAWA, H. NISHIHARA, F. SHIMIZU, T. MAEDA, Y. SANO, T. KANDA
Neurosci., Yamaguchi Univ. Grad. Sch. of Med., Ube, Japan

**Abstract:** Background The blood-brain barrier (BBB) is the brain-specific capillary barrier that is critical for preventing toxic substances. The BBB is primarily formed by microvascular endothelial cells, pericytes, astrocytes and basement membranes. The basement membranes are composed by collagen I, IV and laminins. Recently, we revealed that BBB composed laminin α4 and 5, β1, γ1 (Takeshita et al., 2017 Clin. Exp Neuroimmunol). However, the effect of this laminin isoforms at the BBB is still unknown because of the lack of the *in vitro* models that are specialized to interaction between laminin and other BBB components.
Aim We construct the new BBB model incorporating multi-cultured system of BBB specific laminin isoform (α4 and 5 β1, γ1) and conditionally immortalized human BBB cell lines [endothelial cells (hEC), pericytes (hPCT) and astrocytes (hAST)] by the Nunc UpCell technology. Then, we evaluate whether the barrier function is influenced by the BBB specific laminin.
Method hPCT were co-cultured on luminal side of insert (3 μm pores) with hAST on abluminal side. hEC were cultured on Upcell dish, which can achieve sheet-like detachment of confluent cells and extra-cellular matrix by temperature-shifting to 20 degree Celsius, after coating laminin (α4 and 5, β1, γ1), or blood-nerve barrier specific laminin isoform(α4, β1, γ1). Then sheet-like detachment of confluent hEC and laminin were transferred onto the hPCT, which were co-cultured with hAST on the insert. Solute permeability with 10k dextran was measured.
Result The values of permeability in laminin (α4 and 5, β1, γ1) were significantly lower than laminin (α4 β1, γ1).
Conclusion Our model is the first *in vitro* BBB model to evaluate the crosstalk between BBB specific laminin and other BBB components. This result suggested that BBB specific laminin regulated the barrier function at the BBB.

**Abstract:** Nerve growth factor (NGF) is a well characterized protein and an essential contributor to neuronal survival and maintenance. NGF has shown high pharmacological potential in clinical trials with patients with mild Alzheimer's disease, where human NGF expressing cells were injected into their forebrain. However, biological treatments hold unanticipated risks and may cause serious adverse effects. In addition, free growth factors endure rapid degradation which leads to a short biological half-life, limiting the effectiveness in therapeutics. In previous works which were done in our group; we have shown that conjugation of growth factors to nanoparticles stabilized the protein and extended its biological effectiveness. Here, we have designed and examined high porous chips made of silicon as the drug carriers. The delivery system we have developed, composed of porous silicon (PSi) chips and growth factor, allows sustained and controlled release of NGF. Different PSi nanostructures (vary in size and depth) were fabricated by anodic electrochemical etching of single-crystalline Si wafers and the synthesis conditions were adjusted to allow efficient loading of NGF by physical adsorption. Remarkably, the NGF release profile demonstrates a sustained release for a prolong period of one month. Bio-functionality was examined on PC12 cell culture and *ex-vivo* DRG neuronal culture, common model systems. We have shown that the prolonged release of the bioactive NGF promoted differentiation and neurites outgrowth. Our work demonstrates that NGF entrapment within the PSi chips allows for its sustained delivery constantly over time without any need of external supplement. Currently we examine the therapeutic effects of our novel system on neurodegenerative diseases. We have designed and characterized a model of differentiated SH-SY5Y neuroblastoma cells with Amyloid-β peptide (Aβ), a main component of Alzheimer disease senile plaques. Our novel methodology addresses the challenge of distribution of NGF in a controlled and targeted manner. This system holds a promise for a new strategy of treatment for neurodegenerative diseases.

**Title:** Monoamine oxidase (MAO-A and MAO-B) enzyme occupancy assay - a non-radiolabelled method in rat

**Authors: *J. B. THENTU**, G. BHYRAPUNENI, R. DYAVARASHETTY, K. BANDARU, R. BOGGAVARAPU, H. PANTANGI, N. PADALA, R. NIROGI
Drug metabolism and pharmacokinetics, Suven Life Sci. Ltd., Hyderabad, India

**Abstract:** Monoamine oxidase (MAO) enzymes (subtype A and B) are important to human health because of their regulatory and protective effects in controlling the concentrations of neurotransmitters and drugs. MAO inhibitors are known for their effects in the treatment of depression, Alzheimer's and Parkinson's diseases. Development of new MAO inhibitors can be accelerated by considering the receptor occupancy data as a major threshold measure. Thus in the process of setting up the occupancy assay, selective PET tracers (Harmine for MAO-A and R (-) Deprenyl for MAO-B) were identified and optimized with their non-radiolabelled form (using mass spectrometry, LC-MS/MS) in rat. Tracer suitability was tested by brain regional distribution at different dose and time points. Dose dependent decrease (Harmine) or increase (Deprenyl) of tracer binding in selective brain regions of pre-treated (standard inhibitors) rats reflected gradient MAO-A or MAO-B occupancy, respectively. The ratio of occupancy effective doses (MAO-B $ED_{50}$/ MAO-A $ED_{50}$) of inhibitor drug highlights its in-vivo selectivity and associated enzyme mediated effects. This factor would broaden the application of inhibitors in treatment where the enzyme selectivity is the major factor. Further by using this LC-MS/MS based method, new chemical entities can be screened for MAO occupancy at a faster rate and a correlation can be drawn against the brain or plasma exposures from the same experiments.

**Abstract:** The voltage-gated Kv7.2-Kv7.5 channels are broadly expressed in the central nervous system, where they, among other functions, control the excitability of neurons by acting as a 'brake' on repeated action potential discharges. Thus, pharmacological activation of neuronal Kv7 channels has proven to be a successful therapeutic strategy within partial-onset seizures by use of the Kv7 activator retigabine (Gunthorpe *et al*, 2012). Interestingly, activation of Kv7 channels also holds promise as a therapeutic strategy within psychiatric disorders such as schizophrenia (Sotty *et al*, 2009)) and depression (Friedman *et al*, 2016). In the present study we have characterized the pharmacological profile of the novel, pan-selective Kv7.2-7.5 opener Lu AA41178, using both *in vitro* assays and a broad range of *in vivo* assays related to epilepsy, schizophrenia, and depression. Using two-electrode voltage clamp in *Xenopus* oocytes expressing human Kv7.2-Kv7.5 Lu AA41178 was confirmed to be a pan-selective activator of Kv7 channels. When applying a voltage ramp protocol the activation threshold of Kv7.2+Kv7.3, Kv7.4 and Kv7.5 was significantly left-shifted in the presence of increasing concentrations of Lu AA41178 (0.3-30 µM). Importantly, in a $Rb^+$ efflux assay Lu AA41178 did not display inhibitory effects on human Kv7.1 channels stably expressed in CHO cells, suggesting no impact on cardiac repolarization safety. Next, we tested Lu AA41178 in preclinical *in vivo* models of neurological and psychiatric disorders. In the maximum electroshock threshold test (MEST) subcutaneous pre-treatment of mice with Lu AA4178 significantly increased the electroconvulsive shock threshold, thus demonstrating an anticonvulsant effect. In the mouse forced swim test, a model of behavioral despair with antidepressant predictive validity, AA41178 significantly reduced immobility time to the same extent as the positive control, imipramine. In anesthetized rats we performed *in vivo* electrophysiology recordings of VTA activity, a brain region demonstrated to be hyperactive in animal models of schizophrenia (Lodge and Grace, 2007) and depression (Friedman *et al*, 2016). Here, AA41178 potently reduced both spontaneous firing and burst firing upon IV administration. Behavioral testing of AA41178 was accompanied

by plasma and brain exposure sampling, revealing minimum effective plasma levels below 1000 ng/ml. In summary, Lu AA41178 is a potent activator of neuronal Kv7 channels demonstrating efficacy in animal models of epilepsy, schizophrenia and depression. Thus, it may serve as a valuable tool for exploring the role of Kv7 channels in both neurological and psychiatric disorders.

**Title:** Acupuncture reverses behavioral disturbances and testosterone levels in social isolated rats

**Authors: *A. DAVILA HERNANDEZ**[1], S. ZAMUDIO HERNANDEZ[1], L. MARTINEZ MOTA[2], R. GONZALEZ GONZALEZ[3], S. GUZMAN VELAZQUEZ[1]
[1]Inst. Politecnico Nacional, Mexico, Mexico; [2]Inst. Nacional de Psiquiatría Ramón de la Fuente Muñiz, Mexico, Mexico; [3]Inst. Nacional de Cancerologia, Mexico, Mexico

**Abstract:** INTRODUCTION: A growing number of human and animal studies suggest a modulatory role of testosterone in the regulation of emotionality, stress response, and psychiatric disorders, including depressive-like disorders. Acupuncture has been demonstrated to have antidepressant-like effect in humans and ameliorate depression-related behavior in depression models. However, the effect of acupuncture on testosterone and depressive-like behavior remains unknown. OBJECTIVE: To explore a possible mechanism of acupuncture for relieving depression, the effects of embedding thread in acupoints on depressive symptoms and testosterone serum levels were evaluated in an animal depression model. METHODS: On postnatal day 21, forty Sprague-Dawley male rats were weaned and randomly divided into:

social isolation and acu-catgut embedding (SI+AC); social isolation and sham acu-catgut embedding (SI+Sham); group housing and acu-catgut embedding (GH+AC); group housing and sham acu-catgut embedding (GH+Sham) with 10 animals in each group. Depression model was established by post-weaning social isolation for 8 weeks. In AC groups, surgical suture (acu-catgut) was embedded in Baihui (DU 20), Yintang (Ex 3), Baihui (DM20), Shenshu (BL 23), Pishu (BL 20), Ganshu (BL 18) and Xinshu (BL 15). In Sham groups, the acupoints were punctioned without the embedding thread. Depression-like behavior was evaluated through the Forced swimming test (FST). Testosterone levels in the serum were examined by ELISA. RESULTS: Social isolation increased immobility and reduced active behaviors in the FST respect to rats raised in a group ($P<0.05$). False acu-catgut embedded (Sham group) was ineffective to reverse immobility behavior in isolated rats. However, in the isolated group acu-catgut significantly ($P<0.05$) reduced the immobility time and increased the time that rats spent on active behaviors, reaching the level of the group housed. Social isolation induced a decrease in serum testosterone ($P<0.05$) and treatment with acu-catgut partially restored the peripheral levels of this steroid in socially isolated rats. CONCLUSION: Acupuncture as embedded thread in acupoints, reversed the effects of social isolation on depressive behavior which could be related to its effects in up-regulating serum testosterone.

**Abstract:** The kynurenine (KYN) pathway involves several enzymes, which catabolize the amino acid tryptophan (TRP), via the Kynurenine 3-monooxygenase (KMO) branch, into

quinolinic acid (QUIN) and, through the kynurenine aminotransferase II (KAT II) branch, into kynurenic acid (KYNA). Several TRP catabolites (TRYCATS) have been shown to be altered in CNS disorders such as major depressive disorder (MDD). The KYN pathway is activated by proinflammatory cytokines, which are also elevated in neuropsychiatric diseases. Indoleamine 2, 3-dioxygenase 1 (IDO1) and Kynurenine 3-monooxygenase (KMO) are cytokine-inducible enzymes, which use TRP and KYN, respectively, as their substrate for further degradation. We hypothesized that patients with MDD differ from one another in their TRYCAT levels and that selective manipulation of these pathways can rectify these disturbances. We have identified subgroups of patients with different MDD profiles, which show altered plasma TRYCAT levels compared to other patients within their groups (samples measured within the REDEEM study, Trinity College). One subpopulation of patients that experienced a first depressive episode, revealed very low plasma KYNA levels, whereas some patients with recurrent MDD showed high levels of plasma QUIN. It may be possible that these subgroups respond to different types of TRYCAT modulation. It is proposed that KMO inhibitors shift the TRP catabolism into the direction of neuroprotective KYNA production and also reduce neurotoxic QUIN levels, whereas IDO1 inhibitors lower QUIN levels. Preclinically, we could demonstrate differential manipulation of either the QUIN pathway or the KYNA pathway, using such selective enzyme inhibitors. For this purpose, we have treated mice with a single dose of Lipopolysaccharide (LPS) to induce inflammation-mediated TRYCAT activity. Twenty-four hours were allowed for enzyme induction, at which time a substantial increase in TRYCAT activity could be measured. We could demonstrate very distinguished effects on serum TRYCAT levels by IDO1 and KMO enzyme inhibitors. These data led to our hypothesis that selective modulation of the TRYCAT pathway may display a realistic and ‘personalized treatment’ option for subgroups of MDD patients.

**Abstract:** According to WHO, depression will be the second leading cause of disability by 2020. Even though depression is treatable with medications and psychotherapy such as the Cognitive Behavioral Therapy (CBT), many patients never seek professional help because of high costs, poor accessibility, and social stigma associated with visiting a therapist. Computerized Cognitive Behavioral Therapy (CCBT), i.e. delivering CBT automatically though a computer, is a relatively new approach that has the potential to bridge this gap. However, the existing CCBT tools suffer from multiple drawbacks including lack of personalization and high dropout rates. We have developed a fully stand-alone and freely accessible internet-based tool, TreadWill (treadwill.org), for treating depression. TreadWill is based on evidence-based CBT and educates the user through interactive and multimedia elements. The user interacts with the automated program that adapts to the user's dysfunctional thoughts, intermediate and core beliefs, and profession. To increase adherence to the program, TreadWill also includes social networking features where the users can post their problems in a support group and get help from other users. To test the effectiveness of TreadWill, we plan a double-blinded randomized controlled trial. The results will be compared to an active control: a limited, non-adaptive version of the program in which the users learn CBT through plain text-based material and do not have access to various interactive and social networking features. Both the full-featured and the limited versions of the program are designed to be completed in six weeks. In the trial, about a hundred participants in the age group of 16-35 years will be randomly assigned to the experimental or the control group. The participants will be administered Patient Health Questionnaire-9 (PHQ-9) to assess baseline depression level. Thereafter, self-administered PHQ-9 will be used to measure reduction in the severity of depression after completion of the program and at 90 days follow-up. The total time spent by the users in both the versions will serve as an indicator of user engagement.

**Abstract: Abstract**
**Background**: Gold nanoparticles are a novel device of nanometric scale (1 – 100 nm) that possess physicochemical characteristics, which allow them to be introduced into an organism with very few secondary effects. Nanoparticles can deliver drugs, DNA, proteins, cytokines and other peptides in several systems. To date, the effects of nanoparticles in neural tissues are not well known and limited evidence is currently available. Astrogliosis and Microglial reactivity comprise a complex glial response against external insults, neuroinflammation or neurodegeneration. These glial reaction limits neural damage and activates brain repair. **Objective:** To evaluate the astrocytic and microglial response after an intracerebral injection of gold nanoparticle into the brain parenchyma. **Methods:** Male CD1 mice (P60) were divided in three groups: Gold nanoparticles (AuNP), control-vehicle and control-sham. The AuNP group received a single intracerebral injection of PEGylated AuNP [85 X $10^6$/nl] dissolved in 100 nl of 0.9% NaCl solution in the striatum. The control-vehicle group received 100 nl of 0.9% NaCl solution, whereas the control-sham group was submitted to craniotomy without meningeal disruption. All animals were sacrificed by transcardial perfusion at 7 and 14 days after administration with paraformaldehyde as fixative. The brain was processed and sliced in 30 µm thick sections. We performed GFAP-immunohistochemical detection for astrocytes and Iba1 immunohistochemistry for microglia detection. GFAP+ and Iba1+ cells were counted in the striatum. **Results:** At day 7, we observed that the number of GFAP+ astrocytes and Iba1+ cells was higher in the control-vehicle group when compared to the AuNP group. We did not find statistical significant differences between both AuNP groups when compared astrocytic and microglial reactivity at day-7 vs. day-14 time points. **Conclusions:** This preliminary analysis showed that PEGylated gold nanoparticles do not produce significant or progressive astrogliosis and microgliosis, which suggest that gold nanoparticles produces a limited glial response.

**Title:** Method for screening neuronal tumor cell surface markers for high specificity and rapid internalization as potential oncologic treatments

**Authors: *L. ANCHETA**[1], P. A. SHRAMM[2], D. A. LAPPI[3]
[1]Cytologistics, LLC, San Diego, CA; [2]Advanced Targeting Systems, San Diego, CA; [3]Veiove Animal Hlth., San Diego, CA

**Abstract:** Targeted cancer therapies are drugs or other substances that block the growth and spread of cancer by interfering with specific molecules involved in the growth, progression, and spread of cancer. These therapies are often cytostatic; they block tumor cell proliferation as opposed to chemotherapy that kills tumor cells. A primary approach to identifying potential targets is the ability to compromise a ligand-receptor relationship that causes tumor cell proliferation. There are now many examples of the use of antibodies in tumor therapy to cause a breakdown in that relationship, including the recently approved bevacizumab for glioblastoma. Others in clinical use against brain tumors are antibodies to cell-surface EGFR, VEGFR, PDGFR, and c-kit (Hernandez-Pedro *et al.* http://dx.doi.org/10.1155/2013/716813). These work by down-regulation of the receptor by antibody-mediated internalization. It is crucial to have a method to determine the suitability of an antibody for development as a targeted therapy to cause internalization rapidly and completely, often referred to as “rational design.” Here we describe a method for the efficient determination of internalization of cell surface molecules by antibodies: a cytotoxicity assay utilizing an antibody labeling method to streamline the process of multiple candidate screening. Cells are chosen that have significant levels of expression of the desired marker and the assay readout is definitive: evidence of cell death is demonstrated in 72 hours. This method is designed for the rapid screening of multiple antibodies for specificity and internalization in neuronal tumor cells.

**Title:** Optimization of MRI-guided AAV delivery into de CSF for CNS gene therapy in NHP

**Authors: L. SAMARANCH**[1], P. HADACZEK[1], *J. BRINGAS[1], P. C. ALLEN[2], D. STOCKINGER[2], Y. YU[2], V. SUDHAKAR[1], M. CAMPAGNA[2], W. SAN SEBASTIAN[1], E. A. SALEGIO[2], G. C. HWA[2], K. S. BANKIEWICZ[1]
[1]Dept Neurosurg., Univ. California San Francisco, San Francisco, CA; [2]Valley Biosystems Inc., West Sacramento, CA

**Abstract: Background:** Therapies based on adeno-associated virus (AAV) technology have demonstrated significant potential to correct CNS pathologies. Although parenchymal delivery has been by far the favored route, the potential advantages of CSF infusion of AAV have been recognized particularly for infants, too young for skull-mounted neuronavigation devices. In a number of studies in nonhuman primates (NHP), injections into CSF space have yielded impressive but variable transduction of spinal cord, cortex and cerebellum. **Objective:** Analyze patterns of distribution of different routes of CSF delivery by magnetic resonance imaging (MRI) to understand the fluid dynamics of the AAV infusion in the CSF space. In addition, levels of circulating AAV9 were analyzed to determine the clearance rate of injected vector over time. **Methods**: Thirteen non-human primates (NHP) were infused under MRI control with AAV9 into the CSF via 3 routes of delivery. Animals were randomly assigned to acute cerebellomedullary cistern (CM) injection group (n=3, 6mL/min), bilateral lateral ventricle injection group (n=2, 6mL/min), lumbar injection group (n=3, 6mL/min), cisternal and lumbar combined injection group (n=2, 6mL/min) or slow CM injection group (n=3, 6mL/h). CSF fluid dynamics of the vector was analyzed by sequential acquisition of contrast agent in a MRI scanner along the infusion. Vector clearance from CSF was analyzed by qPCR at different time points (15', 30', 1h, 6h, 12h, 24h and 28 days), and percentages of remaining capsids were calculated for each of the time points. **Results:** Fluid distribution analysis revealed variability in the pattern of vector dissemination regardless route of delivery. qPCR analysis of AAV9 in the CSF established its ½ life to be approximately 3 hours. Vector was undetectable 24h after injection regardless of the delivery paradigm. Acute CM injection revealed longer ½ life of vector in the CSF, while slow CM injection showed fastest clearance rate, most likely due to a dilution effect. **Conclusion:** Our data will allows us to improve CSF delivery, optimizing parameters such as rate and duration of vector infusion and frequency of AAV administration to the brain and spinal cord.

**Title:** Targeting the nicotinic acetylcholine receptor in delivery of drugs across the blood brain barrier

**Authors: *N. I. NISSEN**[1], K. R. ANDERSON[2], S. A. EICHELBERGER[3], J. M. MIWA[2]
[1]Dept. of biological science, Lehigh Univ., Aalborg, Denmark; [2]Biol. Sci., Lehigh Univ., Bethlehem, PA; [3]Ohio State Univ., Columbus, OH

**Abstract:** Several devastating neurodegenerative diseases are caused by genetic mutations resulting in degeneration and death of neurons. Unfortunately, although specific candidate genes causing disease pathology are well-known, no cure for these diseases exist, because at present efficient gene therapy technologies have not been developed. RNA interference can target and silence specific mRNA and therefore offers great therapeutic opportunities in neurodegenerative disorders. The technical limitation of gene therapy strategies lies in the design of the relevant drug and its carrier to get across the impermeable blood-brain barrier (BBB). The nicotinic acetylcholine receptor (nAChR) is expressed on brain endothelial cells denoting the impermeable BBB and widely within the brain, and it is therefore an obvious target for the delivery of drugs across the impermeable BBB.
This project involves the use of a peptide-based nAChR-mediated transport technology to deliver siRNA across the BBB and into neurons to target specific mRNA. This carrier peptide was engineered based on our understanding of nAChR binding proteins interactions. We hypothesis

that this peptide-based nAChR mediated transport is able to carry siRNA across the BBB resulting in knock down of specific mRNA in neurons. We assess mice injected with a peptide-siRNA-complex using quantitative methods to measure knock down of target mRNA, and behavioral assays to assess the functional effects of such knock down.
This technology could have the potential of being used in the delivery of therapeutics in neurological disorders.

**Title:** Chronic exposure to and withdrawal from ethanol induces depressive-like symptoms that are reduced by prenatal choline supplementation

**Authors: N. MORRISS**, *M. J. GLENN
Psychology, Colby Col., Waterville, ME

**Abstract:** Major depressive disorder (MDD) is a chronic, heterogeneous mental illness characterized by somatic, neurological, and behavioral symptoms. Key hallmark features include depressed mood, anhedonia, anxiety, and cognitive deficits. Globally, MDD affects up to 350 million people and is the leading cause of disability. An array of treatment options are available, yet a large number of those afflicted start out as, or over time become, treatment resistant. Thus, there is a need to explore other avenues for intervention and symptom attenuation. Recent literature has indicated the potential for the vital amine, choline, to mitigate depressive-like symptoms in animal models. Choline has widespread beneficial effects on the brain and behavior, many of which are in opposition to MDD's effects: decreased anxiety and despair; enhanced attention and memory; increased adult hippocampal neurogenesis and neurotrophic expression. Supplemental choline during early life is particularly potent, likely through its epigenetic action as a major source of methyl groups for methylation reactions. Unfortunately, a major challenge blocking our understanding of choline and MDD is the deficiencies in animal models: few reliably reproduce hallmark MDD symptoms and none capture the breadth of the disease. Recently, attention has focused on findings in humans and animal models, that chronic ethanol exposure and withdrawal have effects that resemble depressive symptoms: impaired mood and memory, and decreased neurogenesis and neurotrophic expression. In the present

study, groups of adult female and male rats treated prenatally with choline supplementation or a standard diet received daily injections ethanol (1 mg/kg, i.p.) or saline for 21 days. On the final days, anxiety and anhedonia were assessed; in the 5 days after treatment (withdrawal), behavioral despair and spatial learning were assessed. Neural assays included H3-K14 acetylation and adult hippocampal neurogenesis. The main results were robust sexually dimorphic patterns: in standard-fed females, ethanol treatment increased anxiety and decreased H3-K14 acetylation; in standard-fed males, ethanol treatment impaired spatial learning and reduced hippocampal neurogenesis. Importantly, prenatal choline supplementation prevented ethanol's effects in females and males. Taken together, these results support chronic ethanol as a useful tool for modelling aspects of MDD and prenatal choline supplementation as a viable intervention strategy. The sexually dimorphic results demand more attention in light of long-standing deficiencies in numbers of studies that include sex as a biological variable.

**Abstract:** Object
Despite advances in pharmacological therapies, treatment-resistant depression is still difficult to resolve. The development of effective therapies is therefore needed. Wistar Kyoto (WKY) rats are known to be one of the most promising models of treatment-resistant depression. Mesenchymal stem cells (MSCs) are regarded as a potential candidate for treatment of neurodegenerative disorders. In this study, we evaluated the therapeutic potential of MSCs in WKY rats.
Methods
MSCs were transplanted unilaterally into the cerebral ventricle or the striatum of WKY rats (day 0). A sham operation was performed in control WKY rats. An open field test (OFT, day 14) and a forced swim test (FST, days 15 and 16) were performed to evaluate the antidepressant effect of MSCs. All rats received intraperitoneal injections of 5-bromo-2'-deoxyuridine (BrdU, 50 mg/kg)

every 12 h over the last 3 days of the testing period.
Results and Discussion
MSC-transplanted WKY rats did not show significant improvement in the OFT or the FST, compared to control WKY rats. There was no difference in the number of cells positive for BrdU and BrdU/Doublecortin in the subventricular zone and the dentate gyrus of the hippocampus. It was previously reported that MSC transplantation increases hippocampal neurogenesis and counteracts depressive-like behavior in depression-model rats. However, MSC transplantation did not show such an effect in WKY rats. We must consider the optimal location of transplantation, the optimal dose of MSCs, and the optimal administration route in a future study.

**Title:** Antidepressant-like actions of inhibitors of poly(ADP-ribose) polymerase in rodent models

**Authors: *G. A. ORDWAY**[1], A. SZEBENI[1], L. J. HERNANDEZ[1], H. WANG-KEATON[1], J. D. CRAWFORD[1], K. SZEBENI[1], M. J. CHANDLEY[2], K. C. BURGESS[1], C. C. DE PRETER[1], W. ONGTENGCO[1], R. W. BROWN[1]
[1]Biomed. Sci., East Tennessee State Univ. James H Quillen Col. of Med., Johnson City, TN; [2]Hlth. Sci., East Tennessee State Univ. Col. of Publ. Hlth., Johnson City, TN

**Abstract:** The DNA base excision repair enzyme, poly(ADP-ribose) polymerase-1 (PARP1), is a multi-functional enzyme and a member of a subfamily of three PARPs that covalently build PAR polymers onto proteins to regulate their function. Drug inhibitors of PARPs have anti-cancer, anti-inflammatory, and neuroprotective effects. Recently, we reported elevated gene expression levels of PARP1 in postmortem brain tissues from donors who had an active major depressive disorder at the time of death. Since PARP1 gene expression is positively correlated with PARP1 activity, these findings indicate that elevated PARP1 activity may contribute to brain pathology associated with depressive behavior. Therefore, we speculated that drug inhibitors of PARP1 may have antidepressant properties. To determine whether a rodent model could be used to evaluate the role of PARP1 in depressive-like behaviors, rats were exposed to

repeated psychological stressors (social defeat and chronic unpredictable stress) for 10 days. Anhedonia (estimated by sucrose preference) and brain PARP1 gene expression levels were measured. After stress exposure, rats exhibited significantly reduced sucrose preference and significantly higher levels of brain PARP1 gene expression. To examine potential antidepressant activity of PARP inhibitors, rats were administered PARP inhibitors or saline vehicle and were exposed to the Porsolt swim test or repeated social defeat and chronic unpredictable stress. Two PARP inhibitors were investigated, 3-aminobenzamide (3-AB) and 5-aminoisoquinolinone (5-AIQ). PARP inhibitors produced antidepressant-like effects in the Porsolt swim test similar to the common antidepressant fluoxetine by significantly decreasing immobility time and increasing latency to immobility. PARP1 inhibitors did not significantly affect locomotor activity or swim speeds, suggesting that antidepressant-like actions of these drugs were not secondary to a stimulant effect. Treatment of rats with a combination of 3-AB and fluoxetine, at low doses of these drugs that individually did not have antidepressant-like effects, significantly decreased immobility time and increased latency to immobility in the swim test. Finally, treatment of rats with 3-AB significantly increased sucrose preference and social interaction times relative to vehicle-treated control rats following repeated exposure to combined social defeat and unpredictable stress, exhibiting effects similar to fluoxetine treatment. These findings uncover PARP1 as a unique molecular target for the development of a novel class of antidepressants that could be used alone or in combination with existing antidepressants.

**Title:** D-lysergic acid diethylamide (LSD) reverses depressive-like behavior and serotonergic (5-HT) neurotransmission impairments in a murine model of chronic stress

**Authors: *D. DE GREGORIO**[1], Y. EL-RAHIMY[1], L. POSA[1], A. AGUILAR-VALLES[2], M. LOPEZ-CANUL[1], J. ENNS[1], S. COMAI[3], N. SONENBERG[2], G. GOBBI[1]
[1]Dept. of Psychiatry, [2]Dept. of Biochem. and Goodman Cancer Res., McGill Univ., Montreal, QC, Canada; [3]Div. of Neurosci., San Raffele Scientific Istitute, Milano, Italy

**Abstract: Background**: D-lysergic acid diethylamide (LSD) is a hallucinogenic drug that has recently generated interest due to clinical findings reporting its beneficial mood-enhancing properties (Gasser et al. 2014. J Nerv Ment Dis.). However, until now, the effects of LSD in areas of the brain associated with mood regulation have not been well examined in animal models. A previous study demonstrated that treatment with LSD (0.13 mg/kg/day, 11 days) improved active avoidance learning in an animal model of depression (olfactory bulbectomy) (Buchborn et al., 2014 J Psychopharmacol.). Recent studies have demonstrated that low doses of LSD (5-20 μg/kg) decreased the activity of serotonin (5-HT) neurons in Dorsal Raphe Nucleus (DRN), while at higher doses (60-120 μg/kg), LSD decreased the firing rate of dopaminergic neurons in the Ventral Tegmental Area, suggesting a psychotic-like effect at higher doses (De Gregorio et al. 2016. Pharmacol Res.). The aim of this study was to investigate the effect of chronic administration of low-dose LSD in a mouse model of chronic stress (CS), employing behavioural paradigms of depression and *in vivo* electrophysiological recordings. **Methods:** The CS stress paradigm was performed as previously described (Andrus et al. 2012. Mol Psychiatry): 8-week old male C57BL/6J mice were individually placed in restrainers for 2 hours per day, over 14 days. Control mice (CTL) remained undisturbed in their original cages. From the 7$^{th}$ to 14$^{th}$ day of stress, both CTL and CS mice received LSD (15 or 30 μg/kg/day, s.c.) or vehicle (veh); on the 15th day after the CS, the groups of mice were tested separately. Specifically, the Open Field Test (OFT), Forced Swim Test (FST) and Novelty Suppressed Feeding Test (NSFT) were employed. *In-vivo* single unit extracellular recordings of 5-HT DRN neurons were also performed. **Results:** CS mice showed decreased locomotion in OFT, compared to the CTL group ($p<0.05$). Treatment with LSD (30 μg/kg/day, s.c) normalized the distance travelled ($p=0.024$). The CS group showed increased immobility time compared to CTL mice in the FST ($p = 0.009$), while CS mice treated with LSD (30 μg/kg/day,s.c.) showed a decreased immobility time, vs. veh ($p = 0.006$). Moreover, the NSFT revealed that LSD (15 and 30, μg/kg/day, s.c) reduced the latency to feed in CS mice ($p<0.001$), which was increased after 14 days of restraint. Finally, CS mice showed a decreased mean firing activity of 5-HT DRN neurons compared to CTL ($p<0.05$). LSD restored firing rates to CTL group level ($p<0.05$). **Conclusion:** This study demonstrates that chronic treatment with low doses of LSD improves depressive-like behaviour and restores the low 5-HT firing activity induced by chronic stress.

**Title:** Sex differences in ketamine addiction-like behavior and nucleus accumbens spine morphology in chronic mild-stressed rats pre-treated with ketamine

**Authors: *K. N. WRIGHT**, C. E. STRONG, M. KABBAJ
Biomed. Sci., Florida State Univ., Tallahassee, FL

**Abstract:** Major depressive disorder (MDD) is a profoundly debilitating disease that affects roughly twice as many women as men. Among MDD patients who are resistant to traditional antidepressant drugs, sub-anesthetic ketamine infusions possess rapid antidepressant effects. While low doses of ketamine has a clear therapeutic benefit for MDD, chronic exposure to higher doses is well-known for its abuse liability. This is a concern for women especially, since women display a more rapid progression through addiction milestones than men, despite similar levels of drug use. Since MDD is highly comorbid with drug addiction, ketamine's therapeutic potential must be assessed alongside its abuse liability, which has not yet been assessed in MDD patients, females, or in preclinical studies. Previous work from our lab indicates that female rodents are more sensitive to ketamine's antidepressant-like effects than males. Additionally, both males and females display ketamine-seeking behavior under an extinction-reinstatement test following intermittent intravenous ketamine self-administration. The rats used in the aforementioned studies, however, were stress-naïve, and it is unknown whether rats with depression-like behavior will have a greater propensity to self-administer ketamine, and furthermore, whether administration of antidepressant ketamine will increase the subsequent likelihood to self-administer ketamine. To answer these questions, male and female rats underwent chronic mild stress (CMS) and were treated with four intermittent, intravenous infusions of sub-anesthetic ketamine. Antidepressant ketamine infusions ameliorated some of the depression-like traits as measured by the novelty-suppressed feeding test and sucrose preference test. Then, rats underwent self-administration of 0.5 mg/kg/inf ketamine under fixed-ratio 1 (FR1) and progressive ratio (PR) schedules of reinforcement, and incubation of ketamine craving at multiple time points after the last exposure. CMS females displayed greater ketamine addiction-like behaviors than non-stressed females or males of either condition. Interestingly, CMS females pre-treated with ketamine display augmented addiction-like behavior compared to CMS females without ketamine pre-treatment, an effect not observed in male counterparts. Finally, alterations in dendritic spine morphology were measured in the nucleus accumbens, an

area affected by both depression and addiction. Taken together, the integration of these two behavioral models will contribute towards a more complete understanding of ketamine's therapeutic and abusive properties in susceptible populations.

**Title:** Group II metabotropic glutamate receptor blockade promotes stress resilience

**Authors: *J. N. HIGHLAND**[1,2], P. ZANOS[2], P. GEORGIOU[2], T. D. GOULD[2,3,4]
[1]Program in Toxicology, [2]Dept. of Psychiatry, [3]Pharmacol., [4]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

**Abstract:** Stress is one of the most widely recognized and well-studied risk factors for the development of psychiatric disorders, including depression. Enhancing stress resilience may be a therapeutic strategy to prevent the development of depression, or the exacerbation of symptoms. Group II metabotropic glutamate receptor ($mGluR_2$ and $mGluR_3$) antagonists have gained attention for their rapid-acting antidepressant action in animal models; however, the effects of genetic and pharmacological manipulation of these receptors have not been studied as extensively in regards to stress resilience. We assessed the effects of prophylactic treatment with the selective group II antagonist LY341495 and utilized knockout mice lacking either $mGluR_2$ or $mGluR_3$ to determine the role of mGluRs on stress resilience. We also assessed whether activation of group II mGluRs by the selective agonist LY379268 would promote stress susceptibility. Treatment with LY341495 prior to exposure to inescapable shock decreased the development of helpless behavior assessed in the learned helplessness paradigm. In contrast, treatment with the group II mGluR agonist LY379268 increased the number of escape failures in the same paradigm. Neither treatment affected pain threshold assessed via response to shock. Furthermore, we show that $mGluR_2$ knockout ($mGluR_2^{-/-}$) mice are more resilient to stress, as evidenced by decreased immobility time in the forced-swim test and reduced escape failures in the learned helplessness paradigm as compared to wild-type (WT) littermate controls, without altered sensitivity to shock. $mGluR_3^{-/-}$ mice were not significantly different than WT controls in the forced swim test. Following chronic social defeat stress, $mGluR_2^{-/-}$ mice also demonstrated enhanced resilience, as evidenced by a lack of stress-induced sucrose preference deficits. Using both pharmacological and genetic manipulations, our results demonstrate that group II mGluR

activity can modulate susceptibility to maladaptive stress-induced behaviors in mice. Specifically, activation of group II mGluR receptors promotes stress susceptibility, while inhibition of $mGluR_2$ prevents such effects. These data suggest that $mGluR_2$ antagonists may be protective against stress-induced neurobiological changes, which may underlie susceptibility to psychiatric disorders, including depression.

**Title:** Antidepressant-like action of Punica granatum extract in a menopause model in Wistar rats

**Authors: *B. G. VALDÉS SUSTAITA**[1], E. M. ESTRADA[3], C. LOPEZ-RUBALCAVA[2]
[1]Farmacobiología, CINVESTAV-IPN, Ciudad DE Mexico, Mexico; [2]CINVESTAV-IPN, Mexico DF, Mexico; [3]Inst. Natl. Psiquiatria, Distrito Federal, Mexico

**Abstract:** The pomegranate extract has a high content of phytoestrogens and polyphenols that confer estrogenic and chemopreventive activities suggesting its potential use as an alternative for the treatment of depression associated with menopause. The aim of this work was to determine if the aqueous extract of pomegranate (AE-PG) produces antidepressant-like effects in the estrogen deprivation animal model and whether its mechanism of action involved the activation of estrogen receptors. Also, the effect of the combination of AE-PG with citalopram was explored. Thus, the antidepressant-like effect of AE-PG(0.1, 1, 10 and 100 mg/kg) was evaluated in ovariectomized female Wistar rats using the forced swimming test and its effect was compared with that produced by 17β-estradiol ($E_2$, 1.25, 2.5, 5.0 and 10$\mu$ g/rat) and citalopram (CIT; 2.5, 5.0, 10 and 20.0 mg/kg). In a second experiment, AE-PG(1 mg/kg) was evaluated in the presence of the antagonist of estrogen receptors tamoxifen (Tmx; 15 mg/kg). Finally, the combination of suboptimal doses of AE-PG(0.1 mg/kg) and CIT (2.5 mg/kg) was evaluated. All treatments were administered chronically for 14 days. AE-PG produced antidepressant-like effects at 1, 10 and 100 mg/kg decreasing immobility and increasing swimming behavior in a similar manner that ,

CIT (5.0, 10 and 20.0 mg/kg) and $E_2$(5.0 and 10.0 g / rat) Tmx blocked the antidepressant-like effect ofAE-PG confirming the participation of the estrogen receptor (ER). The combination of suboptimal doses of CIT and AE-PG synergies to produce an antidepressant-like effect in the forced swimming test. No treatment produced locomotor activity alterations. In conclusion, the results support the hypothesis that AE-PG exerts antidepressant-like effects in an animal model of menopause.

**Title:** Altered peptide ligands of myelin basic protein produce antidepressant-like effects via inflammatory factors and p11

**Authors: *Y. HAN**[1], C.-Y. SUN[1], S.-Q. MENG[1], K. YUAN[2], J. SHI[3], L. LU[4]
[1]Peking Univ., Beijing, China; [2]Natl. Inst. of Drug Dependence, Beijing, China; [3]Natl. Inst. On Drug Dependence of Peking Un, Beijing, China; [4]Inst. Mental Health,Peking Univ. Sixth Hospita, Beijing City, China

**Abstract: Background:** Cytokine levels are generally changed in both depressed patients and animal models. Altered peptide ligand (APL) of myelin basic protein (MBP) regulates levels of various cytokines, and $MBP_{87\text{-}99}[A^{91}]$ produces an antidepressant effect in rats. **Methods:** The antidepressant effects of two APLs of $MBP_{87\text{-}99}$, $MBP_{87\text{-}99}[A^{91}, A^{96}]$ and $MBP_{87\text{-}99}[R^{91}, A^{96}]$, were evaluated using the forced swim test (FST), learned helplessness (LH) and chronic unpredictable stress (CUS) paradigms in rats. In addition, using immunohistochemistry, western blot and enzyme-linked immunosorbent assay, we assessed the role of inflammatory factors and p11 signaling in the medial prefrontal cortex (mPFC) in the behavioral responses. **Results:** A single dose of either $MBP_{87\text{-}99}$[A91, A96] or $MBP_{87\text{-}99}$[R91, A96] produced prolonged antidepressant effects by reducing the immobility in the FST, reducing the escape latency and failures in the LH, and preventing CUS-induced anhedonia. $MBP_{87\text{-}99}$[A91, A96] dose-dependently produced antidepressant and anxiolytic-like effects in CUS paradigm. However, $MBP_{87\text{-}99}[R^{91}, A^{96}]$ tended to aggravate the CUS-induced anxiety-like behaviors. $MBP_{87\text{-}99}[A^{91}, A^{96}]$ prevented CUS-induced increases in proinflammatory cytokines, and reversed CUS-induced

decreases in p11, p-CREB and BDNF expression in the mPFC. $MBP_{87-99}$[R91, A96] prevented CUS-induced decrease in BDNF in mPFC, and p11 in DG. Moreover, knockdown of p11 in the mPFC by lentivirus-mediated short-hairpin RNA blunted the antidepressant-like effects of $MBP_{87-99}[A^{91}, A^{96}]$ in rats subjected to FST and CUS. **Conclusion:** Immunization with $MBP_{87-99}[A^{91}, A^{96}]$ produced prolonged antidepressant effects in rats, and the behavioral response is mediated by inflammatory factors and p11 signaling in the mPFC.

**Title:** Intraventricular and intrahippocampal infusions of alpha5 subunit-selective negative allosteric modulators of GABA-A receptors produce rapid antidepressant behavioral changes

**Authors: *C. KOSTELNIK**[1], M. MADDEN[1], K. ROBEY[1], S. M. THOMPSON[2], A. BAILEY[1]
[1]St. Mary's Col. of Maryland, St Marys City, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

**Abstract:** Depression is a leading cause of mortality and morbidity worldwide. Current antidepressant medications, such as selective-serotonin reuptake inhibitors, require several weeks to produce behavioral effects and are not effective in treating all patients. Recent work has indicated that systemic injections of negative allosteric modulators of GABA-A receptors with alpha5 subunits (GABA-NAMs, such as L-655,708) produce rapid antidepressant effects in rodents. Their site(s) of action remains unknown however. Given the high expression of alpha5 subunits in the hippocampus, we tested the hypothesis that bilateral intrahippocampal infusions of L-655, 708 (5ng/0.2µL) would be sufficient to induce antidepressive responses in the chronic unpredictable stress (CUS) animal model of depression, and compared the results to those produced by intra-ventricular infusions (ICV). CUS produced numerous depressive-like behavioral outcomes including reduced body weight, reduced sucrose intake, increased latency to eat in a novelty suppressed feeding task (NSF) and a reduced social interaction score. Both ICV infusions of L-655, 708 (5ng/0.2µL) and intrahippocampal infusions of L-655, 708 (5ng/0.2µL) significantly improved behavior in the NSF task 24-hours after infusion. However, ICV and intrahippocampal infusions produced differing effects on sucrose intake and social

interaction. Intrahippocampal, but not ICV, infusions of L-655, 708 reversed deficits in social interaction, but improvement in sucrose intake was seen only following ICV infusions but not direct hippocampal infusions. Our data confirm the rapid antidepressant effects of GABA-NAMs and also suggest their behavioral effects on chronic stress-sensitive behaviors may result from actions on different neuroanatomical circuits.

**Title:** Acute glucocorticoid administration rapidly modulates hippocampal local field potentials

**Authors: *A. B. COLE**[1,2], N. HESSELGRAVE[1,2], S. M. THOMPSON[1]
[2]Med. Scientist Training Program, [1]Univ. of Maryland Sch. of Med., Baltimore, MD

**Abstract:** Glucocorticoids are the major neuroendocrine product of the mammalian stress response and are produced during acute stress. Homeostatic regulation of glucocorticoid levels by the hypothalamic-pituitary-adrenal (HPA) axis is critical, as prolonged duration of elevated glucocorticoids is detrimental to many organ systems including the brain. Dysregulation of the HPA axis is one of the most consistent biological findings in patients with major depression. This dysregulation is evident by administration of the synthetic glucocorticoid dexamethasone (DEX), which is unable to suppress cortisol production in some forms of depression. Glucocorticoid receptors are expressed in the hippocampus at high levels. Recent evidence also suggests glucocorticoid receptors can act rapidly via non-genomic pathways. We therefore tested the hypothesis that glucocorticoids modulate hippocampal neuronal activity rapidly and changes in hippocampal activity are relayed to other downstream nuclei that control corticosteroid secretion, such as the paraventricular nucleus of the hypothalamus (PVN). We have tested this hypothesis by recording local field potentials *in vivo* from the hippocampus and PVN of isoflurane-anesthetized rats. Acute administration of DEX rapidly induced a characteristic pattern of discharge, resembling burst suppression firing seen in electroencephalography, within 10 minutes and this discharge persisted for around 60 minutes. Similar firing patterns were seen in response to acute stress. Highly correlated discharge patterns were recorded simultaneously from the PVN. Our work will further explore the modulation of these firing patterns by glucocorticoids, the role of membrane glucocorticoid receptors, potential glucocorticoid

interaction with anesthetics, and the potential alteration of this signaling in chronic stress models of depression.

**Title:** Synaptic potentiation at the hippocampus-nucleus accumbens synapse modulates reward behavior

**Authors: *T. A. LEGATES**, M. D. KVARTA, S. M. THOMPSON
Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

**Abstract:** The nucleus accumbens (NAc) is a central component of the reward system and is responsible for integrating information from cortical and limbic brain regions to drive goal directed behavior. The ventral hippocampus provides excitatory input to the NAc shell, which is important for modulating NAc activity and providing contextual information to reward processing. This synapse has received increased attention due to emerging evidence of its critical role in mood regulation, specifically in response to reward and motivation to seek rewards. Whether these synapses display activity-dependent synaptic plasticity, and by what mechanisms, remains to be clarified. We used whole-cell electrophysiological recordings in the NAc shell examine the mechanisms of induction and expression of plasticity. Our data show that this synapse is capable of undergoing activity-dependent long-term potentiation (LTP) via postsynaptic mechanisms. The induction of LTP was N-methyl-D-aspartate (NMDA) receptor - and $Ca^{2+}$/calmodulin-dependent kinase type II (CaMKII)-dependent, and was independent of dopamine receptor signaling. We used optogenetic stimulation of this synapse to assay the behavioral consequence of *in vivo* manipulation of this synapse. We found that a brief period of 100Hz high frequency stimulation (HFS) was capable of inducing conditioned place preference, whereas the same number of stimuli delivered at low frequency (4 Hz) did not. HFS but not 4Hz caused a corresponding increase in cFos expression in the NAc shell. This suggests that potentiation of this synapse *in vivo* is important for contextual reward processing. These experiments provide the first detailed electrophysiological characterization of the excitatory

input from the hippocampus to the NAc and provide a functional role for potentiation of this synapse in regulating reward related behaviors.

**Title:** The influence of alpha5 subunit-selective negative allosteric modulators of GABA-A receptors on sexual conditioned place preference in a rodent model of depression

**Authors: *A. BARRETT**[1], K. LA[1], H. STARNES[1], S. M. THOMPSON[2], A. BAILEY[1]
[1]Psychology Dept., St. Mary's Col. of Maryland, St Marys City, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

**Abstract:** Human depression is characterized by significant sexual dysfunction, particularly loss of libido. Negative allosteric modulators of GABA-A receptors (GABA-NAMs) with an alpha5 subunit (such as L-655,708) produce rapid antidepressant effects in rodent models of anhedonia, typically measured as a loss of sucrose preference and a loss of social interaction following chronic stress exposure, but the effects of stress and GABA-NAMs on sexual reward are unknown. Conditioned place preference (CPP) is often used to test the rewarding properties of various stimuli and may be used as another measure of anhedonia. We used the CPP task to measure changes in sexual conditioning to examine the effects of both chronic stress and L-655, 708 on a behavior with ethological relevance. Male rats trained in a standard CPP paradigm showed a significant increase in preference for the chamber associated with a sexually receptive female following six days of conditioning. Animals were then exposed to 15 days of chronic restraint stress (CRS). CRS significantly reduced weight gain, decreased sucrose intake, and reduced sexual behavior (as measured by mounts and intromissions) compared to control animals. One injection of L-655, 708 (0.7 mg/kg; i.p.) significantly increased sucrose intake 24-hours later in animals previously exposed to CRS, replicating the rapid antidepressant effect of L-655, 708 in rodents. Examination of the sexual CPP task following CRS exposure identified a significant increase in time spent in the chamber associated with a receptive female following

injection of L-655, 708 compared to stressed animals given a vehicle injection. Similarly, L-655 increased the number of mounts and intromissions in animals previously exposed to CRS compared to CRS animals given a vehicle injection. We conclude that chronic stress induces sexual anhedonia, characterized by loss of interest and decreased mating, and that L-655, 708 rapidly (24 hrs) reverses these changes, providing additional evidence of the promise of GABA-NAMs as novel fast-acting antidepressants.

**Title:** Differential effects of fluoxetine and citalopram treatments on seizure susceptibility and depressive-like behavior in an animal model of epilepsy and depression comorbidity

**Authors: *A. VALDÉS-CRUZ**, A. DÍAZ-JIMÉNEZ, B. A. GARAY-CORTES, D. U. GONZÁLEZ-MÉNDEZ, M. G. MARTÍNEZ-MONTALVO, P. DOMÍNGUEZ-ZÚÑIGA
Inst. Nacional De Psiquiatría RFM, México, Mexico

**Abstract:** Two of the selective serotonin reuptakes inhibitors (SSRIs) in clinical use for the treatment of depression are fluoxetine (FLX) and citalopram (CIT). Despite the efficacy of both drugs on the depression, the effect on comorbidity with epilepsy remains controversial. Experimental models have shown that SSRIs affects excitability in short time scales which may lead to changes in epilepsy severity. Amygdaloid kindling (AK) is a model of epileptogenesis characterized by sustained increase in seizure susceptibility. Therefore, the goal of the present study was to examine AK epileptogenesis with behavioral correlates of depression in the rat forced swim test (FST) as well as the effects of FLX and CIT on seizure susceptibility and depressive-like behavior. Male Wistar rats (280-320 g) were used. Tripolar electrodes were placed in the basolateral nucleus of left temporal lobe amygdala, and both frontal cortices. AK was induced by daily electrical stimulation (1 s train, 1 ms pulses, 60 Hz, 250-500 μA) until reach AK stage V (tonic-clonic seizure) for three consecutive days. One hour after last seizure, FST sessions were conducted by placing rats in individual glass cylinders (46 cm height; 20 cm diameter). An initial FST of 15 min (pre-test) was performed and after 24 h, was performed a 5 min test. Three FLX doses (10 mg/Kg) or three CIT (10 mg/Kg) doses were administered following a sub-acute schedule, three injections administered between pretest and test sessions

(21 h, 5 h, and 1 h before test session). Animals were assigned to ten experimental groups of seven rats each: a) Control-FST only with FST; b) Control-K only with AK; c) K-FST-FLX, in which AK, FST and FLX injections were applied; d) K-FST-CIT, in which AK, FST and CIT injections were applied; e) K-FST-Vh, AK, FST and Vh (Vehicle, 2 ml/Kg NaCl 0.9%); f) K-FLX, in which AK, and FLX injections were applied; g) K-CIT in which AK, and CIT injections were applied ; h) Sham-FST-FLX, FST and FLX; i) Sham-FST-CIT, FST and CIT; and j) Sham-Vh, FST and Vh. Immobility time in FST and seizure susceptibility on test stimulations of post stage V were assessed. We found a decrement in immobility time in the FST on KEA+PNF+FLX compared with all groups to except KEA+PNF+Vh; and between KEA+PNF+Vh compare to Control-PNF, KEA+PNF+CIT and Sham+PNF+CIT. An increase in swim on KEA+PNF+FLX compare to Control-PNF, KEA+PNF+CIT and Sham+PNF+CIT. Whereas also KEA+PNF+FLX group shows an increase on susceptibility to tonic-clonic seizure. Our results suggest that differential effects of FLX, on seizure susceptibility, and CIT, in non-antidepressive effect, could be by the pharmacodynamic differences at the level of 5-HT receptors affinity of each SSRIs.

**Title:** Cgrp ameliorate depression-like behavior in social defeat stress model mice

**Authors: *N. HASHIKAWA-HOBARA**, S. MISHIMA, S. MATSUUCHI, N. HASHIKAWA
Life Sci., Okayama Univ. of Sci., Okayama, Japan

**Abstract:** Calicitonin gene-related peptide (CGRP), which is produced in both peripheral and central nervous system, is well known as a potent vasodilator. Although CGRP plays an important role in central nervous system, its effect on posttraumatic stress is not clear. In the present study, we used social defeat stress model as an animal models for posttraumatic stress disorder. C57BL6J mice were exposed to and suppressed by a single aggressor animal (ICR mice) each day for 10 min for a total of 14 days. After the last defeat, CGRP (0.5 nmol) were administered by intracerebroventricular injection. To investigate the effects of exogenously increased CGRP on depression-like behavior in stressed mice, we used a forced swim test, tail suspension test and sucrose preference test. We found CGRP decreased immobility time in both

forced swim test and tail suspension test. Furthermore, in the sucrose preference test, which measures anhedonic-like deficits, sucrose preferences were significantly lower in stressed mice and increased by CGRP injection as same as control level. These results suggest that CGRP treatment induces anti-depressant-like effects in stressed mice.

**Abstract:** Neuron-microglia interactions play a crucial role in maintaining the neuroimmune system. The balance of neuroimmune system has emerged as an important process in the pathophysiology of depression. However, how neuron-microglia interactions contribute to major depressive disorders has been poorly understood. Herein, we demonstrated that microglia-derived synaptic changes induced antidepressive-like behavior by using microglia-specific signal transducer and activator of transcription 3 (STAT3) knockout ($STAT3^{fl/fl}$;$LysM\text{-}Cre^{+/-}$) mice. We found that microglia-specific STAT3 knockout mice showed antidepressive-like behavior in the forced swim, tail suspension, sucrose preference and open field tests. Surprisingly, the

secretion of macrophage colony-stimulating factor (M-CSF) was increased from neuronal cells in the brains of STAT3$^{fl/fl}$;LysM-Cre$^{+/-}$ mice. Moreover, the phosphorylation of antidepressant-targeting mediators and brain-derived neurotrophic factor (BDNF) expression were increased in the brains of STAT3$^{fl/fl}$;LysM-Cre$^{+/-}$ mice as well as in neuronal cells in response to M-CSF stimulation. Importantly, the miniature excitatory postsynaptic current (mEPSC) frequency in the medial prefrontal cortex was increased in STAT3$^{fl/fl}$;LysM-Cre$^{+/-}$ mice and the M-CSF treatment group. Collectively, microglial STAT3 regulates depression-related behaviors *via* neuronal M-CSF-mediated synaptic activity, suggesting that inhibition of microglial STAT3 might be a new therapeutic strategy for depression.

**Abstract:** Neuroinflammation has been shown to be involved in pathological conditions like cortical spreading depression, seizures and ischemia. Its involvement in physiological processes like neurogenesis, learning and memory has also been reported. Recent research also points out a role for neuroinflammation in intercellular signaling in the central nervous system, which is triggered by homeostatic imbalance. Based on these findings, we hypothesized that neuroinflammation may have a central role in understanding mechanisms of action of electroconvulsive therapy (ECT), one of the oldest and most effective treatments in psychiatry. Limited data point to a microglial activation after ECT, but to our knowledge, the neuroinflammatory response originating from neurons and other glial cells after ECT has not been examined before. In this study, we investigated whether or not a single electroconvulsive

seizure (ECS), a rodent model of ECT, induced neuroinflammatory response. For this, we examined the release of HMGB1, a proinflammatory molecule at 1, 2 , 4 and 6 hours after a single ECS. We observed translocation of HMGB1 from nucleus to cytoplasm or complete loss of HMGB1 signal in some cells in the hippocampus and medial prefrontal cortex by immunohistochemistry starting 1 hour after ECS and, confirmed HMGB1 release by detecting an increased amount of HMGB1 in cerebrospinal fluid compared to sham group. ECS did not induce HMGB protein expression in the hippocampus and prefrontal cortex as detected by Western blotting. Brain derived neurotropic factor (BDNF) levels were increased in hippocampus and prefrontal cortex 1 hour and 6 hours after ECT, respectively. These findings suggest a potential relationship between the HMGB1 release and increased BDNF expression, which is currently being tested by knocking down HMGB1 expression before ECS.

**Title:** Response to antidepressant treatment is mediated by an indirect relationship between dentate gyrus activity and adult hippocampal neurogenesis

**Authors: C. YOHN**, E. DIETHORN, A. GARINO, S. SHIFMAN, *B. A. SAMUELS
Psychology, Rutgers Univ., Piscataway, NJ

**Abstract:** Depression is a complex psychiatric disorder that remains a burden on society today since only a subset of depressed patients (33%) attain remission upon initial monotherapy with a selective serotonin reuptake inhibitor (SSRI). Chronic SSRI treatment results in increased extracellular serotonin (5-HT) levels, increased adult hippocampal neurogenesis, and increased hippocampal expression of neurotrophic factors such as BDNF. We recently reported that serotonin 1A receptors in the dentate gyrus (DG), a subfield of the hippocampus, are necessary and sufficient for the behavioral, neurogenic, and neuroendocrine response to chronic SSRI treatment. However, further research is necessary to explore the role of the DG in the neural circuitry underlying the antidepressant response and whether the DG mediates the response to other classes of antidepressants. To this end, we assessed possible interactions between

activation of mature DG granule cells during a behavioral experience, adult hippocampal neurogenesis, and behavioral response to chronic antidepressant treatment. Subsequent to chronic corticosterone (CORT) administration to mimic chronic stress, mice were chronically exposed to antidepressant monotherapies with fluoxetine (FLX), bupropion (BUP), or venlafaxine (VEN). Behavioral response to antidepressants was assessed using the Novelty Suppressed Feeding (NSF) task, which permits stratification into responders and non-responders to antidepressant treatment. Following initial exposure to the NSF test, mice were sacrificed and perfused to assess DG immediate early gene expression and adult hippocampal neurogenesis. Preliminary data indicates that behavioral antidepressant response correlates with an indirect relationship between DG immediate early gene expression and adult hippocampal neurogenesis, where responders have more hippocampal neurogenesis and less immediate early gene expression than non-responders to antidepressant treatment.

**Title:** The role of dentate gyrus activin signaling in antidepressant treatment response

**Authors: *M. GERGUES**[1], C. YOHN[2], M. LEVINSTEIN[4], R. HEN[5], B. A. SAMUELS[3]
[1]Cell Biol. and Neuroscience, Psychology, Cognitive Sci., Rutgers Univ., Colonia, NJ; [3]Psychology, [2]Rutgers Univ., Piscataway, NJ; [4]Univ. of Washington, Seattle, WA; [5]Neurosci. and Psychiatry, Columbia Univ., New York, NY

**Abstract:** Approximately 32-35 million adults in the US population (16%) experience an episode of major depression in their lifetime, and commonly used treatments, such as selective serotonin reuptake inhibitors (SSRIs), are not ideal since only a subset of patients (~33%) achieves remission with initial treatment. The reasons why some individuals remit to antidepressant treatments while others do not are unknown. Our overall research program addresses this question by assessing antidepressant treatment resistance in mice. Proper assessment of the antidepressant response in mice first requires manipulations that will yield behaviors associated with negative valence constructs that can then be reversed by antidepressant

treatment. Chronic treatment of mice with corticosterone (CORT) effectively induces multiple changes in behavior associated with enhanced responses to potential harm and sustained threats (David et al 2009). Subsequent chronic treatment with antidepressants such as fluoxetine (FLX) reverses these behavioral changes in some, but not all, of the mice, permitting stratification into responders and non-responders to FLX. We looked for changes in gene expression in dentate gyrus, a region that we recently reported is critical for the beneficial behavioral, neurogenic, and neuroendocrine effects of FLX (Samuels et al 2015). We found several significant differences in expression of Activin signaling-related genes between responders and non-responders to FLX in the dentate gyrus. Furthermore, modulating Activin signaling in the dentate gyrus can convert behavioral non-responders to FLX into responders.

**Title:** Connective tissue growth factor (CTGF) is a novel pro-depressant molecule

**Authors: *C. A. TURNER**[1], V. SHARMA[2], M. H. HAGENAUER[3], C. AYDIN[4], A. M. O'CONNOR[5], R. C. THOMPSON[3], S. J. WATSON, Jr.[3], H. AKIL[3]
[1]Molec & Behav Neurosci Inst., [2]Mol. and Behavioral Neurosci. Inst., [3]Univ. of Michigan, Ann Arbor, MI; [4]molecular and behavioral neuroscience institute, Universty of Michigan, Ann Arbor, MI; [5]MBNI Univ. of Michigan, Ann Arbor, MI

**Abstract:** Little is known about the role of connective tissue growth factor (CTGF) in the brain. We evaluated the expression of CTGF in our selectively bred model of response to a novel environment, where bLRs exhibit increased anxiety-like and depression-like behavior compared to bHRs. We also assessed the expression of CTGF in the human amygdala of individuals with Major Depressive Disorder (MDD). To understand its role in affective behavior, we administered CTGF to rodents acutely and chronically and tested their affective responses. We then assessed

the ability of an anti-CTGF antibody (FG-3019) to alter emotionality and gene expression. Finally, we assessed CTGF expression in various stress paradigms. In three nuclei of the human amygdala, CTGF expression was increased in individuals with MDD compared to controls. In the bHR/bLR model, CTGF expression was significantly increased in the dentate gyrus (DG) of bLRs in adulthood compared to bHRs. When the highly anxious LRs were administered early life fibroblast growth factor-2 (FGF2), a treatment known to decrease anxiety later in life, the expression of CTGF decreased in the DG in adulthood. In outbred animals, acute CTGF (400ng, i.c.v.) increased depression-like behavior. Moreover, both acute and chronic treatment with FG-3019 was antidepressant. Chronic treatment with FG-3019 also altered the expression of molecules that interact with CTGF, as well as decreasing CTGF itself. Finally, four days of social defeat stress in LRs significantly increased CTGF expression in the dentate gyrus. However, two weeks of chronic variable stress in bLRs decreased CTGF expression in the hippocampus. Thus, the region, nature and/or temporal dynamics of the stress are important. In conclusion, molecules that inhibit or decrease CTGF expression may be effective antidepressants.

**Title:** BDNF release and signaling are required for the antidepressant actions of GLYX-13

**Authors: *T. KATO**[1,2], M. FOGAÇA[1], S. DUMAN[1], X.-Y. LI[1], K. FUKUMOTO[1], R. DUMAN[1]
[1]Lab. of Mol. Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan

**Abstract:** Conventional antidepressant medications, which act on monoaminergic systems, have significant limitations for the treatment of depression, including a time lag of weeks to months and low rates of therapeutic efficacy. GLYX-13 is a novel glutamatergic compound that acts as a modulator of the NMDA receptor with glycine-like partial agonist properties, and like the NMDA receptor antagonist ketamine produces rapid antidepressant actions in depressed patients and in preclinical rodent models. Importantly, GLYX-13 does not produce the dissociative and psychotomimetic side effects observed with ketamine. However, the mechanisms underlying the antidepressant actions of GLYX-13 have not been characterized. Here, we use a combination of neutralizing antibody, mutant mouse, and pharmacological approaches to test the role of BDNF-TrkB signaling in the actions of GLYX-13. The results demonstrate that the antidepressant effects of GLYX-13 in three different models, the forced swim test, novelty suppressed feeding, and female urine sniffing test, are blocked by intra-mPFC infusion of an anti-BDNF neutralizing antibody or in mice with a knock-in of the BDNF Val66Met allele, which blocks the processing and activity dependent release of BDNF. The results also demonstrate that pharmacological inhibitors of BDNF-TrkB signaling or of L-type voltage dependent $Ca^{2+}$ channels (VDCCs) block the antidepressant behavioral actions of GLYX-13. Finally, we examined the role of Rho GTPase proteins, which are required for BDNF mediated stabilization of spines. The results demonstrate that infusion of a selective inhibitor of Rac1 but not RhoA into the mPFC blocks the antidepressant effects of GLYX-13. Together, these findings indicate that GLYX-13 causes activity dependent stimulation of VDCCs, leading to increased release of BDNF, subsequent TrkB-Rac1 signaling, and increased spine synapse number and stability that is required for the rapid and sustained antidepressant effects of GLYX-13.

**Title:** GluN2B subunits on GABAergic interneurons in the medial prefrontal cortex and the antidepressant effects of ketamine

**Authors: *D. M. GERHARD**[1], E. S. WOHLEB[2], R. S. DUMAN[3]
[1]Psychiatry, Yale Univ., New Haven, CT; [2]Dept. of Psychiatry and Behavioral Neurosci., Univ. of Cincinnati Col. of Med., Cincinnati, OH; [3]Yale Univ. Sch. Med., New Haven, CT

**Abstract:** Recent studies highlight the rapid antidepressant actions of the NMDA receptor antagonist ketamine. Rodent studies show that ketamine rapidly increases glutamate release, activates mTORC1 signaling and increases translation of synaptic proteins in the medial prefrontal cortex (mPFC) shortly following acute treatment. Furthermore, additional studies show that selective GluN2B receptor antagonists produce similar behavioral and molecular signaling effects. However, the initial cellular trigger underlying the actions of ketamine has not been identified. Collectively, these studies suggest that blockade of GluN2B-containing NMDARs may be a critical mediator for the rapid antidepressant effects of ketamine. We used CaMKII-, GAD67-, parvalbumin (PV)-, and somatostatin (SST)-Cre mice and viral-NR2B shRNA to produce Cre-dependent knockdown of GluN2B receptors in glutamate and GABA neurons, as well as subpopulations of GABA neurons. Mice were then tested in a preswim and open-field test (OFT) to measure baseline effects of cell-specific NR2B knockdown. Viral GluN2B shRNA was infused into the mPFC of the cre recombinase lines and after 3 weeks to allow for recovery and viral expression, the mice were tested before and after ketamine administration in the forced swim test (FST) and novelty suppressed feeding test (NSFT). Viral-mediated knockdown of GluN2B in the mPFC of GAD67-Cre mice produced a significant antidepressant response in the FST, and occluded the antidepressant effects of ketamine in this model; preliminary studies suggest similar effects in the NSFT. Knockdown of GluN2B on

pyramidal neurons in CaMKII-Cre mice did not significantly block the antidepressant response to ketamine in the FST or NSFT. Similar studies were conducted in SST- and PV-Cre mice and preliminary findings suggest that GluN2B on both SST- and PV-Cre neurons mediates the actions of ketamine. These findings indicate that GABA interneurons are the initial cellular trigger for the actions of ketamine. This results in blockade of tonic firing GABA interneurons and disinhibition of glutamate transmission that leads to increased synaptic connectivity and rapid antidepressant behavioral responses. Studies are being conducted to confirm these findings and to extend the results to other behavioral models.

**Abstract:** Activation of pyramidal cells in the prefrontal cortex is implicated in the antidepressant effect of rapid acting antidepressants, including NMDA receptor antagonists such as ketamine. Consistent with this, optogenetic activation of principal neurons in the prefrontal cortex (PFC) has been demonstrated to produce the long term behavioral changes observed after administration of ketamine, as well as many of the proposed mechanistic effects of ketamine treatment. PFC principal cell subtypes have been defined based on morphological complexity, physiological properties, projection targets, and anatomical location within the PFC, and are referred to as Type A and B cells. Recent work demonstrates that Cre-recombinase expression under control of the dopamine D1 (Type B), or D2 (Type A) receptor allows subtype specific targeting with cre-dependent constructs. It is not clear whether the antidepressant response produced by optogenetic stimulation is carried by a particular subtype of principal neuron or whether concurrent activation of both types is necessary. To address this question we expressed cre-dependent channelrhodopsin (Chr2) in type A or type B principal cells within the mouse medial PFC. Behavioral testing occurred 1 day or more after optogenetic stimulation. Stimulation of type B cells produced an antidepressant response in the forced swim test that was evident 24 hours after stimulation and persisted for up to 7 days. Additionally, an anxiolytic response in the elevated plus maze and novelty suppressed feeding test was observed up to 72

hours after stimulation. In contrast, we observed no behavioral changes following stimulation of type A cells. Immediate early gene (IEG) analysis demonstrated that PFC stimulation of type B cells produced activation within the PFC, bed nucleus of the stria terminalis, and basolateral amygdala, but not the dorsal raphe nucleus. Though IEG activation was evident in the PFC after stimulation of type A cells, no changes in IEG expression were observed in downstream regions. Our results indicate that optogenetic stimulation of type B principal neurons in the medial PFC is sufficient to produce a rapid and enduring antidepressant response that is associated with activation of a distributed network implicated in emotional behavior. Experiments are ongoing using inhibitory opsins to test the necessity of type B pyramidal cells to the antidepressant response produced by ketamine administration.

**Title:** Characterization of the signaling mechanisms underlying the rapid antidepressant actions of the ketamine metabolite (2R,6R)-Hydroxynorketamine and GLYX-13

**Authors: *M. FOGACA**[1], F. KENICHI[2], R. S. DUMAN[3]
[1]Psychiatry, [2]Yale Sch. of Med., New Haven, CT; [3]Yale Univ. Sch. Med., New Haven, CT

**Abstract:** Low doses of the NMDA receptor antagonist ketamine produce rapid antidepressant actions even in patients considered treatment resistant. Recent studies demonstrate that the ketamine metabolite (2R,6R)-hydroxynorketamine (HNK) produces antidepressant actions in rodent models, without the side effect profile of ketamine. In addition, the NMDA receptor modulator GLYX-13 also produces rapid antidepressant actions in depressed patients and rodent models, without ketamine-like side effects. We are interested in identifying the cellular target(s) and signaling pathways that mediate the actions of these agents, and have reported that ketamine and GLYX-13 cause activity dependent release of BDNF and stimulation of mTORC1/p70S6K signaling in the prefrontal cortex (PFC), as well as in primary cultured neurons. Here we conduct *in vitro* cortical primary culture studies to extend these findings to HNK and to further test the role of BDNF in the regulation of mTORC1 signaling. Preliminary studies demonstrate that

HNK produces a dose and time dependent stimulation of the phosphorylated and activated forms of mTOR and p70S6K, as well as the upstream kinase ERK in primary neuronal cultures. This is consistent with preliminary *in vivo* studies showing that the antidepressant behavioral actions of HNK are blocked by infusion of the selective mTORC1 inhibitor rapamycin, or by infusion of a BDNF neutralizing antibody into the mPFC. Further studies of GLYX-13 in cultured neurons show that incubation with a BDNF neutralizing antibody prevents the stimulation of mTORC1 and ERK signaling, demonstrating a requirement for extracellular BDNF. Incubation with the VDCC blocker verapamil also blocks GLYX-13-induced BDNF release. Additional *in vitro* studies are being conducted to determine if HNK also causes activity and VDCC dependent release of BDNF in primary cultured neurons. Together these results suggest that rapid acting antidepressants cause activity dependent release of BDNF and subsequent activation of mTORC1 signaling. Studies are being conducted to determine if these agents act directly on principle neurons or indirectly on inhibitory neurons to produce activity dependent signaling and synaptic changes that underlie rapid antidepressant responses. *Supported by NIMH Grants MH045481 and MH093897, and the State of CT.*

**Title:** Sex-dependent persistent alterations in microglial morphology following chronic unpredictable stress

**Authors: *C. Y. XU**, *C. Y. XU, T. C. FRANKLIN, R. S. DUMAN
Yale Univ., New Haven, CT

**Abstract:** Major Depressive Disorder (MDD) is a recurrent mental health illness with more than half of affected patients relapsing after their initial episode. High levels of psychological or environmental stressors are associated with the initial development of MDD and may play a role in recurrent episodes. Interestingly, susceptibility to both stress-induced depressive-like behaviors and immune activation differ between males and females and may play a role in the sexual dimorphic risk associated with psychological disorders such as depression. Our

preliminary results demonstrate that chronic stress promotes long lasting hippocampal microglia morphological changes in male rodents, which coincide with prolonged risk for stress-induced depressive-like behaviors. However, it is unclear if female rodents show similar persistent effects following chronic stress. In this study, we assessed sexual dimorphic effects of long-lasting microglial changes that corresponded with development and recurrence of depressive behavior using a chronic unpredictable stress (CUS) model in rodents. Male and female C57BL6 mice were tested for depressive-like behaviors following CUS (28 days) using a sucrose preference test (SCT) and tail suspension test (TST). Microglial morphological changes were assessed immediately following CUS exposure, and preliminary results demonstrate that female mice show evidence of activated microglia similar to morphological changes to those observed in male mice. To determine if stress-induced microglia alterations persisted in female mice after CUS, additional studies were performed in which males and female mice were exposed to CUS then allowed to recover for 4 weeks. Hippocampal microglia morphological changes were assessed in post stress animals and compared between males and females. Together, these data will provide novel insights into potential sex-dependent differences in stress-induced priming of microglial and subsequent susceptibility to depressive-like behaviors.

**Abstract:** A single, low-dose infusion of ketamine produces an antidepressant effect in depressed patients within a few hours of administration lasting for up to a week, making it one of

the most promising possibilities in the search for antidepressants that are faster-acting and more reliable than those currently available. The neural circuitry that responds to ketamine has yet to be fully characterized. It has been shown that ketamine induces glutamate release in the medial prefrontal cortex (mPFC), and that blocking glutamate transmission in the mPFC also blocks its antidepressant effect. This laboratory has demonstrated that it is possible to produce long-lasting synaptic and antidepressant-like behavioral responses in rats with a single, one-hour, 10-Hz optogenetic stimulation of excitatory neurons in the mPFC, using an rAAV2-CaMKIIα-ChR2(H134R)-EYFP vector. Here, we have found that a one-hour stimulation of ChR2-expressing axon terminals in the dorsal raphe nuclei (DRN) projecting from cell bodies in the mPFC of rat is also sufficient to produce an antidepressant-like effect in the forced-swim test (FST), but not in other assays of depression and anxiety behavior; this effect is present 24 hours after stimulation, but not 7 days after. This result raises the possibility that the DRN may be an important part of the circuitry that underlies the antidepressant response to ketamine. The effect of ketamine on the mPFC to DRN projection is being directly examined by infusing 8OH-DPAT, which inhibits the release of serotonin, into the DRN to test whether serotonin release is necessary for ketamine's antidepressant effect. To better understand how ketamine affects this circuit, immunohistochemical studies are being conducted to assess how the stimulation of these terminals affects neural activity in the DRN and which cells within the DRN are targeted by the activation of these axons. Finally, we are also examining the effect of optogenetically stimulating mPFC-originating axon terminals in the nucleus accumbens, to understand whether the antidepressant effect of stimulating mPFC-DRN terminals is unique to that pathway.

**Abstract:** Post-traumatic stress disorder (PTSD) is a debilitating psychiatric disorder with a life-time prevalence of 7.8% in the general population. Numerous studies suggest that alterations in gene transcription are associated with onset of PTSD. The majority of these studies have focused on peripheral blood transcript changes. While it is likely that many changes observed in the periphery reflect changes in the CNS, there are currently few studies directly examining the transcript changes occurring in brain. However, through recent efforts supported by the VA and the National Center for PTSD, a brain bank is being developed and is providing tissue for studies of the neurobiology of PTSD. We performed high through-put RNA-sequencing on human post mortem subgenual prefronal cortex (PFC) (Brodmann Area 25) from subjects with PTSD, a psychiatric control (major depressive disorder, MDD), and matching controls. Multidimensional scaling revealed significant differences in the gene expression patterns in subjects with PTSD and MDD, as well as some overlap between these groups. Further, we identified gene expression network changes in immediate early genes, inflammatory pathways, and in glucocorticoid signaling. We used classical fear conditioning in rats as an animal model of PTSD and found regulation of several of these transcripts in medial prefrontal cortex (mPFC) after training, consistent with expression changes of these genes in human subgenual PFC. These post mortem and preclinical studies have identified several key factors in PTSD pathophysiology and as a potential new target for therapeutic intervention.

**Abstract:** Maladaptive alterations that result from severe or chronic stress exposure are associated with increased risk for Major Depressive Disorder (MDD). Chronic stress promotes dysregulation of the innate immune system leading to enhanced inflammatory signaling often associated with depressive symptoms. Growing evidence suggests that innate immune cells such as microglia, promote neuroinflammation in response to stress by releasing danger associated molecular pattern (DAMP) molecules leading to increased inflammatory signaling through binding to pattern recognition receptors such as toll-like receptor 4 (TLR4) and the receptor for advanced glycation end products (RAGE). Our preliminary studies show that microglial RAGE is upregulated in response to chronic unpredictable stress (CUS) and enhanced microglial RAGE expression coincides with the *onset* and *recurrence* of stress-induced depressive-like behaviors, even weeks after stress exposure. Most importantly, constitutive RAGE KO mice show an attenuation of stress-induced depressive-like behavioral effects. These novel findings indicate that chronic stress exposure leads to long-lasting alterations of microglia, including increased expression of RAGE, that primes microglia to subsequent exposure to stress and susceptibility to depressive behaviors. We therefore hypothesize that deletion of RAGE specifically in microglial will attenuate depressive-like behaviors following stress due to suppressed DAMP signaling. In this presentation, we will present data from ongoing studies that examine the role of RAGE signaling in the development of depressive-like behaviors following chronic stress. To test this hypothesis, we generated $RAGE^{fl/fl}$:$CX3CR1^{CreERT}$ mice and utilized tamoxifen-induced Cre recombinase system for cell-specific deletion of microglial RAGE. Cre negative animals were used as controls. Tamoxifen-induced conditional RAGE knockout (KO) mice will be tested for cognitive, anxiety and depressive-like behaviors at baseline and after CUS exposure using novel object recognition (NOR), open field test (OFT), tail suspension test (TST) and sucrose consumption test (SCT). Microglial morphological changes will be assessed immediately following CUS exposure to determine if microglial RAGE deficient mice display reduced microglial reactivity following chronic stress exposure compared to littermate controls. Together, these data will provide novel insights into the role of microglial RAGE signaling in stress-induced microglial reactivity and the development of depressive-like behaviors.

**Title:** Rapid antidepressant actions of ketamine require acute inhibition of GABA interneuron firing

**Authors: *S. GHOSAL**[1], M. FOGACA[1], B. D. HARE[4], D. M. GERHARD[2], M. WU[1], M. ALREJA[1], C. H. DUMAN[3], R. S. DUMAN[5]
[2]Psychology, [3]Dept. of Psychiatry, [1]Yale Univ., New Haven, CT; [4]Psychiatry, Yale Sch. of Med., New Haven, CT; [5]Yale Univ. Sch. Med., New Haven, CT

**Abstract:** Imbalance of excitatory and inhibitory neurotransmission within the prefrontal cortex (PFC) circuitry has been implicated in clinical and rodent studies of depression. The rapid antidepressant response to the NMDA receptor antagonist ketamine has been associated with a glutamate burst and activity dependent synapse formation in the PFC. Consistent with these findings we have reported that optogenetic stimulation of principle neurons in the medial PFC produces synaptic and behavioral effects similar to ketamine. Moreover, knockdown of NMDARs on GABA interneurons blocks the antidepressant behavioral actions of ketamine (Gerhard et al., 2017, SfN abstract). These findings suggest that ketamine blockade of tonic firing GABA neurons causes disinhibition of PFC pyramidal neurons, resulting in a glutamate burst and long-lasting synaptic changes that underlie the antidepressant behavioral response. To examine how interactions between distinct types of neurons within the PFC local network contribute to the process of ketamine-mediated antidepressants like effects, we performed a single, one-hour 5-Hz laser stimulation of PFC GAD-positive inhibitory neurons infected with an AAV2-EF1a-DIO-hChR2(H134R)-EYFP construct. We found that optogenetic activation of GABAergic neurons in the PFC attenuated the antidepressant-like effects of ketamine in the forced swim test (FST) and in the novelty suppressed feeding test (NSFT), suggesting that PFC GABAergic interneurons act as the cellular trigger mechanism underlying the rapid antidepressant actions of ketamine. Currently, studies are being conducted to determine if acute, transient suppression of PFC GABAergic interneurons produces antidepressant behavioral effects similar to ketamine. Experiments to test this hypothesis require selective activation and /or inihibition of specific interneuron populations (SST or PV) using a combination of GABA interneuron specific Cre recombinase mice and light or chemically driven manipulation of cell activity. Together these studies will further define the role of GABA interneurons in the actions of ketamine, and determine if ketamine-induced disinhibition underlies a long-term synaptic response that restores the excitatory/inhibitory balances.

**Abstract:** The NMDA receptor antagonist ketamine produces rapid antidepressant actions, even in patients considered treatment resistant, addressing a major limitation of currently available medications. In preclinical rodent models the antidepressant behavioral actions of ketamine are associated with increased number and function of synapses in the medial prefrontal cortex (PFC) and these effects are dependent on mTORC1 signaling. The mTORC1 pathway is a cellular regulator of protein synthesis and is modulated by neuronal activity, endocrine and metabolic signals, including amino acids, notably leucine, which activates mTORC1 signaling via the binding to sestrin2. Here, we examined the influence of NV-5138, a small molecule modulator of sestrin2 that penetrates the blood brain barrier, on antidepressant behavioral responses and induction of spine synapses in the prefrontal cortex (PFC). The results demonstrate that NV-5138 (160 mg/kg) produced antidepressant effects in the rat forced swim test (FST), female urine sniffing test (FUST), and novelty suppressed feeding test (NSFT), without effecting locomotor activity or home cage feeding. NV-5138 also reversed the anhedonia caused by chronic unpredictable stress exposure. The effects of NV-5138 were long-lasting, observed for up to 72hrs following a single dose when there was no detectable brain or plasma exposure. As expected, NV-5138 activated the mTORC1 pathway in the PFC 1 hr after administration, similar to ketamine, and the antidepressant actions of NV-5138 were blocked by infusion of the selective mTORC1 inhibitor rapamycin into medial PFC. We also tested synaptic responses of layer V pyramidal neurons in the medial PFC and found that NV-5138 administration rapidly increased the number and function of spine synapses in the apical dendrites. NV-5138 also increased levels of synaptic proteins in PFC, including GluA1 and synapsin1. Taken together, the results demonstrate that NV-5138 produces rapid synaptic and antidepressant behavioral responses via the direct activation of the mTORC1 signaling pathway, supporting the possibility that sestrin2 modulation is a novel target for development of rapid acting antidepressants.

**Title:** The bodybuilding supplement ZMA, & Ketamine (1 mg/kg) produce an additive increase in the anti-depressive index, "swimming time", but not in the depressive index "immobility time", in the forced swimming test in BALB/c mouse

**Authors: *V. J. MEDINA ARANDA**[1], A. L. ROSADO-PEREZ[1], M. VILLALOBOS[1], S. VILLALOBOS[1], J. C. PINEDA[2]
[1]Res. Dept., [2]Ctr. de Investigaciones Regionales, Univ. Autonoma De Yucatan, Merida, Mexico

**Abstract:** Depression is a disorder with a high rate of resistance to available treatments. Ketamine, an N-methyl-D-aspartate receptor antagonist, produces a rapid and sustained antidepressant effect in patients with treatment-resistant depression. But in therapeutic doses produces psychotic symptoms that limits its use. The bodybuilding supplement ZMA (11 mg of pyridoxine, 450 mg of magnesium and 30 mg of zinc) may be used as antidepressant drug, given that deficiency of zinc or magnesium produced depressive or anhedonia symptoms. We tested whether ZMA can potentiate the action of ketamine in BALB/c mice. **Methods:** 32 BALB/c mice were divided into 4 groups of 8 mice each, received a dose of: Ketamine (1 mg / kg; a subthreshold dose for antidepressant activity); or Ketamine (1 mg / kg) + ZMA (0.028125mg / kg); or ZMA in the same dose; 24 hrs. before each test. The mice were subjected to the open field test, (6 minutes). One week after the open field test the mice were subjected to the forced swimming test for 6 minutes. **Results.** ANOVA $F_{3, 27} = 12.44$ P = <0.0001. Tukey´s posttest showed that immobility time (IT) was reduced when ZMA or ZMA + Ketamine was applied against vehicle, but not when Ketamine was applied alone. While for the swimming time (ST) in the last 4 min. of the test, ANOVA reveled significant differences: $F_{3, 27} = 11.72$. P = < 0.001. Tukey´s posttest showed that significant differences between Vehicle with ketamine ($p < 0.05$), with ZMA ($p < 0.05$) and with ZMA + Ketamine ($p < 0.001$). No changes were detected in the climbing time. No differences were detected in the distance traveled by the mice in the open field test. **Discussion:** Ketamine (1 mg/kg), and ZMA reduced the depressive index and increased the

antidepressant index during the forced swimming test in BALB/c mice. Since the effect of Ketamine and ZMA differ for the IT, while for the ST the effect was additive, it is possible that the action on these two behaviors is not mediated by the same mechanisms.

**Title:** Sex differences in the role of ventral hippocampus following retrieval of context fear memory

**Authors: *L. PAN**, A. A. KEISER, N. C. TRONSON
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

**Abstract:** In males, dorsal hippocampus has been extensively studied, and more recently, ventral hippocampus has also been implicated as a key region in the circuitry underlying context fear memory. In females, however, the precise role of hippocampus and the mechanisms underlying context fear conditioning and retrieval remain less clear. Here we examined the role of, and signaling pathways activated in, ventral hippocampus during retrieval of context fear memory in both males and females. Ventral hippocampus was robustly activated after retrieval of context fear conditioning in both sexes, with females showing greater levels of cFos compared with males. These data suggest a role for ventral hippocampus in retrieval of context fear conditioning in both sexes, but that males and females likely differ in the molecular mechanisms recruited

during memory retrieval. To determine whether ventral hippocampus is required for memory retrieval, male and female mice received infusions of muscimol into ventral hippocampus prior to retrieval of foreground context fear conditioning. We observed decreased freezing, demonstrating that ventral hippocampus is required for context fear memory retrieval in both sexes. Finally, to identify whether males and females recruit different intracellular signaling pathways, we collected ventral hippocampus one hour after retrieval of context fear and conducted western blot analysis to identify the activation of PKA-CREB and mTOR-related signaling pathways. Together, our data demonstrate that ventral hippocampus is required for retrieval of context fear, and that retrieval activates different molecular mechanisms in males and females. These data on contextual fear memory retrieval will advance the development of sex-specific treatments for fear and anxiety related disorders such as PTSD.

**Title:** Retrieval of context fear memory involves sex-specific molecular mechanisms and changes in hippocampal gene expression

**Authors: *A. A. KEISER**[1], L. PAN[2], N. C. TRONSON[2]
[2]Dept. of Psychology, [1]Univ. of Michigan, Ann Arbor, MI

**Abstract:** Disorders of fear and anxiety such as post-traumatic stress disorder (PTSD) are more prevalent in women than in men, possibly due to sex differences in retrieval of trauma-related memories. We have previously demonstrated that female mice display greater context fear generalization and show less activation of hippocampus and more activation of amygdala compared with males. Together with findings demonstrating male-specific mechanisms of context fear conditioning, these data suggest that males and females use both different circuit-based mechanisms and molecular mechanisms of memory retrieval. In this study, we examined how sex differences in context fear conditioning affected memory retrieval at remote time points, and identified sex-specific molecular mechanisms of retrieval using RNA-sequencing. In males, context fear memory becomes less hippocampal dependent and more reliant on cortical structures over time via systems consolidation. We show that eight weeks after background context fear conditioning, females but not males exhibit decreased freezing compared to tests one day after conditioning. That is, females show impairments in remote context fear memory.

Immunohistochemistry determined differential recruitment of hippocampus, amygdala, retrosplenial cortex, and anterior cingulate cortex at remote time points in males and females. Such sex differences in remote memory further support the possibility that males and females employ unique mechanisms of context fear conditioning and its retrieval. In order to step away from a strictly male-comparative approach, we employed RNA-sequencing as an unbiased measure to examine regulation of hippocampal gene expression after memory retrieval in females and males. These data will inform molecular pathways activated in females following retrieval of context fear. Understanding the mechanisms mediating retrieval and maintenance of contextual fear memory in males and females will aid in the development of sex-specific treatments for PTSD and potentially lead to methods of cognitive enhancement in healthy individuals.

**Title:** Isolation induced-forgetting of social memory is regulated by Rac1 activity

**Authors: *Y. LIU**[1], L. LI[2], Y. ZHONG[1]
[1]Sch. of Life Sciences, Tsinghua Univ., Beijing City, China; [2]Tsinghua Univ., Beijing city, China

**Abstract:** During the past decades several independent studies have repeatedly confirmed that long-term social recognition memory is impaired by social isolation (SI) of adult mice and rats. However, the mechanisms mediating this impairment and their whereabouts in the brain are yet to be discovered. Currently, we find that hippocampal Rac1 activity increased in isolated mice whereas Rac1 activity decreased in re-grouped mice. Behavior experiments show that inhibiting Rac1 activity in the hippocampus can block the SI induced-social memory impairment. Furthermore, the LTP deficiency in isolated mice can also be rescued by inhibiting Rac1 activity, providing electrophysiological evidence that Rac1 activity mediates social memory impairment. Thus, based on our previous studies of Rac1 regulated-active forgetting, the current findings here indicate that SI induced-social memory impairment might be a kind of active forgetting caused by hippocampal Rac1 activation.

**Title:** Paternal methyl donor-rich diet reduces kcnmb2 expression and causes synaptic function and memory deficits in offspring F1 mice

**Authors: *L. GUO**
Qingdao Univ., Shandong, China

**Abstract:** BK channel is a known regulator of neuronal excitability, synaptic plasticity and memory. Our previous study showed that a paternal methyl donor-rich diet reduces the expressions of *kcnmb2* which *encodes BK channel beta subunit 2*, and caused memory deficits in offspring mice. To explore the underlying cellular mechanism, we measured the BK current, the neuronal excitability, synaptic transmissions and plasticity in CA1 pyramidal neurons of the offspring F1 mice which father was fed with either methyl donor-rich diet (MD) or regular control diet (CD). Whole-cell patch-clamp recordings revealed reduced resting membrane potential, a decrease in inhibitory synaptic transmission and unchanged excitatory synaptic transmission in CA1 pyramidal neurons of MD F1 mice. Meanwhile, field recordings revealed impaired LTP in hippocampal slices of MD F1 mice. Over-expressions of *kcnmb2* in CA1 region with a viral vector (AAV1-hSYN1-Kcnmb2-IRES-GFP-WPRE) reversed the changes in neuronal excitability, synaptic function and memory deficits observed in MD F1 mice. Those findings thus suggest that reduced expression of *Kcnmb2* by DNA methylation may alter activity of inhibitory neurons in hippocampal network and cause impairment in synaptic plasticity and memory formation.

**Title:** Role of Rac-specific GAP proteins in the forgetting of fear memory

**Authors: *L. LV**, Y. LIU, Y. ZHONG
Sch. of Life Sci., Tsinghua Univ., Beijing City, China

**Abstract:** Molecular mechanisms underlying active forgetting have only recently begun to reveal. Several important proteins have been identified, and their contributions to the forgetting of memory have been assessed in the mushroom body of *Drosophila* and in the hippocampus of mice such as a small G protein Rac1. However, the upstream mechanisms of Rac1 underlying forgetting have not been fully understood. Here we explored the functions of Rac-specific GAP proteins in the forgetting of contextual fear memory induced by weak training. We found that knockdown of one of the GAPs in dorsal hippocampus induces forgetting of fear memory without affecting remote fear memory. Conversely, overexpression of this GAP attenuated forgetting of fear memory. In addition, knockdown of the GAP gene also accelerated forgetting of 24-hr social memory. Electrophysiological evidences show bi-directional regulation of this GAP in the adult dorsal hippocampus. Our findings suggest that at least one of the Rac-specific GAPs is crucial for forgetting of fear memory and social memory in adult mice.

**Title:** Adolescent corticosteroid exposure disrupts decision-making, trkB, and cortico-limbic anatomy in adulthood

**Authors: *E. T. BARFIELD**[1,2,3,4], K. J. GERBER[5], S. L. GOURLEY[1,2,3,4]
[1]Yerkes NPRC, [2]Dept. of Pediatrics, [3]Grad. Program in Neurosci., [4]Dept. of Psychiatry & Behavioral Sci., [5]Mol. & Systems Pharmacol., Emory Univ., Atlanta, GA

**Abstract:** Prolonged exposure to elevated glucocorticoids, as occurs with chronic stress, disrupts the structure and function of cortico-limbic brain regions involved in decision-making, planning, and motivation, and impairs neurotrophin signaling that supports dendritic spine growth and plasticity. However, neurodevelopmental factors remain largely uncharacterized, despite evidence that adverse experiences during adolescence may be particularly impactful. Here, we tested the hypothesis that adolescents are vulnerable to the long-term neurobehavioral consequences of prolonged, elevated glucocorticoid levels. We exposed mice to the primary glucocorticoid, corticosterone (CORT), for 11 days and found that CORT exposure in early adolescence, but not adulthood, impaired goal-directed decision-making, biasing behavior towards stimulus-elicited habits, in adulthood. CORT exposure also disrupted the ratio of tyrosine receptor kinase B (trkB) isoforms throughout multiple cortico-limbic brain regions. Further, dendritic spine densities on excitatory pyramidal neurons in the orbital prefrontal cortex (oPFC) were reduced in adult animals with a history of adolescent CORT exposure. Additionally, goal-directed behavior was positively correlated with the density of mature, mushroom-shaped spines in the oPFC. Stimulation of trkB during adolescence blocked decision-making deficits in CORT-exposed mice. Finally, we examined how CORT±trkB stimulation impacted inputs to the oPFC, in particular those from the ventral hippocampus. Our findings indicate that adolescent CORT exposure induces long-term alterations in neuronal structure, function, and decision making. Pharmacological interventions that augment trkB signaling may be particularly efficacious in blocking enduring neurobehavioral deficits in adolescents exposed to chronic stress.

**Title:** Cognitive bias in zebrafish

**Authors: *F. ESPIGARES**, R. OLIVEIRA
Inst. Gulbenkian De Ciência, Oeiras, Portugal

**Abstract:** According to cognitive appraisal theories, organisms use a set of stimulus evaluation checks in this process that allow them to evaluate its properties (intrinsic valence, familiarity,

predictability, prediction error) and the available coping mechanisms (capacity for control). The fact that cognitive appraisal is involved in the evaluation of stimuli creates the potential for cognitive biases that produce subjective evaluations (i.e. some individuals will consistently evaluate ambiguous stimuli as negative - pessimistic, and others as positive - optimistic). In this study, we have developed a cognitive bias behavioral test for zebrafish, a model organism for which genetic tools are available for visualizing and manipulating neural circuits, establishing therefore the occurrence of cognitive bias in this species. The behavioral test consists in training the fish to discriminate between a positive (P; i.e. reward) and a negative (N; i.e. punishment) color cue. Once fish are capable of discriminating between P and N color cues (as indicated by different latencies in reaching each one), their responses to an ambiguous (A) color between the positive and the negative is tested. Each individual (n=70) was, therefore, classified in an optimistic/pessimistic dimension. Our results, based on qPCR and RNAseq analysis, show that optimistic and pessimistic individuals are characterized by different basal levels of stress-related genes, suggesting that cognitive bias towards optimistic/pessimistic judgments are potentially associated with different stress coping styles.

**Title:** TMEM35 modulates pain and drug seeking behavior

**Authors:** *T. MATVEEVA[1], ***T. MATVEEVA**[1], J. C. GEWIRTZ[3], P. V. TRAN[2]
[1]Psychology, [2]Dept. of Pediatrics, Univ. of Minnesota, Minneapolis, MN; [3]Dept Psychology, Univ. of Minnesota Dept. of Psychology, Minneapolis, MN

**Abstract:** Previously we have shown that TMEM35 (NACHO) KO mice exhibit heightened pain sensitivity (Abstract 2016-S-14895-SfN). Given the comorbidity of pain and drug-seeking behavior, the present study investigated whether TMEM35 KO mice also show increased risk for drug seeking behavior. To test this, we examined conditioned place preference (CPP) for morphine and nicotine in separate experiments. Following habituation, one side of the CPP chamber was paired with morphine (10mg/kg s.c.) or nicotine (0.5g/kg base i.p.) and the other with saline. Mice were given 4 trials with drug and 4 trials with saline. WT and KO male mice were handled for 12 consecutive days. On the day following conditioning, all animals were injected with saline and allowed to explore the apparatus freely for 15 minutes. Preference for

the drug-paired side of the apparatus was measured. TMEM35 KO mice exhibited significantly stronger CPP for both morphine and nicotine than WT controls. For morphine, there was a main effect of genotype and conditioning context, and a significant genotype X context interaction, revealing that the effect of morphine on CPP was greater in the KO animals. Similarly, TMEM35 KO mice showed a significant increase in preference for the nicotine-paired context compared to pre-test, while WT animals showed no change in preference for the drug-paired side. Together, these results provide strong evidence implicating TMEM35 in drug-seeking behavior. Given a recent finding implicating TMEM35 in the expression of functional nicotinic acetylcholine receptors (nAchRs), these behavioral effects in TMEM35KO mice may be associated with the reduced expression of nAchRs. Contrary to a previous report showing a complete loss of a7 expression in TMEM35 KO mice, we report residual a7 expression in KO mouse brain, suggesting alternative mechanisms underpinning these drug-seeking behaviors. We are now conducting a transcriptomic analysis to identify alternative candidate mechanisms.

**Abstract:** Exercise induces resistance against stress-related brain dysfunction, such as memory deterioration and mood disorder. Previous studies have demonstrated mild exercise activates the hippocampus and enhances neuronal plasticity and function. However, the effects of mild exercise on stress resistance remain unknown. In this study, the effects of mild exercise on working memory and gene expression after an acute stress exposure were examined using RNA-Sequencing (RNA-Seq) to understand the mechanisms underlying the beneficial effects of exercise. Mice were subjected to 6 weeks of mild exercise training using a treadmill (5 times per week for 30 min/day). The running speed was 7 m/min, which is considered of mild intensity. Mice in the sedentary group remained sitting on the treadmill for the same amount of time without running. After the last day of training, one cohort of mice was subjected to 2h of acute

restrain stress (ARS). Subsequent to ARS, mice were returned to their home cage for 30 min before working memory was assessed with the Y-maze. Hippocampal tissue was collected 24h after ARS and behavioral testing. mRNA was sequenced using an Illumina NextSeq550 to collect 150bp reads at a sequencing depth of 30M reads/sample. Results were aligned against the mouse genome (mm10) and the numbers of reads for each transcript were normalized against total reads to obtain relative expression levels. Strand software was used to perform statistical analysis to identify differentially expressed genes. The results of the behavior assessment showed significantly decreased spontaneous alternations, a measure of working memory, after exposure to ARS in the sedentary group. Importantly, mild exercise training prevented the ARS-induced decline in working memory. RNA-Seq results showed ARS induced 1,053 changes in gene expression compared to control mice. Exercised mice showed 5,668 differentially expressed genes after ARS. These results provide evidence that regular mild exercise induces resistance to acute stress related memory decline, and the transcriptome under analysis will provide insight into its underlying molecular mechanisms.

**Abstract:** “Chemobrain” syndrome, the adverse cognitive impact of chemotherapy treatment on cancer patients, has been characterised in a range of rodent models. To date, however, the bulk of our understanding is limited largely to breast cancer drugs and the causal and mechanistic links between chemotherapy and cognitive function have yet to be established. We studied the neurological sequelae in mice treated with Ara-C, the first line treatment for acute myeloid leukemia (AML) and other haematological malignancies. Here, we describe our studies in adult, wild-type C57BL6 mice treated intraperitoneally with Ara-C for five consecutive days then assessed by behavioural, morphological, and molecular measurements. We found that treated animals developed remote, hippocampal-dependent memory impairment, in contextual fear conditioning tests. The deficit occurred when mice were trained immediately after treatment then tested 4 to 8 weeks after training; but short-term memory, as well as learning and memory

assessed 6 months post-treatment, was intact, indicating a specific impairment of remote memory reconsolidation. BrdU labeling and Ki67 staining revealed marked inhibition of cell proliferation in the neurogenic niches of the brain as well as in the corpus callosum immediately post-treatment, indicating mitotic arrests in glial and neural progenitors. Gene expression of cell cycle regulator p21 (cdkn1a) was concomitantly and significantly elevated in the hippocampus, cortex and cerebellum of treated mice 24 hours after cessation of treatment, suggesting possible alterations in cell growth and proliferation pathways. Besides cell birth, cell fate choice was also affected: a lower percentage of adult-born granule cells (abGCs) pre-labelled with BrdU became doublecortin (DCX)- or NeuN-positive neurons. Our results extend current understanding of the "chemobrain" syndrome by highlighting changes in neuronal signalling and other processes that add to the alterations in neurogenesis that have been described previously; processes which in sum could affect memory and cognitive processes in animals, representing potential mechanisms that underlie the human syndrome.

**Title:** Chronic mild stress elevates GRK2 expression in BNST of female rats

**Authors: *A. KULP**, M. RUSS, B. LOWDEN, J. D. JOHNSON
Biomed. Sci., Kent State Univ., Kent, OH

**Abstract:** Prior exposure to environmental stressors enhances contextual fear learning. Greater beta-adrenergic receptor signaling in animals with prior stress exposure mediate the enhanced contextual fear learning as administration of propranolol, a beta-adrenergic receptor antagonist, prior to fear conditioning prevent rats from showing exaggerating freezing 24h later when re-exposed to the context. Sensitization of beta-adrenergic signaling can be mediated by G protein-coupled receptor kinase 2 (GRK2) that decouples the receptor from intracellular signaling cascades and pro-inflammatory cytokines. Here, we investigated whether GRK2 and inflammatory cytokines (IL-1, IL-6) are altered by prior stress exposure in the bed nucleus of the stria terminalis (BNST), a brain region previously demonstrated to be critical for stress induced enhanced learning. Twelve female rats were subjected to a 4-day chronic mild stress protocol or remained in their cages to serve as non-stress controls. Brains were collected 24h after the last stressor exposure and the BNST was laser captured from each rat. Following, GRK2, inflammatory cytokines (IL-1, IL-6), and GAPDH were analyzed through real time PCR to measure gene expression. A significant increase of GRK2 mRNA was detected in stressed

animals compared to controls, while cytokine expression was undetectable. These results suggest repeated stress exposure can cause changes in beta-adrenergic receptor signaling in the BNST. Future studies are aimed to alter GRK2 expression in the BNST to determine whether GRK2 is necessary/sufficient for the stress enhanced contextual fear learning.

**Title:** The effect of HDAC2 inhibition on cognitive measures in C57/BL6 mice: Assessing pharmacological, antisense oligonucleotide, and genetic manipulations

**Authors: *H. M. ARNOLD**, S. GLASS, R. DRISCOLL, P. LEACH
Neurol. Res., Biogen, Cambridge, MA

**Abstract:** A growing body of research suggests that histone deacetylase 2 (HDAC2) is a key negative modulator of memory formation and that inhibition of this enzyme could be a therapeutic target for reversing or slowing cognitive impairment in neurodegenerative disease and perhaps for cognitive enhancement more generally. In the current studies we aimed to confirm and extend findings from the literature suggesting such cognitive benefits of HDAC2 inhibition in normal mice. We began by testing the efficacy of HDAC inhibitors to enhance contextual fear conditioning, as has been reported several times in the literature. We dosed two prototypical HDAC inhibitors, SAHA and CI-994 (both at 0, 10 or 30 mg/kg, IP), once daily for 10 days prior to contextual and cued fear conditioning in C57/BL6 mice, but observed no behavioral effects of these treatments on conditioned context or cue freezing 24 h later. We then tested a more selective HDAC2 inhibitor, FRM-0334, after daily dosing for 1, 3, or 10 days prior to training, but again, no enhancement of contextual fear was observed under any dosing regimen. To take advantage of the long-lasting effect antisense oligonucleotides ASOs have on gene and protein knock-down (>12 weeks) we tested whether an ASO, selective for HDAC2, would enhance contextual fear conditioning in C57/BL6 mice. Again, no improvement in fear conditioning was observed nor was performance enhanced in two other cognitive tasks (two trial Y-maze and pre-pulse inhibition of startle). Selectively knocking down HDAC2 using a genetic approach (CRISPR-based knock-down) also failed to alter performance in these three behavioral tasks. Thus, these observations are not consistent with the premise that HDAC2 inhibition is a viable strategy for cognitive enhancement. As these studies were all conducted in healthy, relatively young mice the possibility remains that HDAC2 inhibition could be effective in

instances and circumstances in which cognitive performance is impaired due to age, disease, or neurodegeneration.

**Title:** The role of Gadd45b in DNA demethylation and cocaine action

**Authors: *F. SULTAN**, G.-E. GRAHAM, K. SAVELL, J. J. DAY
Neurobio., Univ. of Alabama at Birmingham Dept. of Neurobio., Birmingham, AL

**Abstract:** Introduction
Epigenetic mechanisms are central regulators of the function and information storage capacity of neuronal systems. Methylation of cytosine nucleobases in DNA is a multifunctional epigenetic regulatory modification capable of exerting powerful control gene. In the brain, activity-dependent changes in DNA methylation are critical for synaptic plasticity and memory formation, and have been implicated in a broad range of neuropsychiatric disease states, including drug addiction. However, although activity-related DNA demethylation requires the *Gadd45* (*Growth arrest and DNA-damage-inducible*) protein family, very little is known about how DNA demethylation regulates the function of brain reward circuits or the role that *Gadd45* family members play in behavioral responses to drugs of abuse.
Methods
Here, we combined unbiased genome-wide transcriptional profiling, pharmacological tools, and CRISPR/dCas9 transcriptional activation with traditional knockout and behavioral approaches in rodent model systems (both *in vitro* and *in vivo*) to dissect the role of *Gadd45b* in dopamine-dependent epigenetic regulation.
Results
We show that acute cocaine administration induced upregulation of *Gadd45b* mRNA in rat nucleus accumbens, but did not alter expression of other methylation-related transcripts. Similarly, acute dopamine treatment in striatal neuron cultures increased expression of *Gadd45b*

and *Gadd45g* mRNA. This effect was mimicked by the Drd1 agonist SKF-38393, suggesting upregulation in Drd1-containing neurons. *In vitro*, CRISPR-targeted transcriptional activation of either *Gadd45b* or *Gadd45g* with a dCas9-VP64 fusion construct was capable of unsilencing a methylated reporter gene, suggesting a mechanistic link between *Gadd45* induction and DNA demethylation. Finally, we show that both dopamine treatment (*in vitro*) and cocaine administration (*in vivo*) induce DNA demethylation, and that *Gadd45b*$^{-/-}$ mice exhibited impaired conditioned place preference for cocaine.

Conclusions

These results suggest that striatal *Gadd45b* functions as a dopamine-dependent immediate early gene to coordinate demethylation of DNA at downstream target genes, and that this action is important for cocaine-related behavioral plasticity.

**Title:** Experience induces rapid nucleus-scale movements of chromatin in cortical neurons

**Authors: *S. RUMPEL**[1], D. F. ASCHAUER[1], T. R. BURKARD[2], F. GRÖSSL[3], W. HAUBENSAK[3], M. PETER[3]

[1]Johannes Gutenberg Univ. Mainz, Mainz, Germany; [2]IMBA Inst. of Mol. Biotech. of the Austrian Acad. of Sci., Vienna, Austria; [3]Res. Inst. of Mol. Pathology (IMP), Vienna, Austria

**Abstract:** The interphase nucleus is functionally organized in active and repressed territories defining the transcriptional status of the cell. Dynamic chromatin movements at the scale of the nucleus have been observed during interphase in a variety of systems ranging from yeast to mammalian cell lines and are believed to support transcriptional alterations. Despite early evidence for nucleus-scale reorganization of chromatin in neurons, to date, no chronic imaging data of chromatin dynamics in living animals is available. Applying *in vivo* two-photon imaging in a novel transgenic mouse model allowing photolabeling of histones, we show that chromatin organization of neurons can undergo rearrangements within minutes, indicating an actively controlled process. In an *in vitro* brain slice model chromatin remodeling can be observed upon pharmacological manipulation of neuronal activity. Furthermore, we show that auditory cued

fear conditioning, a paradigm prompting changes in gene expression patterns in the auditory cortex, induces chromatin remodeling in neocortical neurons *in vivo*. We propose that global chromatin motility acts together with local gene-specific modifications to promote new nuclear organization patterns permissive for transcriptional plasticity at time scales that could not be realized by passive diffusion. Together, our findings open a framework to chronically study chromatin dynamics at the nucleus-scale in a physiologically relevant context.

**Title:** Conserved modules of insulin-like signaling modulate neural function in *Aplysia*

**Authors: *N. KUKUSHKIN**[1], S. P. WILLIAMS[2], T. J. CAREW[1]
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

**Abstract:** Insulin-like signaling is ubiquitous in animals, but its interaction with the nervous system remains largely unexplored. Here we show that the insulin-like system in *Aplysia californica* modulates functional changes in sensory neurons (SNs) induced by human insulin-like growth factor 2. IGF2 has diverse effects: it (i) increases the rate of neurite outgrowth in cultured SNs, it (ii) decreases their excitability, (iii) suppresses a distinct form of activity-dependent growth, and (iv) causes synaptic depression in co-cultures of SNs and motor neurons (MNs). In *ex vivo* preparations of pleural-pedal ganglia, SNs showed similar inhibitory responses to IGF2: reduced excitability in parallel with a decrease in total cellular phosphotyrosine, generally associated with signaling through receptor tyrosine kinases (RTKs). This surprising effect was sensitive to (i) an inhibitor of PTP1B (a tyrosine phosphatase involved in mammalian insulin signaling), (ii) to the mTOR inhibitor rapamycin, and (iii) to GSK1838705A, an inhibitor of mammalian insulin and IGF1 receptors. Blocking synaptic activity reversed both the biochemical and electrophysiological effects of IGF2 in ganglia. Under these conditions, the peptide elicited a stimulatory effect on both excitability and total tyrosine phosphorylation in SNs. In cultured SNs lacking synaptic contacts, inhibitory responses to IGF2 could also be reversed if preceded by a period of nutrient deprivation, suggesting possible modulation by cellular energy status and/or in vivo signaling from synaptic partners. We have identified two insulin-like receptors and five insulin-like ligands expressed in *Aplysia* CNS and confirmed that

a recombinant form of one of these peptides has a glucose-lowering effect. We propose that in response to nutrient-related signals, a subset of endogenous *Aplysia* insulin-like peptides suppresses sensory input by inhibiting RTK signaling in SNs via activation of a PTP1B-like phosphatase, while enabling some long-term stimulatory effects such as elevated rates of neurite growth. This response may partially account for behavioral suppression we observed in *Aplysia* after food intake, possibly representing a "rest-and-digest" response well documented in a wide variety of animals. While the possible combinatorial complexity of this multi-receptor/multi-ligand system in *Aplysia* remains an open question, its responsiveness to a human insulin-like peptide offers an insight into a conserved toolkit of molecular modules integrating neuronal activity, metabolism, and growth.

**Title:** Mechanistic Target of Rapamycin complexes in mGluR-LTD and related cognitive behaviors

**Authors: *P. ZHU**, C.-J. CHEN, M. COSTA-MATTIOLI
Neurosci, Baylor Col. of Med., Houston, TX

**Abstract:** Information storage is thought to have a physical basis in long-lasting modifications of synaptic function in selective brain circuits. At hippocampal synapses, repeated low activity weakens the efficacy of synaptic connections in a processes called long-term depression (LTD). Interestingly, different types of learning processes are associated with LTD. The mechanistic target of rapamycin (mTOR) signaling has been implicated in hippocampal LTD, but most of the evidence supporting its role is based on the use of the mTOR inhibitor and pharmacological agent rapamycin. mTOR forms two complexes: mTOR complex 1 (mTORC1), which is sensitive to rapamycin, regulates protein synthesis and is defined by the adaptor protein *raptor;* and mTORC2 that is largely insensitive to rapamycin, regulates actin dynamics and is defined by the adaptor protein *rictor.* To investigate the role of mTOR complexes in mGluR-LTD, we use genetics to independently silence mTORC1 and mTORC2 functions. Here we report that, mGluR activation triggers the activity of both complexes, mTORC1 and mTORC2. Strikingly, conditional deletion of *rictor* (mTORC2), but not *raptor* (mTORC1), in the postnatal murine forebrain impairs chemical and electrically induced mGluR-LTD. Moreover, rapamycin (1 μM)

blocks mGluR-LTD in both control and mTORC1-deficient hippocampal slices. Consistent with the electrophysiological recordings, hippocampal-dependent object place learning, a behavioral task associated with mGluR-LTD in the hippocampus, was only impaired in mTORC2-deficient, but not mTORC1-deficient, mice. Thus, mTORC2 signaling is required for mGluR-LTD and related behaviors and is a promising novel target for the treatment of mGluR-LTD-linked cognitive dysfunction.

**Title:** GSK-3β-Nrf2 signaling pathway as a neuroprotective mechanism in Alzheimer's disease

**Authors: *C. LEE**[1], G. PARK[2], J.-H. JANG[1]
[1]Keimyung Univ., Daegu, Korea, Republic of; [2]Kyungpook Natl. Univ., Daegu, Korea, Republic of

**Abstract:** β-Amyloid peptide (Aβ) is the major component of senile plaques accumulated in the brains of patients with Alzheimer's disease (AD) and has been reported to cause neuronal cell death via oxidative stress. Therefore, attention has been focused on identifying redox-sensitive transcription factors and their target genes protecting against Aβ-induced oxidative cell death. Nrf2 plays a pivotal role in the transcriptional regulation of antioxidant proteins and detoxification enzymes and blocks apoptosis caused by a wide array of death signals. Ectopic expression of Nrf2 rescued cells from Aβ-induced cytotoxicity, apoptosis, intracellular accumulation of reactive oxygen species and oxidative damages. Moreover, Nrf2 overexpression increased the expression of γ-glutamylcysteine ligase (GCL), a rate-limiting enzyme in cellular glutathione biosynthesis and heme oxygenase-1 (HO-1), a key enzyme in heme degradation process. Conversely, knockdown of Nrf2 gene expression with siRNAor dominant negative mutant Nrf2 exacerbated Aβ-induced oxidative cell death. To further elucidate the upstream regulator for Nrf2 activation, we have focused on glycogen synthase kinase-3β (GSK-3β). Inhibition of Aβ-induced GSK-3β activation by pharmacological inhibitors such as LiCl led to nuclear accumulation Nrf2 and transcriptional activation of Nrf2 downstream target genes and protected against Aβ-mediated oxidative cell death. In another experiment, some dietary and medicinal phytochemicals attenuated Aβ-induced oxidativecell death via suppression of GSK-3β and subsequent activation of Nrf2. Taken together, these findings suggest that GSK-3β-Nrf2 signaling pathwaymay act as a survival mediator against AD.

**Abstract:** Fear-inducing memories can be state-dependent, meaning that retrieval of a memory is the most efficient when occurring under the same state of consciousness as when the memory was encoded. Restricted access to such memories can present a risk for psychiatric disorders and hamper their treatment. We have previously demonstrated that heightened activity of hippocampal extrasynaptic GABAA receptors enabled state-dependent encoding and retrieval. The susceptibility to state-dependent processing of fear memories was determined by miR-33, a microRNA which regulates several GABA-related proteins. Here we analyzed the global changes at the molecular level to identify individual molecules and cellular pathways contributing to state-dependent processing of fear memories. We performed high throughput analyses on samples from mice treated with gaboxadol: (1) proteomic analysis to identify proteins whose amount or activity is altered by the treatment; (2) epigenetic analysis to identify changes in the epigenome specifically associated with state-dependent memory processing. We also performed proteomic analysis on samples from mice treated with miR-33 inhibitor to identify proteins through which miR-33 confers susceptibility to state-dependent memory processing. Results of the proteomic analyses showed that gaboxadol treatment induced alterations in the amount and activity of a limited number of proteins. These proteins were clustered in a very narrow subset of cellular pathways. Proteins whose levels change as the result of miR-33 inhibitor treatment were also clustered in a narrow subset of pathways overlapping those affected by gaboxadol treatment. These results suggest that changes of cognitive states require targeted alterations of a very small number of cellular pathways.

**Title:** GCY-28 mediates naïve approach to benzaldehyde and associative learning of benzaldehyde and starvation in different neurons in *C. elegans*

**Authors: *N. LI**, D. VAN DER KOOY
Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

**Abstract:** Information regarding the innate odor preferences of many animals is encoded in chemosensory neurons. These olfactory responses, however, can be modified by various processes, such as associative learning, whereby an attractive conditioned stimulus is paired with an aversive unconditioned stimulus. To better understand the behavioral changes driven by associative learning, we use the simple model organism *Caenorhabditis elegans*. This nematode worm is naïvely attracted to benzaldehyde, an odorant sensed by the pair of AWC neurons, $AWC^{ON}$ and $AWC^{OFF}$, but learns to avoid it after paired exposure with starvation. Here, we reveal a previously unknown role of GCY-28, a receptor-like guanylate cyclase that has been implicated in mediating attraction to odors sensed by the $AWC^{ON}$ chemosensory neuron as well as sensory integration of conflicting cues in the AIA interneuron. We show that mutants lacking *gcy-28* not only less prefer $AWC^{ON}$-sensed odors but also cannot learn to associate benzaldehyde with starvation, and that GCY-28 modulates these behaviors in distinct neurons: naïve attraction to $AWC^{ON}$-sensed odors in $AWC^{ON}$ versus associative learning of benzaldehyde and starvation in AIA. We further show that the cyclic nucleotide-gated channels CNG-1 and CNG-3 are the downstream effectors of GCY-28 in AIA, and that the observed learning deficit lies in memory retrieval, not acquisition or storage, as memories formed during training are transferrable and can be retrieved within a different context. Using odorants that are differentially sensed by $AWC^{ON}$ or $AWC^{OFF}$, our data indicate that GCY-28 is only required during memory retrieval when both AWC neurons are activated by chemical cues, suggesting that it functions in AIA to mediate the resolution of different signals released from $AWC^{ON}$ and $AWC^{OFF}$ following sensory stimulation. We propose that during signal transduction, GCY-28 functions upstream of the release of INS-1, an insulin-like peptide orthologous to human insulin, from AIA to AWC, and that in the absence of GCY-28 in AIA, INS-1 transmission is diminished, explaining the inability of *gcy-28* mutants to learn. Our results offer new insights about how information is processed in the neural network of *C. elegans* during associative learning. Understanding the components of

associative learning pathways will provide insights into the broader neural mechanisms involved in memory formation and retention.

**Abstract:** The peroxyredoxin6 (PRDX6) is a *Prdx* family member and demonstrates both peroxidase and calcium-independent phospholipase A2 (iPLA2) activities. Recent studies have reported that the PRDX6 plays a critical role in various neurodegenerative diseases including Parkinson's disease and Alzheimer's disease. PRDX6 is also highly expressed in the hippocampus, a brain area which is important for memory formation. Prdx6-iPLA2 activity appears to inhibit neurite outgrowth in neural precursor cells. Moreover, postmortem brain sections taken from schizophrenia patients also showed upregulation of PRDX6. Though PRDX6 seems to be involved in various brain functions and neurodegenerative diseases, the physiological role of PRDX6 in the regulation of synaptic plasticity, learning and memory has not been investigated. Thus, in this research, we aimed to investigate the function of PRDX6 in learning and memory. The 14-week-old Prdx6 knockout (KO) mice were used for behavioral phenotyping using various paradigms including open field, three chamber test, elevated plus maze, Morris water maze tests, and fear conditioning. Results showed that the Prdx6 KO mice exhibited normal locomotor activity, sociability, anxiety-like behaviors and spatial learning and memory, but impaired social novelty (control, $p = 0.017$, $n = 7$; Prdx6 KO, $p > 0.05$, $n = 13$) and increased freezing behavior in both contextual and tone test ($p = 0.01$ and 0.019, respectively, $n = 10$) . Enhanced retrieval of fear memory in the Prdx6 KO mice was accompanied by 2-fold upregulation of *Bdnf* mRNA ($p = 0.0178$, $n = 3$) during memory consolidation. These results indicate that PRDX6 may play a critical in suppressing fear memory formation. Further experiments are ongoing to investigate the underlying cellular and molecular mechanism.

**Title:** Molecular organization of octopus brains reveals first insight into unique memory center signaling

**Authors: *G. C. WINTERS**[1], C. BOSTWICK[1], L. HATFIELD[2], A. B. KOHN[1], L. L. MOROZ[1]

**Abstract:** Cephalopods (*Octopus,* Squid, Cuttlefish, and *Nautilus*) have evolved a degree of behavioral flexibility that rivals that of many mammals. The Vertical Lobe (VL), a structure unique to cephalopods containing intricate memory circuitry, parallels mammalian analogues like the hippocampus in cell number and function, but has evolved independently within the distant molluscan lineage. We used integrative Next-gen sequencing technology and bioinformatic analyses, followed by anatomical validation using in-situ hybridization, to identify the first molecular maps of signaling molecules implemented in cephalopod memory circuitry. We constructed, sequenced and analyzed *Octopus* neural transcriptomes of various tissues (including VL, CNS, SFL-Superior Frontal lobe, and Arm Cords), and individual cells from subpopulations within the VL and other neuronal tissues, including the Amacrine (Am) Interneurons and Large Efferent (LE) Neurons that make up the VL. We compared these transcriptomes to the available Octopus genome and our gastropod mollusc neural transcriptomes including *Aplysia californica*. We identified 16,194 transcripts in the VL (TPM >/=1) and found 4,139 (25.5%) appear to be cephalopod-specific. Remarkably, indicators for many memory related signal molecules and transmitters like NO (NOS) and GABA (GAD) were not identified in VL transcriptomes, suggesting a distinct cephalopod-specific complement of molecules independently recruited in the organization of learning and memory-forming circuits. We used both targeted and unbiased bioinformatic approaches to identify 104 putative secretory molecules in *Octopus* nervous tissues approximately half of which have not been described before in any species, and most of which were uncharacterized in cephalopods. We have systematically cloned and mapped expression of NPs, and have localized 16 NP to the components of the VL circuit. Three peptides are abundantly expressed in the cell bodies of the MSF, where the afferent tract to the VL originates. An additional four peptides label the small amacrine interneuron population in the VL gyri, three of which appear to be unique to

cephalopods like the VL itself. The remaining 9 VL peptides label distinct sub-populations of the large efferent neurons, providing the first evidence for more than one type of large efferent neuron. This expansion of novel signaling molecules in the VL circuit is likely a key feature of the unique memory systems of cephalopods, further implying extensive parallel evolution of cephalopod brains and memory circuits in particular.

**Title:** Neocortical SHANK1 shRNA knockdown impairs associative learning of whisker-trace-eyeblink conditioning

**Authors: *S. M. COLLINS**, R. GALVEZ
Psychology, Univ. of Illinois at Urbana-Champaign Dept. of Psychology, Urbana, IL

**Abstract:** Learning-induced neocortical synaptic plasticity is a well-established mechanism mediating memory consolidation. In support of this theory, our laboratory has demonstrated that the forebrain-dependent associative learning paradigm whisker-trace-eyeblink conditioning (WTEB) induces an increase in neocortical dendritic spine density that returns to preconditioning levels with over-training. In WTEB, rodents learn to associate a whisker stimulation followed by a short stimulus-free delay with a mild periorbital shock. Our previous dendritic spine analyses demonstrated neocortical synaptic remodeling with WTEB, a now widely accepted mechanism for neocortical dependent learning. Although synaptic remodeling is generally accepted as a mechanism of learning, the underlying molecular processes mediating this plasticity are poorly understood. Interestingly, recent studies have identified SHANK1 as a possible mediator of, or at least an important factor for this process. SHANK1 overexpression has been shown to increase dendritic spine density. In contrast, global genetic knockout of SHANK1 both decreases dendritic spine density and impairs learning of cued fear conditioning. These studies have collectively suggested a role for SHANK1 in dendritic spine plasticity; however, a detailed analysis of SHANK1 in specific memory networks during learning has not been explored. The current study aimed to directly examine the role of SHANK1 in associative learning-induced neocortical networks in the following two experiments. Experiment 1: SHANK1 protein expression in primary somatosensory cortex (S1) was examined during distinct learning phases with WTEB. These analyses demonstrated that SHANK1 expression in S1 increased during specific learning phases that are known to exhibit dendritic spine plasticity, further suggesting a

role for SHANK1 with learning-induced dendritic spine modification. Experiment 2: Using shRNA, the effects of knocking down SHANK1 in S1 was assessed on acquisition of WTEB. Our findings demonstrated that knocking down SHANK1 expression in S1 significantly impaired acquisition of WTEB. These findings are consistent with previous studies implicating SHANK1 as a mechanism for synaptic plasticity necessary for learning and further suggest a role for SHANK1 in learning-induced plasticity of specific memory systems. In addition, these studies provide further evidence for SHANK1 as a potential mediator of learning-induced neocortical plasticity underlying memory consolidation.

**Title:** Multi-colored single-molecule fluorescence in-situ hybridization reveals complexity of neural ensemble representation of experience

**Authors: *B. J. GONZALES**, D. MUKHERJEE, B. IGNATOWSKA-JANKOWSKA, N. BLEISTEIN, A. CITRI
The Hebrew Univ. of Jerusalem, Jerusalem, Israel

**Abstract:** Long-term information coding in the nervous system requires temporally defined waves of induced transcription, the earliest of which is comprised of immediate early genes (IEGs). Individual IEGs are widely used to identify neuronal ensembles recruited by distinct salient experiences, with the assumption that different IEGs are co-expressed within ensembles encoding a common experience. However, this assumption has not been tested. We set out to address this notion and to investigate the complexity of neural ensembles recruited by distinct experiences. We have previously observed that different experiences are encoded by unique and robust transcriptional responses, and identified subsets of IEGs sufficient to unambiguously decode the recent salient experience of an individual mouse. To identify the spatial expression within tissue, we performed RNA In-Situ Hybridization (RNA ISH) against robustly induced candidate IEGs following the rewarding experience of acute cocaine. We found that induced expression maps to sub-regions within defined brain nuclei of the reward circuitry. Within the striatum (Str), robust expression was localized the dorsomedial (DM) and ventrolateral (VL) regions. To address whether induced IEGs co-localize in discrete populations with a common functional role, we utilized multi-colored single-molecule fluorescence ISH to compare induction within the two major neuronal populations of the striatum (D1R and D2R expressing neurons), known to have opposing roles in behavior, following acute cocaine. Strikingly,

analysis of overlapping induced transcription of candidate IEGs including *Egr2*, *cFos*, *Arc* and *Nr4a1*, revealed specific enrichment in D1R- but not D2R- expressing neurons of the VL-Str (*Egr2* in 80.7% of D1R-, but only in 35.8% of D2R-expressing neurons; 92.4% of *Fos* expressing neurons were Egr2+/D1R+). Conversely, in the DM-Str similar ratios of D1R and D2R expressing neurons were recruited according to induced IEG expression (*Egr2* in 79.4% of D1R-, and in 65.7% of D2R-expressing neurons; 65.5% of *Fos* expressing neurons were Egr2+/D1R+ and 56.8% were Egr2+/D2R+). These results show that salient experiences induce unique spatially defined transcription signatures, recruiting specific neuronal ensembles. However, these data also imply that neuronal ensembles defined in this manner can be comprised of cells with opposing functionality, revealing unaddressed complexity of neuronal ensembles recruited in salient experiences. Precise manipulation of identified genes and defined engaged neuronal ensembles may determine novel and precise roles in memory formation underlying the development of adaptive behavior.

**Title:** Members of a novel family of cysteine-rich neurotrophic factor-like proteins show differential gene expression during synaptogenesis in *Aplysia* cultured neurons

**Authors: *A. ALEXANDRESCU**, N. V. KUKUSHKIN, T. J. CAREW
New York Univ., New York, NY

**Abstract:** Growth factor signaling is a highly conserved molecular mechanism that is critically involved in neuronal developmental plasticity and is re-engaged in the adult during synaptic plasticity underlying long-term memory formation. The marine mollusk *Aplysia californica* is a powerful model system for studying the cellular and molecular mechanisms of long-term synaptic facilitation in identified sensory (SNs) and motor neurons (MNs), which form monosynaptic connections *in vivo* and in an *in vitro* co-culture system. Our laboratory has identified a novel neurotrophic factor, *Aplysia* cysteine-rich neurotrophic factor (ApCRNF),

which shares structural and functional characteristics with mammalian neurotrophins. We previously showed that ApCRNF is released in the CNS in an activity-dependent manner and is required for the induction of long-term facilitation of SN-MN synapses in culture. Here we describe the identification and characterization of a novel family of cysteine-rich neurotrophic factor-like (ApCRNF-like) proteins. Members of the ApCRNF-like protein family and ApCRNF show conservation of critical cysteine residues known to be essential for the formation of the cysteine-knot structural motif characteristic of growth factors. We show here that the ApCRNF-like transcripts are expressed in the *Aplysia* CNS. In addition, using single-cell qPCR, we have performed an analysis of the gene expression profile of the ApCRNF-like gene family in single cultured L7 and L11 MNs as well as in pleural SNs. The *Aplysia* SN-MN co-culture system offers single-cell spatial resolution for studying endogenous growth factor signaling in the context of synapse formation and plasticity. Moreover, *Aplysia* neurons demonstrate synapse-specificity in culture as *in situ*: SNs form functional chemical synapses with target L7 MNs, but not with non-target L11 MNs. Interestingly, we found changes in the gene expression profile of ApCRNF-like transcripts between single and co-cultured SNs and MNs, as well as between co-cultured SN-MNs with or without putative synapses. These results suggest that gene expression of the ApCRNF-like proteins in single neurons can be differentially regulated in the presence of target or non-target synaptic partners, raising important opportunities to examine the dynamic regulation of this gene family during synapse formation.

**Title:** Growth factor mediated post-transcriptional regulation of the immediate early gene c/ebp by the RNA-binding protein ELAV is critical for long-term memory formation in *Aplysia*

**Authors: *A. A. MIRISIS**[1,2], T. J. CAREW[1]
[1]Ctr. for Neural Sci., New York University, Carew Lab., New York, NY; [2]Dept. of Biol., New York Univ., New York, NY

**Abstract:** We have previously shown that signaling through distinct growth factor (GF) pathways is required for long-term memory (LTM) formation in unique temporal and spatial domains in *Aplysia*. Specifically, (i) TrkB signaling is required in the sensory neuron (SN) synaptic neuropil during Trial 1 of a two-trial LTM training paradigm, and (ii) TGFβ signaling is

required at the SN cell body during Trial 2. TrkB signaling is required for gene expression of *c/ebp*, an immediate-early gene required for LTM formation, at 45 min following Trial 1, but prolonged *c/ebp* gene expression at 60 min requires the presence of TGFβ signaling during Trial 2. This prolonged gene expression is also dependent on TrkB signaling during Trial 1, precluding the possibility that Trial 2 independently increases *c/ebp* gene expression (Kopec et al., 2015). Interestingly, *c/ebp* mRNA contains multiple AU-rich elements (AREs) in its 3' UTR, which confers to it unique characteristics including increased susceptibility to degradation and/or stabilization due to its ability to bind to various RNA-binding proteins. *Aplysia* is known to express ApELAV, an RNA-binding protein which promotes stabilization of *c/ebp* mRNA by binding to AREs in its 3' UTR (Yim et al., 2006). Here we show that: (i) Trial 1-dependent *c/ebp* gene expression at 45 min is transcription-dependent, whereas Trial 2-dependent *c/ebp* gene expression at 60 min is transcription-independent, (ii) treatment with TGFβ1 at 45 min is sufficient for increased *c/ebp* gene expression at 60 min (even in the presence of transcription inhibitors), and (iii) when delivered during Trial 2, CMLD-2, a potent inhibitor of HuR - mRNA interaction, significantly reduces Trial 2-dependent *c/ebp* gene expression at 60 min and blocks LTM formation. Our results directly implicate post-transcriptional regulation and, specifically, stabilization of Trial 1-induced *c/ebp* mRNA by ELAV-like proteins during Trial 2, as a prerequisite for LTM formation.

**Title:** Memory allocation is disrupted in conditional Wilm's Tumor 1 $KO^{DG}$ mice

**Authors: *L. MUNARI**[1], C. MARIOTTINI[2], E. GUNZEL[3], R. D. BLITZER[4], R. IYENGAR[3]
[1]Pharmacol. Sci., Mount Sinai Med. Ctr., New York, NY; [2]Pharmacol. Sci., Icahn Sch. of Med. at Mt Sinai, New York, NY; [4]Dept. of Pharmacol. & Systems Therapeut., [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

**Abstract:** Memory allocation is the process that determines which neurons in a neural network will store a specific memory. Recent findings reported that shared neuronal populations may link distinct memories close in time, and increasing neuronal excitability affects the probability of a neuron to participate in a memory trace or engram (Cai *et al*., 2016). Contextual memories are encoded in sparse populations of neurons in the hippocampus, and the dentate gyrus (DG) seems

to play a major role in this process (Leutgeb *et al.,* 2007). Recently, we have identified Wilm's Tumor 1 (WT1) as a key protein involved in memory retention. Mice lacking WT1 in the forebrain showed better recall in two hippocampus-dependent tests, but memory impairment when both tests were combined in a sequential learning task, suggesting memory interference. Here, we injected AAV8-Cre virus into the DG of $Wt1^{flox/flox}$ mice in order to generate animals that expressed a non functional WT1 protein specifically in that sub region (WT1 $KO^{DG}$). A separate group of animals was injected with both AAV8-Cre and AAV8-hM4D(Gi) viruses. Mice were challenged in a context discrimination test. They were allowed to explore three different contexts (A, B, C), but only one (context B) was paired with a footshock. Freezing time related to each context was assessed 24 hours after contextual fear conditioning. Mice lacking functional WT1 showed increased freezing time in the context A (never shocked) after being shocked in context B, suggesting impairment in context discrimination. We hypothesized that this effect was mediated by an increase in neuronal excitability due to knock down of WT1 in the DG. Hence, we tried to block this effect using a CNO/hM4D(Gi) receptor strategy, and showed that we could reverse the context discrimination impairment previously observed. In addition, we observed that WT1 $KO^{DG}$ mice show significantly enhanced LTP in DG compared to control littermates. In summary, our findings suggest that blocking WT1 activity in DG cells disrupts memory allocation, leading to formation of false memory. We hypothesize that this effect is mediated by WT1's control over hippocampal neuronal excitability.

**Abstract:** During non-REM (NREM) sleep, neuronal populations in the forebrain show highly synchronized patterns of spontaneous activity. In the neocortex, this manifests as the NREM

slow oscillation: large 0.5-4Hz deflections in the extracellular field potential concurrent with population-wide periods of inactivity (DOWN states), which alternate with periods of spiking (UP states). These UP/DOWN alternations ("synchronized" dynamics) are reminiscent of those seen in the neocortex during other periods of behavioral quiescence such as quiet wakefulness and under anesthesia. Using an idealized neural population model, we show that synchronized dynamics are characteristic of recurrent populations under conditions of low external drive and are promoted by neural adaptation mechanisms. The balance between adaptation, recurrence, and neuronal excitability can give rise to either noise-induced or adaptation-induced transitions, which allows for a variety of synchronized regimes with distinct statistics of UP/DOWN state durations, or dwell times. Using a nonparametric method to match dwell time distributions, we find that, unlike other in vivo synchronized regimes, NREM sleep in the rodent neocortex is best represented by an "Excitable$_{UP}$" regime: a network state in which perturbation of a stable UP state results in transient DOWN states. This model is able to account for multiple features of NREM sleep thought to be important for mnemonic and homeostatic functions, such as stochastic or perturbation-initiated slow waves and high frequency oscillations at the DOWN->UP transition. Contrary to the neocortex, the hippocampus shows generally low levels of spiking with occasional bursts of synchronized population activity, or sharp wave ripple events (SPW-R). We find that the in vivo distributions of SPW-R/interSPW-R durations are also well-matched by the same model, albeit in an "Excitable$_{DOWN}$" regime: a network state in which periods of low-activity are punctuated by stochastic or externally-induced population bursts. These results provide a general theoretical treatment of slow adaptation-mediated oscillations in the forebrain, and suggest that despite their apparent differences, hippocampal and neocortical dynamics during NREM sleep may result from similar underlying mechanisms that are tuned to promote hippocampal-cortical interaction.

**Title:** Medial and lateral entorhinal cortex gamma inputs entrain different hippocampal populations during learning and navigation

**Authors: *A. FERNÁNDEZ RUIZ**, A. OLIVA, G. BUZSAKI
Neurosci. Institute, New York Univ., New York, NY

**Abstract:** The two main extrinsic input regions to the hippocampus are the medial and lateral areas of the entorhinal cortex. Both regions process different types of information. While medial entorhinal cortex (MEC) preferentially encode spatial information and distal visual cues, lateral entorhinal cortex (LEC) encodes local item features. Both inputs converge in the dentate gyrus and CA3 areas where they likely support the pattern completion and separation functions characteristic of these hippocampal regions. There is extensive anatomical evidence of entorhinal axons innervating all excitatory (pyramidal neurons, granular and mossy cells) and inhibitory cell types in these areas. However, functional data on how entorhinal inputs modulate the firing dynamics of these cell populations during behavior is lacking. To address these questions, we employed large-scale silicon probes (up to 512 channels) to record local field potentials (LFPs) and single-unit activity simultaneously in all hippocampal subfields and layers of MEC and LEC in rats during various learning and navigational tasks. As a first step, we employed source-separation techniques and pharmacological manipulations to isolate the contribution of MEC and LEC inputs to hippocampal LFPs. We found that both inputs elicit distinct gamma frequency oscillations at different phases of the theta cycle. Coherent oscillations between the dentate target layers and layer 2 of MEC and LEC, respectively, were identified. Different dentate and CA3 neuronal populations were entrained preferentially by MEC and LEC gamma inputs. This input selectivity correlated with the different degrees of spatial coding and remapping properties found in the different cell classes. During running and REM sleep, theta rhythm coordinated gamma oscillations and synchrony across the entire hippocampus-MEC-LEC circuit. The driving strength of these inputs and interregional network coordination changed according to behavioral and memory demands. Our results show that MEC and LEC coordination with DG and CA3 occur at different gamma frequencies and theta phases and contributes differently to behavior. Entorhinal inputs target preferentially different cellular classes in the hippocampus, and this preference may account for the functional specialization of cell types during behavior.

**Abstract:** Neural networks undergo profound changes over the course of development that are critical for establishing cortical functions. These changes are reflected in the spontaneous oscillations generated by developing cortex. Due to the small size and fragility of neonatal brains, determining the characteristic electrophysiological patterns of specific developmental stages in various cortical regions is difficult. Here, we developed and tested a conformable, conducting-polymer based surface electrode array (NeuroGrid) to record from multiple cortical regions simultaneously in awake and sleeping mouse pups (P2 - P14). We detected network oscillations including spindle and gamma, key component of spontaneous neural activity in developing rodents, and determined that features of these oscillations are altered with maturation. Due to the large-scale cortical coverage possible with surface recording, we were able to describe the spatial extent of these oscillations across development. In addition, we observed that precise temporal coordination of spindle oscillations within and between distinct cortical regions was not present at early stages of development, arising only late in the second week of life. Understanding how spontaneous activity emerges and is altered during development will provide insight into the physiological functioning of these early neural networks, and how disturbances of brain oscillations prior to maturation can predispose to neuropsychiatric disease.

**Title:** Neuronal circuit mechanisms of pattern separation in the hippocampal dentate gyrus and CA3

**Authors: *Y. SENZAI**[1], G. BUZSAKI[2]
[1]New York Univ., New York, NY; [2]New York University, Sch. of Med., New York, NY

**Abstract:** Theoretical work, clinical imaging, and lesion experiments suggest that an important computational function of the hippocampal dentate gyrus (DG) is pattern separation. Physiological support for such function has been hampered by a lack of well-defined characteristics that can identify granule cells and mossy cells. We developed a neurophysiology-based classification method to conclusively identify dentate granule cells and mossy cells in neural data acquired from freely moving mice. These two excitatory cell types can first be distinguished from dentate gyrus interneurons based on their wide action potential waveform and increased tendency to burst firing. Three main characteristics then separated the excitatory neurons into granule cells and mossy cells: (1) cell body location relative to the reversal of the DS2; (2) relative firing rates in NREM and waking states; and (3) waveform shape. Granule cells had cell bodies located near the depth of DS2 reversal, had increased firing in NREM compared to waking, and had a sharper waveform. In contrast, mossy cells were located well below the depth of the DS2 reversal, had equivalent firing rates in NREM and waking, and had a more symmetric waveform. We validated these physiological characteristics with optogenetic methods, establishing firm criteria for granule cell and mossy cell identification in vivo. Our classification method allowed us to investigate how these cell types interact and encode spatial information. Granule cells were typically low firing and had a single place field, whereas mossy cells were higher firing and had two or more place fields. Although the sparse coding of spatial information by granule cells could be the basis for the pattern separation, granule cells showed weaker remapping across different contexts in the same room compared to their downstream targets, mossy cells and CA3 pyramidal cells. Furthermore, despite the strongly facilitating nature of granule cell-mossy cell synapses, place fields of most mossy cells could not be explained by the ‘‘inheritance’’ of place fields from single granule cells. These findings suggest that the joint action of granule cells, mossy cells, and CA3 pyramidal cells may be critical for pattern separation (Senzai and Buzsáki, 2017). In order to reveal the contribution of the granule cells to the pattern separation in DG and CA3, we will optogenetically inhibit granule cells in DG and analyze its effect on the place information coding and pattern separation by mossy cells and CA3 pyramidal cells. For this purpose, we will employ POMC-Cre::Ai35 mice that express Arch specifically in matured granule cells in DG.

**Title:** Gamma oscillations, real spurious and their relationship to spikes

**Authors: M. DING**[1], *B. O. WATSON[2], G. BUZSAKI[3]
[1]Neurosci. Inst., New York Univ., New York, NY; [2]Weill Cornell Med. Col., New York, NY; [3]New York University, Sch. of Med., New York, NY

**Abstract:** Gamma oscillations have been observed in many brain regions, and hypothesized to be involved in sensory and cognitive functions. Furthermore, previous work has demonstrated a correlation between broadband gamma spectral power and spike rates at the seconds timescale [1]. It has been proposed that gamma rhythms emerge from excitation-inhibition interactions and enable communication in local cell assemblies [2], but direct demonstration of correlation with inhibitory-excitatory balance has been lacking. Since gamma oscillations are measured as local field potentials (LFP), there is no immediate link between LFP and spiking and here we examine both how the spikes themselves contribute to LFP and secondly how they are coordinated by LFP fluctuations. We used electrophysiological recordings in rodent cortex with high-density silicon probes to answer these questions. First, we found that spikes could directly and prominently contribute to high frequency power in electrodes very localized to the spike itself - this was more true for larger waveforms; therefore, we isolated our analysis of spike-oscillation interactions to distant sites. In our initial analysis, we found that population firing rate changes over time in both pyramidal excitatory and inhibitory cells are positively correlated simultaneous with gamma power changes, especially at higher frequency over about 70 Hz. We then quantified the ongoing E/I ratio over time and found it did not correlate with broadband gamma

oscillation power, but was specifically decreased when power was high in the 70-200 Hz range. It was also found that some neurons were phase-modulated at certain gamma frequency bands detected across several neighboring shanks. Finally, we found instances when gamma power is negatively correlated with spiking. These results imply that gamma oscillations might coordinate activity of individual neurons in cortical circuits in a manner more complex than previously described. 1. Nir, Y. et al. (2008). **Abstract:** Action potential transmission from presynaptic to postsynaptic neurons is the common currency of neural computation. Spike transmission efficacy is thought to critically underlie neural computation and changes in efficacy are critical for information storage. In particular, connectivity from pyramidal cells (PYR) to local interneurons (INT) (feedback inhibition, including lateral inhibition), gates afferent drive and dictates competitive PYR-PYR interactions. Therefore, a mechanistic understanding of circuit operation requires elucidating not only a connectomic map, but also the parameters that affect the dynamic properties of individual

synapses.
Synaptic connectivity and strength are usually assayed through paired intracellular recording of the pre- and postsynaptic cells, which is not practical in behaving animals.. An alternative, indirect, approach is *in vivo* multi-electrode extracellular recordings, which provide spike timing of hundreds of neurons recorded in parallel.. With such data, monosynapses can be deduced from the reliability and precision of spiking in one neuron in the milliseconds after a spike in another. However, detection of such connections requires their isolation from indirect polysynaptic drive and common 'third party' inputs, which have the potential to synchronize neurons that lack direct synaptic coupling. A reliable way to rule out third party coordination is to demonstrate that postsynaptic spikes are causally related to the spiking of a single presynaptic neuron.
To test for monosynaptic connections between neuron pairs, we decoupled pre-synaptic PYR from the ongoing network activity through single cell juxtacellular current injection or optogenetic stimulation. We generated a "ground-truth" dataset to confirm monosynaptic PYR drive of local INT, and validated a model for monosynapse detection. We then identified monosynaptic connections in nearly 30,000 PYR-INT pairs, and examined the functional architecture of the PYR-INT circuit in CA1.
We found that neighboring CA1 neurons were more likely to be connected and to have stronger connections, though superficial PYR projected more to deep INT. Connection probability was skewed, with a minority of highly connected hubs. In general, high frequency pre-synaptic firing led to short-term depression. Synaptic drive was moderately affected by the firing rate of the post-synaptic INT and strongly modulated by its prior spike timing. Finally, we established a short-latency integration window for convergent PYR inputs. These results support a non-homogenous circuit organization and provide a framework for constructing transiently active cell assemblies.

**Title:** Coordinated hippocampus-amygdala reactivations of a place-threat association during sleep

**Authors: *G. GIRARDEAU**[1], I. INEMA[2], G. BUZSAKI[3]
[1]New York Univ. Langone Med. Ctr., New York, NY; [2]McGill Univ., Montreal, QC, Canada; [3]New York University, Sch. of Med., New York, NY

**Abstract:** The association of a context with a specific threat requires both the hippocampus and the basolateral amygdala (BLA). However, how the two structures interact to sustain the consolidation of such an association is still unknown. We designed a novel task where rats have to learn daily the location and direction of an aversive airpuff on a linear track. We recorded large neuronal ensembles simultaneously in the hippocampus and BLA during training and extensive sleep periods preceding and following training. Our results show that the pairwise BLA-hippocampus activity recorded during training is reactivated during NREM sleep following training. These reactivations preferentially involve a subset of BLA cells that are up-modulated during hippocampal ripples. Moreover, the reactivations peak during hippocampal ripples and the joint place-threat representation (airpuff trajectory) is preferentially reactivated compared to the neutral representation (safe trajectory). These results suggest that place-threat associations are consolidated through coordinated BLA-hippocampus activity during NREM hippocampal ripples.

**Title:** Slow gamma frequency dynamics during sharp-wave ripples

**Authors: *A. OLIVA GONZÁLEZ**, A. FERNANDEZ-RUIZ, D. ENGLISH, G. BUZSAKI
Neurosci. Dept., New York Univ., New York, NY

**Abstract:** Sharp-wave ripples (SPW-Rs) are population synchronous events which occur in the hippocampus during consummatory behaviors and non-REM sleep. SWP-Rs have been demonstrated to support memory consolidation of previous experiences (Buzsaki 1989, Girardeau et al., 2009). Although the CA2 region has been shown to play an initiating role during SPW-Rs (Oliva et al., 2016), they are maximally reflected in the local field potentials (LFPs) of the CA1 region. SPW-Rs are composed of a high frequency oscillation (150 - 200 Hz), ripple, in the pyramidal layer and a slow frequency wave (5 - 10 Hz), the 'sharp wave', in the mid-apical dendritic layer. In order to investigate the cellular mechanisms of SPW-Rs, we recorded with high-density large-scale multishank silicon probes from the CA1, CA2 and CA3 hippocampal sub-regions of Long-Evans rats during different memory tasks and sleep. We found that, in addition to the ripple and sharp-wave components, some SPW-Rs events were accompanied by an additional gamma frequency oscillation between (25-30 Hz), as reported earlier (Carr et al., 2012). This gamma oscillation was present in the dendritic LFP signals as well as in the intracellular membrane potential of CA1 pyramidal cells. We classified SPW-Rs into different categories according to sharp wave duration and found that events in these categories also differed in spectral properties and spiking content organization. Longer duration sharp waves often appeared as two overlapping sharp wave events, giving rise to longer duration ripples as well as a 'double-wave'. The presence of the double wave was reflected in the spectrum as slow gamma power and correlated with the synchronous firing of different populations of interneurons in the CA3 region. Interneurons had been shown to synchronize and shape the participation of the principal cells within ripples (Csicsvari et al., 1999, Stark et al., 2015). Therefore, we hypothesized that different subpopulations of pyramidal neurons, putatively processing different pieces of information, coordinate during SPW-Rs to form an integrated representation. These organized representations could sub-serve the replay during sleep of recently acquired memories and could possibly constitute the cellular correlates of trajectories in a spatial memory task (Pfeiffer et al. 2015). We are currently investigating how the slow gamma power during SPW-Rs is affected by a spatial learning task.

**Title:** Place-action transformation in the hippocampus-lateral septum axis during a run-jump-run sequence

**Authors: *D. TINGLEY**[1], G. BUZSAKI[2]
[1]Neurosci., NYU Neurosci. Inst., New York, NY; [2]New York University, Sch. of Med., New York, NY

**Abstract:** Since the discovery of the hippocampal spatial code, many experiments have extended our knowledge of when and how this code remaps, warps, or maintains representations of the external world. Prior to the demonstration of this spatial code, it was clear that hippocampal activity could also be tuned to other variables, such as a specific object or motor sequence (Ranck 1973).
In the current set of experiments, we attempt to examine how hippocampal activity may integrate these disparate coding regimes into a cohesive signal that is transmitted out of the hippocampus. We designed a behavioral task that includes both the traversal of allocentric space and the completion of a specific motor sequence, while allowing for the dissociation of these two variables. Animals were trained to navigate across an elevated linear track, where a gap could be introduced at any location along the track. Correct traversal required the animal to run, jump across the gap, and continue running fluidly, with the jump location and distance of the gap varying on different blocks of trials.
In agreement with previous studies (Lenck-Santini et al., 2008), neurons were found in the CA1 and CA3 regions of the dorsal hippocampus with firing rates that were reliably tuned to the jumping sequence, independent from allocentric position. These neurons also demonstrated single-trial theta phase precession across different phases of the jump sequence, including the duration where animals were airborne.
To examine how these representations of space and action may be integrated, simultaneous recordings from a major output of the CA1/CA3 regions, the lateral septum(LS), were obtained. Using population firing rate vector analyses, we find that LS neurons carry a less precise spatial code and show stronger ‘remapping’ relative to the jump location. These results suggest the LS firing rates carry a stronger representation (relative to HPC) of specific salient actions, while a degraded allocentric spatial code.
In addition to these population firing rate codes, we will present findings that septo-hippocampal cell pairs participate in cross-regional gamma time scale cell assemblies. Furthermore, these functional assemblies appear to be dependent on whether or not the lateral septal cell demonstrates theta phase precession relative to hippocampal theta and allocentric position.

**Title:** Theta-gamma rhythm perturbation by focal cooling of the medial septum in freely moving rats

**Authors: *P. C. PETERSEN**[1], G. BUZSAKI[2]
[1]NYU Neurosci., [2]NYU Neurosci. Inst., New York Univ., New York, NY

**Abstract:** The theta rhythm coordinates neuronal activity in the hippocampus, entorhinal cortex and other areas involved in spatial memory. Theta oscillations are present during behavior and sleep, and the power and frequency of theta increases with running speed (McFarland, 1974; Ravassard, 2013). Lesions and pharmacological inactivation of the medial septal area has shown that the area is vital for theta rhythms in the hippocampus (Lawson and Bland, 1993; Vertes and Kocsis, 1997) and its damage impairs learning and memory (Winson, 1978; Chrobak et al., 1989; Givens and Olton, 1994; McNaughton et al., 2006).
Yet, it is not known what mechanisms generate the rhythm and what role the frequency and amplitude plays. Towards answering these questions, we have performed local thermal perturbation of the medial septum, to alter the frequency of theta. Temperature perturbation is a powerful tool to study brain rhythms as they affect time-scales of natural occurring processes equally without forcing any external dynamics.
We implanted silicon probes in CA1 in hippocampus and a cooling probe in the medial septum in rats. The cooling effect was either attained using dry ice or a Peltier device, mounted in a cooling device on the head of the animal. The cooling-device was connected to a silver rod implanted in the medial septum, that was thermally isolated along the length to attain a focal effect of the cooling (Aronov and Fee, 2011). The animal performed alternating trials on a figure eight maze, with ongoing cooling sessions, for behavioral quantification and to allow us to study the effects on place cell neuronal activity in the hippocampus. We successfully lowered the theta frequency by 2Hz during behavior. We observed degraded performance during the cooling as the animal made more errors on the maze. We also observed increased running during the cooling, and typically also a temporary decrease in movement as the temperature reversed to normal range. Further, we found a sharp drop in mid-frequency gamma power in the hippocampus as an effect of the cooling, an indicator of reduced entorhinal input (Fernández-Ruiz et al., 2017). Finally, we recorded place cells in the hippocampus to learn how the altered theta rhythm affects phase precession.

In summary, our results, to date, suggest that the theta rhythm can successfully be altered by cooling the medial septum and it leads to memory impairment.

**Title:** Inhibition-based theta spiking resonance in a hippocampal network

**Authors: *H. G. ROTSTEIN**[1], T. ITO[2], E. STARK[3]
[1]Mathematical Sci., NJIT, Newark, NJ; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ; [3]Dept. of Physiol. and Pharmacology, Sackler Fac. of Med. & Sagol Sch. of Neuroscienc, Tel Aviv Univ., Tel Aviv, Israel

**Abstract:** Neuronal oscillations emerge in neuronal systems as the result of the interplay of positive and negative feedback effects with different time scales. These mechanisms involve the synaptic interactions between neurons, especially connections between excitatory and inhibitory neurons, and the neuronal intrinsic ionic currents. It is currently unknown how intrinsic cell properties interact with network dynamics to create neuronal oscillations. In this project we address this issue theoretically in the context of a hippocampal microcircuit composed of excitatory (PYR) and inhibitory (INT) cells. *In vitro,* PYR exhibit a preferred subthreshold frequency response to oscillatory inputs (membrane potential resonance) at theta (4 - 10 Hz) frequencies. Contrary to expectation, *in vivo,* these cells do not exhibit spiking resonance in response to direct oscillatory optogenetic activation, though spiking resonance in PYR can be seen when INT are activated. We explain the underlying mechanisms for these seemingly contradictory observations by combining biophysical modeling, numerical simulations and dynamical systems analysis. In our model, direct PYR activation causes PYR subthreshold resonance that fails to be communicated to the spiking regime, in alignment with *in vivo* observations. This failure is primarily due to the strong oscillatory response that remains above threshold over a broad range of input frequencies. On the other hand, direct INT activation causes PYR theta-band spiking resonance as a result of a combination of rebound spiking and a timing mechanism. A hyperpolarization-activated current (h-) is critical for the generation of

rebound spikes at input frequencies that are low enough for supra-threshold voltage responses in PYR. Alone, rebound spiking creates a low-pass spiking filter that is insufficient to generate spiking resonance. The timing mechanisms are responsible generating the theta band-pass filter by either "erasing" the spikes generated by input frequencies lower than theta (deleting mechanisms) or disrupting the production of spikes for these input frequencies (preventing mechanisms). We identified three possible timing mechanisms: (i) network-mediated inhibition from OLM interneurons, (ii) synaptic depression of INT synapses onto PYR, and (iii) presence of subthreshold gamma resonance in INT. We explain how each of them contributes to the generation of theta spiking resonance. The principles identified in this study are applicable to other systems that exhibit theta resonance such as neocortical networks.

**Abstract:** Epileptic seizures reflect a perturbation of the balance between excitation and inhibition, yet the exact role of inhibitory interneurons in the initiation and propagation of epileptic seizures is widely debated. Evidence has emerged suggesting that interneurons play both an anti-epileptic and pro-epileptic role in the maintenance of epileptic brain networks. Enhanced inhibition can suppress spiking of principal cells, but also assists in synchronization of neuronal populations. Specifically, we examined the role of inhibitory interneurons in the dentate gyrus (DG) and CA3 on normal and pathological brain oscillations and spiking activity in a kindling model for temporal lobe seizures in behaving rats. Using a viral construct that restricts the expression of a desired gene to interneurons, we induced expression of an excitatory designer receptor exclusively activated by designer drug (DREADD) into all subtypes of DG and CA3 interneurons of the hippocampus and implanted silicon probes to record LFP and single unit responses. We first tested the effect of tonically increasing inhibitory tone by administering the ligand for the DREADD, clozapine N-oxide (CNO), intraperitoneally in non-epileptic rats to examine the contribution of inhibition from these areas on gamma (40-100 Hz), theta (5-8 Hz),

and ripple (150-200 Hz) oscillations in behaving rats. We next investigated the role of sustained inhibition on afterdischarge and behavioral seizure duration, severity, and development of kindled seizures in animals that were treated with CNO to activate the interneurons every other day. In addition, we compared the rate of interictal epileptiform discharges (IEDs), pathological population spikes that are hypothesized to play a role in the cognitive deficits associated with chronic epilepsy, between days when the animal was given an inert vehicle injection and CNO. Activation of interneurons had a profound effect on the LFP patterns in the intact hippocampus and also reduced the number of IEDs. Unilateral activation of DG and CA3 interneurons produced similar effects but largely confined to the inhibition-activated hemisphere. Surprisingly, tonic enhancement of inhibition exerted a relatively small effect on afterdischarge duration, despite the increased time to develop a fully kindled state. These findings suggest that afterdischarges depend on mechanisms other than disinhibition. The mechanisms underlying physiological and epileptic changes are under investigation.

**Abstract:** Consolidation of declarative memories requires hippocampal-neocortical communication. While substantial experimental evidence supports the role of sharp wave-ripples in transferring hippocampal information to the neocortex, the exact cortical destinations and the physiological mechanisms of such transfer are not known. We used an organic-based conformable microelectrode array to record local field potentials and neural spiking across the extent of the dorsal cortical surface of the rat brain, combined with silicon probe recordings in the hippocampus, to identify candidate physiological patterns. Parietal, midline and prefrontal but not primary cortical areas displayed localized ripple (100-150 Hz) oscillations during sleep, concurrent with hippocampal ripples. Coupling between hippocampal and neocortical ripples

was strengthened during sleep following learning. The findings suggest that ripple-ripple coupling supports hippocampal-associational cortical transfer of memory traces.

**Title:** Medial septum and the formation of hippocampal place fields

**Authors: *V. VARGA**, G. BUZSAKI
Neurosci. Institute, NYU Langone Med. Ctr., New York, NY

**Abstract:** Encoding of locations by hippocampal place cells is a prerequisite of mapping the environment. In the navigating animal information flow in the spatial navigation circuitry is coordinated by theta rhythm paced by the three components , cholinergic, GABAergic, glutamatergic medial septal theta generating network. During theta oscillations, the medial septal input rhythmically disinhibits as well as directly excites pyramidal cells. Depolarization or the induction of dendritic plateau potential may transform hippocampal silent cells to place cells. We asked if the medial septum, by providing all constituents of place cell induction, may be capable and / or necessary for transforming pyramidal cells to place coding units. We recorded the effect of the location-contingent optical stimulation of the medial septal network on the spatial firing of hippocampal neurons. A channelrhodopsin2-carrying, neuron-specific construct was injected into the medial septum and about a month later a multishank, 64-channel silicone probe was implanted into the dorsal CA1 region. Water-restricted animals were tracked at 120 Hz while running for water reward either on a cheeseboard maze or on a modified T-maze. The medial septum was stimulated in a closed-loop fashion by a 450 nm laser diode at 1 Hz or 8 Hz using sine wave stimulation while crossing a predefined area monitored by distance sensors. Stimulation significantly modulated the firing pattern of hippocampal units by inducing either elevation or suppression of activity. Importantly, medial septal activation also affected spatial firing by evoking spikes at the stimulated location but this effect was not carried over to non-stimulated periods. In subsequent experiments we aim to locally manipulate septo-hippocampal fibers and test the effect of stimulation in both familiar and novel environments.

**Abstract:** Episodic memory recollection is thought to be supported by unique computations performed within and across the hippocampal subfields. Theoretically, the CA3 to CA3 recurrent connections contribute to rapid learning through the formation of novel associations between excitatory neurons co-active during learning. Under this theoretical framework, recall is supported by a “pattern completion” process in which partial drive to a specific CA3 network can re-instate the full pattern of co-active neurons that became associated during learning. The lack of recurrent connections in CA1 have led theorists to conclude that this region must contribute to memory in some other way. We tested these fundamental theories of hippocampal processing by optogenetically driving CA1, CA3 and dentate gyrus circuits with patterned light stimulation *in vivo*. First, probe trials were given in which a subset of neurons were driven with focal light stimulation. After these baseline trials, we repeatedly co-activated neurons up to 1000 times with synchronous light stimulation. Different pairing protocols were tested, such as: theta burst stimulation, high intensity/low frequency square pulses, and closed-loop Gaussian stimulation triggered when mice occupied a fixed point in space. Following these pairing trials, we cued pattern completion by giving the partial pattern of light stimulation that had been delivered prior to pairing. In CA1, cued pattern completion was never observed. Moreover, there was no increase in the spontaneous correlation between pairs of neurons that were forced to be co-active during light stimulation. Preliminary analysis of CA3 and the dentate gyrus suggests a similar failure to observe any evidence for cued pattern completion. These negative results

suggest that repetitive co-activity of a small number of neurons does not produce sufficient plasticity to redefine which patterns of activity are stable and which are not.

**Abstract:** Over the last 50 years, the number of *in vivo* simultaneously recorded neurons has been increasing progressively. Advances in microfabrication technology permitted developments of high-channel count and high-density silicon probes (NeuroNexus - 256 sites, IMEC Neuropixel - 966 sites) and allowed electrophysiologists to record the activity of dozens of neurons at the same time *in vivo*. However, it is still challenging to correctly assign spiking signals to their single neuron source. This problem is especially challenging due to overlapping spikes from multiple sources, changes in waveform shape during bursting and electrode drift. Multiple “spike sorting” algorithms have been developed to deal with such large-scale extracellular recordings (KlustaKwik, KiloSort, SpyKING CIRCUS and MountainSort), though there is no community consensus as to which works best, a major impediment being the lack of sufficient ground truth data. Such data necessarily consists of single neurons spikes obtained with a technique which unambiguously assigns spikes to a single cell (such as intra- or juxtacellular recording) and simultaneous extracellular recording of a neural population which includes this same cell.
To produce such a dataset, we performed combined juxtacellular and silicon probe recordings. A 32-channel silicon probe (A1x32-Poly2) was attached to a juxtacellular glass pipette with light cure dental acrylic, and acutely implanted in awake head fixed mice. With this preparation, baseline recordings (at least 20 minutes) were obtained, after which 100 ms pulses of ~1-10 nA were applied to the juxtacellular pipette at 1 Hz until about 1000 spikes were elicited. We began collecting neurons with dual juxta-, extracellular recording methods. These neurons have clusterable size amplitude. Our aim is to collect sufficiently large numbers of simultaneously recorded neurons and test multiple popular spike sorting algorithms to provide the community with a physiological basis for making decisions about which spike sorting algorithms to choose.

**Abstract:** Systems consolidation (SC) is a proposed process whereby recently learned information is gradually transferred from labile hippocampal (HPC) circuits to distributed networks in the neocortex (CTX). The mechanisms underlying SC are thought to rely on repeated spontaneous replay of task-related patterns of neural activity in HPC and CTX during "offline" periods of quiet wakefulness and sleep. This is facilitated by temporal coordination of neural populations in both structures during HPC sharp-wave ripple oscillations (SPW-Rs). Two findings suggest that SPW-Rs are temporally aligned with the transient reorganization of whole-brain dynamics, in service of SC: (i) On the *micro* (local population) scale, spontaneous replay in HPC is coordinated with similar reactivations in task-relevant lower- and higher-order cortices. (ii) On the *macro* (whole-brain) scale, SPW-Rs have been found to coincide with a decrease in BOLD across subcortical regions and increase in BOLD across nearly all CTX regions. Due to the spatial limitations of extracellular physiology and the temporal (and spatial) limitations of the BOLD signal, however, the temporal and regional dynamics of this whole-CTX response to SPW-Rs are unknown. In this study, we outline the development and application of widefield imaging of a dorsal cortical hemisphere, combined with high-density silicon probe recordings in HPC and CTX. This technique allows us to investigate hippocampo-neocortical interaction in the mouse across learning and during subsequent rest, and makes it possible to observe region-wide variation in CTX response to SPW-Rs events with high temporal precision. We find that cortical widefield activity during active periods is distinct from that seen during behavioral quiescence. Active states are characterized by small, rapid fluctuations in fluorescence, corresponding with theta activity in the HPC. Contrastingly, during quiescent periods we observe synchronous activation of regional cortical motifs, reminiscent of the resting state networks observed in fMRI. This activity is accompanied by large irregular activity in the HPC LFP, with interspersed SPW-Rs. Preliminary results suggest that SPW-Rs are associated with a stereotyped spatiotemporal pattern of regional cortical activation. Together, these findings represent progress towards understanding whole-brain coordination during the consolidation of multi-sensory memories.

**Title:** An emergent model of hippocampal sharp wave ripple complexes reveals sublayer-specific stratified disparities

**Authors: *M. SINHA**, R. NARAYANAN
Mol. Biophysics Unit (MBU), Indian Inst. of Sci., Bangalore, India

**Abstract:** The hippocampal CA1 region comprises a heterogeneous population of deep and superficial pyramidal neurons whose somata manifest hyperpolarizing and depolarizing transients, respectively, during a sharp wave ripple (SPW-R) event. Here, we present a forward modeling approach that elucidates the emergence of the SPW-R complex and its relationship to the differential properties and responses of deep and superficial neurons. To generate deep and superficial neuronal populations, we accounted for deep-superficial differences in basal dendrites and *h* channels and employed a multi-parametric (12 active and passive properties) multi-objective (12 *in vitro* measurements) stochastic search spanning 5000 models for each population. An additional layer of search and validation, based on *in vivo* measurements, was imposed when valid models from this search (7 deep and 20 superficial) were subjected to high conductance state (HCS). Further, deep neurons received larger inhibition, and the placement of deep and superficial somata translated to iso-distant Schaffer collateral fibers establishing contacts respectively on their distal and proximal dendrites. To match electrophysiological observations during SPW-R epochs, we introduced dendritic plateau potentials (DPPs) and perisomatic ripple frequency inhibition (RFI) in these neurons. We found that HCS lowered the probability of generating an axo-somatic action potential despite the presence of a DPP. Importantly, the distally placed DPP in deep neurons attenuated to a larger extent compared to their proximal counterparts in superficial neurons, which in conjunction with enhanced inhibition in deep neurons resulted in the differential transients observed in deep *vs*. superficial somata during SPW-R epochs. Next, we built a neuropil made of 440 deep and superficial neurons (220 each), with their somata placed within the stratum pyramidale (SP). We computed local field potentials using the line source approximation method at 17 locations when DPPs and RFI impinged on these neurons. With reference to sharp waves in the SPW-R complex, DPPs in the superficial and deep neurons contributed predominantly to proximal and distal sinks, respectively, together yielding a broad spread of the sink. The ripples in the SPW-R complex and the source in the SP were primarily mediated by inhibitory afferents onto deep neurons, with relatively small contributions from superficial neurons. Our results unveil the differential contributions of deep and superficial neurons to SPW-R complexes, and suggest localized DPP as a key cellular mechanism that links the SPW-R complex to memory consolidation through plasticity induction.

**Title:** Mechanisms of theta cycle skipping in a detailed microcircuit model of the medial entorhinal cortex

**Authors: *M. J. BEZAIRE**, M. E. HASSELMO
Psychological & Brain Sci., Boston Univ., Boston, MA

**Abstract:** Biological and modeling studies indicate a role for HCN channels in precise rebound spike timing and rebound spike theta phase preferences of medial entorhinal cortical layer II stellate cells. These phase preferences vary as a function of dorsoventral location within the medial entorhinal cortex, and may play a role in the gradient of grid cell properties seen along the dorsoventral axis. Here, we developed biologically realistic stellate cell computer models that reproduce the key gradients in electrophysiological properties observed experimentally along the dorsoventral axis. We subjected these models to various input protocols, finding that their rebound spike phase preferences, and the input phases to which they are sensitive, differ according to cell type, theta frequency, and their reliance on the HCN current. We next incorporated these model cells into a microcircuit model consisting of grouped stellate cells and a small number of interneurons. We examined their ability to code for space in one dimension using a model of theta cycle skipping, and found that the different model cell types are differently able to participate in robust theta cycle skipping, and therefore are differently able to reliably code for space in one dimension by way of theta cycle skipping according to our microcircuit architecture.

**Authors: *J. MONACO**[1], H. T. BLAIR, IV[3], K. ZHANG[2]
[1]Biomed. Engin., [2]Dept Biomed Engin., Johns Hopkins Univ., Baltimore, MD; [3]Dept Psychology, UCLA, Los Angeles, CA

**Abstract:** The hippocampal representations of space by place, grid, and border cells are embedded in a web of subcortical networks synchronized to the theta rhythm (6-10 Hz) governed by the medial septum. Theta-rhythmic modulation of spatial cell activity has been long characterized in phenomena such as phase precession across grid and place fields. However, how spatial information or environmental cues modulate theta cells has remained unclear. Here, we recorded both hippocampal and extrahippocampal theta-rhythmic cells (mostly interneurons) for multiple hours as rats explored an 80-cm cylindrical arena with an orienting visual cue. These long theta-cell recordings allowed for adequate sampling of spikes given moderate firing rates (n=8 rats, mean 15.5 spikes/s) and spatial biases in exploratory behavior such as wall following. We calculated the mutual information between position and theta phase of spikes and found 233/840 recordings had significant spatial phase information ($p<0.02$) averaging 0.36 bits/spike. We computed adaptive-kernel spatial maps for firing rate and theta phase and found that theta cells with spatial phase information >0.1 bits/spike also demonstrated high correlations, both positive and negative, between rate and phase. We define ’phaser’ cells using criteria for minimum spatial phase information (>0.1 bits/spike), significant rate-phase correlations (>0.2 magnitude), and minimum firing rate (>3.5 spikes/s): 101/233 recordings from 5/8 rats are classified as phasers. These phaser recordings had low peak spatial firing rates (median 7.3 spikes/s; s.d. 4.2), most (65/101) had negative rate-phase relationships (mean r=-0.3; s.d., 0.4), and were recorded primarily from lateral septum (72/101) compared to a minority found in hippocampal, midbrain, or other subcortical areas. Strikingly, the phaser subtypes segregate along the theta cycle: positive/negative phasers prefer inphase/antiphase firing with hippocampal theta. To establish that apparent spatial modulation was not due to behavioral sampling biases of the animal’s trajectory, we trained statistical general linear models (GLMs) to predict spikes based on spatial (quadratic functions of position, wall proximity) and trajectory (speed, direction) variables. Fitting L2-regularized GLMs to a grid partition of the arena produced highly accurate

reconstructions (n=671 unique cells, median $r^2$=0.94) of firing ratemaps. Model analysis revealed overwhelming reliance on space, not trajectory. Thus, spatial theta cells may convert environmental cues into temporal phase codes without behavioral bias.

**Authors: *A. SHIMBO**[1,2], E.-I. IZAWA[1], S. FUJISAWA[2]
[1]Psychology, Keio Univ., Tokyo, Japan; [2]RIKEN Brain Sci. Inst., Wako, Japan

**Abstract:** To behave adaptively in complex environments, quantification of intervals is one of the most important abilities. In particular, measuring elapsed time between events in seconds to minutes range, referred to as interval timing, is involved in various behaviors, such as, foraging, decision making, associative learning, and sequential motor learning. Although the importance of interval timing is known to, little study has been done to reveal the neural mechanisms of the interval timing. Recent studies have found that hippocampal pyramidal neurons fire sequentially at particular timing between events (Pastalkova et al., 2009; MacDonald et al., 2011). Because of similarity to place cells, these neurons were termed “time cells”. Sequential activities of time cell between events may represent the temporal information between events. However, the characteristics of time cells in interval timing has not been investigated yet. To clarify the characteristics of temporal information encoded by time cells in interval timing, we changed the length of interval which subjects are required to measure within one session. In this study, rats were required to discriminate two different intervals, running on a treadmill, for making a correct choice and experienced different sets of intervals in task conditions, i.e. they experienced 5 s or 10s interval in condition 1, 10 s or 20 s interval in condition 2, and then 5 s or 10 s interval again in condition 3. We recorded neural activities in dorsal CA1 during interval. Here, we found that a subset of CA1 neurons fired at particular moments and showed sequential activities within interval. Comparison with neural activities between condtion1 and condition 2, these neurons changed firing peak to rightward and enlarged firing filed. In condition 3, these neural activates went back to condition 1. Intriguingly even they changed their firing peak and firing field in condition 2, cross-correlations between two neurons was preserved in three task conditions. These results indicated that hippocampal time cells represent temporal information relatively and the order of activation of each neuron was preserved in three task condition. These results is

similar to previous studies related to place cells. So, same neuronal mechanisms are contributed to encode temporal and spatial information in the hippocampus.

**Title:** Attractor transitions for time cell-like elapsed time dependent activity in a hippocampal CA1-CA3 network model

**Authors: *K. TAKADA**[1], K. TATENO[2]
[1]Dept. of Life Sci. and Systems Engin., Kyushu Inst. of Technol., Kitakyushu, Japan; [2]Dept. of Human Intelligence Systems, Kyushu Inst. of Technol., Kitakyushu-Shi, Japan

**Abstract:** The hippocampus is involved in encoding and retrieval of spatial and temporal memory. Place cells and time cells have been discovered in the hippocampal CA1 and CA3 regions. Place cells fire at a specific location in the given environment. Time cells fire at a specific moment within a temporally structured tasks. Transient firing of time cells express elapsed time from an event by firing at a specific moment. In a simple delayed matching to sample task, rats remember odor stimuli across a delay period. Four different odors were represented by different temporally organized ensembles of time cells in the CA1 region. Several theoretical models of time cells activity have been proposed: the temporal context model, the firing chain model, or a combined model. In the temporal context model, the flow of sequential events of cortical activity drives the sequential events in the hippocampus. In the firing chain model, elapsed time dependent activity is explained by a chain reaction of neural firing between excitable cells. A biophysical model of time cells has not been proposed. On the other hand, an attractor model for the pattern completion task has been proposed. Plenty of recurrent CA3-CA3 synaptic connections contribute to pattern completion. We hypothesize that a small group of neurons having strong internal connections represents a given percept and transition dynamics between the attractors can be represented as time cells. In the present study, we reproduced time cell-like elapsed time dependent firing in a hippocampal CA1-CA3 network model consisting of conductance-based neurons. We first constructed a CA3 network model. The elapsed time dependent activity was generated by successive transition of transient firing between cell assemblies. The successive firing transitions were accomplished if neurons belong to a single cell assembly and a part of those neurons had strong cross connections between cell assemblies. In

the CA1-CA3 network model, two temporally organized firing sequences were recalled. The population correlation between firing sequences induced by different initial stimuli were assessed. Evoked firing ensembles of time cells were determined by the initial stimulus. For the same initial stimuli, the population correlation between trials was high, while the different stimuli induced low population correlations. Our results indicate that the temporal representation of time cells is organized by orthogonal memory patterns in the CA3 region. Such sequential firing independently drives multi series of elapsed time dependent activity in the CA1 region.

**Abstract:** Understanding what computations neurons perform and how they are altered in diseases is an overarching goal of neuroscience. Yet, rare are the investigations of how neurons transform different input spiketrains following various complex patterns. We focused on granule cells (GCs) of the dentate gyrus (DG), a neural network long hypothesized to support pattern separation, the process of transforming similar input patterns into dissimilar outputs. To rigorously assess whether GCs exhibit pattern separation, we used mouse brain slices to stimulate DG afferents with input spiketrains of varying similarity and simultaneously recorded GCs output spiketrains. Because pattern separation is dependent on how one defines (1) a pattern of neuronal activity and (2) the similarity between a pair of patterns, we systematically explored different similarity metrics, at various timescales. The Pearson's correlation coefficient (R), the normalized dot product (NDP) or the binless Spike Time Tiling Coefficient (STTC)[1] and SPIKE metric[2] all showed that single GCs exhibit pattern separation at short timescales (lower than 100 ms) by rearranging their spike times. Pattern separation is also achieved through variations in the

binwise firing rate, which becomes dominant at longer timescales. It was assessed by a new metric, the scaling factor (SF), which considers spiketrains as vectors and compares their norm. We show it depends on differences in the average firing rate and differences in burstiness. Pattern separation as measured by SF is altered in kainate-injected mice with temporal lobe epilepsy, likely because of a subset of GCs exhibiting an occasional bursting behavior. These mice also show a strong impairment in a mnemonic discrimination task. We are currently investigating how changes in neuronal computations are correlated to behavioral performance and epilepsy severity. **Abstract:** The claustrum (CL) has been the subject of different theoretical studies with regard to its hypothetical role in integrative neural functions, including consciousness. Anatomical studies have revealed that the CL is a sheet-like neural structure located between the putamen and the insular cortex. It is assumed that claustral neurons are originated from the insula. The CL sends projections and receive afferents from all cortical regions. At present, it is assumed that CL neurons could be involved in cognitive processes and in the integration of different sensory modalities. Nevertheless, CL functions studied in alert behaving animals still remain unknown. We have recorded in behaving rabbits the firing activities of CL neurons during the acquisition of a classical eyeblink conditioning. Recorded cells were identified by their antidromic activation from the medial prefrontal (mPFC) or motor (M1C) cortices of both sides. For conditioning, we

used a delay paradigm: a tone as conditioned stimulus (CS) followed by an air puff as unconditioned stimulus (US) that co-terminated with it. Conditioned responses were determined from the electromyographic activity of the orbicularis oculi muscle. Neurons were recorded with glass and multiple metal electrodes across habituation and conditioning sessions. CL neurons were rarely activated by single stimuli of different modalities (air puffs, tones, light flashes). In contrast, CL neurons were activated during the first sessions of paired CS-US presentations, but their firing was less active in well-conditioned animals. Neurons activated from the M1C were located more superficially in the nucleus and presented different firing profiles than those projecting to the mPFC. Local field potentials recorded in the CL presented a characteristic ≈ 20 Hz oscillation during CS-US presentations. Electrical stimulation of the CL did not evoke any noticeable eyelid motor response even in trained animals. We developed recombinant adeno-associated viruses (rAAVs) equipped with chemically-controlled inducible genetic switches for inducible and reversible silencing of synaptic transmission by expressing a novel destabilized tetanus toxin light chain in the two CLs of rabbits. Silencing of synaptic transmission of CL projecting neurons was effective to delay the acquisition of the classical eyeblink conditioning, but did not evoke any significant effect on the rate of conditioned responses in well trained animals. Therefore, the CL seems to play an important role in the acquisition of associative learning tasks, mostly in relation to the novelty of CS-US association, but not in the expression of conditioned eyelid responses.

**Title:** Prelimbic cortex infusion of antidepressant nomifensine increases distractibility

**Authors: *A. R. MATTHEWS**[1], M. WILLIAMS[1], M. BUHUSI[2], C. V. BUHUSI[2]
[1]Dept. of Psychology, [2]Interdisciplinary Program in Neurosci., Utah State Univ., Logan, UT

**Abstract:** Emotional processing is dysregulated in affective disorders such as depression, phobias, schizophrenia, and post-traumatic stress disorder. Among the processes impaired by emotional distracters, and whose dysregulation is documented in affective disorders, is the ability

to time in the seconds-to-minutes range, i.e., interval timing. Presentation of task-irrelevant distracters during a timing task results in a delay in responding, suggesting a failure to maintain subjective time in working memory, possibly due to attentional and working memory resources being diverted away from timing, as proposed by the Relative Time-Sharing (RTS) model (Buhusi & Meck 2009, Phil Trans R Soc B 364: 1875-1885). According to the RTS model, attentional and working memory resources are diverted away from timing when distracters are presented, depending upon the discriminability of the distracter (Buhusi 2012, J Exp Pscyh: Anim Behav Process, 38: 30-39). We have previously identified the prelimbic cortex as a structure that is involved in the RTS of attentional resources that are reallocated during distractions (Matthews et al. 2012, Front Integr Neurosci 6: 111). In Matthews et al. 2012, some rats received noise presentations paired with foot shock, while others received noise presentations without foot shock pairing. Either way, the noise was a familiar distracter. Here, we sought to further evaluate the effect of nomifensine on novel distracters using a similar procedure as Matthews et al. 2012. Because in Matthews et al. 2012 nomifensine decreased the delaying effect of the distracter, we hypothesized that if nomifensine shifts attentional resources back to the primary timing task, it would decrease the delaying effect of novel distracters. Whereas, if nomifensine affects only the emotional components of attention, it would have no effect on the delay after novel distracters. In contrast to these hypotheses, nomifensine dose dependently increased the delayed in trials with novel distraction presentation, $F(2,18) = 5.68$, $p < 0.05$. These results indicate that while nomifensine has a beneficial effect upon working memory under anxiety-inducing distractions, it is detrimental to working memory when the distracters are novel. Results are discussed in relation to the brain circuits involved in RTS of resources, and the pharmacological management of affective disorders.

**Abstract:** The ability to estimate the passage of time is critical for behavioral adaptation and survival. However, the mechanisms underlying this ability still needs to be elucidated. The prefrontal cortex(PFC) and striatum (STR) seem to be key areas involved in time estimation in the seconds-to-minutes range and constitute a pathway looping through the thalamus. Here, we recorded from neurons in PFC and STR during a timing task. We analyzed single-unit activity and local field potentials, evaluated cross-frequency coupling between PFC and STR, described a possible influence of PFC local field potentials in neuronal activity in STR and assessed the functional connectivity within the prefrontal-striatal pathway.

**Abstract:** Time-based decision-making is critical for adaptive behavior and is impaired in a variety of illnesses (e.g., Parkinson's disease, Huntington's disease, etc.). How individuals make decisions based on temporal information can be studied in rats using the peak interval (PI) procedure. In a PI task, the onset of a cue indicates that reward may be earned for responding after a set 'criterion duration' has elapsed. Probe trials are also included in which the stimulus is presented for 3-4 times the length of the criterion duration and reward is omitted. During probe trials, rats abruptly start responding just before and stop responding just after the criterion duration passes. We examined how the dorsal striatum mediates the decision to start and stop responding during probe trials. Rats were trained on a PI task in which a houselight signaled a 6 second delay to reward. During testing, we infused either a D1 antagonist (SCH-23390) or a D2 antagonist (Sulpiride) into the dorsomedial striatum. D2 blockade delayed the decision to both start and stop responding, whereas D1 blockade selectively delayed the decision to stop

responding. This effect was distinct from infusions in the dorsolateral striatum. We next evaluated start/stop-related striatal activity using electrophysiology. Many striatal neurons showed transient activation or suppression around start or stop times. This activity was preceded by linear firing rate changes that spanned several seconds; the rate of which covaried with when a start or stop occurred. Collectively, these results suggest that neuronal activity in the striatum mediates decision thresholds during timing tasks.

**Abstract:** Considerable methodological progress suggests that sequential firing of cortical neurons plays an active role in processing behaviorally relevant information, yet methods for analyzing the spatiotemporal structure of population neuronal activity, particularly those for detecting sequential firing patterns, are limited. This research introduces "Edit Similarity" to analyze the temporal structure of spike trains in noisy neuronal population activity. Edit similarity was originally introduced in computer science for analyzing arbitrary strings such as words and genomes. The proposed framework applies this metric to sequences of neuronal population spikes. We show in both artificial and real neural activity data (CA1 hippocampal data taken from CRCNS) and from rat prefrontal cortex that the method enables the detection of spike sequences in the presence of various kinds of noise. The statistical relationship between detected clusters and behavior data are also discussed.This work was supported by "the Brain Mapping by Integrated Neurotechnologies for Disease Studies (Brain/MINDS) from Japan Agency for Medical Research and Development (AMED)" and "RIKEN Junior Research Associate Program".

**Abstract:** Categorizing intervals as short or long depends on the ability to perceive the passage of time and to assign different stimuli to specific categories, both fundamental primate cognitive skills. To determine the neural mechanism of interval categorization, we recorded the activity of pre-SMA neurons of monkeys executing an interval categorization task in which the short-long limit changed between blocks of trials. A large population of cells encoded the boundary between categories by reaching a peak of activity at a time close to the subjective limit between the short and long intervals. Notably, these cells changed their time of peak activity depending on the categorical boundary of the current block of trials. In addition, pre-SMA cells also represented the category selected by the monkeys and the outcome of the decision. These results suggest that the pre-SMA adaptively encodes the subjective boundary between short and long durations and contains all the crucial neural information to categorize intervals and evaluate the outcome of such perceptual decisions.

**Title:** Frequency domain structure of spontaneous infraslow dynamics in local cortical microcircuits

**Authors: *M. OKUN**[1], K. D. HARRIS[2]
[1]Dept. of Neuroscience, Psychology & Behaviour, Univ. of Leicester, Leicester, United Kingdom; [2]Univ. Col. London, London, United Kingdom

**Abstract:** Cortical activity is organised across multiple spatial and temporal scales. Most neurophysiological research, however, is concerned with activity on timescales of 1ms - 1s, for the simple reason that these timescales suffice for an extensive range of behaviours (e.g. your ability to recognise pictures or sounds, to get up from a chair, or to recall your yesterday's whereabouts). One prominent exception is fMRI: because of technical constraints, it is limited to measurements in the range of 0.01 - 0.5 Hz, thus a substantial body of knowledge on cortical dynamics on timescales slower than a second also exists. However, fMRI is limited not only in its temporal but also in its spatial resolution, thus while we know how entire cortical areas modulate their activity on slow timescales, very little is known about the underlying behaviour of individual neurons. In the present work we addressed this question by analysing multi-hour recordings of neuronal populations in rodent sensory and association cortex, performed using chronically implanted high-density silicon probes.
At the level of single neurons, we found that the spike count Fano factor increases with window size (for windows between 1ms and 500s). To understand this behaviour we developed an algorithm for generating synthetic spike trains with pre-specified inter-spike interval (ISI) distribution and power spectral density (PSD). We found that these synthetic spike trains quantitatively recapitulated the Fano factors in the original data, which was not the case when each constraint (ISI distribution or PSD) was used on its own. For most neurons, the point process PSD of the spike train in frequencies < 1 Hz behaved approximately as $1/f^{\alpha}$ ($\alpha$ was 0.3±0.21), providing a concise summary of slow modulation in neurons' firing rate which is unaccounted for by the fast (intrinsic) spiking dynamics of the ISIs.
In order to understand how the slow firing rate modulations are coordinated among neighbouring cortical neurons, we estimated the coherency between the firing of individual neurons and the

population rate, thus extending the concept of population coupling (Okun et al., Nature 2015) to the frequency domain. On average, in the 0.01 - 1 Hz band coherence fell with increasing frequency, however in ~20% of the neurons this decrease was not monotonic. Most surprisingly, the preferred phase of ~10% of the neurons was strongly frequency dependent, changing on a logarithmic scale by as much as 180 - 360 degrees. These findings suggest that slow modulations in firing rate are controlled by several different mechanisms with distinct effects across the neuronal population.

**Title:** Cognitive mapping of a virtual olfactory landscape

**Authors: *B. A. RADVANSKY**, D. A. DOMBECK
Northwestern Univ., Evanston, IL

**Abstract:** Olfactory-guided navigation is an animal behavior of crucial ethological significance. But the technical challenge of controlling chemical concentrations in space has posed a barrier to studying the neural basis of this behavior. Here, we overcome this challenge by building an olfactory virtual reality system for mice. This system uses rapid flow controllers and an online predictive algorithm to create and maintain virtual olfactory landscapes. Head-fixed mice on a spherical treadmill in darkness can navigate a linear track comprised of virtual odor gradients while engaging “place cells” in CA1 of the hippocampus. These place cells exhibit similar properties to those previously reported for real and visual virtual environments, demonstrating that olfactory-guided navigation recruits a similar cognitive map to that of multisensory- and visual-guided navigation. In addition to olfactory-guided navigation, this system creates a way forward for studying the neural bases of multisensory integration, innate valence, and low-dimensional sensory-spatial processing.

**Abstract:** It is well known that sleeping after learning can enhance memory retention in both humans and non-human animals. Recent studies in humans suggest that this effect may not depend on sleep per se, but can arise from sleep-inherent reduced sensory stimulation, decreasing memory interference (Craig et al, 2016). To address this issue, we tested the role of sensory stimulation after spatial learning on memory retention in rats and explored possible neural correlates of this memory enhancing effect.
We used an object location memory task in our behavioural studies. Rats were habituated for 10 min each day for 4 consecutive days to the empty testing arena, after which they spent 3 h either in a dimly lit resting box or a resting box illuminated with red light, which rats cannot sense. We used gentle handling to prevent rats from falling asleep whenever they were in the resting box. The next day, animals returned to the testing arena that now contained two copies of the same novel object. Rats could freely explore these objects during the 20 min single training trial. Immediately afterwards, rats returned either to their dimly lit or red light resting box. We tested memory retention for the locations of the objects 24 h after learning. Only rats that spent 3 h in the red light expressed significant object location memory.
These results strongly suggest that the lack of visual stimulation alone promotes formation of long-term object location memory, and that sleep is not necessary for this memory enhancement to emerge. To explore the neural mechanisms underpinning this effect, we assessed place field stability as a function of reduced visual stimulation. We recorded place fields in dorsal CA1 during a 10 min session during which rats randomly foraged in a novel testing arena. Rats were placed either in the dimly lit or the red-light testing box for 3 h immediately after, and then returned to their home cage. The same cells were recorded during two further 10 min sessions in the same arena, 6 h and 24 h after the initial exposure. Consistent with our behavioural results, our preliminary data suggest that reducing visual stimulation after learning promoted the stability of place fields in rats.

Overall, we show that long-term memory formation, in terms of behavioural as well as electrophysiological measures, benefits from reduced sensory stimulation after learning: just being exposed to highly familiar visual stimuli suffices to impair long-term memory retention. Our future studies will explore the neurobiological processes by which visual stimulation disrupts memory retention.

**Abstract:** The traditional experiment in neuroscience relies on measuring neural responses along with an a-priori defined external variable, and then quantifying the extent to which they covary. This approach has many benefits, but also restricts the findings to the pre-selected variables only, potentially overlooking other variables that the researcher did not measure or consider relevant. This is especially unfortunate in in light of the recent technological advances that enable large-scale recording of neuronal activity in behaving animals. To circumvent these shortcomings while taking advantage of the richness of the neural activity data, we developed a novel data analysis approach that allowed us to calculate neuronal tuning curves, regardless of any a-priori external selected variable, but rather with respect to the activity dynamics of other neurons within the same recorded population. We demonstrate the power of our method using several separate datasets with different coding properties: electrophysiological recordings in the thalamus and postsubiculum and $Ca^{2+}$ imaging data from the hippocampus and prefrontal cortex of freely behaving mice. Our analysis uncovered the structure of neuronal activity within the neural code space, exposing key properties of the neural code within these brain regions. Specifically, we were able to reconstruct the internal representation of space and unveil neural tuning curves, but without using any information about the external world. Overall, our approach enables the study of internal representations in neural populations in a generalized and unbiased manner with minimal prior assumptions.

**Authors: *M. TSANOV**[1], O. MAMAD[2]
[1]Trinity Col. Inst. of Neuroscience, TCD, Dublin, Ireland; [2]Trinity Col. Dublin, Institute of Neuroscience, Ireland

**Abstract:** Hippocampus-dependent memories relate rewarding or aversive experiences to environmental context. The hippocampal neurons encode spatial representation but it remains unclear how they encode aversive experiences. Here, we show that the place fields remapped in response to the innately aversive trimethylthiazoline, associated with particular section of the environment. The remapping of the individual place fields followed a specific pattern: the majority of remapped cells showed increased extra-field spiking during the aversive episodes. Optogenetic photostimulation of the basolateral amygdala showed equivalent population and individual remapping pattern. We applied brain computer interface (BCI) to test the hypothesis that the hippocampal remapping is a function of spike-timing proximity between the amygdala activation and hippocampal spiking. We used closed-loop optogenetic photostimulation triggered by selected place cells, during navigation in particular section of the recording track. Immediate, but not delayed BCI photostimulation evoked field remapping of the engaged place cells. Our findings present key evidence that the hippocampal neurons are not merely mapping the static environment but also store aversive episodes, enabling hippocampus-dependent memory for past experience to support future adaptive behavior.

**Abstract:** Grid cells fires when an animal crosses the fields of an hexagonal grid tiling the environment. To provide stable spatial representation, grid cell system must be anchored to external reference frame. Here, we combine winner take all coding and hamming distance coding to analyse population activity of grid cells. We show that the orientation of grid cells offsets from the wall by ~8 degree can minimize the similarity of population coding vector of locations on the segment along the wall within boundary areas. And we propose a reinforcement learning model to achieve the optimal anchoring process. These results explain the experiment data in rodents and point to the underline coding mechanism for grid patterns aligning to the external environment.

**Title:** Theta oscillations are required to generate spatially periodic receptive fields in the medial entorhinal cortex

**Authors: *A. BALACHANDAR**[1], C. G. ASSISI[2]
[1]Biol., Indian Inst. of Sci. Educ. and Res., Pune, India; [2]Indian Inst. of Sci. Educ. and Res. Pune, Pune, India

**Abstract:** Grid cells in the medial entorhinal cortex (mEC) fire at the vertices of a hexagonal grid that tiles the entire space an animal explores. This pattern serves as an allocentric coordinate system for animals to integrate their movement and determine their current location even in the absence of external cues. The stability and precision of this pattern is remarkable given many experimentally measured variables in the mEC - inputs to stellate cells and variability of local field potential oscillations - vary noisily as the animal navigates its environment. How can a stable spatial representation be built upon such shaky ground? We discover that the answer lies in the interplay between theta oscillations and the intrinsic time scales of the system, namely, the conductances expressed in stellate cells. To illustrate the mechanism we simulate a network of physiologically detailed conductance based model stellate cells coupled via inhibitory interneurons. Competitive interactions between stellate cells cause different groups of neurons to fire at different times. The identity of neurons that form transiently synchronous groups is determined by the topology of inhibition and the history of activation of stellate cells. We show that these spatiotemporal sequences can be easily perturbed by noise to the network. Theta oscillations are required to ensure that the same sequence is stimulated every time the animal traverses a particular trajectory. The reliability of these temporal sequences, in turn, translates into the stability of the grid cell's spatially periodic receptive field. Theta oscillations are themselves fickle, in that, the phase of theta is not pinned to the location of the animal as the spiking activity of grid cells are. Further, changes in movement velocity affect the frequency of theta oscillations. We show that these perturbations to theta do not affect the stability of grid fields. Our simulations concur with experimental data demonstrating that when theta oscillations are selectively and reversibly removed by excising input from the medial septum, grid fields dissipate leaving spatially non-specific and temporally imprecise patterns of activity. Our model shows that the formation of spatially periodic receptive fields is an emergent property of the coupling between theta oscillations and the intrinsic rich temporal repertoire of the mEC network.

**Title:** Network mechanisms that represent novelty and familiarity in the Medial Entorhinal Cortex

**Authors: *B. KRISHNAN**, A. BALACHANDAR, C. G. ASSISI
Biol. Sci., Indian Inst. of Sci. Educ. and Res., Pune, India

**Abstract:** Grid cells in the medial entorhinal cortex (mEC) fire whenever the animal is at the vertices of a hexagonal grid. This spatially periodic receptive field is anchored to the external world and can be used to integrate the movement of the animal as it traverses its environment. Specific features of the receptive field can act as markers of the external environment. Changes in the environment can change the orientation of the grid, break its symmetry along specific axes and expand or contract in spatial scale. In this study, we focus on a transformation of the spatial scale of the grid as a function of the novelty of the environment. Here, the environment remains static while the internal state of the animal (its degree of familiarity with the environment) changes over time. When an animal is introduced to a novel environment, the spatial scale of the grid expands and its crystalline symmetry gets perturbed. Over days, with growing familiarity, the scale of the grid contracts and its hexagonal symmetry is restored. The distance between the vertices and the radius of each vertex decreases while the 'gridness', a measure of symmetry, increases. We model this phenomenon using a network of biophysically realistic conductance-based neurons modeled as layer II stellate cells, putative grid cells, that are coupled through inhibitory interneurons. The topology of our model network resembles that of existing continuous attractor network models that have been used to generate the characteristic receptive fields of grid cells. In continuous attractor models, grid formation has been attributed to reciprocal inhibitory interactions between grid cells. We show that stellate cells coupled via an inhibitory intermediary can, under certain conditions, act as reciprocally inhibitory neurons. Inhibitory synapses in the mEC show spike timing dependent plasticity (STDP) and may continually reshape the mEC network as the animal navigates its environment. Further, environmental novelty is also known to affect the frequency of theta oscillations, possibly due to a modulation of acetylcholine levels. We show that a change in theta drive to our model network, coupled with changes in the topology of the inhibitory network effected by STDP can replicate the dynamics observed in the mEC as the animal becomes progressively familiar with its environment.

**Title:** Effect of home location on parasubicular grid cells

**Authors: *J. I. SANGUINETTI SCHECK**, M. BRECHT
Bernstein Ctr. for Computat. Neurosci., Humboldt-Universität Zu Berlin, Berlin, Germany

**Abstract:** The rat parasubiculum is a long (5.2mm) and narrow (0.3mm) parahippocampal structure engulfing the medial entorhinal cortex (MEC) on its dorsal and medial sides. The parasubiculum outputs predominantly to layer 2 of the MEC, selectively targeting the calbindin positive patches (Tang et al., 2016). This puts the parasubiculum in a prime position to shape both spatial and temporal coding in the MEC. Even though the parasubiculum itself contains most of the same functional cell classes (Grid Cells, Border Cells and Head Direction cells) as the MEC (Boccara et al., 2010, Tang et al., 2016), comparatively little is known about their functional role in navigation and the organization of spatial behavior. Grid cells in the MEC have been described as coding space as a robust hexagonal lattice that tessellates every environment in a similar way. Even though arena shape affects the grid, their stability is only mildly altered by changes in context (Diehl et al., 2017) and may shift with novelty at a very slow pace. However, grid cells in the parasubiculum have not yet been scrutinized for their context dependency or their robustness to changes in the environment. We conducted a preliminary study to test whether parasubicular grid cells are stable to the introduction of biologically relevant landmarks in the environment. The homecage, being the place where the animal spends most of the day, sleeps and receives food, is the most relevant landmark in a laboratory setting. We familiarized Long Evans rats (n=4) to a modified homecage with two lateral doors. After two weeks of familiarization with their home, rats were trained to forage for treats in a squared one meter arena, both in the absence or presence of their homecage. In this environment rats showed home preference, in-home grooming and hoarded food pellets from the surrounding towards the home without specific training. Our preliminary results show that the introduction of the homecage in the familiar environment reorganized foraging behavior, causing the rats to relocate their homebase (preferred location for resting and grooming) towards the home and initiate exploratory trips with the homecage as a starting point. We conducted extracellular single unit recordings of grid cells in the parasubiculum of rats (n=2) foraging the same, familiar, squared environment in the absence or presence of their homecage. We recorded (n=14) single units classified as grid cells, out of which six grid cells shifted their firing fields towards the homecage location. Our preliminary recordings show that home location may alter the grid cell pattern of parasubicular cells.

**Title:** Differential dynamics of memory representations in the hippocampal dentate gyrus and CA1

**Authors: *T. HAINMUELLER**[1], M. BARTOS[2]
[2]Inst. of Physiol. I, [1]Univ. of Freiburg, Freiburg I. Br., Germany

**Abstract:** The hippocampus is an essential brain center for the acquisition of conscious memories. Each of its major subfields is home to neuronal ensembles which encode memory-specific contents, such as places, sounds, time or individuals (O'Keefe and Dostrovsky, 1971; Quiroga et al., 2005; Aronov et al., 2017). Activation of these ensembles can be used to manipulate existing memories in mice or to craft artificial ones (Ramirez et al., 2013). While there is extensive knowledge on the stability and dynamics of contextual representations by principal cells e.g. in the hippocampal CA1 region, reports of content specific activity in others, such as the dentate gyrus (DG) remain scarce (Leutgeb et al., 2007, Danielson et al. 2016).
The study of neurons in the DG is hindered by the fact that the activity of granule cells (GCs), the principal neurons of the DG, is extremely sparse, with most neurons being silent throughout behavioral recording sessions (Pernía-Andrade & Jonas, 2014). Therefore, a large number of GCs must be observed simultaneously in order to record activity of the few coactive cells that form a functional memory ensemble. This is hard to achieve using standard electrophysiological recording techniques like tetrode-recordings. Only recently, technical advances have enabled the possibility of direct functional imaging of GC activity in awake, behaving mice (Danielson et al, 2016; Pilz et al., 2016).
In our present study, we have employed a novel approach to chronically image the activity of DG neurons in the intact hippocampal formation in awake, head fixed mice behaving in a virtual environment setup (Dombeck et al., 2010). Mice were trained to collect rewards in different virtual environments and to memorize the reward locations. We tracked the development of contextual representation of neurons in the CA1 as well as DG over multiple days. In agreement with previous studies using other recording modalities (Goodsmith et al., 2017, Senzai et al., 2017), we found that many GCs of the DG as well as pyramidal cells in CA1 represent distinct locations in the virtual environment reliably over multiple days. However, principal cells in these two hippocampal subfields show different remapping dynamics when the virtual environment is altered. Furthermore, we found regional differences in the stability of place representations

across days. These findings indicate, that cellular memory engrams in these two hippocampal subfields may be more suitable for certain types of memory tasks and explain earlier findings of specific and distinct memory impairments arising from lesions of either the DG or CA1.

**Abstract:** Breakdown of neuronal circuit as a result of deposition of pathogenic proteins leads to the decline of cognitive functions in Alzheimer′s disease (AD). One early symptom in AD patients is the dysfunction of spatial memory, in which the hippocampus plays an essential role. However, the precise process leading to functional breakdown of the hippocampal neural circuits

of AD remains unclear, in part due to the technical difficulty of longitudinally monitoring hippocampal activity during pathogenesis. Moreover, most studies of AD have used transgenic mice highly overexpressing amyloid precursor protein (APP), which caused artificial phenotypes such as memory dysfunctions that do not happen in human patients. To address these issues, we expressed a fluorescent calcium sensor G-CaMP7 in a new AD model mouse with single humanized amyloid precursor protein knock-in carrying Swedish, Beyreuther/Iberian, and Arctic mutations ($App^{NL-G-F}$) (Saito et al., 2014). We could observe the activity of 400-700 hippocampal CA1 pyramidal neurons over months with two-photon microscopy from head-fixed mice behaving under a virtual reality system. When we examined cell activity period, the rate of hyperactive cells (activity rate: ≥20%) during running increased in 7-month-old AD model mice compared with control mice, while it was not different in 4-month-old mice. In addition to activity rate, the number of active cells and percentage of place cells identified in 7-month-old AD model mice declined by 19% and 32% respectively, when compared with 4-month-old AD model mice. These abnormal cell functions may be the important factors resulting in memory dysfunctions, because deterioration of spatial memory starts at 6 months in this AD model mice. Interestingly, in the AD model mice, G-CaMP7-positive aggregations were observed in *stratum oriens* starting around the age of 3 months, and expanded with age. Since these dynamic characteristics were similar to Aβ deposition, and Aβ staining was located close to aggregations, they could be a sign of Aβ in vivo without any staining. These results suggest that the functional circuit including place cells in the hippocampal CA1 of AD model mice breaks down after the increase in Aβ deposition.

**Title:** Storage capacity of threshold-linear networks for grid-like continuous attractors

**Authors: D. SPALLA**[1], S. ROSAY[1], *A. TREVES[2]
[1]Cognitive Neurosci., [2]SISSA Intl. Sch. Adv Studies, Trieste, Italy

**Abstract:** Continuous attractor neural networks have been suggested to be involved in spatial memory, allowing for path integration to be implemented by quasi-frictionless movements of a ‘bump’ of activity representing the current or imagined position within a spatial environment. Like discrete attractor networks, also continuous ones can in principle store multiple environments into as many charts, and in [1] their storage capacity was analytically evaluated in the mean field approximation, for a sparse activity model suited to CA3 place cells. Grid cells, however, appear to map space densely and quasi-periodically, and maybe re-use the same chart for several environments. Can their storage capacity be estimated, too?
We report that it can, for a recurrent network of threshold-linear neurons, adapting what in [1] was a warming-up exercise. As in the sparse model, the calculation reduces to finding the solutions of a single equation, which disappear at a critical value of the storage load; but periodic boundary condition have to be imposed on a two dimensional Voronoi Cell (VC). Imposing a hexagonal VC allows to model grid-like charts and, surprisingly, the storage capacity turns out to be very much higher than in the previous toy model with a square VC, by several orders of magnitude.
Moreover, we show (through both analytical calculation and numerical simulations) that 'stripe' solutions, in which coherence is maintained in only one of the two dimensions of the plane, are favored with a square VC over square grids, allowing for a capacity larger by an order of magnitude. These results match the hierarchy of solutions independently derived in [2] for different 2D tiles, in which hexagonal grids are favored over stripes and both over square grids.
In graded-response networks, mixtures of multiple attractors are known to also be stable, though in limited regions of parameter space [3]. In our network, too, we find, in addition to single bumps, a regime in which external cues trigger retrieval in more than one 2D chart simultaneously, in a similar way as described in [4] for two 1D periodic manifolds.

**Title:** Improved method for measuring the topological dimensions of neuronal firing rate space

**Authors: *S. E. FOX**, J. B. RANCK, Jr
Dept Physiol & Pharmacol, State Univ. of New York Downstate Med. Ctr., Brooklyn, NY

**Abstract:** The firing of a class of neurons can be represented as a manifold embedded in a larger dimensional space. For N neurons, the space has N dimensions, each point a vector whose components represent the effect of each spike.
The inductive method to measure the topological dimension exploits the property that a boundary of a subspace with unknown topological dimension n, in an N-dimensional space has n-1 dimensionality. A randomly selected point becomes the center of an n-sphere with a radius small enough to fit inside the space. A point on its boundary is then selected as the center of an (n-1)-sphere. The number of times this process must be applied in order to be left with only 2 points is the inductive dimension (d) of the manifold.
This can be appreciated intuitively in a uniformly populated 3-space. The 1st step produces a 2D surface of a sphere, the 2nd, a 1D circle and the 3rd, 2 points: 3 steps equals inductive dimensionality of 3. The rate space of N neurons is a sparsely populated N-space having an embedded manifold with an inductive dimensionality ($d \leq N$, usually $d<<N$) that represents the number of terms necessary to describe the firing in the subspace.
We measured the inductive dimension of an 89D rate space for 89 place cells (courtesy of Dr. Eva Pastalkova) recorded for 1 hr while the rat foraged for food scattered on a 1 m square open field. To deal with sparsity, the inductive method was modified to use a shell for the boundary, rather than a surface. Last year we reported that the result was 3, not the 2 expected for the 2D floor. Because the shell has thickness, the extra dimension is the “experiential curve” itself, the activity along the rat’s path. We have now eliminated the extra dimension by allowing inclusion of only one intercepted point in each pass through the thickness of the shell. The result was 2 for both the real place cells and models of place cells with and without variance, and was not sensitive to exact radius or thickness of the shell. It was unchanged by reducing N to 45, but N=30 was insufficient. Applying the method to the same number of random spikes gave no result.
Whereas the conclusion was predictable for place cells because the firing correlates are well known, there are many neuronal classes and conditions for which there are an unknown number of terms necessary to account for the firing, e.g. firing with no change in behavior, as in sleep. The topological dimension of manifolds is useful because: 1) it allows more extensive mathematical analyses to be used, e.g. maps between manifolds, combining manifolds, and 2) it allows us to define circumstances in which the experiential curve intersects itself, i.e. in which something is the “same”, as is required in learning and recognition.

**Abstract:** Hippocampal place cells fire at specific locations as a subject moves through space, providing a neural code for the current position during locomotion. This spatial representation can be more or less accurate depending on the quantity and quality of sensory cues available to the animal, and on the level of spatial attention required by the task. The specific contribution of visual cues in the place cell code remains unclear because of their constant mixture with other sensory cues in real environments. In this study, we took advantage of virtual reality to selectively manipulate visual information as mice performed a behavioral task that did not require explicit spatial attention. Mice were trained to go back and forth between liquid rewards at the ends of virtual linear tracks, which differed in the richness of wall patterns, and the presence of virtual 3D objects inside the maze. Once behavioral performance was stable, we performed acute silicon probe recordings (32-64 channels) in area CA1 of the hippocampus. We found that the presence of proximal virtual 3D objects greatly enhanced the quantity of spatially modulated cells (place cells) among active cells and their quality in terms of peak firing rate, spatial information content, stability and in/out field firing. Spatial locations near the objects were over-represented. Virtual 3D objects also favored position over distance coding. Temporal coding of place cells (e.g. theta phase precession) was increased in the presence of the objects. Place cell rate and temporal coding were modified instantaneously upon removal/addition of 3D objects. Furthermore, such online change of 3D objects' availability in a familiar environment (same wall pattern, maze geometry) instantaneously induced an important modification of the place cells' representation (e.g. remapping). We conclude that proximal visual cues, such as visual 3D objects, have a strong impact on hippocampal place cell coding in virtual environments.

**Abstract:** The hippocampus (HPC) is often referred to as a cognitive map. However, it is still not known whether and how this map is learnt and what parameters it encodes. Several lines of evidence support tuning of representation in the hippocampus by outcome-related information. We investigate whether local dopamine (DA) input biases hippocampal representation to a subset of available dimensions in a behaviorally relevant manner. We hypothesize that DA input to the hippocampus serves to mold the cognitive map to represent adaptive dimensions of the sensory input. We recorded from multiple single units and local field potentials in area CA1 of dorsal HPC of behaving rats engaged in a navigation task in which two possible sets of cues are relevant to reward collection. The two sets of cues were manipulated in an independent manner so as to dissociate between neuronal encoding of each dimension. Once rats had learnt to follow one set of cues, the paradigm was shifted and animals had to use the second set of stimuli to get reward. Our results show that CA1 neurons can rearrange to represent the reward-relevant representation and neuronal activity can follow the behavioral set-shift rapidly after the switch to encode the most relevant parameters. To study the dependence of this organization on DA, we locally infused D1/D5 dopamine antagonists to block receptors in the HPC at the time of the set shift. Local injection of DA antagonist slows the set shift significantly. Neuronal activity in infused rats seems to persist in encoding the previously relevant parameters for the first 2-3 days after the switch of paradigm. Then, after more training days, blocking of D1 receptors seems to lead to deficits in place-cell properties. From a network point of view, DA receptors blocking leads to a slight shift in the theta frequency towards slower rhythms. Moreover, beta activity found in sham rats during the first days of learning of the new paradigm is suppressed in the infused rats.

**Abstract:** Pyramidal neurons in the hippocampus participate in dynamic cellular ensemble codes for space and memory. The hippocampus receives spatial and non-spatial information via distinct pathways and combines these two streams of information to create a “cognitive map”, which supports not only spatial navigation but also episodic memory. In these maps, prominent features of the environment can be represented by increased densities of relevant place cells. However, cellular mechanisms for the establishment and reorganization of these maps remain unclear. We thus longitudinally imaged functional cellular maps in the CA1 deep sublayer of novel Thy1-G-

CaMP7 transgenic mice during training on a virtual linear track. In this task, a visual landmark and reward delivery were associated with two distinct locations in a linear track created in a visual virtual environment. Fractions of running time and place cells increased as training progressed. Initially, maps were highly variable but, with repeated training, they increasingly stabilized to an extent correlated with behavioral performance. Representations of environmental salience (i.e., landmark) and motivational salience (i.e., reward) emerged with experience in different rapid versus delayed time courses. Initial establishment of over-represented maps was dominated by selective stabilization of cells that encode each salient location but not by direct formation from non-place cells or lateral recruitment of cells that encode non-salient locations. By contrast, robust reorganization of pre-established maps by rearrangement of these salient features occurred via cooperation between de novo formation, lateral shifts, and selective stabilization of affected representations. These findings reveal the distinct engagement of multiple forms of cellular dynamics in the establishment and reorganization of hippocampal cognitive maps and provide a mechanism through which experience of salient environmental features form lasting and adaptable memory traces.

**Authors: *X. ZHAO**[1], J. C. MAGEE[2]
[1]Janelia Res. Campus, HHMI, Ashburn, VA; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

**Abstract:** Hippocampal place cells play important roles in spatial navigation by encoding specific locations in the environment. It is thus critical to understand what input features give rise to the spatial selective response in place cells. To this goal, we examined CA1 place fields in head-fixed mice with a virtual reality system, in which sensory stimuli can be strictly controlled

and flexibly manipulated. Whole-cell recordings were made from CA1 pyramidal cells during the animal's virtual navigation in a 1-dimensional circular track. Consistent with our previous findings (Bittner et al. 2015), place fields could form after plateau potentials were induced at specific locations. The visual cue closest to the place field was then duplicated at another location on the track. This manipulation did not significantly alter the original field, and generated a smaller but reliable depolarization at the new location. The reduction in depolarization amplitude may indicate contributions from non-sensory inputs, or integration of multiple sensory cues since the animal was able to see more cues than the closest one. To test these hypotheses, partitions were added between each cue to restrict the animal's vision to only one cue at a certain location. With this configuration, duplication of the place field-associated cue generated a second field with similar amplitude compared to the original one. Together, these observations suggest that place fields are strongly driven by sensory inputs during virtual navigation, and multiple cues could be integrated within a single field. Lastly, we recorded place cells when mice were navigating in two dramatically different mazes with one shared cue. Interestingly, the same cue that triggers a robust field in one maze did not produce significant depolarization in the other, which reveals a strong context dependency of sensory-driven responses in CA1.

**Title:** Aversive learning reorganizes ensemble representations of current and prospective locations by hippocampal neurons

**Authors: *S. OKADA**, H. IGATA, T. SASAKI, Y. IKEGAYA
The Univ. of Tokyo, Tokyo, Japan

**Abstract:** Hippocampal place cells specifically discharge when an animal enters a specific zone, so-called a place field. In addition, firing patterns of hippocampal cells are subject to non-spatial information. For example, place fields have been shown to shift to a newly rewarded location, suggesting that the distribution of space represented by place cells is not homogeneous in a space but specific locations related to survival are more strongly represented. On the other hand, little

is known about how aversive environments are encoded by hippocampal place cells. To address this question, we analyzed spiking patterns of neuronal ensembles in the hippocampal CA1 region of rats performing a T-maze alternation task with an aversive airpuff stimulation incorporated onto a specific zone. To obtain reward, the rats needed to actively accept the aversive stimulation. Addition of aversive stimulation altered firing patterns of individual place cells, including changes in firing rates within their place fields, remapping of the place fields, and appearance of new place fields. Especially, spatial representation of place cell ensembles was strongly biased to the aversive zone, same as the preferred representation of reward locations reported in previous studies. Finally, Bayesian decoding analysis revealed that firing patterns during brief pauses at a choice point over-represented the airpuff zone to be visited in near future. These results show that aversive learning reorganizes spatial maps of hippocampal neuronal ensembles for representing both current and future places.

**Title:** A single-cell spiking model for the origin of grid-cell patterns

**Authors: T. D'ALBIS**[1], *R. KEMPTER[2]
[1]Humboldt-Universität zu Berlin, Berlin, Germany; [2]Humboldt-Universität Zu Berlin, Berlin, Germany

**Abstract:** Grid cells are neurons of the medial entorhinal cortex that have multiple spatial firing fields arranged in a strikingly-regular hexagonal pattern (Hafting et al., 2005). Since their discovery, grid cells have been studied extensively, as they are believed to support high-level cognitive tasks such as self-location, memory, and navigation (Rowland et al., 2016). Nevertheless, to date, the origin of grid-cell activity remains unclear.
Treves and coworkers (2008 and 2012) proposed that grid patterns could emerge from a competition between persistent excitation by spatially-selective inputs and the reluctance of a

neuron to fire due to spike-rate adaptation. Their model provided an important proof-of-principle but was formulated at a rather abstract level. In particular, the model included network-level interactions and was limited to rate-based neurons, which made a link to experimental data difficult.
To overcome these issues, we propose here a single-cell spiking model based on similar principles as the work by Kropff and Treves (2008). Our model is, on the one hand, more biologically realistic and, on the other hand, better suited for mathematical treatment. Importantly, we show that grid-like patterns emerge from a single-cell mechanism needless of any network-level interaction. To increase biological plausibility, we consider stochastic-spiking neurons, and we constrain the synaptic weights to positive values. Through rigorous mathematical analysis, we quantitatively predict the requirements for grid-pattern formation, and we establish a direct link to classical pattern-forming systems of the Turing type. Our study lays the groundwork for more biophysically-realistic models of the grid-cell activity.

**Title:** Environmental deformations dynamically shift the cognitive map

**Authors:** ***A. T. KEINATH**[1], R. A. EPSTEIN[1], V. BALASUBRAMANIAN[2]
[1]Psychology, [2]Physics, Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Last year we presented a model that showed how a novel mechanism—boundary-tethered grid shift—could account for diverse effects of environmental deformations on grid and place cells (Keinath et al., SFN 2016). In this model, input from border cells resets the spatial phase of grid cells at environmental boundaries, thus maintaining the learned relationship between grid phase and these boundaries, and transmission of grid input to place cells resets place field locations accordingly. If this model is correct, then distortions observed in the time-averaged activity of grid and place cells during environmental deformations do not arise from rescaling of the grid metric, but rather from discrete `shifts' in grid field locations following boundary contact. Here, we tested this idea empirically. First, we reanalyzed two grid cell deformation datasets (Barry, et al. 2007; Stensola, et al. 2012) and found clear evidence for shifts at boundaries. Indeed, the grid field locations and firing rates in the neurophysiological data closely matched the predictions of our model. Next, motivated by a hypothesized link between grid and place field distortions and human spatial memory during environmental deformations (Hartley, et al. 2004, Chen, et al. 2015), we asked whether we could observe evidence for boundary-tethered shifts in human behavior. We taught participants the locations of objects within a large square virtual reality environment, and then asked them to replace these objects in stretched or compressed versions of this environment. During deformation trials we observed shifts in the replaced locations of objects dependent on the most recently contacted boundary, in agreement with our model predictions. Together, these results provide convergent evidence that environmental deformations do not distort - but rather dynamically shift - the cognitive map, and imply that the internal metric of this map persists unaffected when the environment is reshaped.

**Abstract:** Adult hippocampal neurogenesis is an important physiological process that is not particularly well understood. A reduction in neurogenesis has been linked to deficits in learning and memory performance as well as changes in mood and affect. Likewise, increased neurogenesis has been tied to improvements in mood, learning, and memory processes. Rates of adult hippocampal neurogenesis can be increased by the administration of drugs (e.g., fluoxetine) or through behavioural enrichment including environmental enrichment. Environmental enrichment can be social, spatial, or object based and most paradigms use a combination of all of these. Here, we tested the hypothesis that the type of environmental enrichment would elicit differential effects in male and female rats given each sexes propensity to attend to different types of environmental cues. Expressly, males attend more readily to geometric information whereas females attend to landmarks. Each day for one month, same sex cage mates were placed into an enrichment enclosure for ~1 hour and allowed to freely explore. Pairs were assigned to control (i.e., stable enclosure geometry and landmarks), geometric enrichment (i.e., the environmental geometry/shape was changed daily), or landmark enrichment (i.e., objects within the enclosure were manipulated daily). Animals were injected with BRD-U during the final week of training. c-Fos was used to measure hippocampal neurogenesis. Both enriched groups exhibited increased rates of neurogenesis relative to controls, but a double dissociation between response to geometric or landmark enrichment was observed for the sexes in the predicted direction. These findings imply that we should incorporate innate tendencies in spatial orientation strategies in industrial and environmental design.

**Abstract:** Recent research has provided insight into how the brain assigns meaning to sensory stimuli in the visual and auditory domains. How vibrotactile (VT) stimuli are categorized, however, remains poorly understood. To examine how the brain assigns meaning to VT patterns, we trained 9 participants to categorize VT stimuli. Pulse trains were presented to the right volar forearm. Analogous to our previous work in the visual and auditory systems, we used a morphing algorithm to create a quasi-continuous stimulus space, divided into two categories. The morphing algorithm was applied to 2 VT category prototypes. The Category A prototype comprised a high-pulse-rate stimulus (100pps) near the elbow and a low-pulse-rate stimulus (25 pps) near the wrist, and the Category B prototype was the opposite. Subjects successfully learned to categorize the stimuli, reaching 92.5% accuracy over ~6.5 hours. Following training, subjects completed an fMRI scan in which short blocks of VT stimulus repetitions were presented. At the end of each block, subjects categorized the stimulus. Multivariate pattern analysis (MVPA) was used to decode the neural representations of the stimuli. In a category-selective MVPA, a classifier was trained to discriminate Category A vs B stimuli. In a separate VT feature-selective MVPA, a classifier discriminated between stimuli within the same category. Our analyses revealed a transition from feature selectivity posteriorly in bilateral superior parietal regions to category selectivity anteriorly in left S2, premotor cortex (PMC), and other frontal regions, with overlap of feature and category-selectivity in the left supramarginal gyrus (SMG). The most significant feature-selective regions were in bilateral superior parietal lobule and the left SMG, and the most significant category-selectivity was in the left SMG, S2, and PMC. MVPA classification accuracy in the left PMC significantly correlated with participants' in-scanner performance. Additionally, whole-brain effective connectivity analyses revealed that the PMC exerted top-down influence over the stimulus-selective regions. Our data are broadly consistent with a two-stage model of perceptual categorization from the visual domain, in which feature-selective representations in higher-level sensory cortices interface with category-selective representations in prefrontal cortex. In contrast to the visual domain, however, our preliminary analyses suggest that in the vibrotactile domain, category-level information appears to gradually emerge as stimuli are processed along a posterior-to-anterior hierarchy from parietal to frontal cortices.

**Abstract:** Spatial ability reliably predicts success in STEM fields. While spatial thinking has been examined – and improved – in laboratory-based interventions (Uttal et al., 2013), real-world school curricula do not typically include an explicit focus on spatial thinking (NRC, 2006). The presented study examined the behavioral and neural effects of teaching spatial thinking embedded within a year-long high school course, the GeoSpatial Semester (GSS). Participants were 63 high school students (39 GSS, 24 comparison) who completed three spatially-based tasks (e.g., mental rotation) and a resting-state scan in an MRI scanner before and after the end of the school year. Students in the GSS course showed greater improvement than comparison students on all spatial tasks following the course. To better understand the neural networks underlying these changes in spatial thinking, we applied graph-theoretic analyses to evaluate changes in resting-state and task-based functional connectivity associated with the GSS course. We calculated individual modularity statistics across a range of resolution parameters, and used these scores to predict academic achievement. Preliminary results indicated that, following the GSS course, students showed significantly greater modularity than at Timepoint 1, particularly at smaller resolution parameters (larger communities). Additional analyses were performed to examine whether brain regions that showed high functional connectivity during rest demonstrated a similar pattern of activity during the spatial tasks, as well as whether the efficiency of the neural networks correlated with task performance. Lastly, we examined connectivity strength and flexibility of key regions of the brain that previous research has implicated in spatial thinking. Our findings suggest that improvements in spatial thinking following classroom instruction may be explained in part by changes at the neural level observed both at rest and during spatial tasks.

**Title:** Shifts in effective connectivity across the head direction network reflect changes in imagined facing direction

**Authors: *M. B. PEREZ-LOPEZ**[1], S. AVRAAM[2], M. AVRAAMIDES[3], T. WOLBERS[1]
[1]Ageing and Cognition Res. Group, German Ctr. For Neurodegenerative Dis. DZNE, Magdeburg, Germany; [2]Dept. of Psychology, Univ. of Cyprus, Nicosia, Cyprus; [3]Dept. of Psychology, Univ. of Cyprus., Nicosia, Cyprus

**Abstract:** Imagining changes in facing direction is a crucial ability for everyday life, as it allows us to plan an itinerary, orient ourselves in a map or give navigation instructions to somebody else. This sense of direction is supported by head direction cells, which have been extensively studied in rodents and whose signal has been detected non-invasively in humans over key structures for navigation such as retrosplenial cortex (Marchette et al., 2014), thalamus and precuneus (Shine et al.,2016). However, when imagining a facing direction that differs from one's actual facing direction, one needs to overcome a conflict between both signals. At present, it is unknown if and how the head direction system may contribute to this process.
To address this important question, we systematically manipulated head direction disparity (HDD), the angular difference between an actual and an imagined facing orientation, using a perspective-taking paradigm. Specifically, participants (N=23) were asked to imagine a set of facing directions in a virtual environment (VE) while undergoing 3T fMRI scanning. The VE was memorized prior to testing and consisted of an octagonal room with distinctive objects serving as orientation cues. When instructed to assume a facing direction, participants were also asked to point to a second object for behavioral data collection. FMRI data was analyzed with standard general linear models and region of interest (ROI) analyses, using individually defined masks of the precuneus, RSC and the thalamus. In addition, we tested for changes in effective connectivity between regions by conducting generalized psycho-physiological interactions (gPPI) analyses.
Behavioral results revealed that it is easier to imagine facing directions that are cardinally aligned with the actual facing direction, as opposed to orientations that fall in between these cardinal axes. This effect may relate to the intrinsic axes of the body, which would facilitate access to those orientations aligned with it. Beta estimates extracted from ROI analyses confirmed that orientations of greater behavioral difficulty elicit stronger BOLD responses in precuneus, RSC and thalamus. Furthermore, gPPI analyses results, most notably between precuneus and RSC as well as between thalamus and RSC, show a significant increase in

connectivity for these cardinally-aligned facing directions compared to non-aligned ones. Together, these data suggest a novel mechanism by which the human head direction system may support the imagination of facing directions, even in the presence of conflicting visual and body based cues.

**Title:** Knowledge of ordinal position across lists following transitive inference training

**Authors: *T. KAO**[1,2], B. JURNEY[3], C. E. MICHAELCHECK[2], V. P. FERRERA[4], H. TERRACE[3], G. JENSEN[3]
[1]New York City Col. of Technology/CUNY, Brooklyn, NY; [2]Neuroscience, Columbia Univ., [3]Psychology, Columbia Univ., [4]Neurosci. (in Psychiatry), Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

**Abstract:** Transitive inference (TI) is the ability to infer that, if A>B and B>C, then it follows that A>C. Most animals that have been tested have demonstrated an ability to perform TI. Specifically, they are able to infer the relative positions of items in an ordered list, ABCDE, based only on trial-and-error training of the adjacent pairs (such that A>B, B>C, C>D, and D>E). To demonstrate inference, tests of TI also measure performance for non-adjacent pairs (B vs D) that were not initially trained. However, training on a single list is not sufficient to discover if participants integrate information about absolute position across lists. In our study, 35 human participants (14 males; 21 females) learned five different 5-item lists within a single 1-hour session (520 trials). During training, only adjacent pairs were presented and the correct response was to choose the earlier list item from each pair. Immediately following training, participants were tested with five "derived" lists constructed by taking one item from each of the five training lists. During the testing phase, participants were presented with all ten possible pairs (A>B, A>C, A>D, etc.) for each of these five derived lists. Not only did participants reliably show evidence of transitive inference during the testing phase, but they also responded accurately to each pair on the derived lists, even though all of those pairings were novel. That is

evidence that participants acquired knowledge of each item's ordinal position during training on the original lists. These results point collectively to a representational framework that not only allows transitive inferences with respect to item rank within a list, but comparison of item ranks across multiple lists. Implications for related topics in serial learning are discussed.

**Title:** Effects of estradiol levels on hippocampal-dependent spatial memory

**Authors: *S. ASSUDANI PATEL**[1], A. ARNISTA[1], O. OKIFO[1], C. MITZKOVITZ[1], F. KUHNEY[1], K. M. FRICK[2], P. A. NEWHOUSE[3], R. S. ASTUR[1]
[1]Univ. of Connecticut, Storrs, CT; [2]Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [3]Vanderbilt Psychiatric Hosp., Vanderbilt Univ. Sch. of Med., Nashville, TN

**Abstract:** Estradiol, the primary estrogen hormone, has been found to regulate hippocampal functions including spatial memory. The relationship between estradiol and the hippocampus is sensitive to varying levels of estradiol, either naturally with fluctuations within a menstrual cycle or artificially with the use of oral contraceptives (OCs). Prior research has indicated that lowered levels of estradiol have been associated with an increased risk of dementia and cognitive decline (Shumaker et al., 2003; Yaffe et al., 2007) and an increased risk of anxiety and depression (Newhouse & Albert, 2015). Additionally, studies have shown that women with high estradiol levels outperform women who have low levels on various memory tasks (Graham & Milad, 2013; Hampson & Morley, 2013). Furthermore, OCs deliver a synthetic form of estradiol at low levels across the menstrual cycle (Beltz et al., 2015). It is unclear how this artificial lowering of estradiol affects memory relative to naturally cycling (NC) women. In order to examine the impact of estradiol levels on spatial memory, women at different points of a natural cycle or on an OC were tested on a hippocampal-dependent task. Participants that were on OCs at the time of testing were grouped as an OC group. NC women were broken down into high estradiol (HE) and low estradiol (LE) groups based on estimation of their menstrual cycle. A total of 126 women completed a virtual Morris water task over two consecutive days. This task is known to be sensitive to hippocampal functioning. On day 1, participants are to learn the location of a fixed hidden platform across 12 trials based on cues in the virtual room. The last trial on day 1 is a probe trial in which the platform is removed, without the knowledge of the participant. On day

2, participants start with a probe trial, complete eight hidden platform trials, and then end with one more probe trial. Results indicated no group differences on the overall distance to find the platform across trials on both day 1 and day 2. Furthermore, there were no group differences in the total percent of distance spent in the correct quadrant in probe trial analyses. There was a negative correlation between the length of time taking an OC and the percent of distance in the correct quadrant for the probe trial at the end of day 1. However, this correlation was not significant ($p > .1$). Overall, the findings of this study indicate no obvious differences amongst groups of women with varying levels of estradiol.

**Title:** Frontal midline theta oscillations increase with ambulation in virtual environments, while posterior alpha oscillations increase with rest

**Authors: *M. LIANG**, M. STARRETT, A. D. EKSTROM
Dept. of Psychology, UC Davis, Davis, CA

**Abstract:** Hippocampal theta oscillations increase during movement in spatial environments in both humans and rats. Cortical theta oscillations covary with hippocampal movement-related theta in humans, and thus theta activity recorded by scalp electroencephalography (EEG) might also be expected to show modulations as a function of movement. However, to date, the relationship between movement and frontal midline theta remains unclear. Another issue regards whether movement-related theta is distinct from posterior cortical alpha oscillations, which tend to be robust during “off” periods, although their relationship to still periods remains unclear. One issue in past studies is that most wired scalp EEG recording systems do not permit free ambulation and most human navigation studies have been limited to small-scale environments with limited vestibular input. Here, we address these issues by combining a wireless EEG recording system and an immersive virtual reality allowing free ambulation on an omnidirectional treadmill. To address how frontal midline cortical theta oscillations varied as a function of movement, we asked 10 participants to alternate between two behavioral states,

ambulating in VR and standing still. To detect alpha oscillations, a signature of “off” states, we employed two additional behavioral conditions, eyes open and eyes closed. In block 1, subjects alternated between moving and standing still for 30 second intervals, while keeping their eyes open. In block 2, subjects performed the same task as in block 1 but with their eyes closed. In block 3, subjects alternated between eyes open and eyes closed, while ambulating. In block 4, participants alternated between eyes open and closed while remaining still on the treadmill. We predicted that we would see theta power increases in the frontal midline region specifically during movement, regardless of whether their eyes were open or closed. In contrast, we predicted increases in alpha power at posterior sites during eyes closed compared to eyes open, regardless of movement. Preliminary analyses revealed significant delta and theta power increases (log power differences = 1.373, $p = 0.0236$) in frontal-midline region when subjects were moving compared to still with eyes open. In contrast, we found alpha power increases in posterior regions when subjects were still compared to moving (log power differences = 1.058, trend level $p = 0.1948$). Our findings indicate that frontal-midline theta is associated with movement while posterior alpha is associated with standing still. Together, our results provide a novel means to study human navigation related oscillations non-invasively.

**Title:** The effect of body-based cues on human neural representations for space during active navigation

**Authors: *D. J. HUFFMAN**, A. D. EKSTROM
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

**Abstract:** A central and unanswered question in human spatial navigation regards the impact of vestibular and somatosensory input, termed body-based cues, on our neural codes underlying spatial navigation. Recent advances in virtual reality (VR) technology now permit the construction of visually realistic, immersive virtual environments, thus allowing laboratory experiments to better approximate real-world experiences. However, even VR rendered with head-mounted displays (HMD) lacks the vestibular and somatosensory input that we typically

experience when we ambulate in real-world spaces. Here, we employed a novel omnidirectional treadmill coupled with an HMD to investigate human spatial memory within large-scale, highly immersive virtual environments under varying levels of body-based cues. A recent paper from the lab (Kyle et al. 2015 eLife) demonstrated environment-specific codes within the hippocampus, reminiscent of “place-specific” maps in the rodent hippocampus. We hypothesized that if body-based cues are important for spatial memory in humans, then we should observe behavioral and neural differences in such representations based on the presence (vs. the absence) of these cues during encoding.
In the present experiment, participants completed 2 behavioral sessions. During the first session, participants freely ambulated an immersive virtual city by finding five target locations (stores). Then, participants performed a judgment of relative direction task, with each trial structured as follows: “Imagine you’re standing at Store X, facing Store Y. Please point to Store Z.” Participants performed a total of 4 rounds of navigation interspersed with the direction task. During the second session, participants navigated 3 virtual cities under 3 different levels of body-based cues: 1) “enriched”: translations with movements on the treadmill and head and body rotations with the HMD, 2) “limited”: translations controlled by a joystick and head and body rotations with the HMD, 3) “impoverished”: translations and rotations controlled by a joystick. Preliminary data revealed that participants were able to learn all 3 cities to criterion (subject-specific mean pointing error determined by performance in the first session). Moreover, during a final retrieval phase, the mean pointing error did not significantly differ based on the city or the order in which the cities were learned, suggesting that our training paradigm minimized between-city interference. Subsequent analysis of fMRI data will determine whether environment-specific representations, both within and outside of the hippocampus, vary as a function of body-based input.

**Title:** Modulatory influences of bottom-up vs. top-down cues on human spatial representations during navigation

**Authors: *C. E. PEACOCK**, A. D. EKSTROM
Psychology, Univ. of California, Davis, Davis, CA

**Abstract:** Models of spatial navigation conceptualize it as a multisensory integration process. Consistent with this focus, past studies have suggested a critical role for bottom-up cues like the environmental boundaries ("spatial geometry") and landmarks ("features") in shaping such multisensory spatial representations. However, humans possess a sophisticated ability to employ verbal cues to navigate (Taylor and Tversky, 1992), but how these top-down cues interact with geometry vs. feature cues remains unknown. We developed three experiments to address the roles of verbal cues and sub-vocal verbalization in spatial navigation, each containing two conditions. In the feature condition, participants were instructed to use a colored wall (Exp. 1 and 2) or a mountain range (Exp. 3) to aid their memory of store locations. In the geometry condition, participants were instructed to use the square boundary to learn store locations. Following the cue, participants encoded store locations during navigation of a virtual environment. They then were tested on store locations with a judgment of relative direction (JRD) task, where questions were designed to test spatial memory with respect to the verbal cues and features/geometry from each condition. Participants also completed the Self-Verbalization Questionnaire (SVQ) as an inventory of inner monologue. All experiments showed no significant interaction between verbal cue, alignment, and imagined field of view, suggesting that the verbal cue played no obvious modulatory role in forming spatial representations. A significant interaction between alignment and field of view showed decreased pointing error when the feature was in the imagined heading on misaligned trials. In the absence of featural information, alignment to the environmental axes significantly reduced pointing error and response times. Further, there was a significant correlation between SVQ ratings and pointing error, where lower ratings were associated with increased pointing error. These results suggest that salient bottom-up sensory input provides a dominant influence on spatial representations compared to top-down verbal cues, with a role of inner-verbal monologue.

**Title:** Neural dynamics underlying updating of heading changes as revealed by mobile brain-body imaging (MoBI)

**Authors: F. U. HOHLEFELD**[1], M. KLUG[1], L. GEHRKE[3], *K. GRAMANN[2]
[2]Psychology and Ergonomics, [1]Berlin Inst. of Technol., Berlin, Germany; [3]Psychologie und Arbeitswissenschaft, TU Berlin, Berlin, Germany

**Abstract:** Spatial orienting utilizes idiothetic information, including the vestibular and proprioceptive senses, to efficiently update spatial representations during physical body rotations. This kind of movement-related information can be integrated with allocentric representations of landmarks to provide an allocentric heading representation as a central component of spatial updating. However, neural dynamics subserving physical body rotations are poorly understood, due to restrictions of existing brain imaging methods that avoid movement-related artifacts in brain activity recordings by requesting the participants to sit or lie, while spatial updating was investigated using 2D visual stimuli.To investigate brain dynamics accompanying physical body rotations in dynamic 3D virtual environments, the present study uses a Mobile brain/Body Imaging (MoBI) approach allowing for simultaneous assessment of high-density wireless EEG and motion capture of various body parts. Twenty participants performed a spatial orientation task, which required physical body rotations following a moving sphere in 3D virtual reality presented through a head mounted display. The same task was also performed without body rotations by using a joystick control, while visual flow was presented in 2D on a standard display. EEG data were decomposed by independent component analysis in order to separate brain activity from movement and other non-brain sources. The data revealed neural activity in diverse cortical areas in the 4-30 Hz frequency band, which co-varied with different movement parameters.The present study demonstrates the unique possibility to extract neural correlates of spatial updating in fully mobile participants, overcoming limitations of previous brain imaging studies. In addition, the MoBI approach contributes significant new insights into the brain dynamics accompanying embodied cognitive processes utilizing idiothetic sensory information, here in the context of spatial orientation. Furthermore, the unique MoBI setup is of indispensable relevance for contributing to our general understanding of neural dynamics realizing full-range body movements and active interaction with the environment in healthy and possibly clinical populations.

**Title:** Cortical and subcortical participation in neural processing of passive perception of visuospatial changes

**Authors: *D. MANAHAN-VAUGHAN**[1], M. F. HAUSER[2]
[1]Ruhr Univ. Bochum,, Bochum, Germany; [2]Neurophysiology,, Ruhr Univ. Bochum,Medical Faculty,, Bochum, Germany

**Abstract:** In rodents, passive perception of novel configurations of visuospatial stimuli results in robust synaptic plasticity in the hippocampus, in the form of long-term depression (Kemp & Manahan-Vaughan, 2012, Cerebral Cortex, doi: 10.1093/cercor/bhr233). Hippocampal processing of spatial information may be supported by the cerebellum (Rochefort et al., 2011, Science, doi: 10.1126/science.1207403). Here, we explored in humans, hippocampal and cerebellar participation in the processing of passively perceived visuospatial information. First we assessed event-related potentials (ERPs) recorded during passive perception of novel, repeatedly presented, as well as configurationally, or perspectively, changed three-dimensional objects to verify that passive perception occured. We identified parieto-occipital ERP-components that differentiated between spatially reconfigured, familiar, and novel objects. Using single trial estimation and multivariate approaches, based on rapid event-related fMRI, we then conducted searchlight analysis across the brain, to correlate representational dissimilarity matrices (RDMs) derived from selected regions of interest (ROIs). We observed that the representational profile in the hippocampus significantly correlates with that of the cerebellum across novel, familiar, and spatially changed objects. Looking at the RDMs of our ROIs separately, both the hippocampus and the cerebellar vermis lobules I-V exhibited more unique representations for spatially changed objects. By contrast, vermis lobules VI-X displayed this pattern for all items that displayed some form of novelty. These findings suggest that, during passive visuospatial perception, an evaluative process takes place in the cerebellum that dissociates observer-independent configurational, and observer-related novelty. This process can be expected to support pattern separation in the hippocampus that enables processing of visuospatial change.

**Title:** Reactivation of a motor memory modulates perceptual learning

**Authors: *S. KLORFELD**, N. CENSOR
Sch. of Psychological Sciences, Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv-Yafo, Israel

**Abstract:** Motor and perceptual memories are acquired and consolidated with repeated practice, often resulting in between-session performance improvements referred to as offline learning gains. In parallel, extensive studies in animal models and recently in humans, have suggested that brief reactivation of consolidated memories may modulate learning. In order to test whether this mechanism operate across domains, the goal of the current study was to examine whether reactivation of a consolidated motor memory prior to a visual learning task, will generate higher offline gains than expected by visual practice per se. We investigated this notion in the context of the link between the oculomotor saccade system and efficient visual perception. An experimental design combining a saccade motor learning task with a typical visual texture discrimination task (TDT, Karni and Sagi, 1991) was used, targeting the same retinotopic location in each domain. Participants first learned to execute a saccade towards a location that was 45 degrees clockwise, at a distance of 5 degrees of visual angle from a fixation point which appeared on random locations on the screen. The movement execution was cued by the disappearance of the fixation, abolishing any visual information that could influence performance. Gaze position was recorded and online feedback was provided for movement accuracy, which was the end-point measure for the motor task. On the subsequent day, the motor memory was reactivated with 10 trials of the saccade task. Afterwards, subjects learned the visual TDT. In this task, subjects reported whether a target array of 3 diagonal bars was set horizontally or vertically, with the center of the target array appearing at the same location of the saccade task, relative to a central fixation. The target-to-mask asynchrony (SOA) was randomly changed within the session, to obtain a psychometric curve, from which the SOA discrimination threshold was derived. On the following day, subjects performed the TDT session followed by the saccade task. Preliminary results show that subjects improved in both tasks. Strikingly, the between-day offline gains in perceptual thresholds were enhanced, compared to learning in previous reports of visual practice per se. Furthermore, a positive correlation was found between the motor and perceptual improvements. Taken together, these results may indicate an interaction between different learning domains due to synchronized reactivation and consolidation processes.

**Title:** Consequences of visual production training on object representations

**Authors: *J. E. FAN**[1,2,3], D. YAMINS[1], K. NORMAN[2,3], N. B. TURK-BROWNE[2,3,4]
[1]Psychology, Stanford Univ., Stanford, CA; [2]Psychology, [3]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [4]Psychology, Yale Univ., New Haven, CT

**Abstract:** In the study of language, production has long been viewed as essential for understanding comprehension. By contrast, studies of vision have centered almost exclusively on comprehension (recognition) and have largely neglected production. Here we investigate visual production in its most basic form — drawing. We test the hypothesis that alternating between drawing two objects differentiates their representations, thereby making them more perceptually discriminable. This hypothesis is motivated by our previous findings that: (1) a deep neural network model of the ventral visual stream trained purely on photographs also recognized drawings, reflecting a common feature representation of objects across production and recognition; (2) training people to draw improved the model's ability to recognize their drawings, resulting from reduced feature overlap in the representations of different objects; and (3) this training led to greater categorical perception for trained objects, as measured by a separate perceptual discrimination task. The current study directly evaluates how practice with drawing objects affects their underlying representation in ventral temporal cortex using fMRI. All three phases (pre, training, post) of the study were scanned. During training, participants alternately drew two objects (e.g., table, bed) on an MR-safe tablet. Before and after training, they viewed these and two other control objects (e.g., chair, bench), so that we could obtain estimates of the neural representation of each object. We defined neural representations as the patterns of parameter estimates over voxels from a GLM that averages activity across all trials for each object. Neural patterns were extracted from an anatomical mask of inferior temporal (IT) cortex in the pre and post phases. Additional exploratory analyses will use a searchlight approach (e.g., to discover effects in dorsal stream, motor, and medial temporal lobe regions). We predicted that IT pattern similarity between objects in the trained pair would decrease from the first to third phases, relative to control objects. Our preliminary data are consistent with this

prediction. We also plan to analyze the relationship between the recognizability of drawings produced during training, as measured by the neural network model and separate human observers, and the hypothesized neural changes. Taken together, this work seeks to bridge computational modeling, functional neuroimaging, and psychophysical approaches to understand how perception and action are coordinated in the brain to support complex natural behaviors, including learning and visual communication.

**Title:** Navigating through the air - extending spatial memory and neural representation from two to three dimentions

**Authors: *S. MAIDENBAUM**, M. RABINOVITS, A. AMEDI
ELSC & IMRIC, Hebrew Univ. of Jerusalem, Jerusalem, Israel

**Abstract:** We live in a three dimensional world, yet research into the navigation and spatial memory and representation has focused to date mainly on two dimensional motion. The few human results exploring full 3D are conflicted, with several previous behavioral results suggesting that humans are affected by a series of biases when encoding vertical vs. horizontal location while others suggest that humans might use a 3D isometric representation of space. This is further confounded by a common focus on the vertical relation between 2d platforms (such as floors in a building), comparisons of still images and passive movies instead of full dynamic 3D motion, and on tasks far from the standardized norm in 2D.
Here, we extend into 3D the classical water maze spatial memory paradigm via a flight simulator approach, allowing participants full dynamic 3D motion through the environment. We explore these tasks both behaviorally (n=30) and while subjects undergo fMRI (n=7). Both groups performed the tasks both in 2D and in 3D versions enabling the extraction of the effect of the 3rd dimension.
We find that while subjects subjectively report increased difficulty with the vertical axis compared to the others, their actual behavioral scores demonstrate that performance on all three axis are equivalent though all worse than in 2D. Furthermore, we find that the basic nodes of the brain's navigation and scene-selective network are preserved with the addition of the vertical

dimension, but that there are clear effects within these nodes (with special emphasis on OPA). We further explore the effect on more complex neural spatial signals, finding their preservation as well.
Taken together, these results suggest that on the subconscious level the neural representation of all 3 dimensions are isometric, despite the additional conscious difficulty of the task.

**Abstract:** The Morris water task (MWT) is a test of spatial learning and memory commonly used in research on spatial cognition in nonhuman animals. From these studies it is clear that the hippocampus is necessary for accurate navigation and that males and females sometimes perform differently. Most often, a virtual MWT is used with humans. In our lab, we therefore designed a real-world version of the MWT and found that males, by default, use an allocentric strategy, but females by default use an egocentric strategy to navigate. Based on these findings, we designed allocentric and egocentric tabletop versions of the MWT to study use of these strategies. In the first experiment, 60 subjects (30 women) ages 18-25, were asked to perform an allocentric spatial task in which the hidden goal had a fixed location relative to stable room cues. Male performance was significantly better than females. In the second experiment, 60 subjects (28 women) ages 18-25 were tested in a egocentric spatial task in which the hidden goal was in a fixed location relative to body position at the start of a trial. Females outperformed males. A third experiment allowe either strategy and resulted in no sex differences. Together, these results suggest that sex differences in spatial navigation result from different prepotent spatial frameworks guiding performance.

**Abstract:** Spatial thinking—the visualization and mental manipulation of visuospatial information—has been identified as a key component of success in STEM fields. There is increasing evidence that spatial thinking is malleable and laboratory-based spatial training has identified structural changes in grey and white matter in regions commonly associated with spatial thinking (e.g., posterior parietal cortex). However, training has been limited to laboratory-based tasks, and the extent to which real-world educational experiences support neural and cognitive changes in spatial thinking has been unexamined. Therefore, the present study investigated whether learning-based structural plasticity observed in laboratory training studies extends to classroom instruction in high school sciences classes. Participants were high school students (N=35) enrolled in a science course designed to teach spatial thinking (Geospatial Semester, N=17) or alternative science electives (N=16). Participants completed measures of spatial thinking and a structural MRI (MPRAGE) before and after a year-long science course. Gray matter changes in thickness, volume, and curvature were calculated using Freesurfer for 36 cortical and 10 subcortical ROIs per hemisphere. Relative to the comparison group, students enrolled in the GSS course had greater increases in cortical thickness (left inferior parietal cortex, left postcentral gyrus, right precuneus) and maintained cortical thickness (right inferior parietal cortext, right superior parietal cortex) in regions commonly associated with spatial thinking. These patterns were accompanied by improvements in multiple measures of spatial thinking (e.g., mental rotation, embedded figures). Findings suggest that training spatial thinking within real-world classrooms promotes structural plasticity in adolescents.

**Title:** Persistent changes in resting state connectivity following skill learning

**Authors: *K. CASIMO**, J. WU, J. G. OJEMANN, K. E. WEAVER
Univ. of Washington, Seattle, WA

**Abstract:** Prior electroencephalography (EEG) or functional MRI studies have investigated changes in brain functional connectivity following skill learning in humans. These studies highlight that connectivity is not a static process, but rather changes cross diverse brain regions after a person acquires a new skill. Further changes in connectivity have been observed in resting state periods following the task, which are not identical to those linked to the execution of the task itself. These prior studies have established that changes in connectivity are spread across a large area of cortex, but are limited by either indirect measurements of brain activity via blood flow in fMRI, or by spatial and frequency resolution in noninvasive electrophysiology such as EEG.

We used electrocorticography (ECoG) collected from epileptic individuals undergoing seizure monitoring. We collected six-minute resting state sessions before and after training on a task, which required participants to navigate a three-dimensional virtual environment with the controller orientation rotated 45, 90, or 180 degrees relative to their position. We evaluated change in neural connectivity from before to after learning of the task, and compared these changes to spontaneous levels of variation that naturally occur in the resting state. Pre- to post-task connectivity changes were assessed in resting state sessions with a range of computational interaction measures, including linear regression, phase locking value, and coherence. We performed these evaluations across all brain regions with sufficient data, as identified and grouped by Brodmann area with a standard atlas.

We found connectivity changes over a wide range of cortex, including but not limited to motor regions. Changes in connectivity linked to learning occurred both within single brain regions and between spatially distant regions. These changes appeared across multiple canonical frequency bands from delta (1-4Hz) through high gamma (70-200Hz). The observed changes were similar but not identical across connectivity measures.

Our findings extend prior work evaluating changes in brain connectivity following skill acquisition into ECoG. We estimated changes in connectivity associated with skill learning go beyond natural levels of variation. We provide a unique combination of fine resolution of the high frequency end of the spectrum and spatial clarity relative to previous approaches. We specifically identify changes in higher frequencies not easily accessible in scalp measurements. Future efforts will examine performance differences in the degree of change following task training relative to skill level attained.

**Title:** A dynamic normalization model of temporal attention

**Authors: *R. N. DENISON**, M. CARRASCO, D. J. HEEGER
Dept. of Psychology and Ctr. for Neural Sci., New York Univ., New York, NY

**Abstract: Purpose:** Vision is a dynamic sense that handles a continuously changing stream of input. Although attention is critical for prioritizing the most relevant visual input, most models of visual attention are static. Here, we develop and test a dynamic model of visual attention. **Methods:** We generalized an existing static model of visual attention[1] to the time domain. The model consisted of (1) orientation-tuned channels representing the sensory information, (2) two attention layers controlling the gain of voluntary and involuntary attention, which modulated the gain of sensory responses via feedback, and (3) a decision layer that received input from the sensory layer and represented the model's choice in an orientation discrimination task. Voluntary attention responses were task-related and depended only on the attentional cue. Involuntary attention responses were stimulus-driven and depended only on input from the sensory layer. Sensory neural populations could vary in temporal dynamics, having more sustained or more transient responses. Responses in each layer updated at every time step according to differential equations implementing attentional modulation and normalization. We fit the model to psychophysical data from experiments with human observers in which we manipulated temporal attention - the prioritization of visual information at specific points in time - to a sequence of two

visual grating stimuli with independent orientations. Observers were precued to attend to the first, the second, or both stimuli and postcued to report the orientation of one of the stimuli. The stimuli were separated by a time interval that was fixed, and hence predictable, within a session, but varied across sessions (10 intervals, 100-800 ms). We sought to explain task performance as a function of attention condition, inter-stimulus interval, and stimulus orientation.
**Results and conclusions:** A combination of voluntary attentional gain enhancement and involuntary attentional gain suppression explained the psychophysical data. Voluntary gain enhancement took the form of a limited resource over short time intervals, which was renewed as time passed. This generalizes the idea of limited attentional resources across space at a single moment in time to across time at a single location in space. Including separate neural populations with more transient and more sustained responses reproduced patterns of behavior that depended on the sequence of stimulus orientations. The model makes testable predictions about attentional gain dynamics.

**Title:** Is attention enhanced following performance errors? A test of adaptive control

**Authors: *R. COMPTON**, E. C. HEATON, A. GAINES
Dept. of Psychology, Haverford Col., Haverford, PA

**Abstract:** This study tested whether people adaptively sharpen their attentional focus following performance mistakes, as predicted by current theories of cognitive control. Participants ($n$ = 30) completed a Stroop task in which target stimuli were preceded by an informative spatial cue. Adaptive control theory predicts that following errors, participants should more effectively utilize the spatial cue. Cue validity effects on performance were robust, as were Stroop interference effects, but neither effect was altered by commission of an error on the prior trial ($F$s < 1), counter to predictions of an adaptive control model. Likewise, while predictive spatial cues led to left-right asymmetries in EEG alpha power during the cue-target interval, as expected, and cues also produced validity effects on ERP responses to targets, as expected, neither of these effects was modulated by error commission on the previous trial. Instead, errors were followed by generalized arousal, as measured by decreased EEG alpha power (following errors versus correct responses) during both the response-cue interval and the cue-target interval on the next

trial. Errors were also followed by poorer overall performance in both accuracy and reaction time on the next trial. Results support an alternative theory that post-error changes in neural activity and performance reflect arousal, orienting, or cognitive bottlenecking rather than adaptive control of attention.

**Title:** Event-related brain potentials to focused and divided attention task

**Authors: *S. MENESES-ORTEGA**[1], *S. MENESES-ORTEGA[1], J. PÉREZ-BOUQUET[2]
[2]Inst. de Neurociencias, [1]Univ. de Guadalajara, Guadalajara, Mexico

**Abstract: Introduction**: Focused attention allow to allocate a greater amount of resources for the relevant stimuli, facilitating their processing. On the other hand, dividing attention has a cost. There is evidence that in divided attention tasks reaction time is higher and the percentage of correct responses is lower than in focused attention tasks. It has been proposed that when visual stimuli compete for attention with stimuli of other sensorial modalities, more processing resources are allocated to visual stimuli, however, it remains to be determined whether this preference is associated with perceptual, attentional, or response selection processes. In this work we set out to analyze changes in reaction time and ERPs associated with focused and divided selective attention.
**Method**: ERPs were recorded in five derivations (Fz, Cz, Pz, O1 and O2) under three conditions: a focused visual attention task, a focused auditory attention task and a divided attention task to both modalities. The stimuli were presented for 100 msec with a variable interstimulus interval of 400-600 msec. A two-way repeated-measures ANOVA (stimuli x task) were used to analyze the amplitude of the P1, N1 and P2 components associated with visual stimuli, and the N1 and P2 components produced by the auditory stimuli.
**Results:** In the visual modality, a significant main effect in the reaction time was found ($t(14)=4.11$; $p<0.002$. The reaction time was greater in the divided attention task than in the focused attention task. On the other hand, the reaction time recorded in the auditory attention task showed no differences between conditions. The N1 and P2 components of the visual ERPs showed greater amplitude by the attended stimuli than the no attended ones, but there were no differences between focused and divided attention tasks. In the auditory detection task the P2 component showed a greater amplitude in the divided attention task but there were no differences between attended and ignored stimuli.

**Conclusions**: Visual ERPs showed an effect of attention. This effect was similar between the conditions of focused and divided attention. This effect may be due to the fact that the visual stimuli have a competitive advantage over the stimuli of other sensorial modalities, so that the visual processing is maintained in a similar way when the attention is divided between the visual and the auditory modality.

**Abstract:** We perceive regularities about how objects are arranged in space. This spatial regularity and the inter-object relationship forms the context. Chun (1998) reported facilitation in finding a target when the spatial configuration of distractor and target was learned. This improvement in search times for a target in familiar configuration is called contextual cueing. Evidence for attentional mechanisms that underlie contextual cueing is inconclusive. To investigate the role of familiar configuration in visual processing, we made the participants learn a given spatial configuration and introduced violations to the learned configuration. This contextual violation is achieved by relocating an item from the learned configuration to a new random location on one-fourth of the trials. We further manipulated the reliability of the relocation by changing probability of the relocated item being a target. Experiment 1 (A & B) tested if there is any change in performance when there is a relocation from the familiar configuration. The result revealed separable effects of reliability on the relocated item for the two levels of reliability on performance. Trials were chronologically divided into epochs. The epoch-analysis showed that when the reliability was high the processing of the relocation item improved over the epochs and the performance was best at the final epoch. In the low reliability condition, the relocation was prioritized in the initial epochs but the performance decreased over the epochs and was worst at the final epoch. To further investigate if there is an attentional prioritization for the relocation, in experiment 2 (A & B), we manipulated the display size and looked for slope effects. The slope values were modulated by the reliability of the relocation and the result confirmed the pattern found in reaction times. The slope values for the relocated item increased over epochs when reliability was low and decreased over epochs when reliability was

high. This result shows how attention is modulated by reliability. The present study shows that when there is a violation of familiar configuration, attention is captured by the relocation and this capture is transient and is modulated by the reliability of relocation.

**Title:** Cold blooded attention: Finger temperature predicts performance in attentional tasks

**Authors: *R. C. VERGARA**[1], C. MOENNE[2], P. MALDONADO[1]
[1]Facultad de Medicina, Univ. De Chile, Santiago, Chile; [2]Facultad de Ingeniería, Pontificia Univ. Católica de Chile, Santiago, Chile

**Abstract:** Thermal stress has been shown to increase the chances of unsafe behavior during industrial and driving performance due to a reduction in attentional resources. Nonetheless, a major problem has been to define appropriate safety standards regarding environmental temperature, as modulations in performance would also be affected by task kind, complexity, workload, duration, and previous experience with the task. To bypass this attentional and thermoregulatory problem, we focused on the body rather than environmental temperature. Specifically, we measured tympanic, forehead, finger and environmental temperature accompanied by a battery of attentional tasks and EEG recordings under constant environmental temperature for each participant (environment ranging between 19-25°C). Particularly, we give a 10 minutes' baseline were subjects were instructed to sit and relax, followed by three attentional tasks; a continuous performance task, a flanker task, and a counting task. Using multiple linear regression models we checked which variable(s) were the best predictors of performance. We used EEG spectral tonic activity to compare body temperature measurements with known attentional arousal markers (Alpha and Beta spectral bands). Results showed a drop in finger temperature due to instruction and task engagement which was absent when the subject was instructed to relax. No change was observed in tympanic nor forehead temperatures, while the environmental temperature was kept almost constant for each participant. Particularly, the magnitude of the change in finger temperature was the best predictor of performance in all three attentional tasks. The drop in Finger temperature is concordant with Alpha band power reduction

and Beta band power increment, suggesting an increase in arousal. Our results suggest that finger temperature can be used as a predictor of alertness, predicting better than the environmental temperature the performance in attentional tasks. These findings support strongly that peripheral temperature change can be used to prevent unsafe behaviors and accidents.

**Title:** Discussions of brain activity and eye movement during driving

**Authors: *S. NAKAMURA**[1], S. HIWA[2], T. HIROYASU[3]
[1]Doshisha Univ. Kyotanabe Campus, Kyotanabe-shi,Kyoto, Japan; [2]Fac. of Life and Med. Sci., Doshisha Univ., Kyotanabe-Shi, Kyoto, Japan; [3]Doshisha Univ., Kyotanabe, Japan

**Abstract:** [Background and Objective]90% of traffic accidents are caused by human errors.Human errors are existed by errors in recognition, judgment, and operation in driving.Therefore, it is necessary to develop a driving support system that assists driver recognition, judgment, and operation.In the future driving support system, the quality of driving is improved by using the biological information of the driver.In recent research, acquisition of brain function information using fNIRS, EEG and the like has been carried out.In this study, brain activity and eye movements by fNIRS during driving are measured, and their correlation is examined.
[Methods]In the experiment, driving movie was presented to four subjects.The state of driving by a third person was recorded with driver's viewpoint, and the movie was presented to the examinees.During Rest, plus mark was presented for 30 seconds.During Task, a total of four types of moving images (turn left, two types of straight, turn right) were presented for 30 seconds.Brain activity was measured with the fNIRS device (LABNIRS).Measurement points are the forehead 22 ch and the back head 22 ch.Eye movements were measured with an eye tracker (Tobii X2 - 60).Also, to confirm the driving history, a questionnaire on the latest driving day, driving frequency, and licensing acquisition years questionnaire was conducted.The rest of the cerebral blood flow change model and the integrated value at the time of the task were obtained.Also, gaze point, gaze time and saccade time were calculated.
[Results and Discussion]Subjects were divided into two groups in two-dimensional space of gaze time and saccade time.As a result, it was classified into a group with a lot of gazes and a group with many saccades.The gaze distribution during the left turn of a group with a lot of gazes was concentrated in one central point of the screen. Furthermore, there was a tendency that gaze was

more frequent in groups with more gaze than groups with many saccades. It is said that gaze will gather on one point while driving idly.There is no significant difference from the brain function data, and future study is necessary.As a tendency, in the group in which attention was frequently observed, there were many channels with small integrated values at the time of left turn.Therefore, it is described that the subjects in the group with a high degree of gaze are in a state of seeing the front but in a state in which the brain is not active. In other words, it is conceivable that the subject can't concentrate on the driving.
[Conclusions]Subjects who had less Saccade while driving and focused on one point were observed.In that case, there is a possibility that the concentration status is lacking.

**Title:** Correlating state-based functional connectivity with behavioral performance

**Authors: *S. LAGANIERE**[1], W. CHEONG[2], M. ESTERMAN[3], M. A. HALKO[4]
[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Neurol., Beth Israel Deaconess Med. Sch., Boston, MA; [3]Boston Univ., Boston, MA; [4]Neurol., Harvard Med. Sch. / Beth Israel Deaconess Med., Boston, MA

**Abstract: Background** Several studies have used resting state functional connectivity to predict specific behavior during task, eg. reaction time variability. In these studies, the correlation between resting-state fMRI connectivity and behavior relies on the assumption that rest is a relatively homogeneous state and that task-induced changes in network dynamics are largely similar across individuals. However, resting-state acquisitions may not represent a true *task-free state*. Group-level studies have suggested that task-based functional connectivity may capture relevant changes in network dynamics thereby providing additional insight into the link between network connectivity and behavior. We hypothesized that individuals would exhibit different network connectivity -both within and between networks- at rest vs. task, that task-based connectivity measures between these networks would better predict individual performance, and that individual changes in network connectivity - during the transition from rest to task- would predict performance. **Methods** FMRI was acquired on normal healthy subjects in two different states: a 6-min rest-state and a 10-min task-state during which subjects performed a continuous performance task (gradCPT) for the entire sequence. Commission errors, omission errors,

reaction times, reaction time variability and D' were assessed during the task. Subject-level mean functional connectivity within and between 7 canonical networks -at rest and during task- as well as differences in network connectivity between the two states were computed. Connectivity measures were correlated to behavioral metrics. **Results** Preliminary data in 12 subjects suggests that attentional performance - as measured by D' on the gradCPT- was weakly correlated with connectivity *within* networks both during task and at rest. However, performance was more strongly inversely correlated with connectivity *between* the dorsal attention network (DAN) and the default network (DN). Interestingly, the correlation of the between-network connectivity and performance was stronger in the task-state (r=-0.72) than the rest-state (r=-0.49). The change in connectivity between DN/DAN when transitioning from rest to task at the single subject level also inversely correlated with performance (r=-0.61). **Conclusion** Performance on a sustained attention task is significantly correlated to specific *between* network measures of connectivity. This correlation strengthens during task performance. In addition, increased anti-correlation between DMN and DAN- when transitioning from rest-state to task-state- also predicts improved performance on this task.

**Title:** Reward motivation reduces implicit temporal bias in attentional readiness through compensatory control: Behavioral and pupillometric findings

**Authors: *K. SASMITA**, S. A. A. MASSAR, J. LIM, M. W. L. CHEE
Ctr. for Cognitive Neurosci., Duke-Nus Med. Sch., Singapore, Singapore

**Abstract: Objective** Maintaining attentional readiness is costly and cannot be sustained over longer periods of time. The implicit temporal structure of an environment can help to bias attention towards moments of greatest target probability. Under a uniform distribution of interstimulus intervals (foreperiod; FP) timing expectations can be formed based on the passage of time within the current trial, and stimulus intervals in preceding trials. Responses tend to be faster after long FPs compared to short FPs (foreperiod effect). The foreperiod effect is

modulated by expectations from preceding trials, being more pronounced when following a trial with long FPn-1 and reduced following a short FPn-1 (sequential effect). Both these effects exert temporal biases on response times.
Reward motivation is well known to improve performance (e.g. faster responses). However, it is unknown how motivation influences the foreperiod and/or sequential effects. In this study we analyzed data from a large sample of participants performing a sustained attention task under different reward conditions, with simultaneous pupillometric recordings.
**Methods & Results** Seventy-three participants performed a sustained attention task in which targets were temporally unpredictable (randomly drawn from a uniform distribution; 2-10sec), once to establish baseline (unrewarded), and once in a rewarded run (10c/fast response). Trials were binned according to current foreperiod (FPn; short: 2-6sec; long: 6-10sec), and preceding foreperiod (FPn-1; short: 2-6sec; long: 6-10sec). Results showed that overall performance (in all FP bins) was better in rewarded runs compared to baseline runs. Moreover, reward reduced temporal bias as evident in smaller foreperiod and sequential effects. Pupillometry revealed that reward increased target-locked pupil dilation, particularly at time bins that are normally characterized by low attentional readiness (short FPn), suggesting a compensatory control mechanism.
**Conclusion** The current findings suggest that reward motivation can improve overall attentional performance, and reduce implicit temporal bias, particularly by deploying compensatory control at moments of incomplete attentional readiness.

**Abstract:** Aims: The capacity to pay attention is a prerequisite for the cognitive ability, for example, evaluating an object for its qualities. However, this role is not clearly established for olfaction. The aim of this study was to examine olfactory attention using electro-encephalography recording (EEG). Specifically, we were interested in exploring how the neural

responses after inhaling the same odor differ between tasks with different attentional requirements and in which areas of the brain.
Methods: Nineteen subjects (10F, mean age=24) participated in the study. The odor of 2-phenylethyl-alcohol (a rose-like smell) was presented to the nose using an olfactometer while the subjects breathed nasally. We estimated changes in the cortical processing of odor in attend and not-attend task using olfactory event related potential (ERP) analysis. We focused on P3 component, which is known to reflect late cognitive processing, and compared its amplitude and latency between attend and not-attend odor trials. We localized the sources of P3 data using standard low resolution brain electromagnetic tomography (sLORETA), and identified the brain regions that showed significantly enhanced neural activity for attend than not-attend trials.
Results: The ERP analysis for attend odor trials revealed significant larger amplitude and smaller latency during in P3 component for attend than not-attend odor trials. This effect was observed in the post-stimulus time interval, 850-1050 ms. The source localization of ERP data for this time interval revealed significantly enhanced neural activation for attend than not-attend trials in inferior orbital frontal region, insula, precuneus, and temporal lobes. The odorless stimuli did not replicate these findings.
Conclusion: The findings from our study aligns with the general idea that attention to a stimulus enhances its neural processing. The sLORETA analysis suggests that the enhanced neural processing during olfactory attention is subserved by a network of brain areas that are associated with specific olfactory and general cognitive functions.

**Title:** Increased costs of attentional effort after sleep loss: Evidence from performance, preference and pupillometry

**Authors: *S. A. MASSAR**, J. LIM, K. SASMITA, M. W. L. CHEE
Duke-Nus Grad. Med. Sch., Singapore, Singapore

**Abstract: Objective** Sleep deprivation (SD) has widespread negative effects on cognitive performance in different domains including attention and decision-making. While sustained attention is among the most badly affected domains by sleep loss, most studies have interpreted this as an indication of a reduced capacity to perform. Alternatively, theories of effort-based decision-making propose that performance is subject to a continuous cost-benefit analysis. In the context of sustained attention, the effort associated with task performance can be considered a cost that is weighed against the benefits of performance. We previously found that sleep deprivation alters this effort-based decision process. Here, we examined how performance decrement in sustained attention after sleep deprivation may be explained as an increase in subjective costs.
**Methods & Results** To test the effort-based decision-making model during performance, participants (N=26) performed a sustained attention task (Psychomotor Vigilance Task; PVT) under different incentive conditions (1, 5 or 15 cent for fast responses). Overall, performance improved in higher reward runs, as evident in faster responses, fewer lapses (responses > 500 ms), and less performance decrement with time-on-task. Although performance was poorer during SD for all runs, this SD-effect was more pronounced with lower reward. This suggests a shift in the cost-benefit balance with SD.
To more formally test for this shift, participants performed a discounting task in which they indicated their preference for rewards that were available upon performance of different durations of PVT (1, 5, 10, 20 or 30 min). Results showed that participants discounted reward value based on the proposed duration of the attention task. Importantly, discounting was steeper after SD.
Lastly, pupillometry during the attention task revealed that pupil dynamics were modulated by SD and by reward. After SD, pupil size was smaller and more variable than in the well-rested condition. Incentive motivation increased pupil size and decreased variability, mostly in SD.
**Conclusion** Together, these data demonstrate that attentional performance can be interpreted within a cost-benefit framework. Moreover, findings from both tasks confirm that the allocation of attentional effort in vigilance performance is considered more costly after a night of sleep deprivation, and that reduced capacity does not fully explain the attentional deficits that occur following short-term sleep deprivation.

**Title:** Mindful driving:Brain functional state of mind wandering in driving and PVT task

**Authors: *Y. FUJIWARA**[1], S. HIWA[2], T. HIROYASU[3]
[1]Doshisha Univ. Kyotanabe Campus, Kyotanabe-shi,Kyoto, Japan; [2]Fac. of Life and Med. Sci., Doshisha Univ., Kyotanabe-Shi, Kyoto, Japan; [3]Doshisha Univ., Kyotanabe, Japan

**Abstract:** [Introduction] Mind wandering is a state in which attention deviates from the external environment to the inner thought, and many related studies were performed. It is a state opposite to mindfulness and observed in a daily life. Accidents are caused by temporary carelessness when falling into mind wandering at the driving. To prevent accidents, a driving support system that evaluates the driver's attention state is necessary. When driving operations are performed, cognition, processing, and judgment are carried out in the brain. brain activity is widely used as an index for estimating human condition. when elucidating the brain activity during driving, the performance of the driving support system improves. The goal of this study is to examine which part of the brain is related to attention status during driving with information obtained from an electroencephalograph (EEG). For this purpose, judgment index from the brain wave information is expected in the attention state during driving.
[Method] There were four subjects (age:21) in this experiment, and the dual-task was performed. The main task is an automobile driving task of driving highway course of driving simulator for 10 minutes, and the sub task is Psychomotor Vigilance Task (PVT). brain waves were measured using g.USBamp of EEG (g.tec). A caution interval and an inattention interval were defined from reaction time obtained from PVT, and a power spectrum was calculated from brain wave information. These were regarded as feature amounts, and a comparison was operated between attention state and inattention state.
[Result & Discussion] The result of the reaction time shows that when the reaction time is fast, the attention is not paid not to a driving task but PVT directly. the results in the case of a slow reaction time explain that attention is directed to driving tasks. Comparison of the power spectra of the β wave band (14 to 20 Hz) was performed in two states of care and inattention. The results showed a high tendency in the channel of occipital area when attention was given to driving. Previous studies have reported that an increase in the power of the beta wave in the occipital region is associated with visual attention. This is because the visual cortex in the occipital region is responsible for the visual input adjustment function and the beta wave rhythm is synchronized to enhance responsiveness to the visual input. These studies lead to an increase in the power of the β wave in the occipital region during driving requiring visual attention.
[Conclusion] The results of this study suggest that the power spectrum of the β wave in the occipital region is essential as an index for evaluating the attention state during driving.

**Title:** Reactive shifts of cognitive control under load during continuous performance: An fMRI study

**Authors: *V. EXPOSITO**, T. HAGEN, T. ESPESETH
Psykologi, Univ. of Oslo, Oslo, Norway

**Abstract:** During the execution of a complex task, context information that is actively kept in working memory guides behavior in order to proactively achieve desired goals. Since keeping relevant information in working memory can require attentional resources, a more reactive behavior that relies on external stimuli can be alternatively engaged when processing demands are high. Previous work has shown that proactive and reactive mechanisms of control can be flexibly selected according to task demands. Individual factors may contribute to the priority of one mechanism over the other (for instance, age) but the neural mechanism underlying this preference remains obscure. One possible way of studying why some people tend to behave proactively and some reactively in a given task is to induce a reactive shift in healthy, generally proactive populations. The AX-Continuous Performance Task (AX-CPT) has previously been widely used to study proactive vs. reactive cognitive control. The task consists on the identification of a specific cue-probe pair of letters (so called valid or target pair). During the delay period the cue information (context) should be maintained, and previous studies using physiological and neurophysiological measures suggest different patterns of neural processing for the different cue types (valid cue vs. non-valid cue). In the present work, we developed a novel variant of the task by increasing the load in the cue period. The load manipulation successfully induced a more reactive pattern of behavior in healthy subjects (n = 31). While subjects performed the task, we measured brain activity with functional magnetic resonance imaging (fMRI) and found distinct patterns of activity in the right dorsolateral prefrontal cortex (DLPFC) related to the proactive and reactive modes. The results are consistent with and extend previous fMRI studies. We propose that when task demands are high (global context), the use of context within the task (local context) may be hindered due to excessive processing demands. Thus, reactive processing in cognitive control may be driven by limitations in processing capacity or attentional effort, as indexed by reduced context-processing and hypoactivation of the right DLPFC.

**Authors: *A. DREW**[1], E. HEINY[2], A. T. KARST[3]
[1]Psychology, Miami Univ., Oxford, OH; [2]Psychology, Univ. of Wisconsin Oshkosh, Oshkosh, WI; [3]Psychology, Univ. of Wisconsin, Oshkosh, Oshkosh, WI

**Abstract:** Visual attention operates by rapidly selecting information in series of discrete episodes (Wyble & Bowman, 2009). Previous ERP investigations of visual attention have identified the N2pc component as reflecting processes related to the selection of a lateralized target (Eimer, 1996). Recent work has found support for the hypothesis that the component is reflective of localization of target information in visual space (Kiss et al., 2008; Tan & Wyble, 2015). This hypothesis specifically proposes that processes responsible for the selection of space, rather than of target identity, elicits the N2pc. The current work seeks to further explore this hypothesis by using cue stimuli designed to initiate localization processes in absence of processes linked directly to target identity information. Two experiments employed the use of spatially informative cues prior to target onset, and examined the impact of these cues on the elicited N2pc. Experiment 1 demonstrated that laterally presented cues elicited an N2pc and targets following cues did not. Experiment 2 used a central cue to investigate top-down shifting mechanisms and their relation to localization processes. Preliminary Data reveal that while a peripherally presented target designed to trigger localization elicits an N2pc, a centrally presented cue designed to signal a shift in attention from fixation does not. These results suggest a dissociation of the attentional processes involved in automatic localization of visual target information, and top-down shifting of attention to target information.

**Title:** Depth of language processing for unattended speech

**Authors: P. HAR SHAI**, *E. M. ZION GOLUMBIC
Neurosci., Bar Ilan Univ., Ramat Gan, Israel

**Abstract:** Speech processing requires analysis of auditory input at multiple acoustic and linguistic levels, and a long-standing research question is which stages of language processing require attention. As suggested by the infamous "Cocktail Party" effect (Cherry 1953), as well as the "Irrelevant Sound Effect" (Beaman et al. 2007), at least some unattended content seems to be fully analyzed and can affect behavior. Nonetheless, individuals are typically unable to recall the content of unattended speech.

Here we studied the depth of processing applied to unattended speech, using a novel experimental approach, exploiting the time-scales within speech to systematically probe different levels of linguistic processing (Ding et.al, 2015). Speech materials consisting of isochronously presented syllables (at 4Hz) were structured such that every two syllables created a Hebrew word, two words constructed a phrase and two phrases constituted a sentence. These stimuli (referred to as "hierarchical isochronous speech"; HIS) allow differentiating neural responses to distinct linguistic levels - words, sentences and phrases – as they are uniquely associated with specific frequencies.

We present data from two "Cocktail Party" style experiments in which HIS was presented concurrently with natural speech (dichotically), and was to be either attended or ignored. Using EEG measurements of neural activity, we tested which linguistic levels are represented in the neural response to HIS speech as a function of attention, while varying the attended task. We found that when individuals engaged in a speech-comprehension task, unattended HIS stimuli could nonetheless be analyzed at multiple linguistic levels, without impairing performance on the attended task. In contrast, when the attended task consisted of more demanding target-detection, unattended HIS was only analyzed at an acoustic level and no evidence could be found for higher linguistic processing. Taken together, these results invite nuance when studying the processing applied to unattended speech. Specifically, they suggest that the depth of processing for unattended speech can vary as a function of task-demands applied to attended speech. While in some cases analysis of unattended speech is limited only to the sensory level, in other cases it can undergo full linguistic processing emphasizing the brains' capability, in principle, to process two streams of speech simultaneously. This study paves the way for future research aimed at characterizing the factors affecting the depth of processing of unattended speech and exploring the capacity and limitations of the brain for parallel processing of speech.

**Title:** Anxiety toward fear-relevant stimuli modulates perceptual switch in continuous flash suppression

**Authors: *T. CHIBA**[1,2], K. IDE[3,2], H. MORIYA[4], H. TODA[5], T. YAMAMOTO[1], T. YAMAMOTO[1], M. KAWATO[4]
[1]Military Med. Res. Unit, Tokyo, Japan; [2]ATR, Kyoto, Japan; [3]Hikarinohana clinic, Tokyo, Japan; [4]ATR BICR, Kyoto, Japan; [5]Natl. Def. Med. Col., Saitam, Japan

**Abstract:** Among mammalian, the ability to rapidly detect life-threatening stimuli is crucial for the transport of genes between generations. The attentional priority of phylogenetic fear-relevant stimuli is mediated by an evolutionary shaped fear module. The fear module preferentially associates fear-relevant stimuli with negative affective acts including unconditioned stimuli and anxiety. Thus, the fear module endows the fear-relevant stimuli with enhanced fear acquisition and resistant to extinction, which result in the high prevalence of phobia for phylogenetic fear-relevant such as snakes. However, to the best of our knowledge, no study demonstrated the attentional priority of fear-relevant stimuli among individuals without fear for such stimuli. Previous study analyzed the participants who might had been already fear conditioned to such stimuli. In this study, healthy individuals with varying degrees of anxieties but without fear for snakes and/or spiders were presented with pictures of snakes, spiders and flowers suppressed from view by continuous flash suppression. The suppression times for snakes relative to flowers have been found shorter than those for spiders relative to flowers most probably because of higher trait anxiety scores. This study indicates that phylogenetic fear-relevant stimulus is preferentially associated with anxiety and anxiety enhances the attentional bias toward the stimuli regardless of subjective fear.

**Title:** Two-different resting states - mind blanking and mind wandering

**Authors: *T. KAWAGOE**[1], K. ONODA[1], S. YAMAGUCHI[2]
[1]Shimane Univ., Izumo, Japan; [2]Neurol., Shimane Univ. Sch. Med., Izumo-Shi, Japan

**Abstract:** Study for resting-state brain networks (RSNs) has become an important area of neuroimaging. Usually, neuroscientists assess RSNs using an instruction like “think about nothing in particular” or “let your mind wander.” Such instructions are probably appropriate and at present we know of nothing better than these instructions. However, the difference between the two types of instructions might cause some RSN differences. In the field of cognitive psychology, mind wandering (MW) has become a hot topic over the past 15 years. MW is defined as thinking unrelated to an ongoing task or activity, which is similar to spontaneous and stimulus-independent thought. Recently, another mental state in humans called mind blanking (MB) has been suggested. MB is defined as a lack of conscious awareness. The MW and MB would relate to the two different instructions mentioned above. For our research, we manipulated the participants’ mental states with instructions designed to uncover RSN differences between the two-different mental states, MB and MW. Self-reports confirmed that our manipulations were valid. RSNs data indicated that the default mode network (DMN; a core network during MW) and salience network (a network for detecting subjective “salience”) had a larger anticorrelation during MB conditions than during MW conditions in addition to a change within DMN connectivity. We concluded that two instructions for MB and MW can differentially affect the relationship between and within RSNs and that MB is neurophysiologically distinct from MW.

**Title:** Let's talk about secs: Effects of distraction on speeding and stopping distances in young drivers

**Authors: *A. C. PLOWS**[1], H. N. RIZEQ[1], I. N. NGUYEN[1], K. D. F. RUELOS[1], D. J. GOBLE[1], H. S. BAWEJA[2]

**Abstract:** Distracted driving is driving while doing another activity that takes attention away from driving itself. The types of distractions involve, but are not limited to: a) visual: taking one's eyes off the road; b) cognitive: taking one's mind off of driving; and, c) manual: taking one's hands off the steering wheel. However, the combined effects of speed and distraction while driving remain unclear. Therefore, the purpose of this study was to examine the effects of speed and distraction on driving performance in young adults using a realistic driving simulator. Twenty-six healthy young adults (Average age: 22.8 years, 12 females) volunteered to participate in the study. The driving simulation task involved lane keeping on a 2-lane road with a leading vehicle stimulus braking and accelerating at quasi-random intervals. All subjects performed a total of 6 trials under two experimental conditions: 1) lane keeping with no distractions, and 2) lane keeping with a secondary task (dual tasking with serial-7s). Both conditions were performed at three levels of difficulties: 60, 75 and 90 mph. Lane keeping accuracy was quantified as the root mean squared error between the intended lane position and steering movement sinusoid created by the subject's tracking. Steering variability was quantified as the standard deviation of the detrended steering movement trajectory. The distance covered during the time between the stimulus and paddle depression was also quantified. Lane keeping accuracy and smoothness decreased with increase in speed. Furthermore, distances covered from stimulus to reaction were inversely proportional to vehicle speed irrespective of acceleration and braking stimuli. We find that distraction degraded driving performance, reaction times, accelerating and stopping distances. These findings suggest individuals may not be able to adequately use information and experience previously acquired while they are distracted. The average driving experience in this cohort of subjects was at least 5 years post-licensing. Yet, the failure to benefit from prior driving experience under distraction as seen in the degraded driving performance with distraction is an important finding. The detrimental effect of distraction on driving is ubiquitous in young adults irrespective of gender and driving experience. Previous work has shown that graduated driver's licensing programs in which participants receive more

on the road training results in reduced fatal crashes. Our work is supportive of this notion and extends previous findings by providing objective measures of driving performance.

**Title:** Independent and overlapping neural representations of saccades, attention shifts and reference frames

**Authors: *X. ZHANG**, J. D. GOLOMB
Dept of Psychology, Ohio State Univ., Columbus, OH

**Abstract:** When changing our focus from one location to another, we can either move our eyes or shift our attention covertly. Previous research indicates that saccade execution and attention shifts might share underlying brain networks, including intraparietal sulcus (IPS) and frontal eye field (FEF) (Corbetta and Shulman, 2002). To further explore how neural representations of saccades and covert attention shifts interact, we acquired fMRI data during a combined saccade and covert attention task. Participants began each trial by fixating at one of two fixation points while covertly attending to one of three rapid serial visual presentation (RSVP) streams (left, center, right of screen). There were four critical conditions. On eyes-fixed trials, participants either held attention at the same initial location (hold eyes, hold attention) or shifted attention to another stream midway through the trial (hold eyes, shift attention). On eyes-move trials, participants made a saccade midway through the trial, while maintaining attention in one of two reference frames: (shift eyes, retinotopic attention) and (shift eyes, spatiotopic attention). The retinotopic condition involved holding attention at a fixation-relative location but shifting relative to the screen, whereas the spatiotopic condition involved holding attention on the screen-centered location but shifting relative to the eyes. We used multivariate pattern analysis (MVPA) to decode information about saccades (eyes-fixed vs. eyes-move), attention shifts (hold vs. shift attention), and reference frames (retinotopic vs. spatiotopic attention). Regions where saccade information could be decoded partially overlapped with those where attention shifts could be

decoded, mainly in parietal areas, but we found less overlap in visual and frontal areas. Reference frame (task) information could only be decoded in a few areas (e.g., part of left superior parietal lobe, SPL). Further analyses suggest that this left SPL area may contain representations of both spatiotopic and retinotopic attention allocation. Moreover, we compared shift-eyes with hold-eyes conditions to examine how saccade and attention shift processes might be involved in reference frame representation. The activity pattern of "shift-eyes, retinotopic attention" seemed more similar to the "hold eyes, hold attention" condition in earlier visual areas than in later parietal and frontal areas, consistent with the notion that earlier areas are largely retinotopically organized, while other processes such as saccades might more strongly influence representations in later areas.

**Title:** The impact of transcutaneous vagal nerve stimulation on the amplitude of the P3 event-related potential implicates the involvement of noradrenergic activity

**Authors: *C. M. WARREN**[1], L. OUWERKERK[2], S. NIEUWENHUIS[3]
[1]Psychology, Utah State Univ., Logan, UT; [2]Vrije Univ., Amsterdam, Netherlands; [3]Leiden Univ., Leiden, Netherlands

**Abstract:** We used transcutaneous vagal nerve stimulation (tVNS) in concert with electroencephalogram recordings to test for an impact of tVNS on the amplitude of the P3 event-related potential (ERP) component. Nieuwenhuis, Aston-Jones, and Cohen (2005) proposed that the P3 is a manifestation of phasic norepinephrine release. TVNS is a non-invasive treatment of epilepsy that is thought to exert its putative therapeutic effect through increased norepinephrine release. Previously, invasive vagal nerve stimulation has been linked to the P3 in that patients with epilepsy who responded to VNS treatment also exhibited an increase in P3 amplitude, whereas patients who did not show improvement in seizure frequency also did not show an increased P3 (De Taeye et al., 2014). We applied real and sham tVNS to a group of healthy subjects (n = 24) in a subject-blind cross-over design, while they performed a standard set of "oddball" tasks known to elicit a P3. TVNS did not affect reaction time nor accuracy in the oddball tasks. We used principal component analysis (PCA) to decompose the ERP data into a set of linearly uncorrelated waveforms (Spencer, Dien, & Donchin, 2001). PCA identified two

distinct positive components consistent with the classic P3, and the novelty P3. We observed a reduction in amplitude of both the classic and novelty P3 in the real condition relative to the sham condition. We argue that the inconsistency between our results and those of De Taeye and colleagues (2014) must be due to physiological differences between the patients with epilepsy studied by De Taeye et al. (2014) and the healthy participants who took part in our study, as well as the difference between invasive VNS and tVNS. Regardless, our results provide additional support for the role of the norepinephrine system in production of the P3.

**Abstract:** Understanding the properties of attentional control, along with the neural mechanisms subserving them, has long invited intense scrutiny in research groups. However, it has not been demonstrated how the top-down anticipatory oxygenated hemoglobin and electrical activity activation cooperatively influence the subsequent attentional processing of targets selection. Here, with a concurrent event-related fNIRS-ERP recording, we explored the potential contribution of anticipatory oxygenated hemoglobin (HbO) based activity and low-frequency oscillations to attentional control by examining how HbO and alpha-band oscillations influence the subsequent attentional selection ERP marker. We found that expecting a target led to both a larger increase of preparatory HbO response and a larger decrease of posterior alpha-band (8-12 Hz) oscillations over the visual cortex contralateral to the upcoming target, indicating an increase in cortical excitability in task-relevant sensory neurons to facilitate the processing of subsequent stimulus inputs. Importantly, the magnitude of cue-induced alpha lateralization was positively

correlated with the HbO lateralization in V3 cortex, and such a cue-induced alpha and HbO lateralization were both positively correlated with the subsequent target-evoked ERP N2pc amplitudes assumed to reflect attentional selection. Our results suggest that each individual's attentional target selection ability is predictable in advance via the functional coupling between anticipation-induced changes of HbO and low-frequency EEG signals in the visual cortex.

**Abstract:** Meditation skills learned from mindfulness-based interventions are shown to decrease stress and improve mental and physical health symptoms. However, the mechanisms of action for these benefits are currently unclear due to challenges in measuring internally-oriented attention to the body during meditation practice. The EMBODY task provides a framework to address these measurement issues by applying machine learning methods to fMRI data to identify varied and fluctuating mental states during meditation. The task measures the focus of attention during a core meditation skill, focused attention to the breath, where attention is sustained to sensations of the breath, and brought back to the breath if the mind wanders. The task was piloted and validated in 12 adults, including 7 meditation practitioners ($\geq$ 5 years of weekly practice) and 5 age- and gender-matched novices. In Step 1 of the EMBODY Task, participants were instructed via brief audio instructions with eyes closed to pay attention to 1) sensations of the breath, 2) sensations of the feet, 3) sounds from the scanner, 4) directed thinking about life events, and instructed to 5) stop paying attention and let whatever come to mind (a proxy for mind wandering). Using multi-voxel pattern analysis (MVPA) applied to wholebrain individual-level data, all five neural patterns were recognized above chance (all classification accuracy percents > 41% [chance: 20%], all one sample $t_{11}$'s > 4.52, all $p$'s < 0.001), demonstrating that neural patterns associated with each internal mental state were

distinct. In addition, neural patterns were better recognized in meditators vs. novices specifically for attention to the breath (independent $t_{10} = 2.65$, $p < 0.05$) and not the other conditions ($p$'s > 0.18). In Step 2 of the EMBODY Task, a 10-min period of breath meditation was decoded using the trained neural patterns from Step 1, which produced a second-by-second readout of mental states. These data produced novel metrics of internal attention during meditation, including percentage time spent paying attention to the breath (mean = 22.10%, SD = 7.16) and number of mind wandering events (mean = 27.42, SD = 6.98). The EMBODY task provides a novel framework to measure internally-oriented attention to the body that is trained by meditation, and holds promise to elucidate mechanisms of action from mindfulness-based interventions.

**Title:** What do you think before you fall? Brain activation during a rock climbing specific hang until failure

**Authors: *K. C. PHILLIPS**, B. NOH, H. MAAT, T. YOON
Michigan Technological Univ., Houghton, MI

**Abstract:** The prefrontal cortex (PFC) plays an important role in cognitive control, motor planning, execution of movement, and allocation of attentional resources. Functional near-infrared spectroscopy (fNIRS) allows for a convenient way of investigating PFC activation through measuring the hemodynamic response to cognitive and motor tasks. Rock climbing is a task that involves both muscular and cognitive demands (i.e. movement planning, fatigue, fear of falling, etc.). The purpose of this study is to examine PFC activation during a climbing specific sustained hang until failure. Four experienced male rock climbers (26 ± 3.1 years) took part in this study. After an upper extremity warm up, participants performed three maximal voluntary contractions (MVCs), with their dominant hand, on a climbing specific finger flexor assessment device. Next, participants were equipped with a 16 channel fNIRS sensor pad over their PFC and a two minute baseline measurement was performed. After the baseline, participants were asked to perform a body weight hang from two large climbing holds until they could no longer maintain themselves on the holds. Within 30 seconds after failure, participants were secured back into the finger flexor assessment device and performed one MVC. Lastly, participants

reported their rating of perceived exertion (RPE) at the beginning and failure of the hanging task. The optodes were averaged in three regions of interest for each participant; left PFC (optodes 1-6), frontopolar PFC (optodes 7-10), right PFC (optodes 11-16). The results of this study showed MVC force significantly declined (490 N vs. 413 N, $P<0.05$) from pre to post task. Additionally, participants RPE significantly increased ($P<0.001$) from the start to failure of the hanging task. The PFC showed significant increases in oxygenation in all 3 areas of interest ($P<0.05$), however, there was no difference in increases between areas. Lastly, optode 13 (right dorsolateral PFC) showed a significant correlation with RPE ($r=0.97$, $P<0.05$). These results suggest that the right dorsolateral PFC may play a role in the determination of task termination during a climbing specific hang until failure.

**Title:** High-intensity intermittent exercise improves executive performance by enhancing Stroop-effect-related prefrontal activation: A fNIRS neuroimaging study

**Authors:** *K. BYUN[1], ***K. BYUN**[1], S. KUJACH[2], K. HYODO[1], K. SUWABE[1], T. FUKUIE[1], R. LASKOWSKI[2], H. SOYA[1]
[1]Fac. of Hlth. and Sport Sci., Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Gdansk Univ. of Physical Educ. and Sport, Gdansk, Poland

**Abstract:** High-intensity interval training (HIT), also called high-intensity intermittent exercise (HIE), is well known as a time-efficient exercise regimen that enhances endurance capacity. Current studies suggest that HIE not only has an impact on cardiovascular fitness, but also on cognitive brain functions. However, how acute HIE improves cognitive functions, and its neural substrates, is still unknown. To address this issue, we examined the effects of acute HIE on executive function using the color-word matching Stroop task (CWST), which produces a cognitive conflict in the decision-making process and its neural substrate, with functional near infrared spectroscopy (fNIRS) (Hitachi, Japan). Twenty-five young adults (mean age: 21.6 ± 1.4 years; 9 females) participated in two counter-balanced sessions: HIE and resting control. The HIE session consisted of two minutes of warm-up exercise (50 W load at 60 rpm) and eight sets

of 30 s of cycling exercise (mean: 127 W ± 29.5 load at 100 rpm) followed by 30 s of rest on a recumbent-ergometer. Participants performed a CWST before and after the 10-minute exercise session, during both of which cortical hemodynamic changes in the prefrontal cortex were monitored using fNIRS. Acute HIE led to improved Stroop performance reflected by a shortening of the response time related to Stroop interference. It also evoked cortical activations related to Stroop interference on the left-dorsal-lateral prefrontal cortex (DLPFC), which corresponded significantly with improved executive performance. These results provide the first empirical evidence, to our knowledge, that acute HIE improves executive function, probably mediated by increased activation of the task-related area of the prefrontal cortex, the left-DLPFC.

**Title:** The effects of a semester of aerobic exercise on fitness, cognition, mood, and GPA in college students

**Authors: *J. C. BASSO**, C. CROSTA, M. RASKIN, A. WANG, D. KADAKIA, J. CHOI, E. MILBURN, R. TRIVEDI, W. A. SUZUKI
Ctr. for Neural Sci., New York Univ., New York, NY

**Abstract:** Long-term aerobic exercise enhances mood state and improves a range of cognitive functions including attention, information processing speed and both short- and long-term memory. Though a recent study found that first-year medical school students who regularly exercised attained higher grades than those who remained sedentary, little has been done to assess whether long-term exercise in undergraduate students positively influences cognitive function and academic performance. Therefore, the present longitudinal study examined the effects of an aerobic exercise intervention on mood, cognitive function and academic performance in first-year college students. Preliminary data on thirteen healthy, sedentary students from New York University was collected. These individuals completed a cardiopulmonary fitness test ($VO_2$ max test), a battery of neuropsychological tasks, and a series of self-reported mood and study strategies questionnaires at the beginning and end of one semester in which they maintained their sedentary lifestyles. At the beginning and end of the

following semester, they repeated these tasks, but increased their exercise regimens to include three or more aerobic exercise sessions per week lasting 45 minutes or longer. Grade point average (GPA) was obtained for each semester as well. Compared to the sedentary semester, the exercise intervention significantly increased cardiopulmonary fitness ($F(1,13)=15.246$, $p=0.002$), quality of life ($F(1,10)=4.771$, $p=0.05$), positive affect ($F(1,10)=5.662$, $p=0.039$), information processing speed as measured by the Eriksen Flanker Task (congruent trials $F(1,10)=9.093$, $p=0.013$; incongruent trials $F(1,10)=8.060$, $p=0.018$), short- and long-term memory as assessed by the Wechsler Logical Memory Test (immediate recall $F(1,7)=7.368$, $p=0.030$; delayed recall $F(1,7)=7.744$, $p=0.027$), and creative thinking as assessed by the Remote Associates Test ($F(1,12)=5.758$, $p=0.034$). In addition, those individuals who improved the most in their fitness showed the largest increases in semester GPA ($R=0.733$, $p=0.038$). These results suggest that even a single semester of exercise can improve cardiopulmonary fitness, mood, cognition, and school performance in previously sedentary, first-year college students.

**Title:** Brain mechanisms of reactive and proactive control in children

**Authors: *W. CAI**[1], K. DUBERG[2], R. REHERT[2], J. CHEN[2], K. ZHANG[2], J. NICHOLAS[2], T. CHEN[2], B. PENNINGTON[3], S. HINSHAW[4], J. NIGG[5], V. MENON[6]
[1]Psychiatry and Behavioral Sci., [2]Stanford Univ. Sch. of Med., Palo Alto, CA; [3]Denver Univ., Denver, CO; [4]U.C. Berkeley, Berkeley, CA; [5]OHSU, Portland, OR; [6]Stanford Univ. Sch. Med., Palo Alto, CA

**Abstract:** Inhibitory control is crucial for cognitive development during childhood. Poor inhibitory control is the core deficit of ADHD, one of the most common neurodevelopmental disorders. Understanding brain development of inhibitory control in childhood is thus important for public health. The Dual Control model suggests that inhibitory control operates in two distinct modes: reactive and proactive control. However, little is known about the brain mechanisms underlying reactive and proactive control during childhood.
We acquired task fMRI data from 16 children (9-12 yrs, 5f/11m) who completed a standard and a conditional stop-signal task (SST & CSST) using a simultaneous multi-slice EPI sequence

(TR=490ms, TE=30ms). In SST, participants made responses to a Go signal or stopped response if a Go signal was infrequently followed by a Stop signal. In CSST, a MaybeStop cue (a stop signal might occur) or a NoStop cue (no stop signal will occur) was presented prior to Go signal. Reactive and proactive control were indexed by stop-signal reaction time (SSRT) and response slowing in MaybeStop vs NoStop Go, respectively. GLM contrasts of SuccStop vs. Go and MaybeStop vs NoStop Go were used to probe brain mechanisms in reactive and proactive control. A drift diffusion model was used to estimate decision boundary.
We found negative correlation between response slowing and stop-signal reaction time (SSRT) ($r$=-0.62, $p$=0.02), suggesting that children with better reactive control implement more proactive control. GLM analysis revealed that the right prefrontal-insula-parietal regions were significantly activated in reactive control, whereas dorsomedial prefrontal cortex and anterior insula were involved in proactive control ($p$<0.01, cluster size>133) (Fig. 1). Furthermore, activation in right IFG/MFG in reactive control was positively correlated with SSRT and activation in left thalamus in proactive control was negatively correlated with decision boundary change ($p$<0.01). Overall, similar but distinct brain mechanisms in reactive and proactive control are apparent in late childhood.

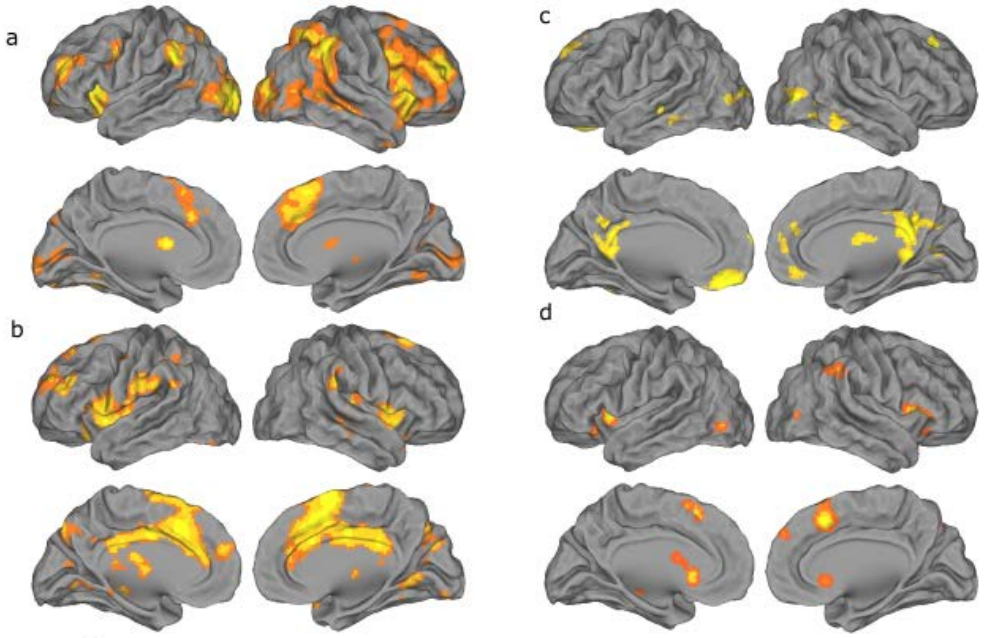
**Title:** Neural mechanisms of response inhibition in children

**Authors: *K. T. DUBERG**, R. REHERT, S.-N. BOSTAN, S. QIN, A. PADMANABHAN, T. BRADLEY, O. ALTAMIRANO, Y. A. MARTIN, V. G. CARRION, V. MENON, W. CAI
Psychiatry and Behavioral Sci., Stanford Sch. of Med., Palo Alto, CA

**Abstract:** Response inhibition, the ability to cancel or withhold inappropriate behavior, is an important feature of cognitive control. The development of cognitive control is particularly important in children since self control is critical to interpersonal and academic success. Although developmental trajectories of response inhibition have been well documented, little is known about brain mechanisms underlying response inhibition in children, since previous neuroimaging studies are limited by their small sample size and have resulted in inconsistent findings.

Our meta-analysis only revealed activation in fronto-insula-parietal regions at uncorrected threshold ($p<0.05$). Poor consensus of previous findings thus calls for a large-scale neuroimaging study. Here we collected behavioral and neuroimaging data from 40 children (9-11 yrs old, 16f/34m). Each participant completed 2 sessions of SST during which they made responses to green arrows, and, occasionally, withheld a response if the green arrows turned red after a short delay. Stop Signal Reaction Time (SSRT) was measured as behavioral index for inhibitory control. fMRI data was acquired on a 3T GE scanner using a T2* gradient echo-spiral in-out pulse sequence (TR=2000ms, TE=30ms).

Participants completed the task well (Go Accuracy: 94±4%, SSRT: 297±50ms). Brain analyses showed significantly greater activation in anterior insula, inferior, middle and superior frontal gyri, angular gyrus, and striatum in successful stop vs go trials. We also found stronger activation in anterior cingulate cortex in unsuccessful vs successful stopping. Interestingly, activation in right inferior temporal gyrus during successful stop trials was negatively correlated with SSRT. Furthermore, we found increased connectivity between right posterior parietal cortex and ventromedial prefrontal cortex in successful stop compared to go. All results were thresholded at $p<0.01$, with cluster size greater than 128 voxels. Together, our study highlights that a fronto-striatal-parietal network underlies inhibitory control function in children.



a) Activation during successful stop vs go trials
b) Activation during unsuccessful stop vs successful stop trials
c) Connectivity during successful stop vs go trials (seed: right Posterior Parietal Cortex)
d) Meta analysis (p<0.05)

**Title:** Association between alcohol use, impulsivity and inhibitory control in adolescents from a Brazilian sample

**Authors: *A. R. WILLHELM**[1], A. S. PEREIRA[2], S. H. KOLLER[2], R. M. DE ALMEIDA[3]
[1]Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil; [2]Inst. de Psicologia, Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil; [3]UFRGS, Porto Alegre, Brazil

**Abstract:** Introduction: The last area to develop in the central nervous system is the prefrontal cortex (PFC), the area also linked to the ability to control impulses. This suggests that

adolescents tend to have more impulsive behaviors that can result in risky behaviors such as alcohol and drugs. The aim was compare adolescences between 13 to 16 years old with and without alcohol first use in the variables impulsivity and inhibitory control. Method: The sample was composed for 122 participants from private and public schools with age 13 to 16, divide in two groups: with (n=95) and without (n=27) first alcohol consumption. The instruments used were: Sociodemographic and alcohol and drugs use questionnaire, Barratt impulsiveness scale-youth, Go/No-go task and Five Digits test. It conducted a Student's t test to compare the two groups. Results: Statistically significant differences were observed in the three dimension of the impulsivity scale (motor: t = -3.161, p = .002; attention: t = -2.447, p=.016, non-planning: t = -2.398, p=0.18), the group that already consumed alcohol has higher mean scores in these variables. It was not found statistically significant differences in the tasks that evaluated inhibitory control between the two groups. In the group that already used alcohol, 40,42% (n=38) considerer that some relative have drinking problems, in other hand, 85,2% (n=23) of the group that never used alcohol considerer that anyone in their family have drinking problems. Discussion: In Brazil, the alcohol consumption is culturally acceptable, even for minors. Unlike the use of other substances, such as tobacco and drugs, the vast majority of the population does not consider the risks to health from the use of alcohol. Along with this, adolescence is the most susceptible stage to risky behaviors such as alcohol and drugs, by an immaturity of the PFC, which can result in greater impulsivity. Data from this study points to this direction, since the group that already tried alcohol showed higher average in the three measurements of impulsivity. It was observed that adolescents with higher levels of impulsivity tend to use alcohol, then performing this risky behavior described in the literature. This is not directly connected with inhibitory control, in which there were no significant differences. Cultural issues surrounding the use of this substance can explain data for the inhibitory control. The damage of alcohol consumption are minimized by the culture and the inhibitory control is characterize by interrupting or changing a behavior that is deemed inappropriate.

**Abstract: Objective:** Smoking is the leading cause of preventable death in the U.S. (CDC, 2005). Most individuals who attempt to quit relapse within two weeks. Maintaining abstinence in this period is a robust predictor of longer-term abstinence (Higgins et al., 2006). Thus, neurobiological changes that occur during the early abstinence period may yield critical predictors regarding successful abstinence or relapse. We examine neurocognitive processes implicated in relapse among smokers who are successful and unsuccessful in maintaining abstinence by assessing cognitive control and reward impulsivity. We aim to build upon initial findings by incorporating real-time stress and physiological assessments and ecological momentary assessment (EMA) data obtained during the period of smoking cessation. **Method:** Neuroimaging and behavioral data were acquired for 15 smokers and 15 non-smokers, matched on age, gender and SES. Participants were scanned twice: 1) following access to their regular cigarettes (smoked 15 minutes prior to scan), and 2) after overnight abstinence (CO verified; order counterbalanced). Brain activation maps of inhibitory control were generated from the Stop Signal Task. Brain perfusion maps were generated using 5 minutes of pCASL. **Results:** Smokers, when abstinent and satiated, demonstrated increased activation during successful inhibition in bilateral inferior frontal gyrus (IFG), relative to controls. Further, smokers, relative to controls, demonstrated lower cerebral blood flow (CBF) in overlapping bilateral IFG regions. Both the activation and perfusion effects were larger when smokers were abstinent. **Conclusions:** The results suggest functional differences in smokers in brain systems underlying inhibitory control. These differences may relate to relapse risk as both the perfusion and activation differences in these brain regions showed enhanced effects when abstinent. To assess the real-world significance of these results, an ongoing study employs mobile technologies to measure stress reactivity, nicotine craving, and EMAs. We aim to merge neuroimaging data that assess the functioning of these impulse control systems prior to abstinence with real-time physiological assessments and EMAs obtained during the smoking cessation period to generate predictive profiles for individuals at highest risk for relapse.

**Abstract:** Cognitive control allows humans to flexibly switch between tasks, to inhibit responses when appropriate, and to deal with competing stimuli/responses. Such goals can be attentionally demanding, requiring trial-to-trial adjustments, which are subject to the waxing and waning of attention. In instances of impaired attentional allocation, these control processes are not always successfully implemented. Smokers who have not smoked for a period of time and are in a state of craving represents such a circumstance (i.e., one in which attention may be diverted from the task at hand). Although previous work from our group has shown that such craving can result in an overall increase in arousal, how craving may impact specific attentional control processes has yet to be determined. To address this, 20 smokers performed a task-switching paradigm, in which several cognitive-control processes were assessed in two sessions (i.e., one just after having smoked and another 'craving session' following a three-hour period of nicotine deprivation). The task entailed an instructional cue indicating the type of judgment to be made by the participant for a subsequent target. The prescribed judgment represented either a task switch, or a continuation from the previous trial. Targets were single digit stimuli, 80% of which required making a response, and 20% to withhold one. Participants received feedback following their response (or successful response inhibition), with fast and correct responses earning them the most points, and the amount of points determining the end of the experiment. Continuous EEG data were recorded for this task during both sessions, and we examined the ERP components to these various trial types as a function of craving. The ERP results were generally in line with previous observations for such tasks, with an increased CNV to the cue for switch vs. repeat trials, an N2/P300 enhancement for NoGo vs. Go targets, a frontal-central negativity for targets eliciting response conflict, and an enhanced P300 in response to the feedback on trials on which fewer points were earned. Interestingly, craving did not interact with all of the aforementioned processes, but showed a selective influence on only specific cognitive control-related processes. Craving had the greatest impact on the cue-elicited and feedback-elicited control processes, with the target processing being less affected. These results suggest that craving has a differential impact on different types of control processes, and indicate a complex interaction between craving and the attentional system.

**Abstract:** Human executive function relies on the ability to detect and compensate for errors. The error-related negativity (ERN) is an electrophysiological correlate of this process. EEG source modeling suggest that the dorsal anterior cingulate cortex contributes to the ERN. However, it remains unknown how the ERN and the error-monitoring mechanism that the signal represents are reflected in the activity of single neurons.
We used intracranial electroencephalography (iEEG) and single unit recordings to investigate error monitoring in human subjects. 28 epilepsy surgery candidates with implanted intracranial depth electrodes performed 85 sessions of a speeded version of a color-word Stroop task. Subjects showed a robust Stroop effect (224.9 ± 20.8ms, $F(1,84) = 116.63$, $p < 10^{-10}$, mixed-effect one-way ANOVA model) and post-error slowing (71.9 ± 21.6 ms (mean ± s.e.m. across sessions), $F(1,214) = 24.66$, $p < 10^{-5}$, mixed-effect one-way ANOVA model).
We isolated 583 neurons in the dorsal anterior cingulate cortex (dACC) and 507 in pre-supplementary motor area (pre-SMA). 28% of all dACC neurons and 40% of all pre-SMA neurons changed their firing rate immediately after subjects made an error, but before feedback appeared. This suggested that the error signals were internally-generated, not triggered by external feedback. The onset of the neuronal error signal in pre-SMA preceded that in dACC by 67 ms.

Given the prominent post-error slowing effect (PES) and error signals, we hypothesized that dACC and pre-SMA are important components of the neuronal circuitry that implements the control processes that result in PES. Indeed, we found that 11% of dACC and 14% of pre-SMA neurons modulated their firing rate only in correct trials that followed an error.
We also simultaneously recorded a robust intracranial error-related evoked potential in both dACC and pre-SMA. These error-related potentials had a negative and positive going component with waveform and latency similar to classical studies of the ERN (Falkenstein et al 1990, Gehring et al,1993). Theta power of iEEG was significantly higher in error trials than in correct trials. Here we again found that the iERN peaks in pre-SMA preceded those in dACC by 38ms. Finally, we found a trial-by-trial relationship between the ERN (a macroscopic signal) and the activity of error neurons (a microscopic signal): The amplitude of the ERN correlated robustly with error neuron firing rates and theta-band spike-field coherence between the two signals was larger during errors.
Together, our findings provide the first circuit-level description of the mechanism of error monitoring and post-error adjustment in human dACC and pre-SMA.

**Title:** Sequential adjustments in cognitive control: Insights from simultaneous EEG-fMRI

**Authors: T. HINAULT**, K. LARCHER, N. ZAZUBOVITS, M. FERREIRA, J. GOTMAN, *A. DAGHER
McGill Univ., Montreal, QC, Canada

**Abstract: Introduction**: Optimal decision-making depends in part on the ability to inhibit the automatic processing of irrelevant information. Previous work has revealed conflict adaptation effects, with reduced interference on items that follow an incongruent stimulus compared to after a congruent stimulus. These studies on sequential modulation of control processes mainly relied on unimodal measures, which suffer from low spatial or temporal resolution. In this study, we simultaneously recorded EEG and fMRI to investigate the spatiotemporal dynamics of proactive

control.
**Methods**: Twenty-two participants performed a numerical Stroop task, in which they were presented visually with two numbers and were instructed to select the number with the higher numerical value, regardless of font size. We contrasted congruent items (i.e., the larger number in size is also the number with the higher numerical value) to incongruent items (i.e., one number is larger in size and the other number is larger in numerical value). To study sequential effects, we focused on the processing of incongruent items as a function of the congruency/incongruency of the preceding item. Participants were equipped with an MR-compatible 64-channel cap while they performed the task in a Siemens Trio 3T MRI. After separate pre-processing for EEG and fMRI data, we conducted a joint Independent Component Analysis (jICA; Calhoun et al., 2006) to couple event-related potential (ERP) time courses and fMRI spatial maps. Furthermore, network analyses were also performed, with Dynamic Causal Modeling (DCM) applied on both modalities.
**Results**: EEG and fMRI provided converging evidence to highlight the engagement of the anterior cingulate cortex and right dorsolateral prefrontal cortex (DLPFC) in reactive adjustments when no preparation was engaged, in a time course consistent with the N200 ERP component. Conversely, proactive adjustments yielded activations of DLPFC, left inferior frontal gyrus and inferior parietal lobule, both during the encoding phase and later with modulations of the conflict SP component. DCM results revealed a larger number of couplings, and higher coupling intensity within this network after the processing of an incongruent trial, in line with increased level of control. Finally, correlations were found between DCM couplings and behavioral adjustments.
**Conclusions**: Results contribute to a framework of the neural bases of proactive adjustments in performance by unraveling changes over time within the cognitive control network, both during the processing of a given item and as a function of the succession of items, and how this network relates to participants' performance.

**Title:** Complexity and effort in the fronto-parietal and cingulo-opercular control networks

**Authors: *S. SHASHIDHARA**[1], Y. EREZ[1], D. J. MITCHELL[1], J. DUNCAN[1,2]
[1]MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom; [2]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

**Abstract:** A specific set of regions identified as the multiple - demand (MD) network, encompassing well-defined frontal and parietal regions, is active during diverse cognitive functions. Results from resting - state functional magnetic resonance imaging (fMRI) suggest a split of the MD network into fronto-parietal and cingulo-opercular subnetworks. The literature gives some evidence of functional difference between these subnetworks: Fronto-parietal subnetwork activity has been linked to complex problem solving, while cingulo-opercular subnetwork activity has been associated with cognitive effort and autonomic arousal. In the current fMRI study, we used a maze task to examine the response of the two subnetworks to different aspects of task demand. In particular, we examined task complexity, manipulated by changing the number and nature of steps required to complete the maze (difficulty manipulation), and two variables, time stress and reward, aiming to alter the cognitive effort committed to solving a problem of fixed complexity. We manipulated time stress by comparing self-paced problem solving with problems visible only for a restricted time. On some of these trials, we also added the possibility of a substantial monetary reward. With these manipulations, we examined the activity profiles of fronto-parietal and cingulo-opercular subnetworks. Concurrently, we measured pupil size as a link to autonomic arousal. The behavioural data showed increased planning times for the difficulty manipulation and similar planning times for the time stress and reward manipulations, as compared to the baseline condition. Eye-tracking data showed larger pupil sizes for the difficulty and the reward manipulations. Whole-brain random effects analysis across participants, along with regions of interest (ROIs) contrasts, using MD network templates from previous studies, showed all ROIs of both subnetworks respond to all task manipulations. We found that, while the cingulo-opercular sub-network showed a modestly greater reward effect than the fronto-parietal, the difficulty and the time stress effects were similar across subnetworks. Despite strong anatomical differences, MD sub-networks show largely similar response to manipulations of task content and conditions.

**Title:** Cognitive and emotional stresses synergetically modulate cognitive control through the cingulo-striatal system: fMRI and EDA Studies

**Authors: *T. MINAMOTO**[1], M. HARUNO[2]
[1]Nat'l Inst. of Info and Comm Technol., Suita, Japan; [2]Natl. Inst. of Information and Communication Technol., Osaka, Japan

**Abstract:** The dorsal part of the anterior cingulate cortex (dACC) is proposed to compute control signal, especially when a task difficulty is high. The region is also shown to be activated in response to pain or emotional stimulus with negative valence. Those findings indicate that activation of the dACC reflects a call for cognitive and behavioral alternation to resolve higher cognitive or emotional stress. In other words, the dACC is likely to respond to any kind of stress in order to produce control signal for a behavioral adjustment. Combining cognitive and emotional stress, the present study aimed to disclose a potential role of the dACC to integrate differential stresses for production of an adaptive control signal. Twenty-seven participants performed the emotional Stroop task that required a judgment of a target facial expression while ignoring congruent/incongruent distractors. Critically, we presented cognitive and emotional stress cues prior to the Stroop task in each trial. A cognitive stress cue indicated a time window given for a face judgment, which was presented for 1000ms. A high cognitive stress cue called for quick response, which was adjusted to individual key-press speed (500-850ms), whereas a low cognitive stress cue gave a time-window of 2000ms. Following to the cognitive cue, an emotional cue was presented for 1000ms, which indicated a presence/absence of pain punishment for incorrect responses. Given that the dACC integrates cognitive and emotional stresses, the region is predicted to produce greater activation in the condition with high cognitive and emotional stress cues. In order to measure stress level in each condition, we recorded electrodermal activity (EDA) of 11 participants outside a scanner. Performing a three-way repeated ANOVA, which included factors of the cognitive stress, emotional stress, and time-point, we found that the higher cognitive stress cue produced greater EDA across time-points, while the higher emotional stress cue showed gradual increase in EDA. Those results indicate that each cue successfully produced psychological stress. In the fMRI data of another 16 participants, we made a conjunction contrast that included main effects of the cognitive and emotional stresses, which allowed us to localize the brain areas showing significant activity in response to cue with high cognitive and emotional stresses. The dACC and the bilateral caudate nuclei showed significant activation, indicating that the dACC may integrate different type of stress in concert with the ventral striatal areas, and send the control signal toward the executive brain regions such as the lateral prefrontal cortex.

**Title:** High trait self-control is associated with reduced engagement of executive and salience networks during voluntary suppression of food craving

**Authors: *J. HAN**, U. VAINIK, K. LARCHER, J. GUAN, A. DAGHER
Montreal Neurolog. Institute/McGill Univ., Montreal, QC, Canada

**Abstract:** Individuals with greater self-control report less desire for food, eat less and are more successful at losing weight. Previous neuroimaging studies implicate the dorsolateral prefrontal cortex (DLPFC) in dietary self-control. Activity in the DLPFC is greater during volitional suppression of food craving, and this predicts food intake and weight loss success. Multivariate analyses also implicate the fronto parietal executive control network, which include the DLPFC, and the salience network, largely anchored in the fronto-insula and dorsal anterior cingulate cortex, in dietary self-control, consistent with their known functions in attention and cognitive control. Indeed functional connectivity within these networks is altered in obesity and related to body mass index. Neuroimaging studies performed to date capture state self-control (self-control in action) and fail to consider the role of trait self-control. In order to identify neural mechanisms that underlie the relationship between trait self-control and eating-related behaviours, we classified young, healthy people as high and low self-controllers (n=28 and 20 respectively) based on the Reward-Based Eating Drive scale, which measures dietary self-control, satiety and preoccupation with food. Subjects underwent fMRI while they performed a food regulation task where they deliberately suppressed craving for comfort foods presented in pictures. After the scan, subjects were left alone and given a bowl of their favorite chips to eat. As expected, high self-controllers compared to the low ate fewer chips ($p<0.05$) and had lower body mass index ($p<0.05$). Voluntary control of food craving increased activity in the left DLPFC and pre-supplementary motor area, which also showed greater functional coupling with the ventromedial prefrontal cortex (FDR corrected $p<0.05$). Interestingly, food regulation-induced activity in the left DLPFC was significantly smaller in the high versus low self-control group ($p<0.05$). Moreover, independent component analysis identified components resembling the executive control, default mode and salience networks whose activity changed significantly during craving suppression ($ps<0.01$). The task-related activity in the salience network was greater in low self-controllers compared to the high ($p<0.05$) and correlated positively with the amount of chips consumed ($r=0.26$, $p=0.07$). The present study helps further characterize trait dietary self-control

by showing that high compared to low self-controllers eat less, have lower body mass index, and display less activation of the DLPFC and the salience network to suppress food craving.

**Title:** Cognitive control networks contain a mixture of diverse connectivity patterns characteristic of predicted flexible hub mechanisms

**Authors: *T. ITO**, M. W. COLE
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

**Abstract:** It is remarkable that task-relevant information distributed across diverse brain systems can be coordinated to perform complex tasks such as reading and interpreting this sentence. Applying the tools of network neuroscience (Rubinov and Sporns, 2010) to this problem, we sought to identify a basis for such inter-network coordination in the human brain's large-scale intrinsic functional connectivity architecture. We recently found evidence that task information is coordinated by flexible hubs - frontoparietal regions with widespread connectivity patterns that change according to task instructions (Cole et al., 2013). We hypothesized that flexible hubs require diverse intrinsic connectivity patterns to select from in order to code for the diverse tasks humans are capable of. We developed a new graph theoretical measure - integrated pattern diversity - to test whether intrinsic functional connectivity patterns are capable of providing such diversity for putative flexible hub networks. We found that the frontoparietal control network (FPN), which was recently identified as a likely flexible hub network based on task-evoked functional connectivity, had the highest integrated pattern diversity. We next characterized why the FPN exhibited such high integrated pattern diversity. Using community detection, we clustered similar connectivity patterns to split each functional network into subnetworks. We found that the FPN subnetwork organization had the highest modularity, suggesting that FPN had the greatest out-of-network connectivity pattern separation. These findings suggest FPN coordinates diverse functionality distributed throughout the brain. This is highly consistent with hypothesized flexible hub functionality and is likely important for coordinating performance of diverse task sets.

**Title:** An effective EEG neurofeedback training protocol to improve executive functions and to reduce depressive rumination

**Authors:** ***P.-Z. CHEN**, W.-L. LIN, S.-H. YU, C.-Y. TSENG
Psychology, Fo Guang University, Yun Hui 512 Rooms, Jiaosi, Taiwan

**Abstract:** Depressive rumination is considered one of the important factors that foster the maintenance and relapse of depression. Recent studies have found this response style closely related to individuals' reduced executive functioning (EF), that is, greater difficulty in updating, switching, or inhibiting negative thoughts. Given that human's prefrontal cortex is where EFs located, the present study aimed at developing an effective EEG neurofeedback training (NFT) protocol to improve EFs and reduce depressive rumination. Previous studies have found that peak alpha frequency (PAF) in prefrontal cortex of healthy adults is normally 10-11 Hz. Thus, in this study, participants in the NFT group (n = 11) were trained to increase 10-11 Hz PAF power in prefrontal detected by auditory feedback for 20 training sessions, 30 min per each. Participants in the active control group (n = 11) did not receive neurofeedback training but instead were instructed to count the prepared sounds while their brainwaves were recorded. All participants were first screened as individuals with high rumination and high depression tendencies and received pre- and post-tests in
EFs tasks (updating, switching, and inhibition), depressive rumination and depression (BDI-II) assessments. The results showed a steady and significant increase of 10-11 Hz activity over 20 training sessions in the NFT group. The power of the rest of the alpha frequencies did not show significantly change. No change in both PAF and whole alpha frequency power were found in the active control group. These findings indicate the effectiveness and specificity of the training protocol applications. In addition, participants in the NFT group gained significant improvement in the EF task performances, while significantly decreasing in depressive rumination and depression symptoms assessments simultaneously. These findings contribute to uncovering the mechanism between EFs and depressive rumination, and provide implications in effectively preventing or intervening mood disorders.

[1]Dept. of Psychology, Florida State Univ., Tallahassee, FL; [2]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

**Abstract:** The lateral prefrontal cortex (LPFC) is essential for higher-level cognition, but how its interactions support cognitive control remains elusive. Previously (Nee and D'Esposito, 2016), dynamic causal modeling (DCM) indicated that mid LPFC integrates abstract, rostral and concrete, caudal influences to inform context-appropriate action. Here, we use continuous theta-burst transcranial magnetic stimulation (cTBS) to causally test this model. cTBS was applied to three LPFC sites and a control site in counterbalanced sessions. Behavioral modulations resulting from cTBS were largely predicted by information flow within the previously estimated DCM. However, cTBS to caudal LPFC unexpectedly impaired processes presumed to involve rostral LPFC. Adding a pathway from caudal to rostral LPFC significantly improved the model fit and accounted for the observed behavioral findings. These data provide causal evidence for LPFC dynamics supporting cognitive control and demonstrate the utility of combining DCM with causal manipulations to test and refine models of cognition.

**Title:** Towards a multidimensional model of everyday cognitive failures: Integrating brain hemodynamics, cognitive functioning, mental health and personality in a sample of young adults

**Authors: *M. A. ROMANO-SILVA**[1], D. S. COSTA[2], D. M. MIRANDA[1], J. J. DE PAULA[2]

**Abstract:** Background: Everyday cognitive failures are state-like difficulties in attention, memory or executive control which occurs in daily life. Previous studies correlated everyday cognitive failures with measures of mental health, personality, and cognitive functioning. There are however few studies investigating its biological underpinnings. There are also only a few studies which tried to integrate these previous factors. **Objective**: analyze how personality, mental health, cognitive functioning and brain fronto-parietal hemodynamics are associated with cognitive failures. **Methods**: we assessed 366 adults, with a mean age of 29±9 years. All answered the cognitive failures questionnaire (CFQ), questionnaires of mental health, personality and psychosocial measures. A subsample of 115 participants was submitted to cognitive assessment, including tests of language, visuospatial skills, memory, attention and executive functions. Another subsample of 28 subjects performed an experimental n-back test, a common neuropsychological measure of cognitive control during fNIRS, a brain imaging technique which allows the analysis of cortical hemodynamics. Regression and mediation models tested the association between all variables. **Results**: we found significant contributions of internalizing and externalizing symptoms with CFQ. CFQ scores were also associated with satisfaction with life, emotional stability, and conscientiousness. At the cognitive level, the main predictor's inhibitory control and cognitive flexibility. Higher left-frontal and lower right-parietal hemodynamics correlated with higher CFQ scores. Structural models suggest that measures of inhibition and cognitive flexibility were associated with mental health. Measures of mental health showed a direct effect in CFQ scores and indirect effects mediated by personality traits. Personality traits also were mediators of the association of CFQ scores and satisfaction with life. **Conclusion**: Brain hemodynamics during cognitive control are associated with cognitive failures, a relationship probably mediated by executive functions and mental health. Personality showed a major role in our model, acting as a mechanism for the association between mental health and cognitive failures and those with life satisfaction.

**Title:** Brain dynamics involved in controlling physiological arousal improve task performance

**Authors:** ***N. WATANABE**[1,2,3,4], J. P. BHANJI[1], H. C. TANABE[3], M. R. DELGADO[1]
[1]Dept. of Psychology, Rutgers Univ., Newark, NJ; [2]Postdoctral Fellowship for Res. Abroad, Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Grad. Sch. of Informatics, Nagoya Univ., Nagoya, Aichi, Japan; [4]Natl. Inst. of Information and Communications, Osaka, Japan

**Abstract:** Successful execution of a difficult task is influenced by the ability to keep calm and carry on while preparing to perform. For instance, the incentive to win the game can cause excessive physiological arousal when a basketball player prepares to take a final free throw. The player must control this response to perform successfully under pressure. An intriguing question is how the brain controls arousal to improve performance. We investigated this question with a simple time-perception-motor task and simultaneous data acquisition of pupil dynamics and BOLD signal by fMRI (n = 22). We identified two brain regions that were recruited prior to task execution - when participants were in a “preparatory phase” - that corresponded with performance. The caudate nucleus correlated with trial-wise reward magnitude, with greater increases associated with trials that resulted in failure ($p < 0.05$ FWE corrected with nonparametric permutation test (NPPT)). The amygdala correlated with trial-wise physiological arousal characterized by pupil dilation, with a relative increase during trials resulting in failure compared to success ($p < 0.05$ FWE NPPT). These results suggested that an exaggerated response in the caudate and amygdala during the preparatory phase compromised performance success. Next, we probed the question of how other cortical regions may contribute to this circuitry to facilitate task performance by using brain-network analyses. First, a physio-physiological interaction functional connectivity analysis was conducted to identify brain regions associated with activation in the caudate and amygdala during the preparatory phase. We

identified a cluster in the orbitofrontal cortex (OFC; $p < 0.05$ FWE corrected). Then, to clarify the dynamics of this system, we conducted an effective connectivity analysis with dynamic causal modeling (DCM; Friston et al., 2003). Post-hoc Bayesian model optimization (Friston and Penny, 2011; Rosa et al., 2012) in DCM revealed the best network model characterized by: (1) driving signal inputs into the OFC; (2) bidirectional positive intrinsic connections between the OFC and amygdala and between OFC and caudate; and (3) the intrinsic positive connection from OFC to amygdala was negatively modulated only in success trials. The confidence level of this model was higher than other candidate models and the ratio of evidence for the best and second best was 164.38. These results are consistent with a potential role for the OFC in controlling and integrating information from amygdala and caudate nucleus during task preparation to improve performance during task execution.

**Abstract:** The goal of this study was to investigate the relationship between BOLD activity and successful performance in a context-dependent rule learning task. In particular, this study examined the contributions of prefrontal, medial temporal, and striatal regions to context dependent rule learning for successful and unsuccessful learners. Healthy participants (n = 31) learned to associate different object pairs with spatial contexts through trial and error during fMRI scanning. Our analyses sought to characterize the relationship between regional activity and behavioral performance in two ways. First, we examined how total average activity across the learning time series (324 trials) was correlated with individual cumulative accuracy. Second, we grouped participants into successful and unsuccessful learning groups and compared activity changes within PFC and striatal regions during early, middle, and late stages of the task. Preliminary analyses revealed strong positive correlations between total average activity and

individual cumulative accuracy in dorsolateral prefrontal cortex, ventrolateral prefrontal cortex, and striatum. Outside of the scanner, participants were given a forced choice retrieval task in which they were provided one half of the object pair presented during learning in a spatial location and were asked to identify the correct associate. We identified a similar positive relationship between accuracy on the subsequent retrieval task and activity during learning in our 3 regions of interest. At the group level, we found that activity in dorsolateral and ventrolateral cortex increased across time in successful learners but not in unsuccessful learners. Activity in these regions was found to be higher during late stages of the task in successful learners. These results suggest that the striatum and regions of the prefrontal cortex play an important role in the successful acquisition of context dependent rules during learning.

**Abstract:** Prefrontal cortex, especially area 10 plays a critical role in creating and maintaining delayed intentions, but it difficult to investigate social delayed intentions in a typical neuroimaging environment where the participant is isolated and limited in movement. In this experiment we used wireless fNIRS to examine prefrontal cortex activations during the maintenance and execution of intentions relating to social vs. non-social cues in a naturalistic environment. The experiment was conducted outside, on a typical London street. 19 participants undertook a prospective memory (PM) task in which they walked around Queen Square performing an ongoing task while also remembering to respond to PM targets. A typical ongoing task was counting particular words on street signs. Social targets were a confederate standing at predetermined locations around the square; non-social targets were parking meters. Participants

were instructed to approach and fist-bump each target. Prefrontal cortex activity was monitored using a 16-channel Wearable Optical Topography (WOT, Hitachi High-technologies Corporation, Japan) fNIRS system (sampling frequency=5 Hz). Data was analysed using NIRS-SPM with a design matrix modelling each task block and the PM events, which fitted for each data channel and signal type (oxyHb / deoxyHb) separately. Relative to baseline tasks, the PM blocks showed to significantly increased oxyHb/decreased deoxyHb in a wide number of medial and lateral PFC regions. There were more specific medial rostral PFC changes relative to the ongoing task only, which is broadly in accordance with findings from fMRI and PET studies of prospective memory. Most critically, the social PM condition saw a significant increase in oxyHb / decrease in deoxyHb in lateral prefrontal cortex regions. These results suggest that the behavioural advantage for pro-social delayed intentions is reflected in differences in activation within prefrontal cortex, and that this can be detected in rich naturalistic settings.

**Abstract:** Longstanding research on the performance monitoring system has shown that error detection often serves as a signal to improve ongoing behavior. Increased activation of the Performance Monitoring Network (PMN) has been shown to lead to improved performance after errors when sufficient time is allotted between trials. However, recent findings show that under time constraints this improved performance following errors is not seen and that activation of the PMN can lead to markedly reduced sensory attention following error commission trials with short response-stimulus intervals (RSIs). To expand on these findings, we applied transcranial direct current stimulation (tDCS), a form of non-invasive brain stimulation, to the Medial-Frontal Cortex (MFC), a subdivision of the PMN. Following either sham or anodal stimulation, we then assessed post-error accuracy (PEA) after error trials with either a short or long RSI. Preliminary data are consistent with recent literature; a significant reduction in PEA was observed for short, compared to long RSI trials, regardless of the stimulation condition. This supports the notion that

the PMN impairs post-error behavior under time constraints. However, given that preliminary data did not demonstrate a significant effect of MFC stimulation on PEA, the data are consistent with the notion that a subdivision of the PMN other than the MFC is responsible for error-induced distraction (i.e. reduced PEA after errors with a short RSI). Data collection remains ongoing and the results will be discussed within the broader framework of the capacity limits of the performance monitoring system.

**Title:** Influence of after-effects on preparatory attention depending on difficulty of tasks

**Authors: *M. TAKAYOSE**[1], R. KOSHIZAWA[2], K. OKI[3]
[1]Nihon Univ. Col. of Industrial Technol., Chiba, Japan; [2]Nihon Univ. Col. of Commerce, Tokyo, Japan; [3]Nihon Univ. Col. of Sci. Technol., Funabashi, Chiba, Japan

**Abstract:** When the stop trial precedes the go trial in the stop-signal task, the executive function of the go trial is affected. Contingent negative variation (CNV) was measured to elucidate the relationship between the after-effects on preparatory attention and the difficulty levels of response pattern-dependent tasks.
In these tasks, the participants were required to press a key when a go-signal was presented; however, in the stop-signal task (SST) and change-signal task (CST), they were required to occasionally withhold this response when the go-signal was followed by a stop-signal and change this response when the go-signal was followed by a change-signal, respectively. In the multi-CST (m-CST), the participants were occasionally required to withhold or change their response when the go-signal was followed by a stop- or change-signal. To obtain the CNV, EEG recordings were taken from all participants during the tasks.
The response time (RT) just after stop and/or change trials was extended in all tasks. In the SST and CST, RT was decreased and the CNV amplitude was larger after successful trials than after trials with failed inhibition/change. In the m-CST, RT was increased and the CNV amplitude was decreased more than in the other tasks. Success with inhibition/change in relatively simple tasks

had little influence of aftereffects on preparatory attention. When the difficulty of the task was higher, its influence of after-effects was larger and may reduce preparatory attention.

**Title:** Corticostriatal networks reveal the role of the dorsal anterior cingulate cortex as a routing hub for cortical output integration

**Authors: *W. TANG**[1], S. N. HABER[2,1]
[1]Basic Neurosci. Div., McLean Hosp., Belmont, MA; [2]Univ. of Rochester, Rochester, NY

**Abstract:** Recent studies have found that cortical projections to the striatum form convergent zones. These special zones, conceptualized as hubs, are likely to facilitate network interactions among the corticostriatal pathways. Similarly, we have also identified a hub in the dorsal anterior cingulate cortex (dACC), which may facilitate corticocortical interactions. To further understand how the dACC hub and the striatum mediate different levels of functional integration, in this study we investigate the anatomical connectivity between the prefrontal cortex (PFC), the dACC hub and the striatal convergent zones.
Tract tracing was carried out in macaque monkeys. Bidirectional or anterograde tracers were injected into areas covering all divisions of the PFC and the dACC. We mapped out (1) the convergent PFC projections to the striatum, (2) the convergent PFC projections to the dACC hub, and (3) the dACC hub projections to the striatal convergent zones. The results showed a three-way connectivity pattern that links the dACC hub with the corticostriatal network: The dACC hub receives inputs from many different PFC areas; the same set of PFC areas form multiple striatal convergent zones. Moreover, the dACC hub projects to significantly more convergent zones than the other dACC regions outside the hub.
These results showed that the dACC hub is influenced by a variety of PFC areas. But, the hub also plays a role in mediating the output of these areas in the striatum. PFC areas directly influence striatal convergent zones while the striatum also receives integrated information from the dACC hub. This mechanism enables crosstalk between different functions, which can be key for flexible switching between behaviors.

**Title:** Contributions of cortico-striatal pathways to the modulation of cognitive flexibility

**Authors:** ***A. E. REIMER**, M.-C. LO, M. F. MURILLO, M. R. MILAD, A. S. WIDGE
Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA

**Abstract:** The involvement of cortico-striatal circuits has been implicated in a variety of cognitive and executive processes, including working memory, decision-making, inhibitory response control, and attentional set-shifting. Deficits in these processes are common in several psychiatric disorders such as schizophrenia, obsessive-compulsive disorder (OCD), and major depression (MDD). Considering that deep brain stimulation (DBS) of the ventral capsule/ventral striatum (VC/VS) is effective in reducing the symptoms of refractory OCD and MDD, we hypothesize that DBS may act by improving executive processes that lead to increased cognitive flexibility. Here, we investigated how DBS-like electrical stimulation of the dorsal portion of the ventral striatum (VS) in rodents affects cognitive flexibility in an operant set-shifting paradigm. Bipolar electrodes were implanted bilaterally aimed to the VS and biphasic DBS (200 μA, 0.1 ms pulse duration, 130 Hz, bipolar) was delivered continuously for 2 h prior to a set-shifting test. Additionally, in a different set of animals, electrolytic lesions were targeted to the same brain region. DBS improved animals' performance, demonstrated by faster reaction times (DBS OFF 2.28 ± 0.26, DBS ON 1.70 ± 0.24), and reduction in the number of errors (OFF 7.33 ± 1.16, ON 3.5 ± 3.17), and trials to complete the test (OFF 35.89 ± 5.27, ON 20.5 ± 7.79). On the other hand, electrolytic lesion impaired animals' performance, demonstrated by slower reaction times (pre-lesion 5 ± 2,00, post-lesion 54.25 ± 2.75) and increase in the number of errors (pre 3 ± 0.95, post 6.57 ± 2.35), and trials to complete the test (pre 18.33 ± 2.80, post 28.14 ± 8.80). Considering the importance of the prefrontal cortex (PFC) in cognitive flexibility, our data suggest that DBS may affect PFC functioning in ways that improve flexibility. This might occur by modulation of striatum/thalamus through efferent cortico-striatal projections, or by antidromically activating those same fibers and directly modulating PFC. Further experiments will clarify which PFC sites are most involved in this modulation.

**Title:** Tonic cortical inhibitory control while withholding a specific action to relieve a strong urge

**Authors: *K. K. SUNDBY**, A. R. ARON
Dept. of Psychology, Univ. of California San Diego, La Jolla, CA

**Abstract:** A better understanding of urge is relevant for clinical disorders, daily experience, and theoretical issues in cognitive/motor control. It has been proposed that an urge has three core components: the experience of discomfort, the impulse to perform an action to relieve the discomfort, and the requirement to withhold the relieving-action itself. Here we tested if tonic cortical inhibitory control (of the action) is indeed a constitutive component of urge. We designed an experiment in which the subject experienced a strong impulse to press a button to relieve heat pain, but needed to resist pressing (over about 8 seconds) to avoid incurring a large loss. In 16 healthy young participants, we used paired pulse transcranial magnetic stimulation (TMS) over the motor cortex contralateral to the finger that could press to relieve the heat pain. With this paired-pulse TMS method we measured short intracortical inhibition (SICI) - which indexes GABAergic tone in M1. ANOVA was performed with finger (relevant, non relevant), and time point (baseline, timepoint 1 early, timepoint 2 late during the urge) with SICI as the dependent measure. There was a significant interaction between finger and timepoint $F(2,30) = 3.37$, $p<0.05$. Subsequent planned comparisons showed that SICI in the task-relevant finger alone was increased above baseline at timepoint 1( $p<.05$ ) and timepoint 2( $p<0.05$). This shows that tonic cortical inhibitory motor control is in place over many seconds during an urge. The result shows that this is specific for the effector that could move to relieve the discomfort - suggesting the result is unlikely a confound of arousal/stress per se. This is the first result to clearly demonstrate tonic suppression of action over multiple seconds.

**Title:** Characterizing human prefrontal cortex representations with fMRI

**Authors: *A. BHANDARI**[1], M. RIGOTTI[3], C. GAGNE[4], S. FUSI[5], D. BADRE[2,6]
[1]Cognitive Linguistics and Psychological Sci., [2]Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI; [3]IBM T. J. Watson Res. Ctr., Yorktown Heights, NY; [4]Psychology, Univ. of California Berkeley, Berkeley, CA; [5]Ctr. for Theoretical Neuroscience, Col. of Physicians and Surgeons, Columbia Univ., New York, NY; [6]Brown Inst. for Brain Sci., Providence, RI

**Abstract:** A central problem in cognitive neuroscience is understanding the nature and form of human prefrontal cortex (PFC) representations, which play a critical role in the expression of flexible, goal-directed behavior. An important property of such representations is their dimensionality. High-dimensional representation of task variables can support flexibility by enabling linear readouts of multiple, different conjunctions of task variables from the same representation. Indeed, in highly trained macaques, PFC representations of task variables approach maximum dimensionality, and this property predicts success on the task. Here we evaluate two proposed methods for estimating dimensionality from fMRI data. The first method involves enumeration of the number of arbitrary conjunctions of task variables that can be successfully decoded through multi-voxel pattern analysis (MVPA) of BOLD patterns. However, we demonstrate through a meta-analysis of published MVPA studies that the base rate for decoding information from PFC patterns is remarkably low, hampering the use of this method for estimating dimensionality. The second method involves estimating the similarity structure of the representation via cross-condition repetition suppression. This use of this method is complicated by the need to simultaneously estimate a large number of repetition suppression effects in the presence of low frequency fMRI noise. We evaluate the efficacy of a variety of fMRI designs, including isolated pair presentation and continuous carry over designs with deBruijn sequences for recovering representational dimensionality in simulations. Finally, we

evaluate this method empirically in an fMRI experiment for estimating dimensionality of prefrontal cortex representations.

**Title:** The role of different prefrontal subareas in the inhibition of proactive interference during verbal working memory

**Authors: *A. LLORENS**[1], I. FUNDERUD[3], A. O. BLENKMANN[3], J. LUBELL[3], M. D. FOLDAL[3], T. R. MELING[2], A.-K. SOLBAKK[3,2], T. ENDESTAD[3], R. T. KNIGHT[4]
[1]Dept. of Neurosurg., [2]Neurosurgical department, Oslo Univ. Hosp. - Rikshospitalet, Oslo, Norway; [3]Dept. of psychology, Univ. of Oslo, Oslo, Norway; [4]Knight Lab., Univ. of California, Berkeley, CA

**Abstract:** Verbal WM (vWM) can sometimes be disturbed by prior relevant information that is no longer needed. This is called proactive interference (PI). The inhibition of PI is fundamental for successful cognition. Imaging studies have found that the lateral prefrontal cortex, specifically on the left side, plays a role in the resolution of PI during vWM. Other studies show that the orbitofrontal cortex (OFC) is involved in WM operations, but its specific function during inhibition of PI is unknown. Our aim was to disentangle the role of prefrontal subareas in inhibitory mechanisms during vWM. We recruited a substantial cohort of patients with focal frontal lesions (17 bilateral OFC lesions, 7 right and 4 left lateral frontal) and compared performance between groups and against a matched healthy (age, education and IQ) control sample (n=16). Behavioral and EEG data were recorded while participants performed a Recent-Probes task. They briefly saw a list of 5 letters presented in succession, and were next asked whether a given letter was in the list. There were four conditions: the letter was (i) in the list, (ii) not in the list, (iii) in the list and in the previous trial's list, and (iv) not in the list but in the previous trial's list. In the last condition (iv), PI will be strongest. The memory trace from the previous list has to be inhibited in order to answer correctly. Behavioral results showed that when left and right lateral frontal lesion groups were merged, there was a significant group effect (p=.010) in the condition with highest PI (i.e: iv). Post hoc analysis revealed that the lateral patients were significantly slower than controls (+217 ms; p=.011) and the OFCs (+182 ms;

p=.035). There was no difference between the OFC and control groups. The main effect remained after splitting the lateral lesion group into left and right, (p=.017) for condition iv. Further analysis showed that the left lateral patients were significantly slower than controls (+294 ms; p=.03) and tended to be slower than the OFC patients (+258 ms; p=.066). Right lateral patients did not perform significantly differently than the other groups. These results indicate a differential role for specific prefrontal subareas during inhibition of PI, confirming that the left lateral prefrontal cortex is critically involved in inhibition of PI, but that the OFC is not. Our next step is to map patient lesion locations in conjunction with analysis of their EEG data recorded concurrently with task performance. We believe that the results will provide important data which are expected to elucidate the underlying electrophysiological dynamics of vWM inhibitory processes.

Biol. Sci., MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom

**Abstract:** A predominant finding in the literature is that the default mode network (DMN) shows decreased activity during externally-focused tasks compared to rest (Shulman et al., 1997). This finding has led to an emphasis in DMN research on internally-focused self-relevant thought processes including mind wandering, autobiographical memory, autobiographical planning, theory of mind and mental navigation. However, more recent research has questioned this emphasis on internal cognition (Baldassano et al., 2016; Chen et al., 2017). Most relevant to our study, Crittenden et al. (2015) found increases in DMN activity related to large changes in externally-focused tasks compared to small task changes or stay trials. Our study aimed to enhance our understanding of the function of the DMN during task switching. Using functional magnetic resonance imaging, we scanned 24 participants whilst switching between different tasks and brief rest periods. As well as replicating DMN task-switch effects, we also found large DMN increases for brief rests and task restarts after rest. Furthermore, multivoxel pattern

analysis showed distinct activity patterns during a task cue period for task types of different stimulus domains. Our findings are difficult to explain using theories of DMN function strictly linked to internal or self-directed cognition. In line with principal results from the literature, we propose that the DMN encodes scene, episode or context, by integrating spatial, self-referential and temporal information. Context encoding, we propose, plays a direct role in implementation and control of current cognition, be it internally or externally focused. Specifically, re-reference to the context is involved in large cognitive switches, from task to rest, rest to task, or between very different task domains.

**Title:** Structural correlates of executive function measures in older adults

**Authors: *H. L. LINDROTH**[1], R. MOHANTY[2], P. ROWLEY[3], V. A. NAIR[4], V. PRABHAKARAN[5], R. D. SANDERS[6]
[1]Anesthesiol., Univ. of Wisconsin-Madison, Sch. of Medicin, Madison, WI; [2]Radiology, Univ. of Wisconsin-Madison, Madison, WI; [3]Radiology, UW Madison, Madison, WI; [4]Radiology, [5]Dept Neurosci, Univ. of Wisconsin Madison, Madison, WI; [6]Sch. of Med. and Publ. Health, Anesthesiol., Univ. of Wisconsin, Madison, Madison, WI

**Abstract: Objective**
To investigate the structural correlates of older adults performance with measures of executive function and verbal fluency.
**Methods**
Prospective cohort study of 29 older adults (≥65yo; mean age 72.9±4.7 years, 14 male)

undergoing an elective noncardiac surgery with a projected length of stay of two or more days. Recruitment is ongoing. Demographics including age, gender and education level were collected through interviews. Participants underwent preoperative MRI structural imaging and comprehensive neuropsychological testing including Trail Making Test B (TMT-B) and Controlled Oral Word Association Test (COWAT). MRI sequences were processed using FreeSurfer software, OSX v.6.0. The ENIGMA-3 protocol was applied for extraction of cortical measures (www.enigma.ini.usc.edu)**.** Statistical analysis was conducted using SPSS, $p \leq 0.05$ was considered significant. Descriptive statistics followed by stepwise regression were performed to identify significant structural predictors of test performance. All brain regions (68) were entered into a stepwise regression equation for model-building. $R^2$ values and statistical significance are reported. Cluster-wise analyses were conducted using Freesurfer Qdec. Age, gender, left and right cortical thickness averages were used as covariates.

**Results**

Twenty-nine participants were analyzed. The mean score on TMT-B was 96.41 seconds (56.86SD) and COWAT-Total 33 words (11SD). The stepwise regression model most predictive of TMT-B performance demonstrated an adjusted $R^2$ of 0.713 ($p$-0.0001) and included left temporal pole, left posterior cingulate, left parstriangularis (inferior frontal gyrus), right parsorbitalis (inferior frontal gyrus) and right paracentral lobule. The regression model most predictive of COWAT-Total demonstrated an adjusted $R^2$ of 0.220, ($p$-0.006) and included left superior temporal gyrus. Age, gender, left and right cortical thickness averages were not significantly correlated with these identified regions and were not selected in the stepwise regression model. Cluster-wise analysis corrected for multiple comparisons revealed a significant correlation ($p$=0.04) between COWAT-Total and the left superior temporal gyrus. TMT-B did not demonstrate a significant correlation in cluster-wise analysis.

**Conclusion**

In this cohort, structural differences in select frontal and temporal regions were predictive of performance on TMT-B and COWAT-Total tests, independent of age and gender. The identified predictive regions are consistent with prior findings in neuroimaging studies of executive function and language.

**Abstract:** Objective: Healthy aging is associated with changes in cognitive domains in the human brain. This study examines how resting-state functional connectivity and thickness of cortical regions correlate to two measures of executive control function assessed during neuropsychological tests, namely, the Trail Making Test-B (TMTB) and Controlled Oral Word Association Test (COWAT) in a group of elderly subjects with the help of a machine learning regression model.
Methods: This study included pre-operative data from 29 subjects aged over 65 years (mean age = 72.9±4.6 years, 15 female/14 male) who underwent non-cardiac surgery. Subjects were scanned for resting-state functional MRI and structural MRI. Additionally, all subjects underwent a battery of neuropsychological assessment that recorded their performance to TMTB (mean score = 96.4±56.8 seconds) and COWAT (32.3±11.1 words) which are typically associated with the executive control function. Seed-based functional connectivity was computed spanning 268 distinct brain regions. Cortical thickness measures were derived from structural MRI over 68 distinct cortical regions. A machine learning support vector regression model was implemented to perform a linear-kernel multiple regression by utilizing both functional and cortical information as input features to predict the two outcomes.
Results: Multiple measures from, both, functional connectivity as well as cortical thickness were involved in predicting TMTB ($R^2 = 0.7283$; $p < 0.001$) and COWAT ($R^2 = 0.7038$; $p < 0.001$) scores. For TMTB, the highly weighted predictors included functional connectivity involving left inferior parietal lobule and left postcentral gyrus, and cortical thickness of left pars triangularis. Among the strong predictors for COWAT were connectivity between left superior parietal lobule and left precuneus, and cortical thickness of left pars triangularis. Additionally, functional and cortical predictors from similar regions of the brain, such as left lingual gyrus, left middle temporal gyrus, etc. were found among the predictors of both outcomes.
Conclusion: Machine learning-based regression model shows potential for identifying specific functional and morphometric correlates of TMTB and COWAT performances. No impact of age and gender was found in either prediction. Emerging predictors involving left pars triangularis of inferior frontal gyrus, left superior parietal lobule are in line with findings in neuroimaging studies of the executive control function.

**Abstract:** Previous studies have shown that propranolol, a beta adrenergic antagonist, can reduce the negative effects of stress on problem solving abilities. Furthermore, propranolol can improve performance on problem solving for the most challenging of tasks without the presence of stress. We aimed to determine whether non-pharmacological approaches could yield comparable effects. For example, the use of paced breathing, a technique used to slow breathing in an experimental setting, has been shown to increase heart rate variability, an indication of increased parasympathetic nervous system activation. This may give rise to increased problem solving ability, especially in terms of convergent and divergent thinking based task performance. The goal of this project is to better understand if paced breathing can be implemented to improve problem solving in addition to convergent and divergent thinking. We hypothesized that paced breathing—as compared to normal breathing—will decrease an individual's cardiovascular response to stress, as measured by electrocardiogram (ECG) and improve performance on convergent and divergent thinking tasks. Using a repeated measures design, participants engaged in counterbalanced paced breathing and normal breathing sessions. In both the paced and normal breathing sessions, cognitive tasks administered include the alternate uses task (scored for originality, flexibility, and elaboration), semantic fluency task (scored for originality and semantic distance), and letter fluency task (scored for originality and elaboration). We expect that scores on originality, flexibility, elaboration, and semantic distance will be higher for paced breathing than normal breathing sessions due to increased cognitive flexibility attributed to decreased cardiovascular response to the stress of cognitive testing. If relaxation techniques are as effective as propranolol in affecting problem solving, it can benefit those who suffer from cognitive or problem solving deficits and cognitive impairments related to stress.

**Abstract:** In social environments, we make decisions, considering what others would do. Specifically, even when we make choices for our own reward, the expectation and associated decision-making often needs to depend on others' behavior. However, it is still poorly understood how humans incorporate the prediction of others' behavior into self-oriented decision in the neural and computational processes. To address this issue, we devised a novel behavioral task under value-based decision-making paradigm in human fMRI, combined with computational modeling. In our task, there are main trial and two types of control trial, self and other trials. Main trial required the subject to choose an option, using the prediction of others' choice, because a set of options to choose depended upon the other's choice. Self and other trials examined each component in the main trials: making ordinary, probabilistic self-value-based decisions and plainly predicting others' decisions themselves, respectively. Probing their behavior, first, we confirmed that the subject's behavior followed self-value difference and predicted-others' value difference in the self and other trials, respectively. In the main trials, the subject chose the option, governed by a balance of the two possible self-value differences that would be generated by two different predictions of others' choices (predicted-others' value difference), and the relative contribution of the two self-value differences varied along with the difficulty of predicting others' choices or the magnitude of predicted-others' value difference. Imaging results showed distinct neural circuits for predicting other’s choices between the other and main trials. In the other trials, the prediction significantly correlated the activities in anterior insula and right temporoparietal junction (TPJ), and also in ventromedial prefrontal cortex (vmPFC). In the main trials (and also self trials), the vmPFC activations were significantly correlated with the subject's own choices but not with the prediction. The prediction had

significant activations in dorsomedial prefrontal cortex and posterior insula across the subjects, and the rTPJ activations were rather correlated with the degree of performance in the mail trials. These results together indicate that additional neural circuits, and also differential roles of respective brain regions, are recruited for making use of prediction others' in self-oriented decisions.

**Abstract:** The neural signals of internal reward valuation process comprise a self-oriented currency for decision-making. In social setting, our decisions are influenced by social concerns such as reward to others. However, it is poorly understood how social values converges into self reward valuation in the neural and computational process. Here, we demonstrate the social value conversion process, using a novel behavioral paradigm in human fMRI with computational modeling. The task is consisted of 3 types of trials. Standard trials access a basic valuation process, in which the subject chooses between two options, each of which is associated with one's own probabilistic outcome (standard reward). Other trials examine social value conversion, in which a number in an option additional to standard reward indicates an additional reward to others (donation to a pre-selected charity), while bonus trial is a control in which an additional number indicates an additional reward to the self (bonus), respectively. We indeed found a significant modification on the choice behavior by the others' reward, although the extent is weaker than that by bonus given the same face amount. We hypothesized three key elements for the neural process of social value conversion into self-own decisions: (1) other-value in offer, (2)

the effective influence by the offer on choices, as the effect (even with the same offer) may vary dependent on standard value difference and (3) the final decision value that accounts for both of the standard and additional rewards. The offered other-value was encoded in the right temporoparietal junction (rTPJ), and also in the left dorsolateral prefrontal cortex (ldlPFC), wherein the offered bonus value was encoded not in the rTPJ but in the ldlPFC. The effective other-value was reprsented in right anterior insula (rAI) activation and the final decision value in ventromedial prefrontal cortex (vmPFC). Psychophysiological interaction analysis lent a support for a staged processing of our hypothesis, from the offer to the effective influence on choices and then to decision; the rTPJ and ldlPFC responses significantly modulated the rAI responses that, in turn, influenced decision signals in vmPFC responses. By contrast, the ldlPFC responses had a direct impact on the vmPFC responses for bonus value. Further, we found that these characteristics of social neural conversion underlie different socio-behavioral isotypes, demonstrating the variability in the conversion between prosocial and selfish subjects: emphasis of rAI and ldlPFC coupling to vmPFC responses, respectively. These findings identified primary neuro-computational processes for social value conversion.

**Abstract:** Computational psychiatry provides a promising avenue for translating basic psychological and neuroscientific knowledge into the clinic (Huys 2016). Within this new field, there is increasing interest in computationally modeling individual differences in decision making and associating them with psycho-pathologically relevant traits. This approach has successfully linked specific decision making deficits to trait impulsivity (Gillan 2016) and trait depression (Huys 2012). However, to-date, little computational work has been done to

characterize the aberrant decision making observed in anxiety. Anxious individuals are known to find uncertainty aversive (Mitte 2007). We have previously shown trait anxiety to be linked to impoverished use of environmental volatility to update learning about aversive outcomes (Browning et al., 2015). Preliminary data from our lab also indicates that anxious individuals are ambiguity avoidant when making decisions about primary aversive outcomes (see poster by E Lawrance). In the current study, we investigate whether healthy volunteers show ambiguity seeking versus avoidance behaviors when making probabilistic decisions and investigate whether this varies as a result of psychopathy related traits including trait anxiety and trait depression. Participants performed a probabilistic decision-making task under conditions of reward and loss. The two options chosen between varied in probability and magnitude of outcome. For 50% of trials, information required to calculate probability of outcome was missing; level of missing information was manipulated in a continuous fashion. Preliminary data (n=120) reveals that participants are predominantly ambiguity averse under reward, but switch to be ambiguity seeking under loss ($t=-7.49$, $p<0.001$). This categorical effect was attenuated as choices became less ambiguous, with many individuals becoming ambiguity-neutral at low levels of ambiguity. Our preliminary data also suggests that in contrast to situations with primary aversive outcomes, trait anxiety is not significantly associated with increased ambiguity aversion under conditions of financial reward gain or loss ($r(118)=0.15$, $p=.20$; $r(118)=0.12$, $p=.27$). The specificity of anxiety-related ambiguity aversion to conditions involving potential future primary aversive outcomes fits well with existing characterizations of anxiety.

**Abstract:** There is ambiguity associated with many choice options we encounter. For people with clinical or subclinical anxiety, intolerance of uncertainty and decision making difficulties are key psychological features, negatively interfering with daily life. It has been proposed that anxious individuals are also strongly ambiguity averse. Here we use a computational decision making framework to interrogate how anxiety influences probabilistic decision making under conditions of ambiguity about aversive future events.
Within the computational decision making literature, categorical and parametric ambiguity have been examined by manipulating, respectively, the presence or level of missing information about action-outcome contingencies. In the current study, we investigated how individual differences in trait anxiety influenced participants' performance on a probabilistic aversive decision making task while fMRI data were acquired. The experimental design used allowed us to separate out effects of categorical and parametric ambiguity. On each trial, the two options presented varied in probability and magnitude of outcome. For 50% of trials, information required to calculate the probability of outcome for one of the two options was obscured; level of missing information was manipulated in a continuous fashion. Our findings indicate that both categorical and parametric ambiguity aversion are present across our participant cohort, in line with previous demonstrations of ambiguity aversion. Across participants, both categorical and parametric ambiguity aversion varied positively with trait anxiety levels. Increased blood oxygen level dependent (BOLD) responses to categorical ambiguity were observed in dorsal anterior cingulate cortex (dACC) and inferior frontal sulcus (IFS). BOLD responses in these regions were also modulated by parametric ambiguity, with increased response to higher levels of missing information. The representation of missing information was also apparent in rostrolateral prefrontal cortex for subjects with high trait anxiety. A further model separating trials by choice revealed that high trait anxious subjects primarily show an increased IFS and dACC response to ambiguity on trials where they go on to choose the ambiguous option. This is consistent with high trait anxious participants requiring increased recruitment of these regions to overcome their heightened propensity to ambiguity aversion.

**Abstract:** Information gathering is an integral part of learning and decision-making. Yet we know relatively little of how people implement the decision to know or remain ignorant. Classic theories focus on the instrumental utility of information. However, human behavior does not always fit nicely with those models, as in the case of patients at risk who avoid medical screening even when treatment is available. Here, we examine the hypothesis that information gathering is modulated by affect. In two studies we manipulate the expected valence of information and the affective state of the participants. We then record their willingness to pay (WTP) in order to receive or avoid information about their earnings in a financial market task. The information was non-instrumental; it could not be used to alter rewards and did not influence the earnings participants received at the end of the task. Our results reveal that participants were willing to pay more (1) to receive good news and *avoid* bad news and (2) in volatile markets. We next examined whether these effects were related to the affective state of the participants. We found that the influence of volatility, but not valence, on the desire for information was related to anxiety. In Study 1 more anxious individuals exhibited a stronger effect of market volatility on WTP for non-instrumental information. In Study 2 we induced anxiety using an acute stress manipulation. Consistent with the results of Study 1, individuals whose anxiety levels increased the most showed the strongest effect of market volatility on WTP for non-instrumental information. Our results highlight the tight relationship between affect and information seeking and suggest that anxious individuals attempt to reduce the burden of uncertainty by gathering (non-instrumental) information.

**Abstract:** We are interested in the influence of mood and personality traits on temporal choice behavior. Previous research suggests that there is a link (Hirsh et al., 2010; Koff & Lucas, 2011;

Manning et al., 2014; Whiteside & Lynam, 2011). However, this research was underpowered. Here, we exposed 600 participants to stimulus material - music - known to induce changes in mood. Using this high powered sample, we can show that music does influence mood in predictable ways, but the effect of music on temporal choice behavior is modest, on the order of 1/25 of a standard deviation. In addition, personality traits such as extraversion or neuroticism did not predict temporal choice behavior. Our results put a low ceiling on the influence of music on temporal choice behavior and suggest that individuals are more impervious to deviate from rational choice due to incidental circumstances than commonly believed.

**Title:** Vicarious subjective value representation in the human brain: An fMRI investigation

**Authors: *M. R. PIVA**[1], K. VELNOSKEY[2], R. JIA[1], I. LEVY[3], S. W. CHANG[2]
[1]Interdepartmental Neurosci. Program, [2]Psychology, Yale Univ., New Haven, CT; [3]Section of Comparative Med., Yale Sch. of Med., New Haven, CT

**Abstract:** When making economic decisions, people are usually biased to the present moment. When asked if they would rather receive $5 today or $6 in 5 days, most would choose $5 today. However, when asked to choose between $5 in 180 days or $6 in 185 days, people are much more likely to choose the delayed higher amount. Thus, people seem to discount future rewards in a time-inconsistent manner when making choices that impact their own well-being. Extensive previous research cutting across economics, psychology, and neuroscience has indicated that decay of subjective value with increasing delay follows a hyperbolic rather than exponential decay function and is computed by a defined set of neural structures (e.g., Kable and Glimcher, 2007). By contrast, the behavioral and neural processes underlying how people make decisions that directly impact another individual remain largely unclear. Exploring this additional dimension of decision-making is both highly relevant to everyday life, in which making decisions for or about others is exceedingly common, and to further elucidating the computation of value representation in the brain. To address this issue, we designed a study in which participants were asked to make choices between an immediate monetary reward and various monetary rewards of greater values delivered following a delay. In half of trials, participants made decisions for themselves (“Self” trials), while in the other half of trials, participants made decisions for a randomly selected other participant (“Other” trials). We hypothesize that

ventromedial prefrontal cortex (vmPFC), ventral striatum (VS), and posterior cingulate cortex (PCC) encode subjective value in Self trials, while an overlapping but distinct set of neural structures encode vicarious subjective value in Other trials. Preliminary behavioral findings based on data from 15 participants indicate that Other choices, like Self choices, follow the expected hyperbolic rate of decay rather than exponential decay. We also found that participants displayed a higher rate of discounting in Self trials than in Other trials ($t(14) = 2.52$, $P = 0.025$, two-tailed paired *t*-test). Finally, choice consistency before and after each participant's determined indifference point was significantly higher in Self trials than in Other trials ($t(14) = 3.58$, $P = 0.003$, two-tailed paired *t*-test). These behavioral and upcoming univariate and multivariate analyses of concurrent BOLD signals acquired during fMRI sessions can provide additional insight into the shared as well as distinct neural activations underlying decision-making for self and other.

**Title:** Activity in the temporoparietal junction (TPJ) tracks dynamic changes in uncertainty when observing goal directed action

**Authors: *K. R. VELNOSKEY**, S. W. C. CHANG, G. MCCARTHY
Psychology, Yale Univ., New Haven, CT

**Abstract:** The temporoparetal junction (TPJ) is a critical region for processing goal directed behavior (Allison, Puce, & McCarthy, 2000), yet the mechanism by which this occurs remains unknown. While some suggest that the TPJ is organized in domain-specific social modules (i.e. Deen et al., 2015), others suggest that it serves a domain general function (Geng & Vossel, 2013; Lee & McCarthy, 2016). In social contexts, this general function may be critical for modeling predictions about expected behavior. We propose that the TPJ is involved in dynamically updating such a model, and, in particular, that TPJ activation tracks changes in neural parameters for generating predictions over time.

We tested this hypothesis using a novel fMRI task in which participants (N=21) viewed a dot traversing a complex maze containing two possible goals. Participants continuously expressed their certainty about the goal that the dot was trying to reach by moving a horizontal slider. Mazes were either barrier free (High Uncertainty condition) or included some barriers to constrain the dot's path and reduce subjective uncertainty about the goal (Low Uncertainty condition). Critically, the dot's path was matched in both conditions. We examined how TPJ activity was modulated by these conditions using whole-brain general linear models (GLM) including a regressor derived from participants' slider positions for estimating subjective changes in goal target uncertainty over time.
The High Uncertainty v. Low Uncertainty contrast revealed significant activation clusters in bilateral STS, bilateral insula, left primary motor cortex, and SMA. However, only bilateral TPJ and insula were parametrically modulated by participants' own changes in subjective uncertainty over time. The correlation of participants' subjective uncertainty with activation in left and right TPJ ROIs revealed a significant main effect of TPJ ROI, $F(1,14)=19.66$, $p<0.001$, with higher correlations (*r)* in right TPJ, $M=0.090$, $SD=0.131$, than in left TPJ, $M=0.003$, $SD=0.093$. Analyses of task dependent connectivity between STS/TPJ and other brain regions using psychophysical interaction (PPI) are being conducted to examine how uncertainty modulates network level responses, and computational modeling is being applied to further specify the relationship between STS/TPJ activity and goal observation with respect to uncertainty estimation. The current results suggest that STS/TPJ responses to goal directed behavior are in part explained by uncertainty in modeling the external world.

**Title:** Latent cause inference in social biases

**Authors: *Y. SHIN**[1], Y. NIV[2]
[1]Neurosci., [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

**Abstract:** When making decisions in a social environment, how do we form impressions about a group of people whose members are diverse? If the majority of members are similar to one another with few members who are dissimilar from other people in the group, would experiences with those rare members influence the overall impression? Here, we explore how seemingly

irrational biases where rare events gain prominence in overall estimation may result from normative inference of latent causes-causal structures of the world that generate a set of observations. We hypothesized that sparsity of events may lead to inference of unique latent causes for such events. This tendency to separate rare events to small latent causes, while grouping common events in large latent causes that explain multiple events, can cause overweighting of rare events in learning, if averaging is across latent causes rather than individual events. We tested this hypothesis by manipulating sparsity of non-overlapping event distributions. We first simulated the inference process, and showed the predicted effects of our theory. We then tested these predictions empirically in four decision-making experiments. Subjects observed a sequence of coin donations and were subsequently asked to estimate the average donation. As predicted by the latent-cause model, average estimation was biased toward sparse distributions (Exp 1 and 2). This bias was not explained by correctly averaging log-transformation of the donations (Exp 3), and disappeared when we interrupted the latent cause inference process by introducing step-by-step average estimation (Exp 4). These results suggest that social biases that have been found in empirical social cognition research may be the results of a semi-rational Bayesian latent cause inference process. Our theory also applies to formation of impressions about an individual on the basis of multiple interactions, and not only to evaluations of groups of people.

**Title:** How to build a bias: A role for confidence in belief formation

**Authors: *A. ZYLBERBERG**[1], D. M. WOLPERT[2], M. N. SHADLEN[3]
[1]Neurosci., Columbia Univ., New York, NY; [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Neurosci., Howard Hughes Med. Inst. - Columbia Univ., New York, NY

**Abstract:** Humans and other animals can extract and exploit the statistical regularities of an environment to make better decisions. A case in point is the learning of prior probability in decision making. The prior is often ascertained from observations (e.g., base rates). This is a

straightforward process if the observations that inform the prior are certain and countable (e.g., in Laplace's rule of succession). However, such observations are often derived from sequences of decisions whose outcomes are unaccompanied by explicit feedback. Without clear feedback about decision outcome, the prior must be estimated through a process resembling probabilistic reasoning. Just as a single decision is informed by a sequence of samples of evidence of unknown reliability, so too is the belief in a base rate informed by a sequence of decisions whose veridicality is only known to a degree of certainty (i.e., confidence). We hypothesized that in the absence of explicit feedback, decision confidence guides the apprehension of prior probability. Five human participants viewed a patch of randomly moving dots and decided if the net direction of motion was rightward or leftward. Within a block of 15 to 42 trials, one direction of motion was more likely, but which direction was more likely (and by how much) was unknown to the participant. Participants made four responses on each trial. They first reported the perceived direction of motion and the confidence that the decision was correct ("choice and confidence about motion direction", CCMD). They next reported whether they believed the bias of the block favored rightward or leftward and the confidence in this belief ("choice and confidence about bias", CCB). They received no feedback after the trial. Consistent with previous studies, we found that the block's bias influenced CCMD. This implies that subjects could rapidly learn the bias of the block and use this knowledge to make more accurate decisions. Further, participants used CCMD to revise their prior. This was reflected by the incorporation of the prior in the perceptual decisions as well as in the CCB reports. A bounded evidence accumulation model explained the decisions about motion by incorporating an estimate of the bias in the accumulation. In turn, the bias was updated based on the likelihood that the motion was rightward or leftward. The model predicted the dynamics of belief about the direction bias over the block. The findings expose a role for confidence in belief updating, suggesting that the brain maintains probabilistic representations over decision hierarchies and time scales: direction over one trial and bias over many trials. These probabilities are accessible for explicit report.

**Title:** Information processing dynamics predict extreme political beliefs

**Authors: *M. ROLLWAGE**[1,2], R. J. DOLAN[1,2], S. M. FLEMING[1]
[1]Wellcome Trust Ctr. For Neuroimaging, London, United Kingdom; [2]Max Planck Univ. Col. London Ctr. for Computat. Psychiatry and Ageing Res., London, United Kingdom

**Abstract:** Holding extreme and inflexible political beliefs is commonplace, and often leads to negative consequences including "gridlock" in public policy. While societal drivers of this effect have long been posited, we were concerned as to whether extreme beliefs might have unsuspected links with characteristics of basic information processing that govern insight into the correctness of one's own beliefs (metacognitive ability) as well as the degree of integration of new evidence. In a large, web-based sample (N=379), participants were asked to discriminate patches of flickering dots, which was either directly followed by a confidence rating or by additional evidence presentation before the confidence rating. Metacognitive ability was measured as the correspondence between confidence ratings and actual performance on decisions without additional evidence, whereas post-decision evidence integration is characterized by a change in confidence due to additional evidence. Following correct choices, additional evidence should normatively increase participants' confidence (due to integration of confirmatory evidence) whereas for incorrect choices, additional evidence should lead to a decrease in confidence (due to integration of disconfirmatory evidence). A factor analysis of political attitudes resulted in a two-factor solution with factors of orientation (liberal/conversative) and extremity/dogmatism of belief. We show that metacognitive ability predicts individual's sensitivity to post-decision evidence. Critically, dogmatism was negatively predicted by metacognitive ability and also by disconfirmatory evidence integration, while political extremeness was associated with reduced integration of disconfirmatory evidence. Our results indicate that low-level information processing dynamics predict dogmatic world views, potentially contributing to a pervasive resilience of extreme political beliefs.

**Title:** Decoding representation learning in the orbitofrontal cortex during dynamic attention to relevant dimensions

**Authors: *N. DRUMMOND**[1], A. GEANA[2], N. SCHUCK[2], Y. NIV[3]
[1]Neurosci., [3]Princeton Neurosci. Inst., [2]Princeton Univ., Princeton, NJ

**Abstract:** In order to make effective decisions we must learn what aspects of the environment are relevant to procuring reward and avoiding punishment. Learning and basing decisions on only the environmental dimensions that are relevant to the current task improves performance, speeds learning and simplifies generalization to future situations. To study how we learn to attend to relevant dimensions, Niv et. al (2015) developed the "Dimensions Task," a stochastic and dynamic version of the Wisconsin Card Sorting Task in which on each trial subjects are asked to choose one of three stimuli in order to obtain rewards. Each stimulus has a color, a shape and a texture, but only one of these dimensions determines reward. *It is still not clear how exactly feedback on a certain trial affects attention on the next trial, that is, what is the computational and neural mechanism for learning from experience what to attend to.*
A main hurdle in the way of understanding how attention changes trial to trial, is that we do not know what the subject is attending to on each specific trial. In the computational framework of reinforcement learning, the information relevant for making a decision is called the "state," and decision-making occurs by comparing values of different actions at each state. In the case of the Dimensions Task, the state can be thought of as the dimension relevant for reward. As the subject focuses attention on the relevant dimension, they are effectively in the "state" of the task relevant for reward. Specifically, based on a wide range of findings, we have hypothesized that the orbitofrontal cortex (OFC) contains a moment-by-moment representation of the current state of the task.
Combining these two lines of work, here we use MVPA fMRI decoding methods to track, trial by trial, the evolution of state information in the OFC as subjects play the Dimensions Task. Directly measuring how experience affects task states in an attention learning task allows us to elucidate the fundamental process by which we learn what to attend to in the service of optimal decision making by tracking the learning process. Moreover, our results provide additional support for the theory that the OFC contains dynamic state information.

**Abstract:** Neural substrates and mechanisms that mediate online[1] social cognition are poorly understood largely due to challenges of neuroimaging in natural conditions. However, recent developments in functional near-infrared spectroscopy (fNIRS) enable simultaneous neuroimaging (hyperscanning) of dyads during live social interactions. Prior behavioral findings suggest that social disparities signal “in” and “out” group memberships, although neural encoding of social disparities during dynamic interpersonal interactions has not been investigated. In this study, 84 individuals (19 high and 23 low disparity dyads) of mixed gender, race, and age were scanned during natural dialogues using an 84-channel fNIRS system (Shimadzu, LABNIRS) with 42 channels covering both hemispheres of each participant. A post-scan self-report survey indicated that high disparity dyads were more anxious than low disparity dyads; however, acoustic analysis of spoken narratives revealed no evidence for a difference in total spoken words between groups. We hypothesized that a contrast difference would be observed in the right temporal-parietal junction based on prior associations with social behavior; however, results did not support this hypothesis. Rather, increased neural activity based on deoxyhemoglobin signals was observed in the left dorsolateral prefrontal cortex (DLPFC) of high disparity dyads relative to low disparity dyads using SPM voxel-wise and discrete channel-wise analyses ($p<0.05$). Both analysis approaches suggest that executive planning and speech production mechanisms are more engaged during verbal interactions between individuals from disparate socioeconomic groups. We further hypothesized that cross-brain coherence between partners would vary as a function of disparity. Consistent with contrast findings, increased cross-brain coherence of fNIRS signals was found between DLPFC and premotor cortex for high disparity dyads. However, for low disparity dyads, cross-brain coherence increased between fusiform gyrus, the subcentral area, and somatosensory cortex, consistent with reciprocal signaling of face information. This is the first demonstration of a neural basis for altered dynamic interactions during social communication between pairs of individuals from highly disparate socioeconomic backgrounds, and advances a theoretical framework for such interactions by suggesting an extended role for executive planning mechanisms in real-life conversations.

**Title:** Frontal EEG theta oscillation differences during two-person, live, eye-to-eye contact compared to picture gaze

**Authors: *J. A. NOAH**[1], Y. ONO[5,1], X. ZHANG[1], S. DRAVIDA[2], J. HIRSCH[1,3,4,6]
[1]Dept. of Psychiatry, [3]Neurosci., [4]Comparative Med., [2]Yale Sch. of Med., New Haven, CT; [5]Dept. of Electronics and Bioinformatics, Meiji Univ., Kanagawa, Japan; [6]Dept. of Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom

**Abstract: Background.** Human eye-to-eye contact is a primary source of social cues and communication. Functional neuroimaging studies (fMRI and fNIRS) have suggested that brain responses to viewing actual faces compared to pictured faces are dependent on the gaze of the eyes. Distributed face-selective regions, including the fusiform gyrus, amygdala, superior and middle temporal gyrus, and orbitofrontal cortices are more sensitive to direct than to indirect gaze.
**Aim:** Our goal here was to test the hypothesis that the eye-to-eye contact effect is represented in specific frequency bands of the EEG signal.
**Methods.** Twenty-six adults (13 pairs, 22+/- 6 years old, 15% female, 100% right-handed (Oldfield, 1971)) participated in a paradigm that cued dyads of partners to look at each other or at a fixation object placed ten degrees to the side of their partner in block design in which three seconds of eye viewing was interleaved with three seconds of fixation object viewing. Subjects also participated in an identical paradigm in which both individuals concurrently looked at the eyes of a calibrated photograph instead of their partner using the same block design. EEG recordings were obtained at a sample rate of 256/sec from electrode positions at F3, F4, F7, F8, C3, C6, PO7, and PO8 according to the 10-20 standard EEG layout. Gaze data was also obtained using a two-person eye-tracking system. EEG signals were averaged and smoothed using a median filter with a 0.10 s window, effectively a 7 Hz low-pass filter.
**Results and Discussion.** Gaze data confirmed the statistically comparable eye behavior between the eye-to-eye and eye-to-picture conditions. Point-by-point t-tests of event-related potential (ERP) indicated altered frontal activity 2s after onset of the active eye-to-eye contact relative to the eye picture gaze. In comparison, there was no difference between the two waveforms during the resting baseline ERPs. Wavelet decomposition analysis shows ERP results are specific to theta band when comparing direct eye-to-eye contact versus eye-to-picture conditions ($p = 0.01$). Other frequency bands were not differentiated by this condition. Findings extend models of eye-to-eye contact in live social situations to include theta-specific oscillations.

**Title:** Neural correlates of a smile: An fNIRS investigation

**Authors: *J. PARK**[1], J. A. NOAH[2], X. ZHANG[2], S. DRAVIDA[3], J. HIRSCH[2,4,5,6]
[1]Yale Univ., New Haven, CT; [2]Dept. of Psychiatry, [4]Neurosci., [5]Comparative Med., [3]Yale Sch. of Med., New Haven, CT; [6]Dept. of Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom

**Abstract:** A naturally generated smile is a significant affective social cue that often conveys intention to communicate. However, the associated neural correlates are not well understood largely due to the challenges of movement artifacts in fMRI. Because of the salient social significance of the smile expression, we hypothesized that the underlying network will include neural systems known to be involved in social cognition in addition to the motor systems necessary to form the facial expression. Here we employ functional near-infrared spectroscopy (fNIRS), a neuroimaging technology with head-mounted optodes providing 105 channels distributed over both hemispheres of each participant (Shimadzu, LABNIRS). This system is tolerant of limited movement and was employed to determine the neural correlates of a natural smile generated by expression-inducing visual stimuli. Twenty-two healthy participants viewed intermixed neutral and smile-inducing images during 15 sec epochs that each included 3 images with 5 sec duration. The picture epochs alternated with 15 secs of baseline epochs for a total of four minutes. A video recording and facial classification system, GE Sherlock, was synchronized with the fNIRS signal acquisitions, and automatically identified the smile expression in addition to rating the magnitude from 0 – 1 based on facial landmarks such as the size and shape of the mouth opening. The automated classification system was validated by manual ratings. The deOxyHb signal, a proxy for neural activity similar to the BOLD signal, was analyzed based on both the task and rest periods and on continuous smile classification ratings as a regressor using conventional GLM methods. The observed neural activity based on the smile magnitude included: visual association cortex (V3), pre- and supplementary motor cortex, bilateral supramarginal gyrus (SMG), left superior temporal gyrus (STG), and bilateral frontopolar area ($p<0.05$). Consistent with the social cognition hypothesis, these novel findings provide evidence that the production of a smile is associated with processes within social and communicative neural systems in addition to expected visual and sensory motor systems.

**Abstract:** Cannabis is one of the most commonly used illicit substances worldwide. In unintoxicated long-term users, evidence has shown associated deficits across many cognitive domains, especially in verbal learning, memory, and attention. There are some domains where the evidence remains mixed, including decision-making and reward-related processing. Some studies have shown that long-term cannabis use is associated with increased risk-taking behaviour, however this behaviour has not been found in other studies. One task proposed to simulate real-life decision-making that involves risk, reward and punishment is the Iowa Gambling Task (IGT). The IGT consists of four decks of cards for subjects to choose from. Each card selection causes monetary gain or loss. Two of these decks are disadvantageous, yielding greater gains but even greater and more frequent losses, resulting in a net loss. The other two decks are advantageous, giving only small gains but smaller and less frequent losses, resulting in a net gain. This study aimed to determine if long-term cannabis users (n=16) show differences in reward-related behaviour in comparison to non-users (n=17) using the IGT. The IGT, programed in Psychtoolbox, allows participants to choose from four decks of cards over the course of 100 trials, with a feedback screen after each card selection. Each card selection causes monetary gain or loss with subsequent feedback. Behavioural data were separated into five bins of twenty responses and compared using an ANOVA in SPSS. Despite some trends in behaviour whereby cannabis users chose the riskier decks over the advantageous decks, there were no significant differences found ($p=0.749$). These results are in line with previous studies including those in chronic heavy cannabis users, which found no difference in the IGT. Findings from other literature have suggested that financial risk-taking may be less sensitive than other types of risk-

taking behaviour, whereby studies investigating behaviours associated with risk-based decision-making have not typically dissociated probability of risk from magnitude of reward. Furthermore research into assessing how cannabis users evaluate and respond to feedback has been sparse. Future research should target risk-based decision-making that differentiates risk from magnitude of reward and how participants respond to feedback for future decisions.

**Title:** Influence of attentional modulation on the construction of reward value

**Authors: *M. MORADI SPITMAAN**[1], E. CHU[1], A. SOLTANI[2]
[1]Psychology and Brain Sci., [2]Psychological & Brain Sci., Dartmouth Col., Hanover, NH

**Abstract:** Over the past four decades, prospect theory has been successfully used to capture choice under risk. An often-neglected aspect of this theory is the editing phase which can facilitate decision making by simplifying the comparison between gambles with many possible outcomes. Editing is especially important for evaluating real-life options which involve many possible outcomes. However, most experiments testing prospect theory involve gambles with only two possible outcomes (reward and no reward, gains and losses). Here, we designed an experiment to examine the construction of subjective value for more complex gambles and to test prospect theory for capturing choice between such gambles. In the first session of the experiment, human subjects selected between a sure option and simple gambles which yielded variable-size reward or no reward with specific probabilities. Each simple gamble was presented with a rectangle consisting of two portions with different colors. The color of each portion indicated the magnitude of possible reward outcome, and the size of each portion signaled the probability of each outcome. The choice behavior from this session was used to estimate the utility and the probability weighting functions for each subject, and to tailor pairs of equally preferable mixed gambles (gambles with three possible outcomes). This was done to allow detection of additional mechanisms involved in the construction of subjective value. The subjects selected between these pairs of tailored gambles during the second session of the experiment. We used various models to fit subjects' choice behavior in the second session in order to identify

additional mechanisms involved in the construction of subjective value. More specifically, we extended prospect theory to include the possibility that alternative gamble outcomes could be weighted differently before they are combined to form the overall gamble value. Our results supported several assumptions of prospect theory. Subjects constructed values using a concave utility function and an inverted S-shape probability weighting function. We also found, however, that most subjects assigned greater weight to the outcome with the largest reward magnitude compared to the other two outcomes. This differential weighting of possible outcomes could be instantiated via attentional modulation and enabled subjects to more easily choose between gambles with similar subjective values. Overall, our results reveal additional mechanisms involved in the evaluation of mixed gambles and highlight the role of attention in the construction of reward value.

**Title:** Tonic activity at striatal dopamine 2/3 receptors encodes subjects' confidence in their policies

**Authors: *R. A. ADAMS**[1], M. MOUTOUSSIS[1], D. LEWIS[1], M. NOUR[2,3], T. DAHOUN[2,3], K. FRISTON[1], J. ROISER[1], O. HOWES[2,3]
[1]UCL, London, United Kingdom; [2]King's Col. London, London, United Kingdom; [3]Imperial Col. London, London, United Kingdom

**Abstract:** Objective
'Active inference' is a computational decision-making model based on the premise that perception and action maximise Bayesian model evidence - or minimise prediction error. Under

active inference, dopamine is thought to encode the precision (inverse variance) of an agent's beliefs that its policies will achieve its goals.
This precision plays a similar role to the inverse temperature parameter in standard (softmax) decision models - i.e. it affects the stochasticity of decision-making - but, unlike inverse temperature, it is updated in a Bayes-optimal fashion according to the context. In this way, when the agent is confident that a policy will achieve its goal, its choice of a policy becomes less stochastic and more deterministic.
Previous work has shown that dynamic updates to this precision during a task correlate with BOLD activation in the dopaminergic midbrain during fMRI (Schwartenbeck et al., 2014). We wished to demonstrate a relationship between dopamine receptors themselves and precision using positron emission tomography (PET). We hypothesized that tonic dopamine signalling in the associative striatum encodes a subject's prior on this precision.
Given tonic signalling activates dopamine 2 receptors (D2Rs), we predicted: i) Prior precision, estimated using an active inference model of a Go NoGo task, would correlate with D2R availability, estimated using [11C]PHNO PET imaging. ii) Given both total D2R concentration and tonic D2R occupancy by dopamine affect D2R availability, the relationship between prior precision and D2R availability would be quadratic.
Methods
43 healthy participants performed a Go NoGo task (Guitart-Masip et al., 2012) and also underwent [11C]PHNO PET scanning to measure striatal D2/3R availability (BPnd). Participants' prior precisions were estimated using an active inference model.
Results
Prior precision (Go NoGo task) had a quadratic relationship with D2/3R BPnd ($r^2$=0.12, p=0.035) in the associative striatum ROI. When subjects who performed the cognitive task >3 weeks apart from the PET scan were excluded (n=20 remaining), more variance was explained ($r^2$=0.23, p=0.021).
Conclusions
These results indicate that tonic dopaminergic signalling in the striatum may encode subjects' prior beliefs about the precision of their policies; i.e. their initial confidence that their actions will achieve their goals, and hence the degree of stochasticity of subsequent actions.

**Abstract:** Dopamine dysfunction is central to psychotic disorders, which are characterized by cognitive and perceptual abnormalities. An intriguing hypothesis is that dopamine may be critical for processing epistemic value, or the meaningful information content of observations, which drives adaptive belief updating about the (hidden) states of the world. To test this hypothesis, 39 healthy subjects (mean age 26y, 22 male) performed an fMRI task that allowed us to decompose sensory information into information-theoretic surprise (reflecting unexpected but not necessarily meaningful information content) and Bayesian surprise (reflecting actual shifts in beliefs due to meaningful information). Trial-wise regressors for information-theoretic and Bayesian surprise were generated by fitting a computational model based on Bayesian belief updating to individual subjects' behavior (model $R^2$= .67). 36 subjects also had a [$^{11}$C]-(+)-PHNO PET scan to quantify dopamine 2/3 receptor (D2/3R) availability in the substantia nigra/ventral tegmental area (SN/VTA) and ventral striatum (VS). 17 subjects had a second PET scan 3 hrs following 0.5mg/kg oral amphetamine, to quantify striatal dopamine release capacity. In line with previous findings, Bayesian surprise was encoded in the SN/VTA and VS, putatively reflecting dopaminergic activity. The SN/VTA BOLD signal effect size correlated negatively with SN/VTA baseline D2/3R availability (rho = -.43, P=0.009), consistent with studies indicating that D2/3R act to inhibit midbrain dopamine neurons. VS activation correlated negatively with VS amphetamine-induced dopamine release (rho = -.66, P=0.005), indicating that subjects with high dopamine release capacity (as is also found in schizophrenia) showed blunted striatal activation in response to belief-changing information. Information-theoretic surprise was encoded by a network including the supplementary motor cortex and anterior insula, and showed no association with D2/3R availability or dopamine release. Our results indicate that the dopaminergic SN/VTA and VS are involved in processing the meaningful information (epistemic value) of observations, as reflected in Bayesian belief updating. They provide further evidence that (unsigned) belief updates depend on dopaminergic activity, at variance with classical interpretations of dopamine function in terms of (signed) reward prediction errors. This is highly relevant for theories of aberrant belief formation in psychosis, which posit that mesostriatal dopamine dysfunction results in the formation of false beliefs about the causes of sensory information, leading to hallucinations and delusions.

**Title:** Emergent oscillations in the subthalamic nucleus of a simulated basal ganglia

**Authors: *T. M. SHEA**, J. J. RODNY, A. S. WARLAUMONT, D. C. NOELLE
Cognitive and Information Sci., Univ. of California, Merced, Merced, CA

**Abstract:** The subthalamic nucleus (STN) has been shown to support conflict resolution during perceptual and cognitive decisions by indirectly inhibiting motor responses. Excitatory efferent synapses of the STN modulate the overall inhibitory output of the internal segment of the globus pallidus (GPi). During a high conflict perceptual decision (e.g. flanker task) or an interrupted response (e.g. stop signal task), local field potentials (LFP) recorded from the STN exhibit increased power in the theta and beta bands and increased theta-locked neuronal firing. However, the mechanisms contributing to conflict-related oscillations measured in the STN remain unclear. We propose low signal-to-noise ratio stimuli (high conflict) fail to suppress noise-evoked activity, leading to widespread neuronal synchrony.
We simulated a thalamic-cortical-basal ganglia network with 6,000 spiking neurons and ~500,000 synapses. Connectivity in the model was based on linear topology, such that neurons in the GPi performed off-center, on-surround signal selection of the associated thalamocortical loop. To our knowledge, this is a novel use of topological connectivity in a spiking neural network to explain conflict-related oscillations. We injected Gaussian-shaped “bump attractor” stimuli into the model thalamus and randomly varied the stimulus signal-to-noise ratio while recording the ratio of stimulus-evoked action potentials to noise-evoked action potentials.
We identified two distinct classes of response in our results, corresponding to low and high conflict stimuli. The threshold between low and high conflict stimuli was not built into the model, but emerged from the interactions between neuronal populations. During low conflict stimuli, the model exhibited robust noise suppression and weak oscillations. For high conflict stimuli, noise suppression was delayed or inadequate. High conflict stimuli induced greater power in the simulated LFP of STN in theta and beta bands. These oscillations emerged when the injected stimulus was insufficiently strong to overcome inhibition via the hyperdirect pathway. In simulations with the GPi output disabled, both low-conflict noise suppression and high-conflict oscillations were eliminated.
These results indicate a potential mechanism for the emergence of conflict related oscillations due to the topology of the direct, indirect, and hyperdirect pathways. This mechanism supports recent work on neuronal ‘communication through coherence’ and entrainment to STN

oscillations. Importantly, the model demonstrates that oscillations emerge without intrinsic neuronal dynamics (e.g. bistability) or local recurrent circuits.

**Abstract:** Disruption of the synaptic balance between excitation and inhibition (E/I balance) in cortical circuits is a leading hypothesis for pathophysiologies of neuropsychiatric disorders, including schizophrenia and autism. Disrupted E/I balance is generally linked to arising cognitive deficits, such as impaired decision making. However, a mechanistic understanding is lacking for how E/I disruptions at the synaptic level may induce cognitive deficits at the behavioral level.
To investigate these issues, we studied how altered E/I ratio may impair perceptual decision making in a biophysically-based computational model of an association cortical circuit. We perturbed E/I balance in the model bidirectionally through hypofunction of NMDA receptors at two sites: on inhibitory interneurons (elevating E/I ratio via disinhibition), or on excitatory pyramidal neurons (lowering E/I ratio). We found that both elevated and lowered E/I ratio can similarly impair decision making, as assessed by standard psychometric performance, following an inverted-U dependence.
Nonetheless, these distinct E/I perturbations differentially alter how perceptual evidence is

accumulated over time in the circuit. Under elevated E/I ratio, decision making is impulsive: evidence early in time is weighted much more than late evidence. Under lowered E/I ratio, decision making is indecisive: evidence integration and winner-take-all competition between options are weakened overall. The time course of evidence accumulation can be characterized using multiple psychophysical task paradigms, which provide dissociable predictions at the behavioral level.
These results are well captured by an extended drift-diffusion model, which is modified so that integration is imperfect via a self-coupling term: impulsive decision making under elevated E/I ratio is captured by unstable integration, and indecisive decision making under lowered E/I ratio is captured by leaky integration. This link to the psychological drift-diffusion model provides theoretical insight and allows fitting to experimental results.
In general, our findings characterize critical roles of cortical E/I balance in cognitive functions, and the utility of timing-sensitive psychophysical paradigms. Our model makes specific predictions for behavior and neural activity that are testable in humans or animals under causal manipulations of E/I balance and in disease states. Furthermore, they provide a testbed for Computational Psychiatry demonstrating that neural circuit models can play a translational role between basic neurophysiology and clinical applications.

**Abstract:** In series of recent models we have targeted the neural dynamics of cortico-striatal circuits and analysed the way their multistable dynamics are affected by aberrant learning (as e.g. in addiction). These models predict that the amount of information required to change policy or

action strategy, adapting to a changing environment, can be used as a measure of the transient dynamics characterising cortical striatal circuit. We hypothesize that the ventral cortico-striatal circuit is involved in conditions of greater uncertainty, as it is dedicated to forward planning. To test this hypothesis, we have designed a novel *3-option continuous bead task, based on* a well-established decision making task (the bead task), to allow a precise manipulation of conditions of uncertainty and evidence accumulation. In each trial, a coloured bead is extracted from one of three jars containing beads of three colours (visible ratio of 80%-10%-10%). The participants have to decide from which jar each bead is extracted from. No feedback is provided after each decision, but the participants can estimate the source of each bead based on the last few extractions, which are shown on screen. This design was used to compare *low uncertainty* (3 or more repeated extraction of beads of the same colour), *moderate uncertainty* (two repeated extractions) and *high uncertainty* (an new colour extracted after a series of 3 or more). We assessed this task in an fMRI study with healthy volunteers. First, we found significant activity in nucleus accumbens and ventromedial prefrontal cortex, when contrasting trials with moderate uncertainty vs. trials with low uncertainty. Second, we found a trend highlighting increased activity in the insula and nucleus accumbens when comparing trials of high uncertainty vs trials with low uncertainty. These results suggest a single trial of confirming or conflicting evidence has clear-cut effects in terms of neural activity. We hypothesise the activity of the ventral circuit drops as a direct function of uncertainty because confirming information can be largely ignored in forward planning. Conversely, unexpected information is mediated by insula and nucleus accumbens, to signal mismatch in predicted information and saliency, even in the absence of a reward. We hypothesise these systems jointly signal a new cycle of evidence has to be taken into account. In the continuous sequence of confirming and conflicting information offered by the task, the ventral circuit is only reactivated by accumulating confirming evidence (i.e. two beads of the same colour), which allow planning future actions rather than performing random choice selections.

**Title:** Toward a proof of concept for neuroimaging-based financial-system regulation: Near-infrared spectroscopy (NIRS)-recorded lateral neocortical activity in lab markets with monotonically decreasing or peaked fundamental values

**Authors: *J. L. HARACZ**
Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

**Abstract:** Objective: To build an experimental design that could yield a proof of concept for neuroimaging-based financial-system regulation, the present review aims to: 1) find evidence that near-infrared spectroscopy (NIRS) could detect low lateral neocortical activity as an asset-price bubble biomarker and 2) seek a lab-market paradigm that could model the uncertainty that financial-system regulators have about whether rising asset prices represent a bubble.
Methods: A systematic literature review focused on NIRS and lab-market studies to develop the above experimental design.
Results: NIRS-recorded prefrontal cortical activity was higher in the "cold" deliberative version of the Columbia Card Task (CCT) compared to the "hot" affective CCT version (Holper & Murphy, 2014). These results suggest the use of NIRS to detect low lateral neocortical activity as a bubble biomarker, consistent with the hypothesis that evolutionarily ancient or new neurocircuitry, respectively, drives decision making during bubble or non-bubble periods of financial market activity (Haracz, 2013). A proof of concept for using this biomarker in a financial-system regulatory setting would be enabled by designing a lab-market paradigm that reliably generates asset-price increases during either bubble or non-bubble market periods, thereby modeling the above regulators' uncertainty. Two versions of a well-studied continuous double auction paradigm (Smith et al., 1988) could be used: assets in standard (S) lab markets would have a monotonically decreasing fundamental value that typically yields price bubbles (Smith et al., 1988), whereas assets in peaked (P) markets would have a fundamental value that peaks (i.e., rises in early periods of asset trading and falls in later periods [Noussair & Powell, 2010]). In P markets, asset prices tend to closely track fundamental value, so no bubble is yielded typically. This tendency could be strengthened by adjusting subjects' cash and asset endowments. Price peaks represent a bubble in S markets, but not in P markets. A subject acting as a regulator could observe computer-displayed NIRS-recorded lateral neocortical activity from asset-trading subjects along with ongoing asset prices and trades, but the omission of fundamental values would blind the regulator to whether markets are S or P. Therefore, the regulator would be trained to use NIRS data (i.e., low lateral neocortical activity) to detect bubbles and implement asset-holding caps (Lugovskyy et al., 2014) to deflate bubbles, thereby yielding a proof of concept for neuroimaging-based financial system regulation.
Conclusion: NIRS and lab market studies could yield the above proof of concept.

**Title:** Single molecule fluorescence *In situ* hybridization in the mouse retina

**Authors: *M. THOMSEN**[1,2], M. VISWANATHAN[2], H. ZHAO[2], S. HATTAR[1]
[1]Section on Light and Circadian Rhythms, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Biol., Johns Hopkins Univ., Baltimore, MD

**Abstract: Purpose** High-throughput transcriptomic data sets often yield hundreds of interesting candidate genes for further study, but confirmation of this data in vivo often relies on methods of in situ hybridization that are time-consuming and technically challenging. To facilitate rapid, robust screening of gene targets from transcriptomic studies, we have adapted a protocol for single molecule fluorescent in situ hybridization (smFISH) for use in whole-mount mouse retinas. smFISH requires less than half the time of conventional in situ hybridization protocols and permits single transcript resolution and quantitation. **Methods** We used computational methods to design a library of 20-30mer oligonucleotide probes that tile >100 mRNA sequences of interest with minimal off-target binding. Each probe was flanked by universal primer sequences and gene-specific orthogonal priming sequences that permit amplification of probe sets for a single gene from the library. The total library of >12,000 oligos was chemically synthesized and suspended in a small volume of TE buffer. Probe sequences for each gene were amplified from the library using several rounds of PCR with gene-specific primers. Following amplification of probes for each gene, antisense fluorescent oligonucleotide probes were generated by PCR with fluorophore-coupled primers. Freshly dissected mouse retinas were quartered and lightly fixed in 4% PFA then permeabilized in 0.5% TritonX-100/PBS. Following permeabilization retinas were incubated overnight with fluorescent probes in hybridization buffer. After hybridization, retinas were washed several times in 10% formamide/2XSSC, mounted, and imaged immediately. **Results** smFISH robustly labeled transcripts in the ganglion cell layer (GCL) of mouse retinas with little background fluorescence. Individual transcripts for more than 20 genes were visualized and quantified. **Conclusions** We have optimized a method of smFISH for rapid and reliable detection of individual mRNA transcripts in the mouse retina. This method has significant advantages over conventional in situ hybridization including shortened protocol time, single transcript resolution, and improved reliability.

**Authors: *A. LAEREMANS**, N. LI, E. PARK, X.-J. MA, N. SU
Advanced Cell Diagnostics, Newark, CA

**Abstract:** Recently, a universal class of endogenous noncoding RNAs that is generated by "head-to-tail' splicing has emerged as a new promising type of RNA with biomarker potential. This particular spicing event results in the covalent linkage of the 5' end of one exon with the 3' end of another exon and creates stable single-stranded circular RNA molecules (circRNA) in eukaryotes. These highly conserved circRNAs are characterized by tissue- and developmental stage-specific expression patterns. More specifically, it was recently shown that circRNAs are particularly enriched in the brain where they are often derived from genes that code for synaptic proteins, and with expression dynamics independent of the linear mRNA transcripts. Although abundantly expressed in the nervous system, their function remains largely unknown. Also, evidence has emerged across different fields that pinpoints a role for circRNAs in various diseases, including cancer, possibly by regulating gene expression levels through interaction with other molecules (eg. miRNAs). Therefore, the accurate detection and localization of circRNAs is a key factor to elucidate their functions especially given the fact that they could serve as putative clinical biomarkers. BaseScope™ is a novel *in situ* hybridization technology that allows the visualization of specific exon-exon and exon- (retained) intron junctions in a highly specific and sensitive manner in cells and tissues. Besides the robust identification of splice junctions, BaseScope™ *in situ* hybridization also provides high resolution single-cell spatial information within the morphological tissue context. To illustrate the strength of this BaseScope™ application for the intriguing field of circular RNAs, we present the specific anatomical localization and cellular distribution of various brain plasticity-related targets including the Alzheimer's disease-related *Dlgap1* gene. For these targets their circRNA and linear mRNA counterpart are visualized supplemented with the corresponding quantification in P1, P10 and P30 C57Bl/6J mouse brains.

**Title:** Sequencing and proteomic approach illuminates mRNA and protein isoform diversity and their contributions to neural development and disease

**Authors: *T. RAY**[1], K. J. COCHRAN[2], W. J. SPENCER[3], G. ALEXANDER[4], N. SKIBA[5], J. N. KAY[6]
[2]Computer Sci., [3]Pharmacol., [4]Genomic and Computat. Biol., [5]Opthalmology, [6]Neurobio., [1]Duke Univ., Durham, NC

**Abstract:** Alternative splicing and alternative promoter usage are two mechanisms by which single genes can encode multiple protein isoforms. These processes are capable of exponentially increasing the functional capacity of the genome, because they can generate protein variants with distinct interaction partners and hence distinct functions. For these reasons alternative splicing of cell-surface receptors is an appealing mechanism to pursue how neurons communicate during development to set up highly specific synaptic connections. Despite mounting evidence that isoform diversity is critical to neural circuit formation, this diversity is still widely disregarded in gene expression and protein function studies, leading to inaccurate characterizations of gene function. One reason for this problem is the lack of tools for cataloging isoforms at the mRNA and protein level. While high throughput RNA sequencing has become commonplace, the short reads generated in typical RNAseq create an incomplete representation of the transcriptome, making subsequent gene isoform analyses dependent on computational assembly of transcripts—a problematic approach. Consequently, incomplete cataloguing of gene isoforms results in incomplete predicted protein libraries, thereby hindering protein identification using mass spectrometry.
Here we describe an experimental and bioinformatic workflow to overcome these limitations. First, we analyzed standard RNAseq data and identified cell-surface receptors with unannotated high isoform diversity in developing mouse retina. Of these, 31 were chosen for targeted single molecule PacBio sequencing, which yields long reads and therefore permits full-length isoform identification. We sequenced developing and adult retina to identify isoforms that correlate with key neural developmental hallmarks. Bioinformatics tools (Iso-Seq, ToFU) were used to

catalogue isoforms, and molecular tools were used to verify temporal (RNAseq, qPCR) or spatial (BaseScope in situ hybridization) expression of isoforms in the retina. The catalog of full-length PacBio-sequenced isoforms was used to generate an in silico protein library of unannotated "dark" isoforms (i.e. isoforms absent from RefSeq based libraries). Then we performed mass spectrometry on cell-surface protein preparations from retinal tissue,and searched for novel protein isoforms using our library. This pipeline proved robust in identifying novel cDNA isoforms that are translated into protein. We found a surprising number of "dark" isoforms, many of which are positioned to diversify the functions of genes known to influence retinal development and disease.

**Abstract:** The rodent hippocampus is generally described as being functionally segregated along the septotemporal axis. However, the specific delineations used to define subregions along this axis are not consistent, and current anatomic, genetic, and physiological data propose varying categorizations. In this study, we used the neural activity dependent immediate-early gene (IEG) *Homer1a* (*H1a*) to map the behaviourally induced putative activity of neurons along the septotemporal axis of CA1.
While electrophysiological studies suggest a continuously decreasing gradient in the proportion of active cells from septal to temporal areas, our IEG expression data indicate that hippocampal modules can be classified as a domain with no gradient in the septal half of CA1, an abrupt drop in IEG expressing cells in intermediate CA1 and an substantial increasing gradient from intermediate to temporal CA1. The increase in the temporal direction corresponds roughly to amygdalar input to CA1, with increasing IEG expression corresponding to increasing amygdalar input in temporal areas; however, further experiments will be needed to determine the basis for this pattern of functional topography.

**Authors: *T. TA**, M. K. KEAVENEY (SAYEG), X. HAN
Biomed. Engin., Boston Univ., Boston, MA

**Abstract:** Genetic modifications to specific neural subsets allow for the discovery of their functional role(s) in the brain. We recently developed microRNA-guided neuron tags (mAGNETs) as a novel strategy for targeting viral transgene expression to neuronal subtypes by exploiting endogenous microRNA (miRNA) regulation. We previously demonstrated that the mAGNET technique is capable of targeting inhibitory cells in the cortex of mice at ~82% targeting rate, when packaged in lentivirus. Since this preliminary study, we have been able to improve the targeting rate in mice to >90% by incorporating a different promoter, and >95% by packaging in adeno-associated virus (AAV). We additionally tested these GABA targeting mAGNETS in rats, and found that they successfully targeted inhibitory neurons in the cortex, although not as efficiently as in the mice. Altogether, these optimized mAGNETs provide a novel method of virally targeting cortical inhibitory neurons in the rodent brain.

**Abstract:** Adult neurogenesis supports performance in many hippocampal dependent tasks. Recent studies have demonstrated that adult born neurons exhibit heightened excitability and plasticity during a critical developmental period, which may be essential for their contribution to certain tasks. However, it remains largely unknown how these unique biophysical and synaptic properties may translate to networks that support behavioral function. Recently, we transiently silenced adult born neurons at different ages using optogenetics while mice were performing a location discrimination task. We discovered that adult-born neurons promote location discrimination during early stages of development, but only if they undergo maturation during task acquisition. Optogenetic silencing of young adult-born neurons also produced changes extending to the contralateral hippocampus, detectable by both electrophysiology and fMRI measurements, suggesting young neurons may modulate location discrimination through influences on bilateral hippocampal networks. To further explore how synaptic integration of young neurons influences their network and behavioral impact during the critical period, we developed novel optogenetic tools to tag synapses, and tracked synaptic integration of adult born neurons throughout their maturation period.

**Title:** Transcription architecture of synaptic connectivity and signaling underlies cortical GABAergic neuron identity

**Authors: *A. PAUL**[1], M. CROW[2], J. GILLIS[2], Z. HUANG[3]

**Abstract:** Understanding the biological basis of neuronal identity is necessary to decipher brain cell diversity towards discovering the organization logic of neural circuits. Here, through single cell transcriptome analysis of phenotype-defined cortical GABAergic neurons and a computational genomic screen for transcription profiles that jointly distinguish them, we have discovered the transcriptional architecture of cardinal neuron types and subpopulations. This genetic architecture encodes neuronal connectivity and input-output properties and consists of functionally congruent gene families that include cell adhesion molecules, transmitter-modulator receptors, ion channels, membrane-proximal signals protein, neuropeptides and vesicular release components, and transcription factors. Combinatorial and coordinated expression of select members across these families shapes a multi-layered and coherent molecular architecture along cell membrane, thereby customizing the patterns and properties of synaptic communication. This molecular genetic framework of core neuronal identity integrates, explains and predicts cell phenotypes along multiple axes and provides a foundation for cell type discovery and classification.

Col. of Med., Tallahassee, FL; [4]Sch. of Big Data, Fudan Univ., Shanghai, China; [5]Departments of Statistics and Finance, Princeton Univ., Princeton, NJ; [6]Florida State University, Col. of Med., Tallahassee, FL

**Abstract:** We set out to identify candidate genes that are either “controllers” of region specific gene expression in the adult mouse brain or that are proximally controlled by “controllers”. For this identification we used a large dataset consisting of transcriptomic (RNA-seq) data from 4 brain regions, cerebellum, hypothalamus, hippocampus and neocortex, with an n of 12 for each brain region. As a first step towards identifying the “controller” genes, we hypothesize the existence of “switched” genes, defined as genes which exhibit an on/off pattern of expression. We specify that on/off transcripts have only two levels, an “off” state that is indistinguishable from zero expression and an “on” state that is statistically greater than the “off” state and which also is not different statistically among the brain regions that are not “off”. Note that this on/off definition delimits only a small proportion of the transcripts that are differentially expressed. For example, we define hi/lo transcripts as having a non-zero low state, i.e., the low state is significantly greater than zero expression, and many transcripts have more than two levels of expression. We identified on/off switched genes using ANOVA/GLM (with Benjamini-Hochberg FDR corrections) followed by all 6 possible pair-wise post-hoc tests and also with genome wide criteria for specifying the “zero level” of expression”. This is possible because of the small number of brain regions analyzed and the power contributed by the 12 replicates. With only 6 pair-wise combinations a pattern matching approach is both feasible and exhaustive, i.e., statistical criteria can be specified that allows all transcripts in the dataset to be assigned to the “on/off” switched type or not. For the transcripts with only 2 levels of expression regression analysis of the minimum expression level vs the maximum expression level for each transcript shows that there is an inverse relationship ($r=-0.69$; $p<10^{-100}$) between the step-size (i.e., the difference between the on-state expression and the off-state expression) and the minimum level of expression. Some of the transcripts with the lowest off-state expression levels showed increases of over 1,000-fold in the on-state. A pattern analysis of the post-hoc comparison results

shows that on/off switched transcripts exist for all possible combinations of the 4 brain regions analyzed, i.e., on/off in 1/3, 2/2, or 3/1 tissues. Approximately 25% of the on/off transcripts are transcription factors. A preliminary evaluation of the tissue specificity of the on/off transcripts using the Allen Brain Atlas indicates that they are not only brain region specific but also cell type specific.

**Abstract:** The expression of select genes at specific times in appropriate neurons is required for brain development and function. *Drosophila* has emerged as an important model system to identify the gene networks underlying neuron types and functions. However, existing approaches that quantify gene expression using sequencing methods mainly rely on isolated cell populations, in which neurons are extracted from their native context. RNA fluorescent *in situ* hybridization (FISH) is a powerful technique that allows measuring mRNA levels with subcellular resolution within preserved tissue, but its application to adult *Drosophila* brains has proved difficult due to limited probe penetration and sample autofluorescence. Here, we describe a FISH method that permits detection of the localization and abundance of single mRNAs in cleared whole-mount adult *Drosophila* brains. The approach is specific, rapid, quantification with subcellular resolution on a standard confocal microscope. We further demonstrate single-mRNA detection across the entire brain sample using a custom Bessel Beam-Structured Illumination microscope (BB-SIM). We anticipate this method will constitute an important tool for addressing the cellular and molecular basis of brain function.

**Title:** Overexpression of miR-200a in the regulation of Keap1 < Nrf2 mRNA expression > spinal cord motor neuron cell lines

**Authors: *D. WIWATRATANA**[1], W. D. ATCHISON[2]
[1]Comparative Med. and Integrative Biol., Michigan State Univ., East Lansing, MI; [2]Dept Pharmacol & Toxicol, Michigan State Univ. Dept. of Pharmacol. and Toxicology, East Lansing, MI

**Abstract:** One pathogenic mechanism occurring in several neurodegenerative diseases is associated with the perturbation of cellular oxidative stress and antioxidants. Nuclear factor-erythroid-2-related factor 2(Nrf2) is a transcription factor responsible for inducing several cellular antioxidants. The functional activity of Nrf2 is negatively regulated by Kelch-like ECH-associated protein 1(Keap1) which sequesters Nrf2 in the cytoplasm and undergoes Nrf2-ubiquitin proteasome degradation. To defend against oxidative stress, reducing the Keap1 protein could be a potential target to enhance Nrf2 activity. A small non-coding RNA called microRNA plays a role in the regulation of mRNA expression by complementarily binding to target mRNAs. It has been reported that miR-200a regulates Nrf2 and Keap1 expression in human breast cancer cell lines. In this study, the miR-200a, regulated by tetracycline promotor, was transduced by lentivirus into the neuroblastoma spinal cord cell line 34 (NSC34), a motor neuron cell line. A treatment of 1µg/ml of doxycycline (Dox) was introduced to regulate the expression of miR-200a. The majority of the NSC34 clones (5 out of 7) indicated the upregulation of miR-200a after 48h of 1µg/ml Dox application. The expression of Keap1 and Nrf2 mRNAs were inconsistent among these 7 clones. However, the clone with the highest level of miR-200a expression (3.14 fold of induction) indicated the down regulation of Keap1 (0.9 fold of induction) and upregulation of Nrf2 mRNA (1.4 fold of induction). The discrepancy of Keap1 and Nrf2 mRNA expression between these clones could be due to, 1) the location of the miR-200a integration into the chromosome, 2) the timing of miR-200a regulation of the Keap1 mRNA expression and 3) the timing to regulate Nrf2 activity after Keap1 knock down. This research is supported by NIH grant R01 ES024064.

**Title:** Targeting dopamine progenitors with *In utero* electroporation in mice

**Authors: *J. P. KESBY**[1,2], R. SUÁREZ[1], D. W. EYLES[1,3]
[1]Queensland Brain Inst., St. Lucia, Australia; [2]UQ Ctr. for Clin. Res., Univ. of Queensland, Brisbane, Australia; [3]Queensland Ctr. for Mental Hlth. Res., Wacol, Australia

**Abstract:** Schizophrenia is a chronic psychiatric disorder with a poorly understood aetiology. Altered brain function and psychotic symptoms present prior to disease onset suggesting a developmental origin. Dopamine is a neurotransmitter that has been implicated in the cause and treatment of schizophrenia and thus represents a core developmental drug target in schizophrenia. Understanding the consequences of altered dopamine neuron development requires the use of techniques that allow for the specific manipulation of dopamine progenitors in the embryonic brain. We are developing a protocol using in utero electroporation that will allow for the transfection of small interfering RNA (siRNA) to dopamine neurons in mice. A reporter plasmid encoding a yellow fluorescent protein was injected into the mesencephalic ventricle of e11 mice embryos. Electroporation was accomplished using a triple electrode configuration. The head of each embryo was held between two positive circular electrodes, positioned laterally but ventral to the floor plate, with a third negative electrode held dorsal to the embryo head to generate a ventral electrical field vector that transfects the plasmid into the ventral mesencephalon. We will present evidence using immunofluorescence microscopy that demonstrates the specific transfection of dopamine progenitors in the ventral mesencephalon. These data suggest the targeting of developing dopamine neurons early in development is possible with the use of in utero electroporation. Furthermore, this work demonstrates the feasibility of future experiments transfecting siRNA against dopamine differentiation factors in the embryonic mouse brain. When combined, the use of targeted in utero electroporation and siRNA will allow us to gain a better insight into the role of specific differentiation factors in dopamine neuron development.

**Abstract:** Mutations in *MECP2* cause Rett syndrome (RTT), an X-linked neurological disorder characterized by regressive loss of neurodevelopmental milestones and acquired psychomotor deficits. However, the cellular heterogeneity of the brain impedes understanding of how *MECP2* mutations contribute to RTT. We therefore developed cell type-specific biotin tagging of MeCP2 in mice bearing RTT-associated mutations and profiled their nuclear transcriptomes. Although most gene expression changes are largely specific to each mutation and cell type, lowly expressed cell type-enriched genes are preferentially disrupted by MeCP2 mutations, with upregulated and downregulated genes reflecting distinct functional categories. Subcellular RNA analysis in MeCP2 mutant neurons further reveals reductions in the nascent transcription of long genes and uncovers widespread post-transcriptional compensation at the cellular level. Finally, we overcame cellular mosaicism in female RTT models and identified distinct gene expression changes between neighboring wild-type and mutant neurons, altogether providing contextual insights into RTT etiology that support personalized therapeutic interventions.

**Authors: J.-H. CHOI**, E. DUBOUÉ, J. CHANCHU, *M. E. HALPERN
Carnegie Instn for Sci., Baltimore, MD

**Abstract:** The bilaterally paired dorsal habenulae (dHb) are part of an evolutionarily conserved pathway that connects telencephalic nuclei to the midbrain interpeduncular nucleus (IPN). In zebrafish, the left and right dHb differ in their size, molecular properties, neuroanatomical organization, and connectivity. Previous studies have demonstrated that the dHb contain a number of specialized neuronal populations, including those producing acetylcholine, substance P and somatostatin. Connections between dHb neuronal subtypes and subregions of the IPN have not been well-defined. To produce a precise dHb-IPN connectivity map, we are generating transgenic lines that label specific neurotransmitter and neuropeptide cell populations using CRISPR/Cas9-mediated integration. We have introduced the QF transcription factor of *Neurospora crassa* into genes whose expression demarcates specialized dHb cell types. These lines can be used to drive expression of a variety of QUAS- regulated reporter and effector transgenic lines, enabling tracing of neuronal processes, optogenetic activation or calcium imaging. For example, we identified a small, cholinergic neuronal cluster in the right dHb that is preferentially innervated by bilaterally projecting olfactory neurons. This distinct cluster of dHb neurons projects to a sub-region of the ventral IPN. Identification of the olfactory cues that modulate these right dHb neurons will help elucidate the function of this asymmetric neural circuit.

**Title:** The issue of cross-contamination with Affymetrix's ViewRNA© *In situ* hybridization histochemistry procedure: Work around and other tips

**Authors: *S. YOUNG**, J. SONG
Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract:** The advent of sensitive non-radioactive in situ hybridization histochemistry (ISSH) procedures has enabled rapid and sensitive exploration of gene expression in the brain and other tissues (Young et al., 2015). Two, in particular, are being used based on the same original patent employing multiple pairs of probes to reduce background upon which the amplification is built: ACD's RNAscope© and Affymetrix's ViewRNA©. These procedures also enable duplex and even multiplex detection of transcripts in the same sections.
We began to use ViewRNA© to perform duplex ISHH to explore expression of various genes in the CA2 area of the hippocampus. The ViewRNA© duplex technique on tissues uses two type of probes that visualize alkaline phosphatase deposition: Type 6 that are developed using Fast Blue followed by Type 1 that are developed using Fast Red. These reagents generate blue visible and far red fluorescent colors followed by red visible and red fluorescent colors, respectively. We became concerned that the Fast Blue color was being deposited inappropriately on the Type 1 probes in addition to the appropriate Type 6 probes. We assured ourselves that this was not a problem with our fluorescent filter cube sets (TRITC: EX->511-551, EM->573-613; Far Red: EX->610-640, EM->750-810) as single probe ISHH show no bleed-through of Type 6 blue development into the TRITC channel and vice versa.
We discovered that if, instead of following the manufacturer's recommendation to develop the Type 6 probe before the Type 1 probe, we reversed the order, we had no cross-contamination (on either probe type). The resultant duplex ISHH looked like the expected summation of the two individual ISHH. We have seen this phenomenon now with several different Type 6/Type 1 pairs. We will present speculations as to the cause of this cross-contamination as well as other tips to get the most out of this powerful technique.

**Title:** Methodology for building Nissl stain and cell type-based brain atlases for vertebrate species

**Authors: *R. MUÑOZ CASTAÑEDA**, K. UMADEVI VENKATARAJU, M. BOTA, P. OSTEN
Cold Spring Harbor Lab., Cold Spring Harbor, NY

**Abstract:** We consider cell types to be the elementary building blocks of the brain, as they determine the properties of local circuits that can be built to serve the area-specific brain functions. While, there is a growing knowledge of cell type-specific cell anatomy in the mouse brain, there are virtually no data on quantitative, brainwide cell-type distribution in any other vertebrate species. Yet, it seems clear that knowing cell type distributions across brains of a broad range of species would greatly advance our understanding of how neuronal populations combine to form local and long-range circuits that give rise to structure-specific and, in some cases, species-specific brain functions.
Here we describe a set of anatomical tools, initially developed in our laboratory for the study of mouse brain anatomy, which form a versatile methodological pipeline for the generation of Nissl stain-based 3D brain atlases and tissue autofluorescence-based 3D reference brain volumes for data registration and quantification. The creation of the Nissl stain-based brain atlases is based on modifications of the iDISCO+ protocol (Renier et al. 2016). Thereafter, the samples are imaged by Serial Two Photon Tomography (STPT) (Ragan et al 2012), which generates complete brain volumes with minimal tissue distortions. The tissue autofluorescence-based brain volumes are generated by STPT and light sheet fluorescence microscopy (LSFM), resulting in the generation of brain volumes with detailed anatomical features that can be used for automated and precise data registration. Finally, the cell type maps are generated using iDISCO+ immunostaining with antibodies against cell type-specific protein markers. This methodology is applicable for brain atlasing and cell type mapping across a broad range of vertebrate species.

**Title:** Interrogating the logic of neuronal projections using *In situ* barcode sequencing

**Authors: *X. CHEN**[1], J. M. KEBSCHULL[1,2], H. ZHAN[1], G. M. CHURCH[3,4], J. H. LEE[1], A. M. ZADOR[1]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Watson Sch. of Biol. Sci., Cold Spring Harbor, NY; [3]Wyss Institute, Harvard Med. Sch., Boston, MA; [4]Dept. of Genet., Harvard Med. Sch., Boston, MA

**Abstract:** Cortical neurons in a single area project to diverse targets in the mammalian brain. These neuronal projections form the structural basis for information flow within and out of the cortex. Several major classes of cortical projection neurons project to various targets, but individual neurons project to only a subset of the targets predicted by the classes. Single-neuron tracing experiments can resolve projection patterns at cellular resolution, but the throughput of most methods is too low to allow for the statistical analysis of the organization of projections. To infer the logic behind the organization of cortical projections of single neurons, we therefore developed a highly-multiplexed technique that maps single-cell projections *in situ*. We have previously presented MAPseq, which allows for massively parallel neuronal projection mapping at single neuron resolution (Kebschull et al., 2016). In MAPseq, each neuron expresses a unique RNA sequence (barcode) that fills both the soma and the axons. By dissecting out the brain areas in interest and sequencing the barcode, we can thus read out the projection patterns of single neurons. MAPseq, however, does not preserve information about the precise spatial location of the neurons. To overcome this challenge, we have adapted *in situ* sequencing to efficiently read out RNA barcodes *in situ*. Combining *in situ* sequencing with MAPseq (*in situ* MAPseq), we were able to interrogate the projections and locations of thousands of neurons in mouse auditory cortex at cellular resolution. Each experiment requires about two weeks. We used hierarchical clustering to find clusters that correspond to known classes of projection neurons. The laminar

distribution of these classes was consistent with previous results. To look for subclasses beyond those that have previously been identified, we decomposed single cell projection patterns into linear combinations of groups of correlated projections, which we denote projection “modules”. The spatial distribution of neurons expressing certain modules was spatially more compact than neurons without these modules, indicating that modules also show laminar preference. Unlike the clusters, however, modules were non-exclusive, so that a given neuron can express more than one module. These results suggest that cortical projections are hierarchically organized with different rules at each layer. The methods presented here can be applied to any brain region, and will allow for the systematic analysis of projection patterns and spatial organization throughout the brain.

**Title:** Dissection of neural pathways using anterograde transsynaptic transfer of AAV1

**Authors: *B. ZINGG**[1], X.-L. CHOU[1], Z.-G. ZHANG[2], L. MESIK[1], F. LIANG[2], N. K. ZHANG[3], H. W. TAO[3], L. I. ZHANG[3]
[1]Neurosci. Grad. Program, [3]Zilkha Neurogenetic Inst., [2]USC, Los Angeles, CA

**Abstract:** To decipher neural circuits underlying brain functions, it is essential to map the input and output connectivity of specific neuronal populations, which is facilitated by applying viral tracers. Although retrograde transsynaptic viruses are widely used for identifying the presynaptic sources of transduced neurons, analogous anterograde transsynaptic tools for tracing neural pathways downstream of postsynaptically targeted neurons remain under development. Here, we explored the potential application of adeno-associated virus (AAV) for anterograde transsynaptic

mapping of brain circuits. AAV1-Cre from transduced presynaptic neurons effectively drove Cre-dependent transgene expression in selected postsynaptic neuronal targets, and thus allowed the tracing and functional manipulation of axonal projections from the latter input-defined neuronal population. Application of this tool in superior colliculus (SC) revealed that SC neuron subpopulations receiving different corticocollicular projections specifically drove different types of defense behavior. This anterograde transneuronal tagging is thus useful for the forward screening of distinct functional neural pathways embedded in complex brain circuits.

**Title:** The whole mouse brain-on-tape for volume electron microscopy and cellular connectomics

**Authors: *S. MIKULA**
Electrons - Photons - Neurons, Max-Planck Inst. For Neurobio., Martinsried, Germany

**Abstract:** The development of methods enabling the mapping of all synaptic connections between all neurons comprising an individual mammalian brain would lead to brain-wide circuit reconstructions that precisely define the neuronal networks underlying and responsible for generating the diverse behavioural repertoire for that individual. Recent advances in mouse whole-brain electron microscopic (EM) sample preparation (Mikula & Denk, 2015) and multi-beam scanning electron microscopy (mSEM, Kemen et al., 2015) have brought us closer to a complete mouse whole-brain cellular connectome.
Several obstacles remain, however. Here, I report on an approach using mouse whole-brain ultramicrotomy and serial-section SEM.
For serial sectioning, it is convenient to collect automatically cut sections on a tape conveyor belt (e.g., automated tape-collecting ultramicrotomy, or ATUM). Different tape substrates were tested for mouse whole-brain section collection, including Kapton, carbon nanotube-coated PET, and copper, iron and aluminum foils. Of these, aluminum foil was chosen due to its intrinsic electrical conductivity, low cost, low atomic number (which results in better EM contrast), thin passivation layer and long-term stability.
However, commercial ATUM systems damage aluminum foil during the course of section

collection and thus a custom section collection system was designed specifically to accommodate the collection of mouse whole-brain ultra-thin sections on aluminum foil. A working prototype consisting of two DC rotary motors, which actuated source and target tape reels, collected more than 5000 serial sections of mouse mid-sagittal sections at 80 nm thickness.
Serial section SEM indicates that sample membrane contrast and section thickness are sufficient for identifying matching neurites across adjacent sections. Synapses can be readily identified. Quantitative assessments of neurite traceabilty and synapse detection across the whole-brain serial sections are ongoing. Preliminary results suggest that the whole mouse "brain-on-tape" will be a useful tool for mouse whole-brain volume electron microscopy and cellular connectomics.

**Abstract:** The connections between neurons determine the computations performed by both artificial and biological neural networks. Recently, we have proposed SYNseq, a method for converting the connectivity of a biological network into a form that can exploit the tremendous efficiencies of high-throughput DNA sequencing. In SYNseq, each neuron is tagged with a random sequence of DNA-a "barcode"-and synapses are represented as barcode pairs. SYNseq addresses the analysis problem, reducing a network into a suspension of barcode pairs. Here we formulate a novel and complementary synthesis problem: How can the suspension of barcode pairs be used to "clone" or copy the network back into an uninitialized tabula rasa network? Although this synthesis problem might be expected to be computationally intractable, we find that, surprisingly, this problem can be solved efficiently, using only neuron-local information. We present the "one barcode one cell" (OBOC) algorithm, which forces all barcodes of a given

sequence to coalesce into the same neuron, and show that it converges in a number of steps that is a power law of the network size. Rapid and reliable network cloning with single synapse precision is thus theoretically possible.

**Abstract:** Deeper exploration of the brain's vast networks requires new tools for high-throughput structural and molecular profiling of the diverse populations of synapses that connect those networks. Immunofluorescence array tomography allows both structural and molecular discrimination, but depends critically on the availability of high-quality antibodies that are rigorously validated for this specific application. Evaluating large numbers of antibodies against the same target antigen for effective and specific immunolabeling of array tomography samples is a difficult and labor-intensive process that requires manual inspection of the images. Furthermore, determining which antibody is best suited for this purpose is a subjective process, with varying levels of agreement between different experts.
We propose instead to use an automatic query-defined probabilistic synapse detection algorithm to quantify the results of antibody screens. For each test, the user controls synaptic markers and marker puncta sizes to consider. This model-based algorithm incorporates fundamental biological knowledge of synapses and how they are manifested in the immunofluorescence data by the selected antibody being tested [1]. Using this algorithm, we consider the automatically-detected synapse densities and the background noise levels (both the noise floor and the number of false positive blobs) to evaluate the efficacy of each antibody.

We tested this approach on several different antibody datasets. Each dataset consisted of multiple antibodies against the same synaptic protein, imaged alongside one or more known synaptic protein antibodies. The proposed method correctly identified the top antibody each time, and correctly picked the top three antibodies 75% of the time (as determined manually by an expert). This approach opens the door for high-throughput antibody screening analyses, as well as for antibody quality control. All data, code, and data derivatives will be made available after publication.

**Abstract:** Mouse models are widely used in biomedical research, but do they provide a satisfactory model for Homo sapiens? Much of our current understanding of the molecular basis

of neuropsychiatric diseases is based on studies in rodents, but surprisingly little is yet known about the similarities and differences between the synapses of mice and men, though this knowledge will be a crucial step toward developing new drugs directed at synaptopathies. The introduction of array tomography enables acquisition of hyperspectral proteometric data, allowing identification of multiple synapse subtypes in both mouse and human tissue, critical data that can allow this comparison.
We had previously developed an automated query-defined probabilistic synapse detection algorithm and validated it in mouse brain tissue [1]. We now show that this algorithm performs equally well on human tissue obtained from brain surgeries, and use it to quantify similarities and differences between human and mouse synapses, with a focus first on excitatory glutamatergic synapses in neocortex.
Our results show that excitatory synapse sizes and densities differ between mouse and human neocortex, with human synapses being larger and sparser. However, many of the correlations between the size of synapse postsynaptic densities and their AMPA and NMDA receptor content, previously documented in rodents, also hold true for human cortical synapses. We further refine this comparison by including variables such as the type of vesicular glutamate transporter present in the presynaptic bouton, the abundance of mitochondria, and the type of postsynaptic target. This computational approach opens a door to thorough comparison between human and animal model synapses, as well as to a data-driven discovery of novel synaptic arrangements in human brain. The methods developed for this application are readily applicable to other datasets. All data, code, and data derivatives will be made available after publication.

**Title:** SMLocalizer, a CUDA based ImageJ plugin for PALM/STORM data analysis

**Authors: *H. BRISMAR**, K. BERNHEM, L. WESTIN
Applied Physics, KTH, Royal Inst. of Technol., Stockholm, Sweden

**Abstract:** Single molecule localization microscopy (SMLM) has in the last decade been developed as an important technique for diffraction unlimited microscopy. Super resolution imaging is here achieved by a combination of switching fluorophore molecules and mathematical analysis software. A challenge for the non-expert user is the complexity of the computational analysis with a multitude of input parameters. Many algorithms and methods have been developed, often specific for a particular variant of SMLM.
Here we present a software solution, SMLocalizer, which reduces the complexity in SMLM analysis by automatically obtaining most of the input parameters iteratively from the data and requires minimal user input for accurate analysis. We demonstrate the performance of the algorithms and make a comparison to other software in terms of localization error and detection probability as function of signal to noise ratio on synthetic and real imaging data. The software can be used to analyze 2D and the majority of established 3D modalities. The algorithms are implemented as a plugin for the well-established ImageJ toolkit and provide a significant speed-up of analysis by use of GPU acceleration. We demonstrate the application of the algorithms in a study of co-distribution of the neuronal specific alfa3 isoform of Na,K-ATPase and NMDAR in hippocampal neurons.

**Abstract:** In mammals including human, cognitive function such as memory and attention depends on various brain neurotransmitters. Neurotransmitters are mainly divided into 3 groups; peptides, monoamines, and amino acids. Especially, amino acids represented by glutamate, gamma-aminobutyric acid (GABA), and serotonin play a pivotal role in central nervous system and closely involve severe neurological disease such as Alzheimer's disease, depression, and epilepsy. The amine neurotransmitters are considered to indirectly interact with each other to maintain brain functions, and the impairment of the homeostatic balance contributes to pathological states in brain. Conventionally, activities or expressions of related enzymes and amount of single neurotransmitter have been measured by biochemical assays and microdialysis, but these traditional approaches have not enabled us to directly analyze abundance and distribution of multi-neurotransmitters on brain tissues. Here, we conducted a comprehensive analysis of cerebral amine neurotransmitters by a recently-developed method, laser desorption/ionization imaging mass spectrometry (LDI-IMS) against mouse brain samples. In this study, firstly we prepared mouse brain sections on indium tin oxide (ITO)-coated slides using 6-8 weeks old male C57BL/6 mice. Secondly, we sprayed a unique reagent, 4-[3,5-Dimethyl-4-(4-nitrobenzyloxy)phenyl]-4-oxobutyric acid succinimidyl ester (DNPO-SE) on the sample slides, and derivatized amino acids in brain tissues. Finally, we detected the ionized products derived from derivatized amino acids and comprehensively visualized amine neurotransmitters in brain by imaging mass spectrometry (IMS) with iMScope (Shimadzu). As a result, we successfully detected and visualize the distribution of the eight amines simultaneously; alanine, serine, taurine, methionine, GABA, cysteine, glutamate, and serotonin in the mouse brain tissues. Interestingly, each amine showed a different spatial distribution in the brain. Notably, serotonin characteristically located in the raphe nucleus that contains numerous serotonin-producing neurons. In conclusion, utilizing a derivatizing reagent DNPO-SE enables us to inclusively analyze amine neurotransmitters in mouse brain tissues by matrix-free LDI-IMS. The newly-developed approach may have applicability to other reactive amines, and it may be a simpler and quicker experimental technique than conventional matrix-assisted IMS methods. The matrix-free IMS using DNPO-SE make it possible for us to simultaneously investigate the group of amine neurotransmitters in normal status and pathologic conditions in brain.

**Abstract:** *Introduction.* Accumulation of 2-hydroxyglutarate (2HG) is known to occur in isocitrate dehydrogenase (*IDH*)-mutant gliomas. Detection 2HG is possible by 3.0-tesla single voxel magnetic resonance spectroscopy (SVMRS), thus making non-invasive diagnosis of *IDH*-mutant gliomas possible. We set out to determine whether reliable detection of 2HG is feasible in *IDH*-mutant World Health Organization (WHO) grade 2 through 4 gliomas. *Methods.* A total of 110 patients harboring WHO grade 2 through 4 gliomas underwent preoperative MRS evaluation to detect 2HG and other metabolites. MRI/$^{1}$H-MRS analysis was performed using a 3.0-tesla system (Signa LX, General Electric). First, proton density images (Fast Spin Echo; TR/TE = 5000/40; FOV: 20 x 20 mm; matrix: 256 x 256; slice thickness: 5 mm; inter slice gap: 2.5 mm) were taken. The slice with the largest depiction of tumor on proton density images was selected for SVMRS. A point-resolved spectroscopic sequence (PRESS), with chemical-shift-selective water suppression was used with the following parameters: (TR: 1.5 s; TE: 30 ms; data point 512; spectral width 1000 Hz; number of acquisitions: 128 -196; volume of interest (VOI): 12-20 x 12-20 x 12-20 mm). Presence of *IDH*-mutations was determined by IDH1 R132H immunohistochemical analysis and DNA sequencing of surgically obtained tissues. *Results.* Thirty seven out of 66 (56.1%) grade 2/3 gliomas and 6 out of 44 (13.6%) GBs were *IDH*-mutant. *IDH*-mutant gliomas exhibited significantly higher accumulation of 2HG (median 5.029mM for grade 2/3 gliomas, 3.191 mM for GBs vs. 0.000 mM for *IDH*-wildtype grade 2/3 and GBs, both $p < 0.0001$, Mann-Whitney test). Also, lower levels of Glx (the sum of Glutamine and Glutamate) were detected in *IDH*-mutant grade 2 through 4 gliomas and lower levels of Glutathione in *IDH*-mutant grade 2/3 gliomas. A cutoff of 2HG = 1.489 mM achieved 100% sensitivity and 68.4% specificity and 83.3% sensitivity and 92.6% specificity in determining *IDH*-mutation in grade 2/3 gliomas and GBs, respectively. Grade 2/3 gliomas with high 2HG accumulation had significantly longer overall survival than those with low 2HG accumulation ($p = 0.02$, Log Rank test). *Discussion.* Non-invasive and reliable detection of 2HG in *IDH*-mutant grade 2 though 4 gliomas was possible by 3.0-tesla SVMRS.

**Title:** Synthesis and preclinical evaluation of [11C]BA-1, a PET tracer for brain CSF-1R

**Authors:** ***G. M. BORMANS**[1], B. ATTILI[2], M. AHAMED[2], S. CELEN[2]
[2]Radiopharmaceutical Res., [1]KU Leuven, Leuven, Belgium

**Abstract:** **Introduction** Positron emission tomography (PET) provides a sensitive non-invasive imaging technique to study receptors and enzyme expression and occupancy. A radiolabelled ligand with high affinity for a receptor which is overexpressed during neuroinflammation is highly desired as an imaging agent for neuroinflammation.[1] The colony stimulating factor-1 receptor (CSF-1R) appears to play a significant role in neuroinflammation. Since, it is profoundly expressed in microglia, the CSF-1R can be a potential target for visualization of neuroinflammation.[2] No specific radiotracer is available for visualizing CSF-1R with PET yet. Herein, we describe the synthesis and preclinical evaluation of [$^{11}$C]BA-1 for imaging of CSF-1R. **Materials and Methods** Synthesis of reference and precursor were done according to literature methods[2]. [$^{11}$C]-methyl triflate reacts with the precursor in presence of a base at room temperature for 2 minutes providing carbon-11 radiolabeled [$^{11}$C]BA-1 which was purified by reversed-phase high pressure liquid chromatography (RP-HPLC). Baseline biodistribution and blocking study performed in mice. Baseline and blocking microPET imaging studies were performed on a Focus™ 220 microPET scanner with female rats and non-human primate. **Results** Biodistribution study demonstrates a high tracer uptake in the brain (4% ID at 2 min post injection). Baseline microPET scans in rats suggest good uptake of tracer into the brain with SUV 1.2. MicroPET studies with non-human primates confirm high tracer uptake in the cortical regions in line with literature, and this uptake was reduced by pretreatment with BLZ-945, a CSF-1R inhibitor. Therefore, the present findings indicate that the developed tracer could be a suitable molecule for the in vivo imaging of CSF-1R. **Conclusion** We successfully synthesized, optimized radiochemistry and preclinical evaluation was done with [$^{11}$C]BA-1 tracer as a selective for brain CSF-1 receptor imaging. **References** 1. **Title:** Systematic screening of the molecular markers of leptin signaling in the hippocampus: role of pi3k pathway

**Authors: *B. DE CARVALHO BORGES DEL GRANDE**[1], M. B. CELANI[1], A. G. SILVA[1], J. ANTUNES-RODRIGUES[1], J. DONATO JR[2], L. L. K. ELIAS[1]
[1]Physiol., Sch. of Med. of Ribeirao Preto - Univ., Ribeirao Preto, Brazil; [2]Inst. of Biomed. Sci. - Univ. of Sao Paulo, Sao Paulo, Brazil

**Abstract:** Leptin plays a pivotal role in the control of energy balance through its action via LepR in hypothalamic nuclei. The LepR is also expressed in the hippocampus, a structure involved in learning and memory processing. Leptin administration into the hippocampus suppresses feeding and appetitive behaviors. However, which signaling pathway is recruited in the hippocampus by leptin has not been defined. Our study aims to identify molecular markers of leptin signaling pathways in the hippocampus as well as to systematically screen the changes in transcript levels following leptin treatment, using a qPCR array (PAMM-030ZA-6, Qiagen). Intraperitoneal injection of saline (0.15M NaCl, in 5µl/g) or leptin (2.5µg/g, in 5µl/g) was performed in adult male C57BL/6 mice. As studies have extensively suggested that STAT3 pathway is the main pathway by which leptin promotes its hypophagic effects in the hypothalamus, we assessed the phosphorylation of STAT3 in response to leptin in the hippocampus. In contrast to the robust leptin-induced STAT3 phosphorylation in the hypothalamus, leptin promotes no STAT3 phosphorylation in the hippocampus. To visualize the LepR expressing neurons, we crossed the LepR-Cre, a knock-in strain that coexpresses Cre-recombinase with the *Lepr* gene with the R26-tdTomato mouse, which induces the expression of a red fluorescent reporter protein. To evaluate neuronal activation in response to leptin we assessed c-Fos expression and c-Fos/LepR-Cre tdTomato colocalization in the hypothalamus and hippocampus. A higher number of c-Fos/LepR-Cre tdtomato expressing cells in the hypothalamus, but not in the hippocampus, was found in response to leptin. Because the hypophagic effect of leptin depends in part on the activation of PI3K and ERK signaling pathways in the hypothalamus, we further investigated

ERK and PI3K signaling in the hippocampus. There was no leptin-induced changes in pERK1/2 expression in the hippocampus. However, we found that leptin stimulates the PI3K pathway in the hippocampus of wild type mice, characterized by an increased expression of total AKT protein and an increased phosphorylation of AKT at S473 residue. Phosphorylated AKT in the hippocampus was shown to colocalize with LepR-Cre tdTomato expressing cells. Our data suggest that leptin signaling pathways in the brain are site specific. In the hypothalamus, c-Fos, STAT3 and ERK pathways mediate leptin actions. On the other hand, remarkably, the PI3K-AKT pathway is recruited by leptin in the hippocampus. Molecular markers downstream PI3K-AKT may underlie the mechanisms involved in the role of leptin in the hippocampus which affects feeding behaviors and cognitive processes.

**Title:** Stimulus sensitivity of narrowband gamma oscillations in human visual cortex

**Authors: *B. L. FOSTER**, W. BOSKING, M. BEAUCHAMP, D. YOSHOR
Dept. of Neurosurg., Baylor Col. of Med., Houston, TX

**Abstract:** Grating stimuli (e.g. Gabor patches) are commonly used to study neural responses in visual cortex. Across several species, grating stimuli reliably elicit narrowband gamma oscillations in the local field potential that peak around 30-70 Hz. Recordings from macaque V1 have shown that increases in the visual contrast of presented gratings shifts the peak frequency of induced gamma oscillations rightward (e.g. grating-contrast:gamma-frequency = 25%:38Hz; 50%:44Hz; 100%:53Hz; Ray & Maunsell, 2010). More recently, human intracranial V1 recordings have suggested that narrowband gamma oscillations are uniquely driven by grating stimuli, and not naturalistic images (e.g. faces or houses; Hermes et al., 2015). This sensitivity to stimulus attributes has important implications for the role of gamma oscillations in perception, and the mechanisms of neural circuit rhythmicity. We therefore sort to replicate these observations of stimulus dependence in human visual cortex using intracranial recordings from 7 subjects viewing grating (n = 7) and object (n = 4) stimuli. To improve the number of visual

recording sites, hybrid micro/macro electrocorticography (ECoG) strip electrodes were employed. Electrode location in visual cortex was verified through MRI/CT imaging and receptive field mapping. During Experiment 1 large field static grating stimuli (sine-wave; 1 cycle/deg.) were presented randomly at 20%, 50% and 100% Michelson contrast. Stimuli were presented for 500 ms, with a 200 ms pre-stimulus fixation cue and a random inter-stimulus interval between 500-1500 ms. During Experiment 2 grayscale object images (faces, bodies, cars, houses, limbs, numbers, letters, scrambled) were randomly presented for 500 ms with a random inter-stimulus interval between 500-1500 ms. Spectral analysis revealed large increases in narrowband gamma power in response to grating stimuli. In addition, the peak frequency of gamma oscillations was parametrically increased with higher contrast levels, as was the power of response (e.g. grating-contrast:gamma-frequency = 20%:28Hz; 50%:40Hz; 100%:48Hz). Consistent with non-human primate recordings (Ray & Maunsell, 2010) the specific peak frequency of gamma oscillations, and their contrast dependence, was variable between subjects but typically shifted through a range of ~25-65 Hz. Consistent with human recordings (Hermes et al., 2015) object stimuli did not induce similar narrowband gamma oscillations, but did produce clear broadband spectral responses. These findings provide a strong replication of stimulus dependent gamma oscillation frequency in primate visual cortex.

**Title:** Modulation of postmenopause and premenopause on resting state electroencephalographic power in women

**Authors: *E. G. GONZÁLEZ-PÉREZ**, S. SOLÍS-ORTIZ
Med. Sci., Univ. De Guanajuato, León, Mexico

**Abstract:** Hormonal changes that characterize postmenopause may influence cortical electrical activity. This study investigated whether postmenopause influences resting-state electroencephalogram (EEG) power in the frontal, central, parietal and occipital cortical regions compared with premenopausal women who have regular menstrual cycles. EEG recording were conducted in the resting state in twenty early postmenopausal healthy women between 48 and 60 years and twenty premenopausal healthy women between 40 and 45 years. The resting EEG spectral absolute power in the frontal, central, parietal and occipital cortical regions was

analyzed during eyes closed condition. The frequency bands considered were the delta, theta, alpha1, alpha2, beta1 and beta2 and were compared among participants. Postmenopausal women compared to premenopausal women showed theta power increased in frontal regions, alpha1 power increased in the frontal region, alpha2 power increased in the frontal and central regions and beta1 power increased in the frontal, central and parietal regions. Delta and beta2 bands did not show changes among participants. These findings suggest that suggest that the hormonal status of women may impact on brain function leading to states of low and high cortical activation, which may affect behavior and cognition.

**Title:** Sensory gating alterations in major depressive disorder, and their relationship to clinical symptoms

**Authors: *S. DE LA SALLE**[1], M. BIRMINGHAM[2], P. BLIER[2], V. KNOTT[2]
[1]EEG, Univ. of Ottawa Inst. of Mental Hlth. Re, Ottawa, ON, Canada; [2]Univ. of Ottawa Inst. of Mental Hlth. Res., Ottawa, ON, Canada

**Abstract:** The use of electroencephalography has shown promise in detecting cortical dysfunction in major depressive disorder (MDD). Cognitive impairments in MDD are evidenced across all functional domains, including pre-attentive auditory sensory and attentional processes. Physiological measures that can be used to index these impairments include the P50 and N100 event-related potentials (ERPs). Reduced P50 gating is thought to index impaired filtering of irrelevant sensory information, while reduced N100 gating may signify impaired attention. However, differences in the P50 and N100 ERPs between patients and healthy controls and the relationship to clinical symptoms requires further study. The main objective of this study was to investigate differences in sensory gating and attention between medication-free depressed individuals and healthy controls. The study also aimed to determine whether P50 and N100 processes were related to the severity of clinical symptoms. 20 healthy non-patient male and female controls were matched, based on age, sex, smoking status and handedness, to a population of 20 outpatient volunteers with a documented diagnosis of DSM-IV MDD. All participants were administered the Beck Depression Inventory, the Stress Reactive Rumination Scale, and the Dysfunctional Attitudes Scale. Following the questionnaires, the auditory paired-

click paradigm was administered and electrophysiological responses were acquired using a 32-electrode array. P50 and N100 peak amplitudes (μV), latencies (ms), and gating indices (ratio [rP50] and difference scores [dP50]) were quantified and statistically analyzed using a two-tailed t-test for comparison between control and depressed groups. Finally, correlations between physiological measures and clinical symptoms were carried out. The depressed group exhibited reduced sensory gating and attentional processes compared to the healthy control group. Significant correlations between clinical symptoms and P50, N100 measures were observed. These findings provide additional support for sensory and attentional impairments in MDD.

**Title:** Head angle during image acquisition impacts interpretation of DBS electrode position

**Authors: *S. A. NORRIS**[1], M. MILCHENKO[2], A. Z. SNYDER[2], M. C. CAMPBELL[1], M. USHE[1], J. L. DOWLING[3], K. M. RICH[3], J. S. PERLMUTTER[4]
[1]Neurol., [2]Radiology, [3]Neurolog. Surgery, [4]Neurology, Radiology, Anatomy, Physical and Occup. Therapy, Washington Univ. Sch. of Med., Saint Louis, MO

**Abstract: Background:** Deep brain stimulation (DBS) in the region of the subthalamic nucleus (STN) produces variable motor, psychiatric and cognitive effects in patients with Parkinson disease. This variation may be due to differences in electrode location relative to targeted areas of STN. Thus, the ability to accurately localize electrodes and their movement during the post-operative period is crucial for ongoing research trying to determine regional effects of DBS.

**Objective:** To quantitatively assess post-operative DBS electrode displacement, accounting for head position during image acquisition. **Methods:** We studied 56 patients with bilateral implantation of STN DBS electrodes who underwent immediate pre-operative MRI (DBS-MRI) and post-operative head computed tomography (DBS-CT) in supine position and delayed head CT (DEL-CT) with variable degrees of head tilt. We determined electrode locations using a novel method involving three-stage maximization of CT signal integrated over an analytic model of DBS implant. DBS-MRI, DBS-CT and DEL-CT images were co-aligned by optimizing a 6-parameter rigid body transform. In addition, DBS-MRI were affinely aligned to standard (MNI152) space, and CT images were also resampled to this space using a combination of computed transforms. We compared electrode location in standard space between DBS-CT and DEL-CT and computed the correlation coefficients *r* between the magnitude of displacement between scans versus the time between scans, volume of postoperative subdural air (median = 3.9 $cm^3$), and delta head angle between scans. **Results:** On average, electrode displacement from DBS-CT to DEL-CT in MNI152 space occurred in the rostral-ventral-lateral direction (right: $x$ = -0.12, $y$ = 0.43, $z$ = -0.83; left: $x$ = 0.14, $y$ = 0.44, $z$ = -0.89) with increased curvature (average radius = 366 mm vs 223 mm), each independently different from zero. Magnitude of displacement and degree of curvature was independent of elapsed time between CTs. Delta head angle significantly correlated with electrode displacement ($p$=1e-10, $r$=0.46 for both sides); a weaker correlation with subdural air on DBS-CT was observed ($p$=1e-2, $r$=0.21 and 0.25 for left and right sides, respectively). **Conclusion:** These data support a role for post-operative electrode movement, with head angle at the time of image acquisition significantly contributing to electrode movement. Accurate interpretation of post-operative DBS electrode position must account for the angle of image acquisition.

**Title:** 7T mri probabilistic stn atlas for use with 3T mri

**Authors: M. MILCHENKO**[1], S. A. NORRIS[2], A. Z. SNYDER[1], K. L. POSTON[5], M. C. CAMPBELL[2], *M. USHE[3], J. S. PERLMUTTER[4]
[1]Radiology, [2]Neurol., [3]Dept Neurol, [4]Neurology, Radiology, Anatomy, Physical and Occup. Therapy, Washington Univ., Saint Louis, MO; [5]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

**Abstract: Background.** Deep brain stimulation (DBS) of the subthalamic nucleus (STN) effectively reduces motor symptoms in most patients with Parkinson disease (PD), yet also may produce untoward effects. Investigation of DBS effects requires accurate localization of the STN which can be difficult to unambiguously identify on magnetic resonance images (MRI) collected with clinically available 3T scanners. Objective: To develop a high quality STN atlas using a 7T scanner that can be applied to standard 3T images.
**Methods**. We created a high definition probabilistic STN atlas derived from seven elderly subjects imaged at 7T. This atlas was nonlinearly registered to a standard template representing 56 patients with PD imaged at 3T. This process required development of novel methodology for non-linear multi-modal image registration. STN in individuals can be localized by registration of a 3T image to this 3T template.
**Results.** We demonstrate mm-scale STN localization accuracy by comparison with another publicly available 7T atlas. We also demonstrate less agreement with an earlier histological atlas. STN localization error in the 56 patients imaged at 3T was less than 1 mm on average.
**Conclusions.** Our methodology enables accurate STN localization in patients imaged at 3T. The STN atlas is freely available to the research community. This new image registration methodology may be generally applicable to other datasets.

**Title:** Pharmacological functional MRI analysis of dopamine D1 receptor interventions with 11.7 T high field MRI scanner

**Authors: Y. KIMURA**[1], S. NAKAZAWA[1], Y. MORI[2], K. NISHIGORI[1], *M. YAMANAKA[1], J. ICHIHARA[1], Y. YOSHIOKA[2]
[1]Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan; [2]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol. (NICT) and Osaka Univ., Osaka, Japan

**Abstract:** Dopamine D1 receptor (D1R) is an important therapeutic target associating with schizophrenia, Parkinson's disease, attention deficit hyperactivity disorder and attracting attention. Pharmacological-fMRI (phfMRI) is useful to investigate the neurophysiological function of particular receptors and to evaluate pharmacological interventions. However, the neurophysiological function of D1R is largely unknown. In this study, we investigated the effects of D1R interventions on the BOLD effects using phfMRI with a preclinical high-field MRI scanner. All MRI experiments were conducted using an 11.7-T vertical-bore Bruker Avance II imaging system and a volume radio frequency coil for transmission and reception. During the MRI session, 8-week-old male Wistar rats (final N = 21) were anesthetized with 1-2% isoflurane, via a face-mask. Structural and fMRI data were obtained by multi-slice rapid acquisition with relaxation enhancement (RARE) sequence. After 60-minute sequential scan (pre-treatment scan), SKF82958 (3 mg/kg, an agonist of D1-like receptors), SCH39166 (1 mg/kg, an antagonist of D1-like receptors) and saline (as control) were subcutaneously administrated for each group, respectively. The 90-min follow-up scan (post-treatment scan) was conducted immediately after those treatments. We used SPM12 for the slice realignment, co-registration, and spatial normalization. SPM also generated parametric maps of statistical significance of BOLD effects with a general linear model. In this study, we found a significant increment of the BOLD signal intensity in the striatum, thalamus, and cerebellum by SKF82958 treatment ($p<0.05$, FWE-corrected). In contrast, SCH39166 showed a significant decrease in similar regions where we found signal increment with SKF82958 treatment ($p<0.05$, FWE-corrected). Temporal analyses revealed that the peak effect was found at 30-60 min after the SKF82958 treatment, whereas that was found at post 60-90 min after SCH39166. In summary, phfMRI detects D1R-modulated BOLD effects in the specific brain regions, including the striatum which contains the high D1R distribution. Thus, we successfully visualized D1R-derived neural activation in various brain regions. PhfMRI can contribute to the *in vivo* pharmacological assessment of targeting dopamine receptors.

**Abstract:** Temporal latencies between constituent parts of any complex dynamical system are an important factor in determining its function and stability. This is the case in neural systems where precise timing of the arrival of neural spikes and signals that propagate along axons is of fundamental importance. While there is a great effort today in reconstructing brain connectivity maps, there is no reliable framework to determine latencies in such networks. To address this, we use a multi-modality approach, combining structural and functional networks, each with their own latency estimates. Using structural information obtained with Mean Apparent Propagator (MAP) MRI data, we estimate the conduction velocity distribution (CVD) from the measured axon diameter distribution (AAD) in white matter. Using functional information derived from transcranial magnetic stimulation (TMS) evoked potentials (EP) via electroencephalography (EEG), as well as time-series analysis of magnetoencephalography (MEG) and electroencephalography (EEG) recordings, we have an independent assessment of the functional brain network connectivity. In deriving the latency from such data it is important to distinguish between temporal delays between neural events and true latencies that we aim to reconstruct. Latencies obtained from time-series analysis can only establish Wiener-Granger causality while incorporating TMS measurements and structural information about axons morphology and white matter path lengths provide additional information that can aid in deducing the true causality. In this abstract, we present preliminary results, with a focus on theoretical aspects and simulations. Our goal here is two-fold: 1) to improve the estimation of latencies from neural recordings using both stationary and non-stationary time-series approaches, and 2) to develop approaches that combine results from different imaging modalities, e.g., diffusion MRI and fMRI. In 1), we compare existing analytical methods that utilize similarity and statistical dependence measures (cross-correlation, transfer entropy, etc.) on time-series, as well as our proposed approach, that is based on non-stationary features of time-series. We test all the approaches using simulations on

four types of models: a) linear delay, b) multivariate autoregressive model, c) coupled non-linear dynamical systems, and d) brain network simulations based on known connectivity. We also apply and compare all the methods considered to MEG recordings (resting state with eyes closed). In 2) we use diffusion MRI-derived latency distributions as priors in a Bayesian framework combining the results from different modalities.

Disorders and Stroke, Bethesda, MD

**Abstract:** Descriptors of cytoarchitecture and tissue microstructure such as average axon diameters (AAD) can provide valuable information about the functional organization of normal and pathological white matter. The linear relationship between the diameters of myelinated axons and their action potential propagation velocities is well-established in the literature. Using a recently proposed diffusion MRI method, called Mean Apparent Propagator (MAP)-MRI, we can measure the probability density function of net displacements of water molecules in brain tissues and compute the return-to-axis probability (RTAP) along the orientation of major white matter pathways. In compact white matter regions, myelinated axons can be modeled as collections of parallel impermeable cylinders. In this case, the RTAP allows the estimation of the AAD, from which we can compute the average conduction velocity (ACV) assuming the linear relationship ACV[mm/ms] = 5.5AAD[μm] based upon electrophysiology studies on mammalian myelinated nerves. From the same diffusion MRI data, we can visualize white matter pathways

using whole-brain fiber tractography, and derive estimates of the lengths of white matter pathways connecting different cortical or deep gray matter regions. Finally, by combining ACVs and fiber length measurements we obtain an estimate of the mean latency at a millisecond time-scale between pairs of cortical regions and construct a mean latency matrix (MLM). Whole-brain visualization of AADs is consistent with previous post-mortem studies in monkeys showing larger values in pathways supporting fast sensory integration, e.g. visual/motor functions, and smaller values in association pathways connecting temporal/frontal regions. The MLM shows blocks corresponding to interhemispheric (longer) and intrahemispheric (shorter) latencies. Our results support the potential to non-invasively infer information transfer and functional organization of the human brain at a millisecond time-scale from microstructural measurements using diffusion MRI. The proposed MLMs may provide valuable developmental, neuropathological and functional information complementary to fMRI and standard measures of cognitive performance.

**Title:** The brainstem response to respiratory-gated auricular vagal afferent nerve stimulation (RAVANS) at ultrahigh-field (7T) fMRI and its effect on vagal autonomic outflow

**Authors: R. SCLOCCO**[1], *N. W. KETTNER[2], R. G. GARCIA[1], J. R. POLIMENI[1], K. ISENBURG[1], N. TOSCHI[3], R. BARBIERI[4], V. NAPADOW[1]
[1]Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sc, Charlestown, MA; [2]Radiology, Logan Univ., Chesterfield, MO; [3]Univ. of Rome Tor Vergata, Rome, Italy; [4]Dept Anesthes Critical Care, Massachusetts Gen Hosp., Boston, MA

**Abstract:** Transcutaneous electrical stimulation of the auricular branch of the vagus nerve (ABVN) has been used as a neuromodulatory therapy for multiple disorders, and primary brainstem relay occurs in nucleus tractus solitarii (NTS) (Nomura and Mizuno, 1984). We have previously proposed that ABVN stimulation effects are optimized by gating stimulation to the respiratory cycle (Napadow et al. 2012), with increased NTS response shown for exhalation-gated RAVANS (eRAVANS) compared to inhalation-RAVANS (iRAVANS) (Garcia et al. 2017). Here, we exploit the enhanced spatiotemporal resolution afforded by ultrahigh-field functional MRI (7T fMRI) to evaluate brainstem response during RAVANS, concurrently estimating stimulus-evoked instantaneous vagal outflow with a point-process algorithm (Barbieri et al. 2005). Four (4) healthy subjects experienced two 8-minute fMRI runs, with moderately strong (but not painful) eRAVANS or iRAVANS delivered to the left cymba conchae of the ear (450 μs pulse width at 25 Hz, 1 s duration). A third resting state run was used to deliver sham stimulation, and an identical event-related fMRI analysis controlled for respiratory cycle influence on medullary response. Brainstem BOLD fMRI data were collected on a Siemens 7T scanner (1.2mm isotropic voxels, 38 coronal slices, TR=0.99s, TE=23ms, 500 volumes), concurrently with electrocardiogram and respiration monitoring at 500Hz. General Linear Model analyses were performed on preprocessed (RETROICOR, slice-timing, motion and distortion correction, FWHM=2mm spatial smoothing) fMRI brainstem data using both a canonical HRF and a modified HRF having a shorter latency (3s) to peak response. Group maps demonstrated an increased response during eRAVANS compared to iRAVANS and Sham in ipsilateral medulla, consistent with purported NTS. This was not evident when using the canonical HRF during modeling. Vagal outflow increased in response to eRAVANS compared to iRAVANS and Sham, providing promising basis for therapeutic applications of eRAVANS in disorders involving autonomic disruption.

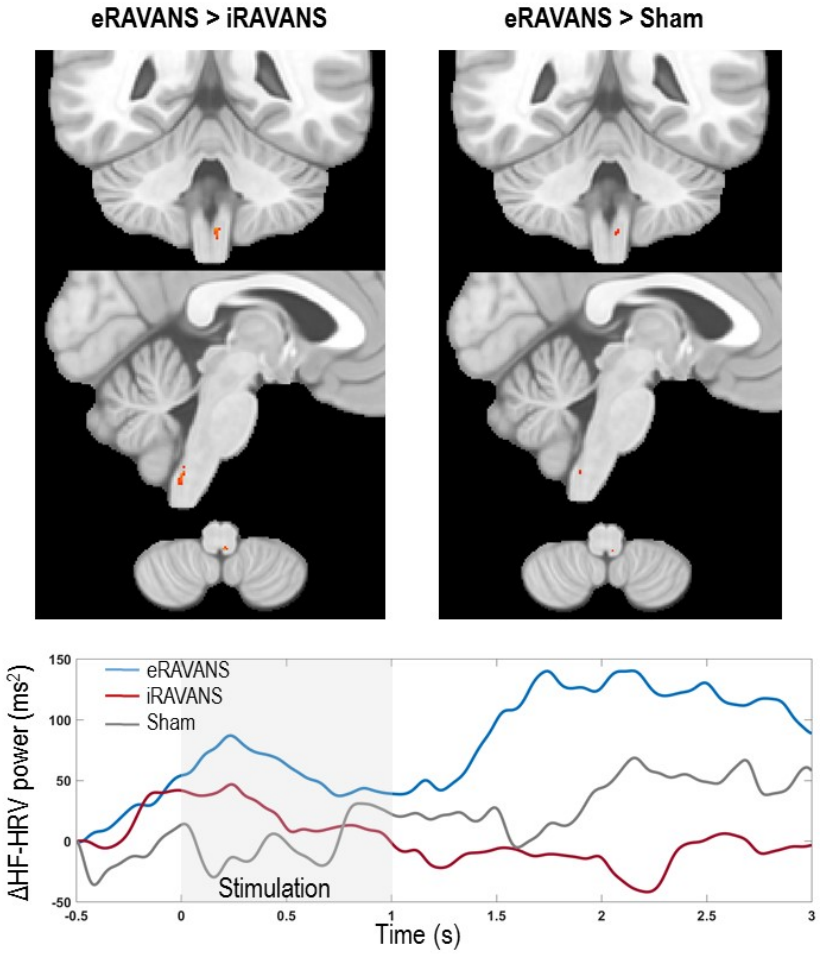

**Figure 1 –** Top panel: group maps (N=4) showing greater NTS activation during eRAVANS compared to iRAVANS and Sham. Bottom panel: peri-stimulus plot of the vagal outflow, as measured by the high-frequency component of the heart rate variability (HF-HRV), showing higher power increase in eRAVANS compared to iRAVANS and Sham.

**Title:** Resting state connectivity of the BNST and CeA in patients with anxiety disorders

**Authors: *S. TORRISI**[1], G. ALVAREZ[2], A. X. GORKA[2], C. GRILLON[2], M. ERNST[2]
[1]Section on the Neurobio. of Fear and Anxiety, [2]Section on Neurobio. of Fear and Anxiety Natl. Inst. of Mental Hlth., Natl. Inst. of Mental Hlth., Bethesda, MD

**Abstract: Background:** The bed nucleus of the stria terminalis (BNST) and central nucleus of the amygdala (CeA), constitute the extended amygdala. They are uniquely implicated in the anxiety response and are suspected to underlie altered threat processing in psychopathological anxiety (Davis et al. 2010). Both the BNST and the CeA are infrequently studied in humans due to their small size and not at all investigated in anxiety patients. Prior work in our group utilized high resolution imaging to map the resting state functional connectivity (rsFC) of the BNST and CeA in healthy subjects at 7 Tesla, confirming and extending structural findings in human and animals (Torrisi et al. 2015; Gorka et al. 2017). In the present follow-up study, BNST and CeA rsFC were contrasted between healthy subjects and anxiety patients. We expected to identify abnormal patterns of rsFC in anxious patients.
**Methods:** 30 patients carrying anxiety diagnoses (generalized anxiety and/or social anxiety) and 30 matched healthy subjects participated in the analysis. The 7 Tesla, 10-minute resting state scan was 1.3 mm isotropic. The T1-weighted structural was 0.7mm isotropic. Publically-available probabilistic BNST and CeA masks were used to extract averaged time series. A two-sample t-test compared rsFC across the brain between healthy subjects and anxiety patients for both structures. Preprocessing and analyses were performed in AFNI.
**Results:** Within-group analyses replicate previous findings showing strong BNST connectivity with many regions including the medial PFC, dorsal amygdala, medial head of caudate and precuneus in both groups. Within-group analyses also replicate previous findings showing CeA connectivity with medial PFC but also temporal and thalamic regions relevant for sensory processing. Between-group analyses revealed that patients displayed hypoconnectivity between the BNST and the left IFG. It was also observed that patients displayed hypoconnectivity between the CeA and the right anterior insula. Patients also displayed significant hyperconnectivity between the CeA and right STS.
**Conclusion:** This is the first resting state study of anxiety patients that probes resting functional connectivity of the BNST and CeA, regions highly implicated in anxiety disorders. Results reinforce the potential for high resolution fMRI to elucidate connectivity with small regions. Findings also suggest that there are distinctions in resting BNST and CeA connectivity in patients with anxiety in prefrontal and temporal regions which may relate to high level cognitive impairments, social processing and the propensity for diagnostic phenotypes such as worry and difficulty concentrating.

**Title:** A probabilistic stereotaxic structural atlas of five mesopontine tegmental nuclei from *In vivo* 7 Tesla MRI

**Authors: *M. BIANCIARDI**[1], C. STRONG[2], N. TOSCHI[1,3], B. L. EDLOW[4], B. FISCHL[1], E. N. BROWN[5], B. R. ROSEN[1], L. L. WALD[1]
[1]Dept. of Radiology, MGH & Harvard Med. Sch., Boston, MA; [2]Dept. of Neurosurgery, Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA; [3]Med. Physics Section, Dept. of Biomedicine and Prevention, Fac. of Medicine, Univ. of Rome "Tor Vergata", Rome, Italy; [4]Dept. of Neurology, A. A. Martinos Ctr. for Biomed. Imaging, MGH and Harvard Med. Sch., Boston, MA; [5]Dept. of Anesthesia, Critical Care and Pain Medicine, MGH, Boston, MA

**Abstract: Introduction:** Mesopontine tegmental nuclei, such as the cuneiform (CnF), pedunculotegmental (PTg, or "pedunculopontine"), oral pontine reticular (PnO, or "pontis oralis"), paramedian-raphe (PMnR) and caudal-linear-raphe (CLi) nuclei, are crucial for arousal and motor functions. Their localization in conventional MRI of living humans is difficult due to limited MRI sensitivity/contrast. Aim of this work was to develop a tool - a probabilistic atlas of these nuclei - to identify them in *in-vivo* human MRI.
**Methods:** On 12 subjects (6m/6f, age 28 ± 1 - under IRB approval) at 7 T, we acquired 1.1mm-isotropic diffusion tensor MRI (60 directions, b ~ 1000 s/mm$^2$, 7 "b0" images, TE/TR = 60.8/5600 ms, 4 reps), and, after preprocessing, computed fractional-anisotropy (FA) maps, and the average $T_2$-weighted ("b0", $T_2$w) MRI. For each subject, M.B. performed semi-automatic segmentation of FA maps and $T_2$w MRI by k-means clustering. This yielded single-subject labels of the 5 nuclei, which where aligned to MNI space, and averaged across subjects to generate probabilistic atlas labels. This atlas was validated by computing for each subject the Hausdorff distance (mm) between each semi-automatically-segmented label and: (i) each manually segmented (by C.S) label; (ii) the probabilistic label obtained using the other 11 subjects (leave-one-out approach). As a further validation (iii), we compared the segmented-nuclei volumes with *ex-vivo* nuclei volumes [1].
**Results:** The probabilistic labels in MNI space of the 5 nuclei are shown in Figure 1A. Results of the atlas validation are shown in Figure 1B.
**Conclusions:** We created a validated *in vivo* probabilistic atlas of 5 mesopontine tegmental

nuclei by 7 T MRI. This atlas might aid the nuclei localization in conventional (e.g. 3 T) MRI; it might improve the accuracy of interventions (e.g. placement of DBS electrodes), lesion evaluation, and the assessment of arousal/motor connectivity pathways in disorders of consciousness, sleep disorders and neurodegenerative diseases.

**References:** [1] Paxinos et al, Organization of brainstem nuclei, Elsevier, 2012.

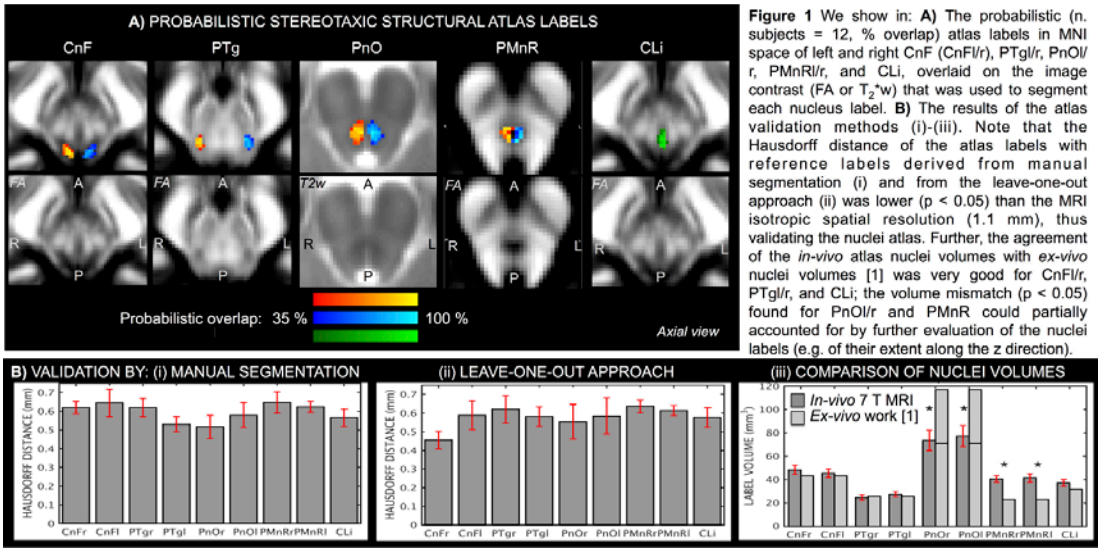

**Figure 1** We show in: **A)** The probabilistic (n. subjects = 12, % overlap) atlas labels in MNI space of left and right CnF (CnFl/r), PTgl/r, PnOl/r, PMnRl/r, and CLi, overlaid on the image contrast (FA or $T_2$*w) that was used to segment each nucleus label. **B)** The results of the atlas validation methods (i)-(iii). Note that the Hausdorff distance of the atlas labels with reference labels derived from manual segmentation (i) and from the leave-one-out approach (ii) was lower ($p < 0.05$) than the MRI isotropic spatial resolution (1.1 mm), thus validating the nuclei atlas. Further, the agreement of the *in-vivo* atlas nuclei volumes with *ex-vivo* nuclei volumes [1] was very good for CnFl/r, PTgl/r, and CLi; the volume mismatch ($p < 0.05$) found for PnOl/r and PMnR could partially accounted for by further evaluation of the nuclei labels (e.g. of their extent along the z direction).

**Abstract:** Introduction: T1-weighted (T1w) MR-based brain morphometry relies on scans that are obtained without gadolinium-based contrast agents (GBCAs). Contrast-enhanced (CE) T1w scans using GBCAs are obtained for many clinical indications like cancer. These represent potentially a wealth of untapped morphometric data that could be used to answer important biomedical questions. However, signal intensity changes from GBCAs confounds image registration, skull stripping, segmentation, etc. In this work, we have created a novel image-processing pipeline to assess the validity of automated brain morphometry derived from CE T1w scans.
Methods: The data set consists of 50 subjects with non contrast-enhanced (nCE) and CE T1w images. For performing any volumetric studies, it is important to construct an atlas for spatial normalization. In most cases spatial normalization is not possible because of the lack of such an atlas. Our current CE atlas is constructed with the help of associated nCE images. The CE images are rigidly registered with NC with 6 DoF using (Figure 1). Steps 2-3 illustrate the NC template construction. Step 4 shows the label transfer from the EVE template to the NC template. The transformation in step 1 and 2 are combined to allow for aligning the CE images. Step 3 and 4 are repeated for CE images. The nCE and the CE templates along with probabilistic ROI definitions are shown on the right. All registrations are computed using ANTS [1].
Conclusions: In this paper, we have proposed an atlas for CE T1w images. The atlas also contains the probabilistic ROI definitions for 175 ROIs in the EVE template [2]. Availability of such an atlas will help us conduct further morphometric analysis with the huge number of CE images across the world.

**Abstract:** The Human Brain Project is building an ICT-based scientific research infrastructure that will permit researchers to advance our knowledge in the fields of neuroscience through data exploration, analytics and simulation at multiple levels of brain organization. Experimental neuroscience is connected to the infrastructure through systems for organizing and managing heterogeneous research data. These data systems are initially tested by data producing laboratories in the HBP, and will ultimately be opened for the community. HBP data curation services support users in elevating the level of data consistency and in the migration of data to the open domain. The starting point for research projects that will use HBP resources is the HBP Collaboratory, a rich collaborative workspace which is open to the community. The Collaboratory provides guidance and access to resources, including storage for data and a workbench for entering and organizing metadata. As a central element, the Collaboratory provides high-quality reference atlases of the rodent and human brain, together with appropriate tools and workflows that allow users to register data to the atlases for their study, and to perform initial analysis of data. It also links to important external data repositories and services. Here we present an overview of currently available reference atlases, tools and workflows. We exemplify the use of these resources in a range of neuroscience projects, ranging from brain-wide mapping of molecular level information to identification of precise location of electrophysiology recording sites. With coordinates corresponding to reference atlas space, harvested through the workflow, valuable metadata for future search and analysis of data are captured. Furthermore, with data aligned to reference atlases, analysis of the spatial distribution of events, labeled elements, and regions of interest in image material is strongly supported. Following registration

to reference atlas, subsequent image processing and analysis steps delivers lists of extracted features corresponding to atlas structures, enabling quantitative regional analysis. We exemplify analytical workflows producing automated quantification and spatial analysis of labeling in series of histological section images from whole rodent brain. These and other atlas related workflows will be made available as HBP software services.

**Title:** How gyral geometry affects cortical fibre trajectories; from tract tracing to diffusion MRI tractography

**Authors: *M. COTTAAR**[1], T. E. BEHRENS[1], S. JBABDI[1], S. N. HABER[2]
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. of Rochester, Rochester, NY

**Abstract:** Diffusion MRI tractography streamlines terminate predominantly at the gyral crown, rather than more uniformly across the cortex as seen in histology. This bias to the gyral crown is generally attributed to the limited resolution of diffusion MRI, which is insufficient to resolve the axon curvature at the cortical boundary.
Cortical axons leaving the grey matter to distant regions form a dense, narrow “stalk” (seen as heavily stained, elongated bundles of fibres in individual slices) before splitting up into separate bundles that connect to the striatum, the capsules, and the corpus callosum. This dense stalk implies that at least for the long-distance connections there is a unique relationship between the injection site and the fibre trajectory through the gyral white matter. Our goal is to use tracer injections spread across gyri to delineate the rules governing this relationship and develop new algorithms to guide tractography streamlines more accurately through the gyral white matter to the appropriate cortical termination site.
Ten stalks were charted in six different monkeys with injection sites in the frontal cortex. Six stalks charted in the dorsal prefrontal gyrus show a complicated pattern. In individual slices these stalks can often be seen to have sharp curvature. Furthermore, the in-plane fibre orientations of these stalks were often misaligned and sometimes perpendicular to the long axis. This implies that the elongated shape of the stalks observed in most slices is not due to the projection of a

cylindrical stalk onto the plane, but rather reflects the inherent elongation of the stalks cross-section. In contrast the fibres tended to align with the long axis for stalks in the caudal lateral prefrontal, ventral prefrontal, and premotor gyri, which might reflect the simpler geometry of these gyri. We will present results illustrating how the three-dimensional gyral geometry influences both the shape of the stalk and the fibre orientation. Most importantly for tractography we will present validations of models predicting the path of the stalk based on the injection site and the gyral geometry.

**Abstract:** Malformations of cortical development (MCD) are heterogeneous disorders frequently associated with epilepsy. The onset of these pathologies is related to alterations of cell proliferation, cell migration, and cortical organization. However, little is known about their pathogenesis. To analyze the architectural abnormalities in the cortical layering of MCD, we exploited the possibility of combining high-resolution 3D imaging with clearing methodologies.

In particular, we successfully integrated the SWITCH immunohistochemistry technique with the TDE clearing method to image pediatric as well as adult human brain tissue. Both light sheet and two-photon fluorescence microscopies were used to reconstruct the three-dimensional structural organization of neurons in human brain cortex. Our data demonstrate that the comparison of neurons distribution in the cortex of healthy and affected individuals allow exploring anomalies in the 3D structural organization of the brain, providing novel insights into the pathogenesis of MCD.In conclusion, this new approach enables to characterize large human brain specimens with high-resolution optical techniques, giving the possibility to expand the histopathological studies to the third dimension.

**Abstract:** Major depressive disorder (MDD) is a disabling illness of high prevalence [1]. There is a pressing need to elucidate the pathophysiology of MDD to better target treatment. Previous studies have shown an association between hippocampal subfield volumes and MDD, making them potential biomarkers for the disease [2-4]. Using 7 Tesla (7T) MRI to perform volumetric analysis can allow for more accurate measurements enabled by increased contrast and resolution. In this study, we demonstrate the feasibility of automated hippocampal subfield segmentation for

MDD at high resolution 7T MRI. Hippocampal subfield volumes are computed using Automatic Segmentation of Hippocampus Subfields (ASHS) software [5]. We perform a preliminary analysis on differences in subfield volumes between MDD patients and healthy controls. Thirteen MDD patients (ages 29-55) and seven healthy controls (26-55 years) underwent an MRI scan at 7T (Magnetom, Siemens). The imaging protocol consisted of MP2RAGE (TR 6000 ms, TI1 1050 ms, TI2 3000 ms, TE 5.06 ms, voxel 0.8x0.8x0.8 $mm^3$) and $T_2$ TSE (TR 9000 ms, TE 69 ms, voxel 0.45x0.45x2 $mm^3$) acquired at a coronal oblique orientation. We report subfield volumes computed by ASHS for CA1, CA2 3, CA4 DG, and subiculum in the left and right hemispheres. A comparison of the MDD patients to healthy controls was performed for each subfield volume, with age and gender regressed. A significant difference was found between patients and controls in CA1 on the right side ($p=0.0449$), with marginally significant difference in CA1 on the left side ($p=0.1034$). No significant differences were found in the other subfields. We have demonstrated feasibility of automated hippocampal subfield segmentation at 7T for MDD patients and controls. Significant volumetric differences were found in CA1 on the right side, which is concordant with the literature on hippocampal subfield changes associated with stress-related disorders [6, 7]. This volume loss may be due to a reduction in astrocyte density [7]. Future work includes manual tracings of the subfields to validate automated results and increasing the sample size. Hippocampal subfield volumes may serve as imaging biomarkers for MDD, which may help design more targeted treatments for the disease.

Center, IOL, Hartford, CT

**Abstract: Background:** Schizophrenia (SZ) and autism spectrum disorders (ASD) are severe psychiatric conditions that co-occur at elevated rates. Recent reports indicate phenotypic similarities and shared genetic risk factors, thus stimulating debate about shared underlying neuropathology. The current study examined fMRI resting-state functional connectivity patterns in SZ, ASD and healthy controls (HC), within the default mode network (DMN).
**Methods:** Resting-state fMRI was collected from 100 individuals: 33 SZ, 33 ASD, 34 HC (ages 18-35). Temporally distinct resting state components were determined using the group independent component analysis (ICA) toolbox (GIFT) with a 100 components model. Eight components were identified as DMN nodes, based on the Stanford functional ROI atlas, including 2 frontal, 4 posterior cingulate (PCC), 1 precuneus (PrC) and 1 lateral parietal (LP) nodes. The functional network connectivity (FNC) toolbox was used to compute group differences in DMN components coherence (i.e. connectivity, measured as between-nodes correlations).
**Results:** One way ANOVA demonstrated significant group effect for four pairs of DMN nodes. Post-hoc pair-wise group comparisons indicated that in three of those node-pairs (PCC1-PCC2 $p=0.006$; PCC1-PrC $p=0.024$; PCC2-PrC $p<0.001$) both SZ and ASD had significantly lower correlation than HC (with SZ and ASD not significantly different from each other). For the fourth node-pair (PrC-LP $p=0.025$), SZ showed significantly lower correlation than HC (and although not significant, ASD showed a similar pattern).
**Conclusions:** These preliminary results indicate lower intra-DMN functional connectivity in both SZ and ASD groups, as compared to HC. Interestingly, connectivity of the posterior portions of the DMN (PCC and PrC) was mainly implicated.

**Title:** Rich club organization of the neonatal functional connectome in newborns with complex congenital heart disease

**Authors: J. D. CRUZ**[1], M. T. DONOFRIO[2], G. VEZINA[2], *C. LIMEROPOULOS[3]
[1]Radiology, Children Natl. Hlth. Syst., Washington, DC; [3]Diagnos. Imaging & Radiology/Developing Brain Res. Lab., [2]Children's Natl. Hlth. Syst., Washington, DC

**Abstract:** Congenital heart disease (CHD) affects brain development over the life span. Recent quantitative MRI studies have demonstrated structural and biochemical disturbances in the brain as early as the fetal/early postnatal period. However, the extent to which functional brain connectivity may be affected is currently unknown. We hypothesize that neonates with complex CHD will have atypical functional brain connectivity likely secondary to *in utero circulatory disturbances*.

We acquired resting state data from 30 neonates (postmenstrual age, PMA: 39.4 weeks, 38.9-39.7 [median, interquartile range]) diagnosed with complex CHD before surgery and compared their rich club organization to 82 healthy, term neonates (PMA: 41.5 weeks, 40.7-42.1). Rich-club organization refers to the tendency of highly connected (higher degree, *k*) brain regions to connect with each other compared to other areas of the brain. Both CHD and control networks demonstrated rich-club organization, however, the range of degrees at which the rich club regime was observed was narrower in CHD infants compared to controls: $k$ = 4-18 versus $k$ = 3-21, respectively. In addition, rich club coefficients were significantly reduced ($p$ = 0.01, paired t-test) in CHD newborns compared to controls. These findings suggest reduced number of connections among rich-club nodes in CHD. The rich club anatomy of the two groups overlapped and included regions such as bilateral hippocampi and insulae, regions identified as rich club nodes in healthy adults and neonates using DTI. The controls' rich club, however, had more members at 24 nodes compared to 13 in CHD. Areas absent in CHD included limbic structures such as the thalamus and amygdala, bilateral Heschl gyri, and parahippocampal cortices, among others.

In summary, we describe for the first time alterations in rich-club organization in neonates with complex CHD before open heart surgery. These finding likely reflect immaturity in brain functional networks possibly due to early life hemodynamic disturbances. Further studies are

needed to elucidate how these alterations impact the long-term neurodevelopment of CHD survivors, which are currently underway.

**Title:** A study of the brain functional MRI in the patients with alcohol dependence

**Authors: *S. FUKUSHIMA**[1,2], S. H. T. T. TAKEFUMI UENO[1]
[1]160 Mitsu Yoshinogari,, Natl. Hosp. Organization Hizen Psychiatric C, Kanzaki / Saga, Japan; [2]852-8501 1-7-1 Sakamoto ,Nagasaki, Nagasaki Univ. Hosp., Nagasaki, Japan

**Abstract:** Introduction: The World Health Organization estimates that as of 2010 there were 208 million people with alcoholism worldwide (4.1% of the population over 15 years of age). Alcoholism directly resulted in 139,000 deaths in 2013 up from 112,000 deaths in 1990. A total of 3.3 million deaths (5.9% of all deaths) are believed to be due to alcohol. It often reduces a person's life expectancy by around ten years. Alcohol dependence is complex, multifaceted disorder often characterized by cycles of cutting out alcohol, craving, and relapse. They repeat these cycles despite often-severe negative consequences. This disease results in social problems, health problems, and risky situations.
Objective: Functional magnetic resonance imaging (fMRI) was used to test whether brain activation was detectable in regions previously associated with illegal drugs cue-induced craving. We tried a study to investigate brain activation, using Alcohol images.
Method: 16 patients of Alcohol-dependent and 10 normal controls participated in this study. Blood oxygenation level dependent (BOLD) functional activation was measured with 1.5 T MRI during presentation of visual stimuli containing alternating intervals of orange juice, alcohol-related and mosaic scenes. This study were designed as “block design” and had two blocks. Each block task contained four pictures (orange juice or alcohol drink at random) in 120 sec. The duration of one picture was 15 sec, and the duration of interval between each picture was 15 sec with mosaic scenes. In total, we performed 240 sec (80 scans) on each subject. SPM12 was used to analyze BOLD fMRI data within each subject, as well as a group.
Results: We have a group analysis between 16 patients and 10 healthy people, we detected an interaction effect between brain activation of patients and healthy people with region of interest

(ROI) as right posterior cingulate gyrus (PCC) for analysis. Showing alcohol drinks, the activation of patients is higher than that of healthy people, and showing orange juice, the activation of them is lower with each significant differences (p=0.026, p=0.038). Conclusions: These results suggest that functional MRI may be a useful tool to study the neurobiological basis of cue-induced craving. And, alcohol dependent patients may overreact many kinds of alcohol drinks.

**Title:** Test-retest reliability of short-interval intracortical inhibition in patients with schizophrenia

**Authors: *X. DU**[1], A. SUMMERFELT[1], J. CHIAPPELLI[1], K. WISNER[1], P. KOCHUNOV[1], F.-S. CHOA[2], L. E. HONG[1]
[1]Maryland Psychiatric Res. Ctr., Catonsville, MD; [2]UMBC, Baltimore, MD

**Abstract:** Schizophrenia is a heterogeneous psychiatric disorder with a broad spectrum of clinical and biological manifestations and inhibitory-excitatory (I-E) imbalance has increasingly been proposed as a fundamental mechanism. One of the robust measurements of clinical I-E abnormality *in vivo* is the short-interval intracortical inhibition (SICI) vs. intracortical facilitation (ICF) elicited by paired-pulse transcranial magnetic stimulation (ppTMS) at 1-6 ms and 9-25 ms, respectively. Reduction of SICI in different stages of schizophrenia has been well demonstrated in the literature. However, the test-retest reliability of SICI in patients with schizophrenia has not been tested which largely limited the application of using SICI in assisting schizophrenia diagnostic. In the present study, the SICI and ICF profiles were obtained using inter-stimulus intervals (ISIs) from 1 to 500 ms, on 2 occasions about 3 weeks apart in 25 patients with schizophrenia (SZ) and 29 age- and gender-matched healthy controls (HC). The TMS coil was placed over left motor cortex for eliciting motor evoked potentials (MEPs) from the right dorsal interosseous. The ppTMS pulses were delivered with a subthreshold stimulus (80% resting motor threshold or RMT) followed by a suprathrehold stimulus (120% RMT) at 1, 3, 6, 9, 12, 15, 18, 21, 30, 40, 80, 120, 200 and 500 ms ISIs. Intraclass correlation coefficient (ICC), a standard method to examine the test-retest reliability, was obtained with a two-way mixed model. Raw MEPs showed moderate-to-good test-retest reliabilities across all ISIs and groups (ICCs for HC: 0.6-0.9; for SZ: 0.7-1). Importantly, moderate test-retest reliability was found for SICI (1 and 3 ms ISIs) in patients (ICCs: 0.6 and 0.7) and controls (ICCs: 0.7 and 0.7). Patients with schizophrenia, but not healthy controls, also showed moderate reliability for ICF (ICC at 9 ms ISI: 0.6 and 15 ms ISI: 0.8). Poor test-retest reliability at other ISIs (e.g., 18 to 500 ms) were observed across groups. To our knowledge, this is the first study demonstrated the acceptable reliability of SICI measurement in schizophrenia. The present data suggests that SICI could be a reliable biomarker for schizophrenia and be used for the development of diagnostics and for improved clinical decision-making.

**Abstract:** The application of robust clearing techniques to embryonic development across gestational time points and species can benefit many research areas, including neuroscience. Recent advances in tissue clearing have enabled the direct, 3D visualization of whole organs, leading to higher throughput and improved spatial resolution in a variety of tissues. A key step in tissue clearing is transcardial perfusion, which flushes the endogenous blood and uniformly fixes the tissue, especially in hard-to-access areas. However, transcardial perfusion is not directly applicable to mammalian embryos, due to the presence of the placental barrier that separates the maternal and fetal circulations, thus limiting the application of clearing techniques across mid-to-late gestational time points. Furthermore, species lacking distinct maternal-fetal circulations (e.g. chickens, zebrafish, etc.), lack the capacity for utilizing maternal vasculature to flush endogenous blood and deliver fixative to the developing embryo. While some workarounds exist for removing autofluorescence due to the presence of blood, improper fixation degrades the tissue epitopes and endogenous fluorescence signal. Here we describe methodologies to facilitate improved clearing techniques in embryos with and without accessible vasculature. We characterize the effects of fetal perfusion on fluorescent signal preservation in embryonic tissues of mice expressing Bcl11b-mCitrine and Bcl11b-mCherry reporter alleles compared to previously described techniques relying on immersion fixation. Additionally, we present clearing techniques for visualizing the neural crest in early stage chicken embryos by detecting endogenous fluorescence with subsequent immunohistochemistry and HCR on intact embryos. Samples from both studies were imaged with confocal and light-sheet microscopy. Together,

these clearing, labeling, and imaging techniques can aid in the characterization and visualization of neurodevelopmental processes during gestation.

**Title:** Combined soft and osseous tissue clearing for visualization and precise localization of *In situ* implants

**Authors: *A. GREENBAUM**, N. FLYTZANIS, K. Y. CHAN, C. CHALLIS, V. GRADINARU
Biol. and Biol. Engin., Caltech, Pasadena, CA

**Abstract:** Brain implants such as optical fibers for optogenetics and photometry, and microelectrode arrays for neuronal recording are essential tools for neuroscience research. Given the common practice of removing such implants before tissue examination, it can be difficult to evaluate the implant's exact placement with respect to the brain tissue. In addition to the glial scarring that is caused by implant insertion, implant retraction can result in further tissue damage, widen the implant tract, and distribute blood and necrotic cell debris across a larger volume. This tissue damage approximately marks the implant's tract, however, this approximation lacks precision. Consequently, important experimental details such as the identity of recorded cells or the precise location of the implant relative to region targeted, may be lost. We have therefore developed a technique for preserving the position of the implant and

surrounding tissue during histological processing. This ultimately enables optical investigation of the interface between the implant and the targeted cells. Toward this end, we build upon our previous bone clearing work (Greenbaum, Chan, et al, Science Translational Medicine, 2017), by clearing the brain tissue without removing the skull. This approach ensures that the implant remains firmly anchored and relatively unperturbed during the clearing process – minimizing tissue damage. The clearing process removes minerals with ethylenediaminetetraacetic acid (EDTA) and extracts light scattering lipids, thus allowing for optical investigation of the soft tissue below the skull. This method could be used with a variety of implants such as optical fibers, microelectrode array, EEG sensors and more.

**Abstract:** Creating an atlas of all cells in the brain is essential for understanding how complex cellular interactions determine brain function. Extensive efforts have been made to histology-based mapping of the brain. But these methods can map only a few molecules or sites per brain and require averaging over a large number of brains. Although the resulting averages are useful as references, they ignore high inter-individual variabilities. Moreover, the number of molecules and cell-types that these methods can analyze are fundamentally limited by the number of

samples available, creating a particular challenge when studying rare samples such as human embryos. To address this challenge, we have developed a rapid and cost-effective platform for creating an integrated 3D brain atlas with true cellular resolution. To achieve this, we developed eTANGO (electrophoretic Transport of Activity-modulated molecules in a Nanoporous Gel Organ hybrid), a technique that enables uniform staining of SWITCH-processed entire mouse brains in 1-3 days at a fraction of the cost of passive staining methods. To integrate the resulting organ-scale datasets across repeated rounds of labeling at true cellular resolution, we developed a scalable feature-based co-registration algorithm. The combined framework may allow integrated single-cell-resolution mapping of mammalian brains as well as key tissue architectures such as myelinated fiber tracts and vasculatures from a single mouse brain.

**Abstract:** Recent advances in intact brain imaging, such as the CLARITY and the MAP (Magnified Analysis of the Proteome) tissue clearing techniques, make it possible to collect large volumetric images of brain tissue at fine subcellular resolutions. The high throughput and high resolution brain imagery, however, poses a challenge for efficient processing and analysis. There is currently no effective tool for automated large-scale connectivity analysis at single fiber resolution. To tackle this unmet need, we developed a semi-automated long-range dense axonal fiber tracing pipeline which consists of four main modules: 1) a convolutional neural network (CNN) detects axon voxels, 2) image processing techniques, such as morphological operations, are applied to extract axon centerlines, 3) tracking logic connects axon segments across low-intensity gaps and unresolved axon crossings, 4) 3D fiber connectivity graphs are computed for network connectivity analysis.
We implemented our algorithms on a CPU cluster, and tested our pipeline on a 250 GB volume

of SMI-312 densely labeled axons, imaged from parts of the hippocampus and cortex of a MAP-processed mouse brain (resolution: 0.325 um in x, y and 1 um in z).
Original tissue size is 5 mm x 5 mm x 170 um. Imaging was performed after 4-fold tissue expansion.
Our automated pipeline traced fibers up to 1 mm long across gray matter and white matter in less than a day, as compared to weeks for one fiber done manually. An interactive front end user interface has also been developed for quick reviews of the raw data and results, allowing for editing of the traces. Accuracy is currently being assessed by experts and will be reported in the poster. Manual review of several 1 mm long fibers found that these were correctly traced.
We are in the process of scaling up our automated axon tracing to analyze terabyte-sized datasets. We plan to expand our algorithms to track other neuron components (e.g. cell bodies and dendrites), for a more complete network connectivity graph. The automated pipeline using CNN is the building block for state-of-art long-range fiber connectivity analysis at resolutions that have not been explored.

**Abstract:** Genetically encoded fluorescent proteins have greatly facilitated breakthroughs in dissecting neural circuits. Tissue clearing approaches, such as CLARITY, SWITCH, MAP, iDISCO, and CUBIC can render intact brains transparent to visualize 3D structures or expand tissues for nanoscale resolution imaging. However, these approaches often cause loss of fluorescent signals due to the exposure to unphysiological conditions (e.g, high temperature, organic chemicals, detergents) used in these methods. To address this challenge, we have developed a novel strategy, called SHIELD, for protecting fluorescent proteins from denaturation in biological tissue. By combining this technology with our Magnified Analysis of the Proteome (MAP) protocol we can preserve fluorescence in expanded, intact brains. Using SHIELD-MAP, we establish a novel process for rapid, multiscale circuit imaging of a single intact brain sample. This allows us to generate whole brain mesoscale connectome as well as nanoscale synaptic connectivity maps within the same sample. This new method for processing, imaging, and analyzing tissue will unify and expand understanding of whole brain cellular and synaptic connectivity.

**Abstract:** Holistic understanding of complex biological systems, from single biomolecules to cell interactions across whole organs, will require integrated methodologies that can simultaneously probe both nucleotides and proteins in intact tissue. While several tissue preservation strategies, such as CLARITY, SWITCH, and MAP, have been explored to preserve individual molecular features (e.g endogenous fluorescence of protein reporters, mRNA transcripts, or protein antigenicity), a universal tissue clearing method to profile all biomolecule types remains to be developed. Here, we demonstrate how multifunctional cross-linkers with

tightly regulated reaction kinetics can form cohesive tissue gels by binding together biomolecules of interest. We find that these flexible and multifunctional linkers protected proteins and nucleotides from deteriorating in harsh chemical conditions by forming both intra- and intermolecular bonds. This strategy, called SHIELD, enables simultaneous molecular profiling of nucleotides, proteins, and fluorescent reporters in intact tissue, such that correlative studies, from single transcripts to whole organ features, can be performed.

**Abstract:** Intact tissue processing techniques such as CLARITY have facilitated three-dimensional (3D) navigation of biological structures. Magnified analysis of proteome (MAP) further improved the spatial resolution by physically expanding intact tissues and enabling super-resolution imaging of 3D proteome with diffraction limited microscopy. However, the compatibility of MAP with various tissue types and molecular probes remains to be explored. Here, we present an advanced MAP technique, which extends its application to a wide range of tissue types and further enhances antibody compatibility. We confirmed that 36 antibodies targeting diverse synaptic proteins are compatible with MAP tissues, including Western-blot-

compatible antibodies that show no specific signal in PFA-fixed tissues. We were also able to process postmortem human tissues with MAP and achieved 3.5-fold expansion. Using this framework, we mapped diverse cell-types, their projections, and molecular architectures of their synapses. We anticipate that the advanced MAP technique will provide spatial and molecular accessibilities to biological samples beyond conventional approaches.

**Abstract:** The ability to use light to gain insight into the structure and function of complex biological samples has been invaluable in extending our understanding of biology. These advances have been propelled by improvements in imaging instrumentation and molecular and genetic tools. However, a limitation to optical imaging is imposed by the opacity of biological tissue. Recently, several methods to optically clear tissue have been developed; however, none are compatible with living tissue. To address the challenge of improving imaging resolution and depth in functioning neuronal circuits, we developed a biocompatible clearing agent, iodixanol-ACSF, which is capable of increasing the transparency of living neuronal tissue while still maintaining tissue function and health. Surprisingly, brain-cleared mice were motile and performed well on a variety of behavioral tasks, and extracellular recordings showed that many cellular and circuit phenomena were well-preserved. In live, iodixanol-ACSF cleared mouse brain tissue, both transmission and cellular-resolution fluorescence microscopy indicate improvements of 150-200% in depth penetration with one-third to one-half the laser intensity

when compared to untreated tissue. We successfully imaged calcium activity in behaving animals with iodixanol-cleared brains. Our results show that iodixanol-ACSF clearing can enable deeper imaging and be used to extend our understanding of neuronal circuit function. As this clearing technique is straightforward to implement, this technique can be incorporated into many currently existing setups to further extend our collective understanding of biological processes.

**Title:** Large-scale reconstruction of the endoplasmic reticulum and intracellular organelles of neurons using SBEM

**Authors: *M. HABERL**[1,2], E. P. CAMPBELL[3], T. DEERINCK[2], S. PHAN[2], E. BUSHONG[2], B. L. BLOODGOOD[3], M. H. ELLISMAN[2]
[1]CRBS, [2]Natl. Ctr. for Microscopy and Imaging Res., [3]Divsion of Biol. Science, Neurobio., UCSD, La Jolla, CA

**Abstract:** The endoplasmic reticulum (ER) of neurons extends from the nuclear envelope throughout the axonal and dendritic arbors (Lindsey and Ellisman, 1985). Extensions of the ER reach into dendritic spines (Martone et al., 1993; Spacek and Harris, 1997) forming a distinctive organelle, the spine apparatus, that is commonly found in mature, potentiated spines. Throughout the neuron, the ER comes into extreme proximity to, and even merges with, other organelles, such as mitochondria and the nucleus, as well as the plasma membrane, referred to as membrane contact sites (MCS) (Phillips and Voeltz, 2016). The specialized ER substructures and interfaces with organelle/plasma membranes are important sites for signaling and inter-organelle communication yet their numbers and distributions have not been described. This is largely because reconstructing the ER is a multiscale problem spanning from the nm-scale of MCS to the mm-scale of neuronal projections. Following it in dendrites and axons requires large-scale data acquisition at EM resolution. We have used serial block-face-scanning electron microscopy (SBEM) of the rodent brain and applied learning algorithms for automated reconstructions of these intracellular details as well as other intracellular organelles (mitochondria, Golgi apparatus, nucleus, and nuclear pores). In addition, we performed multi-tilt electron tomography for high-resolution structural reconstruction of the spine apparatus. Our work contributes to deepen the understanding of this fascinating cellular organelle as well as its interactions within the cell.

**Abstract:** Electron microscopy (EM) resolves neuronal ultrastructure; however more “user friendly” optical imaging approaches like confocal microscopy (CM) have recently been used as an alternative to EM analysis to provide limited cellular detail while maintaining neuronal morphology and identity. CM cannot resolve individual synapses, neuronal cytoskeleton or organelles. Thus, we developed an EM method to generate zoomable, Google map-type EM image sets that integrate anatomical localization, neuronal identity, and ultrastructural detail. Our integrated workflow permits acquisition and analysis of complete sections of the murine brainstem for assessment of anterior-posterior position, cranial nuclei, neuronal/glial identity, and organelle morphology in single tiled EM image sets. Brainstem sections (400µm) were fixed in osmium tetroxide, infiltrated with uranyl acetate, dehydrated and flat embedded in resin. Ultrathin sections of the entire brainstem were cut and placed on a silicon wafer for imaging in a FEI Helios FIB-SEM equipped with a concentric backscattering (CBS) detector (accelerating voltage - 2kV; landing current: 200 pAmps; Pixel dwell time: 3 msec, pixel size: 2.095 nm, horizontal field of view: 6.4 µm). Tiled CBS images were acquired using FEI MAPS software, and adjacent images overlapped by 20% for stitching. Tiled CBS images of the entire brainstem were collected at 600X to map regions of interest (ROIs). These ROIs were then imaged at 1000X to assess cellular identity as well as some ultrastuctural detail. Finally we selected a specific 420x240µm area within the ROI to image at 80,000X. Using these image sets we could reliably integrate anatomical, cellular and organelle changes of specific brainstem regions *in silico*. We focused on the hypoglossal nucleus (nXII) in the *LgDel* mouse, a genomically

accurate model of human 22q11 Deletion Syndrome (22q11DS). *LgDel* nXII motor neurons have circuit and excitability changes that likely contribute to perinatal dysphagia, a clinical complication for children with 22q11DS and a robust phenotype in post-natal *LgDel* pups. Our EM analysis of nXII at low, intermediate and high resolution *in silico* demonstrates altered *LgDel* nXII motor neuron and interneuron cellular morphology as well as synapse loss and evidence of oxidative stress. The specificity of this integrated analysis was made possible by our novel approach to EM data collection to guarantee anatomical precision and high quality ultrastructural detail. *Supported by DC Intellectual and Developmental Disabilities* (NIH U54HD090257) and *GW Program for Pediatric Dysphagia* (P01 HD083157).

**Title:** Localization of endogenous compounds in connectomics-grade volumetric electron microscopy imagery of brain tissue

**Authors: *T. TEMPLIER**[1,2], O. URWYLER[3,2], R. H. HAHNLOSER[4,2]
[1]Univ. of Zurich and ETH Zurich, Zuerich, Switzerland; [2]Neurosci. Ctr. Zurich, Zurich, Switzerland; [3]Inst. of Mol. Life Sci., Zurich, Switzerland; [4]Inst. of Neuroinformatics, Univ. of Zurich/ETH Zurich, Zuerich, Switzerland

**Abstract:** Electron microscopy (EM)-based cellular-resolution Connectomics lacks the ability to visualize endogenous compounds within uncompromised connectomics-grade volumetric EM imagery.
Using postembedding immunohistochemistry after non-destructive ultrathin serial sectioning of connectomics-grade resin-embedded brain tissue we show promising results for the localization of:
1. genetically encoded tags whose antigenicities survive harsh connectomics-grade EM embedding
2. genetically encoded tags that can be labeled
a) in vivo
or b) postmortem without permeabilization in thick tissues by complementary tags whose

antigenicities survive harsh connectomics-grade EM embedding
3. endogenous proteins that are labeled postmortem without permeabilization in thick tissues by tags whose antigenicities survive harsh connectomics-grade EM embedding.
Our approach, if successful, will complement volumetric connectomics-grade EM imagery with multiplexed imagery (fluorescent or cathodoluminescent) showing endogenous compounds (possibly genetically encoded and possibly in a stochastic manner) such as synaptic proteins or tags delineating neuron morphologies.

**Title:** Correlative light electron microscopy (CLEM) and quantification of synapses using immunofluorescence

**Authors: I. E. O. REPO**, A. STILLAR, *A. C. WEEKS
Nipissing Univ., North Bay, ON, ON, Canada

**Abstract:** Quantification of synaptic number in a given brain structure has been traditionally performed using electron microscopy since this approach provides sufficient magnification and resolution for accurate identification. Transmission electron microscopy (TEM) is, however, very time consuming due to need for physical sectioning of tissue and stereological reconstruction from slices to volumes. This issue makes TEM only practical for analyzing small synaptic populations in small tissue volumes and not entire brain regions. While confocal laser scanning microscopy is able to sample large tissue volumes due to the optical sectioning, it has lower resolution than TEM and does not allow for direct visualization of functional synaptic contacts. The present study examined the capabilities of confocal microscopy to study synaptic populations by visualizing the co-localization of pre and post synaptic proteins (SV2A and PSD-95 respectively) and determining the efficacy and accuracy of this method at detecting specific synapse. Here, correlative light electron microscopy (CLEM) was employed to reveal the underlying ultrastructure of confocal images. Results demonstrated that a confocal approach can be used to accurately estimate the total number of synaptic contact in a given brain area.

**Abstract:** Disintegration of axonal myelin sheaths leads to impaired impulse transduction and is associated with severe neurological/neurodegenerative diseases. Yet, spatially resolved assessment of myelin content in the brain remains a challenge. Currently, magnetic resonance imaging (MRI) methods such as magnetization transfer (MT) assessing the amount of macromolecules including myelin, and diffusion MRI (dMRI) inferring on axonal direction by probing the directionality of water diffusion are methods of choice, though they are not directly reporting on myelin levels. The recently developed *small-angle X-ray scattering tensor tomography* (SAXSTT)[1,2] might constitute a more immediate approach for probing myelin content and fiber direction given its sensitivity to a structural feature of the myelin sheath, its ~17.5nm periodicity[3].
We applied SAXSTT to mouse brain, and compared it to readouts obtained from MT and dMRI. Specifically, brains from 5-month-old C57BL/6 mice were studied *in vivo* and *ex vivo* using MRI and *ex vivo* with SAXSTT. In general, we found a high correlation between myelin content measures from MT and SAXSTT, though the quality of the correlation varied across brain regions with deviations found in frontal and lateral temporal cortex as well as olfactory tracts. Given the molecular signature of the SAXSTT signal (17.5nm periodicity) we attribute these differences to confounding contributions from other macromolecules to the MT signal. Comparisons of dMRI- and SAXSTT-derived fiber directions displayed a high level of similarity; yet region-specific differences were observed as well, e.g. for cingulum and brainstem. This discrepancy might arise from fundamental differences in properties measured: while SAXSTT probes the orientation of structural elements of myelin sheaths, dMRI assesses

the direction of intra-axonal water diffusion. Imaging results on myelin content and fiber directions were validated by histological analysis using Luxol Fast Blue and whole brain analysis using CLARITY[4] and anti-neurofilament staining.
In summary, the sensitivity to structural features renders SAXSTT an attractive technique for probing the local concentration and orientation of specific molecular entities in tissue *ex vivo* at high spatial resolution. SAXSTT might complement and validate experimental and clinical (MRI) readouts of brain disorders affecting neural connectivity, for which myelin content and integrity of white matter tracts play an important role.

**Abstract:** Here we describe results of our efforts to develop conductive reagents and sample preparation workflows that together overcome the challenges of “charging” and “electron beam damage” posed by volume electron microscopy. Our efforts began with a conductive epoxy resin developed and optimized for infiltration, immunocytochemistry, and serial-sectioning. Although the resin did not infiltrate evenly throughout the tissue sample and did not serial-section well, it provided tissue section stability as well as eliminated tissue section charging, beam damage, and shrinkage. These results led to the development of an electron conductive *en bloc* stain and sample preparation workflow. Prior to embedding the tissue sample in a non-conductive epoxy resin, the tissue sample was made electron-conductive using an *en bloc* stain. This *en bloc* stain coupled with the sample preparation workflow dramatically increased tissue contrast and electrical conductivity to overcome challenges posed by charging, radiation, ion beam- and electron-induced surface contamination/artifacts. However, again, serial-sectioning was an issue. These results then led to a third development, an *en bloc* electron-conductive ionic liquid stain and sample preparation workflow. The workflow dramatically increased tissue contrast in addition to electrical conductivity and overcame challenges posed by charging, radiation, ion beam- and electron-induced surface contamination/artifacts. It also serial-sectioned well and allowed for the segmentation / volume rendering of spinal motor neurons as well as their dendritic arbors and spines. On-going developments in volume electron microscopy specimen preparation, such as those described here will allow us to overcome challenges and permit artifact free neural circuit reconstruction.

**Abstract:** We present our development of an integrated imaging platform based on light sheet and light field microscopy strategies, to allow structural and functional neural imaging of whole small animals such as the zebrafish larvae. Light sheet microscopy, also known as Selective Plane Illumination Microscopy (SPIM), enables high resolution, high speed, low-photodamage imaging, ideal for following changes to brain structure and activity as a function of behavioral states. Light field microscopy, with the tradeoff of reduced resolution, enables synchronous volumetric imaging, where a single snapshot captures information over an entire extended 3D volume. This enables observation of neural activity at speeds even higher than possible with SPIM, and allowing for the sample to move in space during acquisition. We recently introduced Selective Volume Illumination to light field microscopy (SVIM), illuminating only the volume of interest of the sample, hence significantly reduce the background and enhance the contrast. We apply SPIM and SVIM to a variety of neural imaging applications, from observing sleep/wake behavior, to monitoring structural and functional changes due to learning. We envision the integration of SPIM and SVIM, spanning the full performance space of high-resolution to high-speed to whole-animal coverage, as the ideal platform for experimental paradigms that aim to record and understand neuronal structures and functions across scales, from the cellular to whole-brain, and correlating them with the animals' behavior.

**Abstract:** Correlative methods are a powerful tool to obtain multiple types of information on biological samples with increasing resolution. The samples can be imaged with microtomography, light microscopy (LM) and electron microscopy (EM) to achieve a complete overview, both in 2- and in 3-dimensions. We developed a workflow to apply correlative imaging between fluorescent LM and focused ion beam-scanning EM (FIB-SEM) to visualize the organization of aberrant endolysosomal structures in neurons within the dendrite and under synaptic spines.
Proof of concept experiments were performed by overexpressing CC2D1A-GFP in HEK cells. CC2D1A (coiled-coil and C2 containing 1A) is a key regulator of intracellular signaling via endosomal trafficking, and is mutated in intellectual disability and autism spectrum disorder. Previous studies have shown that gain or loss of function of CC2D1A in different cell types disrupts endolysosomal trafficking and signaling, generating enlarged vesicular structures. Transfected HEK cells were cultured on gridded glass coverslips, fixed, and imaged by both fluorescent and transmitted LM over the entire coverslip on a FEI CorrSight microscope. CC2D1A-GFP expressing cells of interest were then imaged again to build a 3D stack of fluorescent features. Cells were then embedded in resin for EM analysis and imaged again using transmitted light. All fluorescent and LM data were loaded on FEI MAPS software, which allowed the following alignment between the LM and EM images. The following EM analysis has been performed with the FEI Helios NanoLab 660 dual beam FIB-SEM. The fluorescent cells were identified in the MAPS software, and the same cells were localized with the FIB-SEM, using as reference the coordinates acquired during the LM. The FIB-SEM instrument allowed to build a trench in the resin in the region of interest (ROI), 20-50nm thickness serial sections were removed with the gallium ion beam and exposed block faces were imaged using SEM to obtain serial images with ultrastructural resolution. The images from up to a 15µm area were then aligned, and the volume of endosomal vesicles segmented with Arivis software. The entire process was performed at the Nanofabrication and Imaging Center at GWU.
This workflow allows to identify specific cells or subcellular ROIs via fluorescent LM and to reconstruct the fluorescent features at the ultrastructural level in 3D. We confirmed that CC2D1A-GFP-positive regions within the cells colocalize with enlarged and abnormal vesicular structures, and we are now extending these studies to correlative imaging analysis of endosomal vesicles under the dendritic spines of primary neurons.

**Abstract:** Over the past decade, the field of connectomics has emerged as one of the most promising approaches to exploring the nature of neural circuits. A microscale (~1 $mm^3$) connectome—a neuron-to-neuron wiring diagram of a neural circuit—would potentially contain a vast trove of information regarding information processing and memory. The field is held back, however, by the great difficulty in consistently collecting anatomical datasets with serial section electron microscopy. In the cerebral cortex, for instance, a local circuit is contained in a cubic millimeter, but single sections—obtained by cutting plastic-embedded brain samples with a diamond knife—must be 40 nanometers or thinner, thus requiring 25,000 consecutive sections to be processed. Here, we present novel tools for high-throughput, high-reliability, batch serial section processing that will enable rapid, millimeter-scale neural circuit reconstruction. (1) Using modern microfabrication technologies, we have developed high packing density substrates that are compatible with either serial section transmission or scanning electron microscopy (see Figure 1a, scale bar: 10 mm). Our substrates, with silicon nitride windows, are electron transparent, do not exhibit charging in the electron microscope, and are patterned with hydrophilic domains to eliminate misplacement of sections. Heating substrates during the section placement process allows for rapid evaporation of water droplets and facilitates wrinkle-free dry-down of ultrathin sections (see Figure 1b, scale bar: 100 um). (2) With off-the-shelf, high precision linear actuators, high-resolution cameras, and custom image processing, we have developed a semi-automated, robotic method for picking up and placing individual serial sections onto our heated substrates. High-magnification images of resulting ultrathin sections exhibit sufficient contrast for segmentation (see Figure 1c, scale bar: 1 um). The integrated toolset promises high-throughput, high-reliability ultrathin section processing for serial section electron microscopy.

**Abstract:** Tracer compounds such as cholera toxin B (CTB), wheat germ agglutinin (WGA) and tomato lectin have greatly increased our understanding of central nervous system (CNS) cell function, location and connectivity. Organic dye derived fluorophores are currently the most popular tracing conjugates even though they are highly susceptible to photobleaching, compete heavily with brain and spinal cord autofluorescence, and cannot be used for drug delivery. CNS tissue autofluorescence is high across a range of fluorescent excitation wavelengths from 300-650nm, particularly due to flavoprotein and reduced pyridine nucleotide (NADH) levels that correlate with neuronal excitability and metabolic activity *in vivo*, as well as from common neurotransmitter precursor amino acids such as tryptophan amongst others. Nanoparticles can offer the same advantages of fluorescent dyes for tracing studies but have superior properties that

give them photostability and clear signal discrimination over tissue/cellular autofluorescence. We have developed fluorescent nanoparticle conjugated tracers with near-infrared or infrared excitation, which are beyond the excitation wavelengths that produce almost all CNS autofluorescence. Fluorescent nitrogen vacancy centre nanodiamonds and lanthanide based upconversion nanoparticles were conjugated to CTB, WGA or tomato lectin via PEG using EDC/NHS based chemistry. These tracers were added to neurons, microglia and astrocyte cells. Uptake capacity and specificity were characterised at time points ranging from 1 minute to 4 hours by widefield and confocal microscopy. Our novel conjugated tracers were readily endocytosed by CNS cells over time, their presence and spectra were confirmed by single particle fluorescence spectroscopy and they demonstrated excellent photostability. The long and tuneable fluorescent lifetimes of these nanoparticles are ideal for time-resolved imaging, allowing for the detection of eight or more populations simultaneously, which is not possible using conventional dyes. Thus, the novel tracers developed here are ideal for future use in long term *in vivo* or tissue slice neuroimaging in a background fluorescence-free environment whilst also offering great multiplexing capabilities.

**Abstract:** Electron microscopy (EM) analysis using 3D reconstruction from serial ultrathin sections has attracted considerable attention, even after the introduction of super resolution microscopy, because EM is the most reliable method to analyze dense nanoscale details of biological structures, e.g. synaptic connections. The volume EM datasets for analysis were obtained using a several kinds of new EM system including automated tape-collecting ultramicrotomy (ATUM), in addition to conventional serial-section EM using an ultramicrotome in conjunction with transmission electron microscopy (TEM).
The ATUM method automatically collects large numbers of ultrathin sections quickly, consistently and continuously and is capable of repeated observations of the ultrathin sections on tape. We found a novel, optimal tape for ATUM, plasma-hydrophilized, carbon nanotube (CNT)-coated polyethylene terephthalate (PET) tape with an extremely high surface conductance. The CNT-PET tape was superior in many features in comparison to the currently used carbon-coated Kapton tape (polyimide film, DuPont, Wilmington, USA), which is not completely optimal due to its imperfect conductivity, hydrophobic surface nature and/or frequent surface scratches. SEM of brain tissue sections on CNT-PET tape stained using a modified en bloc staining protocol revealed detailed synaptic structures and vesicles. The images are comparable to those obtained with the tissue section on the carbon coated Kapton tape.
In conclusion, CNT-PET tape is a useful addition to automated serial sectioning workflows and is expected to facilitate serial-section SEM reconstructions of brain circuits, which we expect will lead to substantial advances in brain microcircuit analysis.

**Title:** An optical clearing and labelling platform for 3D cytoarchitectural characterization of large adult human brain samples

**Authors: *S. HILDEBRAND**, A. SCHÜTH, A. ROEBROECK
Maastricht Univ., Maastricht, Netherlands

**Abstract:** Optical clearing of brain tissue rapidly became a standard for investigating the rodent brain [1], [2]. However clearing and staining of adult human brain tissue proves to be far more difficult and currently only imaging of thin human specimen has been performed [3], [4]. This is partly due to the clearing capacity of the protocols, but even more to the limited penetration of common labels. Here, by combining an optimized clearing approach with small molecule dyes, we demonstrate 3D cytoarchitecture in thick adult human brain samples.
Brain tissue of 3 body donors, giving informed and written consent regulated by Dutch law, was obtained. Tissue was first perfusion fixed with 10 % formalin, post-fixed in 4 % PFA in PBS and sectioned into slices of approx. 15 x 20 x 5 mm.
Several dyes were tested for fluorescent Nissl or nuclei labeling by immersing slices in 6 ml solution for 2 - 7 d at $4^0$C.
Clearing was performed via a modification of the iDISCO+ method [1] with a new refractive index matching solution (RIMS) of the same RI as dibenzyl ether (DBE).
Light sheet fluorescent microscopy was performed with an Ultramicroscope II (La Vision Biotech, Germany; 2x objective, 4-10 mm working distance (WD)), two-photon laser scanning microscopy on a Leica TCS SP5 MP (Leica Mikrosysteme Vertrieb GmbH, Germany; HXC APO L 20x, 2 mm WD water immersion objective).
The iDISCO+ protocol [1] in combination with our new RIMS renders samples of human brain highly transparent (Fig. 1), while being less toxic, corrosive and photobleaching than DBE.
With the tested labels it is possible to stain thick samples reliably and fast (5 mm deep labelling possible in 5d). These inexpensive dyes provide a broad basis for cytoarchitectonic labeling and

counterstaining for cleared specimen, with various wavelengths to match research questions and microscope setups.
This opens up the possibility of high-throughput processing and imaging of human brain tissue for the examination of human neocortical architecture at the mesoscale.

**Abstract:** Multi-Electrode cortical arrays are key neuronal interfacing systems in neurophysiological and clinical research to better understand healthy and pathological brain dynamics. One of the major challenge is to propose a biocompatible device that remains stable over a long period of time and therefore that minimizes undesirable brain tissue reactions. Several studies indicate that surface structuration can promote neuron adhesion to the implant surface while it could limit glial cell proliferation. As the major implant surface is composed of the insulating material, we investigated different plasma etching procedures to get reproducible nanostructure topologies of SU-8, polyimide and parylene polymers. We have shown that, using a simple and rapid etching technique we were able to get nanostructures with controllable size. In a second step, the biocompatibility of these different nanostructured polymers was studied on rat primary cortical cells cultures.

**Title:** The enteric nervous system 'connectome' with and without the microbiome

**Authors: *V. SAMPATHKUMAR**[1], V. DE ANDRADE[3], R. VESCOVI[1], H. LI[1], K. FEZZAA[3], M. DU[4], V. LEONE[2], E. CHANG[2], N. B. KASTHURI[1]
[1]Neurobio., [2]Med., Univ. of Chicago, Chicago, IL; [3]Advanced Photon Source, Argonne Natl. Lab., Lemont, IL; [4]Materials Sci. and Engin., Northwestern Univ., Evanston, IL

**Abstract:** Despite increasing evidence that the gut microbiome influences neurological functioning, little is known about how microbiome changes the cellular and synaptic

organization of neurons. Part of the problem is that many studies focus on the effects of microbiome on the large and complicated central nervous system (CNS), where finding the putative site(s) of influence remains difficult. The enteric nervous system (ENS), often termed the 'second brain', has a potentially simpler structure than the CNS, functions in a semi-autonomous manner, and is far more proximate to the microbiome and its potential influences. It can thus serve as an ideal model system to study neuronal connectivity changes influenced by the microbiome. We have developed a multi-scale imaging pipeline that maps the cellular composition of large samples of the ENS (~1 $cm^3$, ~ 1μm resolution) using synchrotron source x-ray microscopy (μXCT) and nanometer reconstructions of neuronal connectivity in the same sample using automated large volume serial electron microscopy (EM). We are applying this pipeline to create unbiased maps of the cellular and synaptic differences in the ENS of wild type (WT) and germ free (GF) mice . Preliminary data already reveals potential cellular, vascular and neuronal changes in the absence of the microbiome. This data will reveal, for the first time, the influence of intestinal microbiota on the normal development of ENS and serve as a model for similar studies of CNS.

**Title:** Effect of incubation with streptolisynie o, in the pore formation in boar spermatozoa

**Authors: *M. BARRIENTOS**[1], E. JACOME-SOSA[1], B. DOMINGUEZ-MANCERA[1], P. CERVANTES[1], A. HERNANDEZ BELTRAN[1], M. JUAREZ-MOSQUEDA[2]
[1]Univ. Veracruzana, Veracruz., Mexico; [2]Facultad de Medicina Veterinaria y Zootecni, Univ. Nacional Autonoma de México, Mexico DF, Mexico

**Abstract:** The aim of the present study was to determinate the formation of pores in the plasma membrane of the boar spermatozoa, after incubation with streptolysin O (SLO) and determining the effect on the viability post-thawing. The study was conducted at the reproduction biology lab of the diagnostic unit "Augusto R. Mancisidor Ahuja" at the "Torreón Del Molino" ranch. Fifteen ejaculates of four boars were obtained by the gloved hand technique. The inclusion criteria of the sample was ≥ 4 for mass motility and ≥ 70% for individual motility. The Scanning

electron microscopy was used to observe the presence of transmembrane pores. The Eosin-Nigrosin test and Coomassie Brilliant Blue in combination with Hypo-Osmotic Swelling Testing (HOST) were used for assessment of sperm viability and acrosome damage. Cells were incubed with SLO (0.6 UI/ml) and trehalose (200 μM) at three periods: T1: 5 minutes, T2: 15 minutes and T3: 30 minutes, all treatments at 37 °C for the membrane permeabilization. In the presence of trehalose (200 uM) and a control group (TC: diluted semen). After this, they were cryopreserved by the protocol described by Westendorf (1975); for sealing pores fetal bovine serum (FBS) was used at 5%. The data obtained were analyzed through Kruscal Wallis H test program STATISTICA V7.01. Was concluded that SLO is capable of forming pores in the plasma membrane of swine sperm cell. The motility do not have difference ($p > 0.05$) between T1 and T2, but there is with the T3 ($p < 0.05$). The TC had the highest percentage of living cells and functional membrane ($p < 0.05$) compared to other treatments, same as were similar between them ($p > 0.05$). The percentage of sperm with intact acrosome was similar between the TC, T1 and T2 ($p > 0.05$) treatments, as well as between T2 and T3 ($p > 0.05$). It can be concluded that in this study the SLO was able to form pores in the plasma membrane of swine sperm cell; however, incubation in SLO and trehalose was not a determining factor in the increase in viability after thawing.

[1]Johns Hopkins Med. Sch., Baltimore, MD; [2]Depts Neurol, Neurosci, Johns Hopkins Univ. Dept. of Neurol. and Neurosurg., Baltimore, MD

**Abstract:** We have created a human neuronal cell line, HC-1, by immortalizing partially differentiated hESC cells with Sv-40 large T, MycT58A and hTert genes. Upon differentiation with the presence of human Activin A, GRO/MGSA (growth regulated protein/melanoma

growth stimulatory activity), NGF, GDNF and cAMP, these cells extended neurites and displayed human DRG characterizations. Specifically, they expressed high levels of neuronal markers such as TPRA, P2x3, TrkA, TrkB, TrkC, Trpm8, P75, GDNF and Pirt. Immunostaining and ELISA confirmed they were also positive for beta-3 tublin, neurofilament, calcium binding protein S100B, GFAP, isolectin B4 and CGRP proteins. In addition, they exhibited functional properties of human nociceptive afferent sensory neurons in electrophysiological studies. About half cells (51/116) were able to fire spikes upon the current pulse injection. Voltage clamp traces showed that HC-1 cells also expressed $Na^+$ currents, which could be blocked by pretreatment of 1 *u*M TTX. Complex outward current and voltage-gated potassium and sodium currents could also be evoked by depolarizing pulse protocol in these cells. Importantly, over 50% of the HC-1 cells (23/41) were responsive to capsaicin (a TRPV1 agonist). Calcium imaging confirmed that 15.38% (20/130) of cells responded to capsaicin and 23.07% (30/130) responded to menthol. We have tested HC-1 cells' suscepility to anticancer drugs cisplatin, *bortezomib, and taxol by measuring ATP production after treatment for 48 hours. About 40% of toxicity can be observed at 2 uM, 20nM and 10 uM, respectively, and higher concentrations of the drugs resulted in more toxicity.* These results indicated that these cells might be used in high throughput systems for the discovery and development of new drugs for the treatment of peripheral neuropathy in chemotherapy patients. Further more, we have conditioned HC-1 cells in a culture system in which glutamine, other than glucose, was used as the major source of nutri-energy. These adapted cells were susceptible to high glucose stress at physiologcal pH, and 35-45% toxicity (loss in ATP level) was recorded after treatment for 24 hours with 25mM glucose. This indicated yet another application of the cells in exploring the leads to the treatment for diabatic neuropathy.

**Abstract:** Oligodendrocytes (OLs) are the only cells capable of generating myelin in vertebrate central nervous system (CNS). Myelinated axons are crucial for efficient and rapid conduction of action potential throughout the CNS. In multiple sclerosis (MS), pathological insults have been shown to cause a loss of OLs, leading in turn to demyelination, neuronal axon degeneration and ultimately irreversible neurological disability. Remyelinating therapies are keys for changing the long-term course of the MS progression. The development of myelination/remyelination therapies requires a reliable and sensitive in vitro myelination system. Although co-culture of neuron-oligodendrocyte or slice culture has been used to study myelination and remyelination, however, these in vitro myelination assays have limited throughput and sensitivity for drug efficacy studies. We present here the development of a myelination assay using purified mouse oligodendrocyte progenitor cells (OPCs) and custom-designed nanofibers that mimic white matter as suitable scaffolds for myelin wrapping. We found that immunopurified mouse OPCs are capable of differentiating into mature OLs and forming concentric wraps along the nanofibers, as revealed by electro-ultrastructure analysis. When OPCs were treated with thyroid hormone T3, a known activator of OPC differentiation and myelination, we found significant increases in the number of immunostained PLP+ and MBP+ cells in the nanofiber culture system. Moreover, these cells show longer myelin length and extended myelin wrapping along the fibers compared with controls. The efficacy of other repurposed drugs that have been shown to promote OL differentiation and myelination/remyelination has also been tested in the system. Our data demonstrate that mouse OPCs can differentiate into OLs and form multiple-layers of myelin wrapping on the nanofibers without axonal signaling. This system can be used effectively to evaluate the potential of remyelinating therapies. In addition, the use of mouse OLs in this culture system could provide a new avenue to investigate the mechanism of action of therapeutics by taking advantage of the mouse genetic system.

**Abstract:** Both stroke and retinal ischemia (RI) acute neuronal injury involve L-Glu-mediated excitotoxicity. Compounds that enhance L-Glu clearance represent promising tools for providing an efficient protection against ischemic injury, however only a few compounds promptly activate L-Glu transporters. In this context, we have investigated molecules isolated from spider venoms such as Parawixin10 (Pwx10), which presents a potent activity in increasing L-Glu uptake and did not present behavioral changes in neuroethological assessment. To evaluate the neuroprotective effects of Pwx10, we submitted Wistar rats to translational models of stroke and RI that reproduce ischemia and reperfusion. Thereby, in RI model, intraocular pressure was increased to 120 mmHg for 60 min in ischemia (ISC), which could be followed by reperfusion (IR). Pwx10 (2µg/µL), Riluzole (23,45 µg/µL) or Saline (0.9%, 1µL) injections were administrated intravitreal and neuronal protection and neurodegeneration were evaluated by quantification of Hematoxylin-Eosin (HE) and Fluoro-Jade C positive cells (FJC), respectively. The Pw10 protected the retina ganglion cell layer (GCL) more effectively than treatment with Riluzole both in HE ($n=6$; $p<0.0001$) and FJC ($n=6$; $p<0.0001$) assessment. In stroke model, rats were implanted with a steel guide cannula into the piriform cortex to access Middle Cerebral Artery (MCA) and in the right ventricle to deliver drugs. Occlusion of the right MCA was induced in awake rats by endothelin-1 (ET-1; 400ρmol in 4µL) injection. SHAM animals were injected with saline (in 4µL). Neurologic deficit (inclusion parameters) were evaluated 10 minutes after ischemia in Open field test (OFT) and Tail Suspension Test (TST). Treatment was conducted 30 min from behavioral analyses, with Pwx10 (2µg/µL; 1µL) or Saline 0.9% (1µL) injections. Neurologic deficits were assessed by OFT, TS additionally with Adhesive Test (AT), after 3 days post stroke. Neuronal death in cortical and striatal infarcted areas was evaluated with FJC and triphenyltetrazolium chloride (TTC) method. Treatment with Pwx10 improved neurological function in AT test ($n=6$, $p<0.001$), and in OFT ($n=6$, $p<0.0001$) and TST tests ($n=6$, $p<0.001$). More remarkably, Pwx10 was efficient in reducing infarct volume area ($n=6$, $p<0.0025$) in TTC method and decreasing FJC-positive cells in the cortex ($n=7$, $p<0.0001$) and striatum ($n=7$, $p<0.0001$). Our findings suggest that Pwx10 presents neuroprotective effect and L-Glu transporter activators can be considered a safe and effective approach to treating conditions involving excessive L-Glu such as ischemic injury.

**Abstract:** Parkinson's disease (PD) is the second most frequent neurodegenerative disease. There are no cures or disease-modifying therapies for PD, and this may be due in part to our inability to monitor biological markers of disease. Currently, PD patients are diagnosed, cared for, and assigned to clinical trials based on relatively arbitrary clinical scales. In order to develop disease-modifying therapies, dependable and robust biomarkers are required for monitoring disease progression and facilitating patient stratification. In this study, we employed parallel reaction monitoring (PRM) mass spectrometry to develop a targeted quantitative method for elucidating potential biomarkers in cerebrospinal fluid (CSF). By using both in-house data dependent mass spectrometry analyses and literature mining, we produced a list of over 125 quantifiable peptides representing 90 protein targets, including neurocan (*NCAN*) and vitamin D-binding protein (*GC*). Quality control analyses of these protein targets show high reproducibility with a CV < 15% for the majority of peptides assessed with the PRM method. Preliminary results from CSF analyses from 21 control and 19 PD patients indicate altered protein levels for a subset of these proteins. Among several disease relevant findings, altered vitamin D-binding protein was observed in patient compared to control CSF, and vitamin D insufficiency has been associated with PD. Currently, all 90 protein targets are being quantified with PRM in a validation cohort of 160 CSF samples from control and PD patients to assess their potential for biomarker application. In summary, we have developed a reliable quantitative targeted mass spectrometry platform to explore multiple putative biomarkers in PD that can be applied to other disorders.

**Abstract:** Alzheimer's disease (AD) is a complex and multifactorial disease for which various attempt to rescue memory impairment are still not produced actual results. We found that reactive astrocytes aberrantly and abundantly produce the inhibitory transmitter GABA by over-expressed monoamine oxidase-B (MAO-B) in AD. Based on this novel target, we have developed a promising lead compound that shows excellent selectivity and efficacy against hMAO-B and fully restores the cognitive impairment of APP/PS1 mice. It also displays excellent drug-like properties in ADME/Tox test. We proposed novel disease-modifying therapy in AD which inhibit aberrant GABA synthesis in reactive astrocytes.

**Title:** Molecular mechanisms underlying the oligomerization and activity of sigma 1 receptor

**Authors: M. XU**, H. YANO, *L. SHI
NIH, Baltimore, MD

**Abstract:** The sigma 1 receptor (σ1r) is a unique endoplasmic reticulum membrane protein, which shares no sequence homology with other mammalian proteins. It is involved in numerous cellular processes by interacting with various client proteins as a chaperon or modulator. Such extensive interaction network implicates its vital role in several human diseases such as drug addiction, depression and neurodegenerative disorders. Moreover, some σ1r ligands have been reported to alter the oligomeric state and the cellular behavior of σ1r. The categorization of these compounds, however, were based on different assay models and often not entirely consistent. Thus, it is essential for us to investigate the structure-function relationship for σ1r, in order to clarify the ambiguity of the classification and predict the pharmacological profile for new ligands. The recent crystal structures solved by Schmidt *et al. 2016* lay the foundation for this mission. The structures were solved as trimers and each subunit is composed of a single transmembrane helix and a barrel-like ligand-binding domain. Starting from the crystal structures, we investigate the conformational change of σ1r under different oligomeric states and ligand-bound conditions, using all-atom molecular dynamics (MD) simulations. Specifically, we characterized the different binding modes for four σ1r ligands, (+)-pentazocine (PNT), PRE084, PD-144418 (PD) and haloperidol (HDL) in both the trimeric and monomeric σ1r models. To this end, by the network analysis of the MD data, we identified the gate and anchor regions in the ligand-binding domain that have distinct dynamics under different conditions. The gate region, featured by the GXXXG motif, can adopt two states, open and closed. We demonstrate that all the trimeric conditions stabilize the gate in the closed conformation, which is further stabilized by binding with PD or HDL. The anchor region is where the transmembrane helix is attached. The mutation E102Q in this region was found to affect the mobility and activity of σ1r in the apo or PNT-bound conditions by Wong *et al. 2016*, which may play a role in amyotrophic lateral sclerosis. The analysis of our MD data showed different interaction networks within the anchor region, which are more well-connected in the PNT-bound and E102Q mutant conditions. In summary, our MD simulations are in line with the results from the previous studies and our BRET assay, indicating that the gate region is critical for the oligomerization of σ1r, whereas the anchor region contributes significantly to the activity of σ1r. The uncovered conformational changes also shed light on the pharmacological profiling for the σ1r ligands.

**Abstract:** The sigma 1 receptor (σ1R) is a structurally unique transmembrane protein not sharing sequence homology to any other known protein family. Mainly functioning as a molecular chaperone in the endoplasmic reticulum (ER), its ligands have shown therapeutic potential in cancer, neuropathic pain, and psychostimulant abuse. Despite physiological and pharmacological significance, mechanistic underpinnings of structure-function relationships for σ1R are poorly understood. Particularly, the distinction between agonist and antagonist is not clearly defined, due to the lack of congruence among results from different assay models, which can be influenced by specific cellular environment and events leading up to specific assay readouts. Here we have established an assay system away from the downstream readout models. By incorporating a molecular proximity assay, bioluminescence resonance energy transfer (BRET), we categorized σ1R ligands independent of factors preceding the readout events. By focusing on the ligand induced conformational changes associated to σ1R-σ1R homomeric interaction, we have parsed out the ligands into those that promote the interaction and those that do not. In comparison, we demonstrated that the non-promoting ligands can reduce the BRET signals elicited by the promoting ligands. Further these results were substantiated with other cellular functional readouts for immediate downstream effects such as ER and intracellular calcium activities. In light of the seminal work of recent crystal structures by Schmidt *et al.*, we carried out molecular dynamics (MD) simulations in parallel in the trimer as well as monomer states. A consistent correlation regarding the differential characteristics of the ligand binding modes induced by interaction promoting and non-promoting ligands have been observed. Together with the results observed from MD simulations, we propose a novel BRET assay herein as a reliable method to functionally categorize σ1R ligands based on the conformational states of the receptor that a particular ligand would prefer or induce. The method could serve as a useful pharmacological profiling tool in its relevance within neuropharmacology.

**Title:** Pharmacological inhibition of the neuron restrictive silencer factor under hypoxia situations

**Authors: *Y. A. RODRIGUEZ**[1,2], J. C. MARTINEZ[1], M. L. SERRANO[3], C. CASTILLO[1], J. CARBALLO[1]
[1]SALUD, Fundacion IDEA, Caracas, Venezuela, Bolivarian Republic of; [2]Dept. de Biología celular, Univ. Simon Bolivar, Caracas, Venezuela, Bolivarian Republic of; [3]Facultad de Farmacia, Univ. Central de Venezuela, Caracas, Venezuela, Bolivarian Republic of

**Abstract:** It is known that the neuron-restrictive silencer factor (NRSF) or Repressor Element 1-Silencing Transcription factor (REST), is part of a repressor complex that acts in the promoter region of more than 2000 neuronal genes. Patients suffering from a stroke have an increase in NRSF/REST expression that increases post-ischemic neuronal death in the affected regions. Therefore, the aim of this study was to evaluate if the use of a drug that prevents the transcriptional repression carried out by NRSF/REST could reduce neuronal death in hypoxia situations. The lysine-specific histone demethylase 1 (LSD1) participates in the repression complex of NRSF and was selected as a target protein to direct the search for drugs, because it was available in its three-dimensional protein structure and had been co-crystallized with several ligands. Then, it was used to screen compound libraries to look for drugs that were validated by molecular docking tools (AutoDock software, Vega ZZ) followed by *in vitro* assays. We chose the four best potential inhibitors based on their binding energy (C1, C2, C3, C4). When evaluating these compounds using *in vitro* assays in rats neuroblastoma Neuro 2A cells, none was found to have cytotoxic effect. In addition, we investigated the neuroprotective action of the compounds against oxygen-glucose deprivation (OGD)-induced injury. Cell viability was investigated using the 3-[4, 5-dimethylthiazol-2-yl]-2, 5 diphenyl tetrazolium bromide (MTT) reduction assay. When the compound C3 was present, we observed a significant increase in cell viability compared to control treatments. When we examined the expression of the *HIF-1α* gene, a REST target gene, using RT-PCR, we found that the C3 compound favored the expression of the HIF-1α gene. This gene has been reported to exert an anti-apoptotic effect, which suggests the usefulness of such drug to promote cell survival. The compound C3 could be an epigenetic drug for treatment of strokes or could be a scaffold for future epigenetic drug discovery.

**Title:** Enhanced CNS uptake of prodrugs of the GCPII inhibitor 2-PMPA following intranasal administration

**Authors: A. J. GADIANO**[1], S. C. ZIMMERMANN[2], R. P. DASH[2], C. GARRETT[3], J. ALT[1], C. ROJAS[3], A. G. THOMAS[1], Y. WU[1], P. MAJER[4], R. RAIS[2], *B. S. SLUSHER[1]
[2]Neurol., [3]Mol. and Comparative Pathobiology, [1]Johns Hopkins Drug Discovery, Baltimore, MD; [4]Inst. of Organic Chem. and Biochemsitry, Acad. of Sci. of the Czech Republic, Prague, Czech Republic

**Abstract:** 2-(Phosphonomethyl)pentanedioic acid (2-PMPA) is a potent and selective inhibitor of glutamate carboxypeptidase-II (GCPII), a membrane-bound zinc metalloprotease that plays a key role in regulating extracellular glutamate availability in the brain. As disrupted glutamate homeostasis is implicated in several neurological and psychiatric conditions, GCPII is a promising drug target. Several independent laboratories have shown robust neuroprotective efficacy with 2-PMPA in dozens of preclinical neurological and psychiatric disease models (e.g. e.g. neuropathic pain, peripheral neuropathy, stroke, schizophrenia, addiction, multiple sclerosis, traumatic brain injury), when given at very high systemic doses ($\geq$100 mg/kg) or when directly injected into the brain. However, the clinical development of 2-PMPA has been hampered by its low brain penetration, presumably due to its multiple acidic functionalities. We recently reported an improvement in the brain-to-plasma ratio of 2-PMPA after intranasal (IN) dosing in both rodents and primates. We also recently employed a 2-PMPA prodrug strategy to decrease its polarity and showed that we could improve its oral availability by >20-fold in both rodents and dogs We therefore hypothesized that combining a IN delivery with a prodrug approach could further enhance permeability and increase drug exposures in the brain. Herein, we have undertaken the synthesis of several 2-PMPA prodrugs with masked γ-carboxylates and performed pharmacokinetic evaluations of these compounds in Wistar rats and rhesus macaques.

Our results show that the prodrugs investigated have enhanced lipophilicity and further improve brain as well as systemic delivery of 2-PMPA after IN administration. When compared to IN 2-PMPA in rats at 1 hour post-administration, the prodrug γ-(4-acetoxybenzyl)-2-PMPA (JHU 144)**,** resulted in substantially higher 2-PMPA delivery to both plasma (4.1-fold) and brain (11-fold). Subsequent time-course evaluation of JHU 144 also showed high brain and plasma 2-PMPA exposures with the brain/plasma ratios of 1.45, 0.23, and 0.20 for olfactory bulb, cortex, and cerebellum, respectively. Further, in primates IN administration of JHU 144 more than doubled 2-PMPA concentrations in the CSF relative to previously reported levels and provided a CSF to plasma ratio of 1**.** In conclusion, the results of these experiments provide a promising strategy of enhancing delivery of drugs that demonstrate therapeutic potential for neurological and psychiatric disorders.

**Title:** microRNA 34b/c and alpha synuclein gene expression in SH-SY5Y cells for Parkinson's disease study

**Authors: *E. HAHS**, S. KHOO
Cell and Mol. Biol., Grand Valley State Univ., Grand Rapids, MI

**Abstract:** Parkinson’s disease (PD) is the second most common neurodegenerative disorder, affecting 1-2% of adults over the age of 60. The pathological hallmark of PD is alpha synuclein (aSyn) protein inclusions, known as Lewy bodies and Lewy neurites, in the brain. Accumulation of this misfolded protein, especially in the dopaminergic neurons, has been implicated to cause PD. Thus, developing new drug therapies that block aSyn aggregation could potentially slow or stop the disease progression. MicroRNAs (miRNAs) are small RNAs that bind to messenger RNA (mRNA) and regulate their gene expression. miRNA-34b and 34c are predicted targets for aSyn and are shown to be down-regulated in PD brains. Here, we aim to establish a cell model to study the effects of miRNAs on aSyn aggregation. SH-SY5Y cells were incubated in DMEM/F12 and 10% FBS. Retinoic acid and brain-derived neurotrophic factor were then added

for cell differentiation. Trypan blue was used for cell viability assay. Rotenone, a pesticide that can induced Parkinson-like phenotypes in cell, was added in day 8 and cells (in triplicate) were collected every day at day 9-16 of differentiation. RNA that contains miRNAs was extracted from cells using Qiagen miRNeasy kit. Quality and quantity of mRNA and miRNA were measured with a Qubit fluorometer. Using quantitative real-time PCR, we found miR-34b/c expression down-regulated in rotenone treated SH-SY5Y cells that mimic PD when compared with non-treated control (miRNA-34b p-value = 0.0073; miRNA-34c p-value = 0.0006). However, aSyn gene expression was not up-regulated in rotenone treated cells when using Taqman primers that cover short aSyn transcript (exon 1-3; Hs01103383_m1). Our next step is to use primers that cover aSyn full-length transcript (exon 1-5; Hs00240907_m1) and anticipate up-regulation of aSyn in rotenone-treated cells. This study will allow testing of miRNA mimics or inhibitors to investigate their effects on aSyn aggregation to provide valuable information on future miRNA-based therapies for PD.

**Authors: *J. W. BROWN**, V. A. RODERWALD, H. M. ROBB, C. Z. ZHU, E. G. MOHLER
Neurosci. Discovery, AbbVie, North Chicago, IL

**Abstract:** In-vivo discovery efforts to screen and validate novel therapeutics for Alzheimer's Disease (AD) predominantly use transgenic mice harboring human mutations associated with early-onset familial AD (APP, PS1, and PS2). While Tg AD mice do have utility in certain applications, particularly when evaluating therapeutics whose mechanism of action is directly linked to such proteins and pathways, they model only a tiny fraction (1-5%) of the AD patient population. SAMP8 mice have been considered as a model of senile dementia and non-familial sporadic AD and therefore may be a more representative model of the predominant AD population of late-onset. SAMP8 mice, in addition to an accelerated aging phenotype, are reported to feature many AD-like characteristics (e.g., increased Aβ and pTau, neuroinflammation, neuron loss, synaptic dysfunction, and cognitive dysfunction), some of which are often absent in Tg AD mouse models. To confirm the reported phenotype of SAMP8

mice, we evaluated 6, 9, and 12 month old male and female mice in a cross-sectional design using commercially-sourced animals from a purpose-bred colony at EnVigo (Indianapolis, USA) using a variety of cognition, biochemical, and immunohistochemical (IHC) assays. While both male and female SAMP8 mice had significantly reduced lifespan compared to sex-matched SAMR1 controls, consistent with the established accelerated aging phenotype for these mice, no robust cognitive impairments or AD-like pathological changes were observed relative to SAMR1 controls. There were no strain differences in Barnes Maze, contextual fear conditioning, or spontaneous alternation in cross-maze across all ages. Only in the inhibitory avoidance task were SAMP8 mice impaired relative to SAMR1 mice, but there was no age-related decline in performance observed. Biochemical analysis of whole brain homogenates by Meso Scale Discovery immunoassay revealed no increases in $A\beta_{40}$, $A\beta_{42}$, total tau, pTau, or neuroinflammatory cytokines in SAMP8 compared SAMR1 across all ages. Furthermore, IHC analysis of the CA3 region of hippocampus demonstrated no strain differences in pTau (AT8) or microglial activation (Iba-1) across all ages as well. The lack of strain differences across multiple measures of cognition and absence of AD-like pathological features reported here suggests the possibility of phenotypic drift in SAMP8 mice sourced from EnVigo, at least in the colony of mice produced for our purposes.

**Abstract:** Information about the concentration of drug candidates and their pharmacodynamic (PD) effect in the brain and cerebrospinal fluid (CSF) is vital to decrease the attrition rate in drug discovery/development; poor pharmacokinetics has been recognized as one of the leading causes of failure in the clinic. Therefore, the ability to measure concentrations of a drug candidate and its PD effect in the brain, CSF and plasma as biomarkers are of particular interest. Metabolites of kynurenine pathway (KP) are implicated in the pathophysiology of neurodegenerative disorders including Huntington's disease (HD). Kynurenine 3- monooxygenase (KMO) inhibitors may have potential to treat HD, given that KMO inhibition should shift the metabolism of kynurenine to increase the formation of the neuroprotective metabolite kynurenic acid and reduce the neurotoxic metabolites 3-hydoxykynurenine and quinolinic acid in the brain. This has been confirmed in rodent and non-human primate microdialysis studies using the potent KMO inhibitor CHDI-00340246. In the present study, CHDI-00340246 or vehicle was dosed in a Latin square design up to 10 mg/kg p.o. in awake, cynomolgus macaques. To enable serial CSF collection, a catheter was placed in the cisterna-magna and connected to a subcutaneous port under anaesthesia. CSF and plasma was sampled at pre-defined time-points across a 60 hour period following a minimum of a 1 week recovery period after surgery. The maximum concentration of CHDI-00340246 in the CSF was found at 2 hours post-dose, correspondingly in the plasma the maximum concentration was found at 1 hour after drug administration at 10 mg/kg p.o. Furthermore, concentrations in CSF were significantly lower compared to plasma. The maximal concentration of kynurenic acid, indicating KMO inhibition, was dose-dependently increased in the CSF, whereas in the plasma a maximal increase was found at 3 mg/kg. Comparison to results from a previous microdialysis experiment in the cynomolgus macaque revealed that the concentration of CHDI-00340246 in the CSF is 1.3 - 2.7 fold lower than that measured in the brain directly via microdialysis. Finally, CHDI-00340246 increased kynurenic acid concentrations in the brain, CSF and plasma, however, kynurenic acid concentrations rose more rapidly in plasma compared to the brain and CSF. These findings demonstrate that PK and PD parameters in the CSF can be helpful as a biomarker for CHDI-00340246 reflecting brain concentration and on target effects.

**Abstract:** Synucleinopathies, including Parkinson's disease (PD), Lewy body dementia (LBD) and multiple system atrophy (MSA) are all characterized by aggregation and deposition of α-synuclein in the brain. Though the normal cellular function of α-synuclein is unclear, the protein is highly enriched at presynaptic terminals. Multiple observations suggest that misfolding and self-association of α-synuclein into oligomers and aggregates may cause neural dysfunction and neurodegeneration in these diseases. Nonetheless, diagnosis of synucleinopathies is challenging due to overlapping symptoms among the synucleinopathies themselves and with other atypical parkinsonian syndromes. Thus, reliable biomarkers for these diseases are highly sought after. Recently, exosomes and other extracellular vesicles (EVs) isolated from blood have been shown to provide a useful source of biomarkers for Alzheimer's and Parkinson's diseases. Following similar strategy, here, we used antibody-coated magnetic beads to immunochemically isolate EVs released by neurons or oligodendrocytes from serum of healthy individuals and patients with PD and other synucleinopathies and measured biomarker concentration in them by a highly sensitive electrochemiluminescent ELISA. Our data show that although the α-synuclein concentrations are indistinguishable between healthy and patient samples of whole serum or serum exosomes, a significant difference is found in α-synuclein concentration in neuron- and oligodendroglia-derived blood exosomes. Supporting previous reports, the α-synuclein concentrations observed were substantially lower in the exosomes isolated from healthy individuals compared to patients with PD. Our data support the use of brain-derived blood exosomes for diagnosis of synucleinopathies, and suggest that the method can be expanded for other neurodegenerative diseases.

**Abstract:** The NINDS Parkinson's Disease Biomarkers Program (PDBP) promotes biomarker discovery to improve clinical trial design for PD and related disorders. Over 1400 participants, to date, have contributed data and biosamples to the PDBP. The program has four pillars: 1) Standardized longitudinal clinical data and biosample collection from PD subjects and healthy controls, harmonized with complementary PPMI and BioFIND biomarker cohorts. The NINDS PDBP recently expanded to include subjects with Atypical Parkinsonisms and other movement disorders (e.g. Multiple System Atrophy, Corticobasal Degeneration, Progressive Supranuclear Palsy, Essential Tremor), as well as four studies on Lewy Body Dementias (LBD) that will enroll 590 participants. 2) Laboratory-based biomarker discovery and replication studies utilize platforms including whole genome sequencing (WGS), transcriptomics, digital immunoassays, and exosomal characterization. The studies include longitudinal follow-up and independent replication of candidate biomarkers. 3) PDBP biospecimens banked and distributed to the research community through the NINDS Biorepository (BioSEND). New efforts in 2017 include collection and banking of PBMCs at the NINDS Human Cell and Data Repository (NHCDR). 4) The PDBP Data Management Resource (DMR) infrastructure, provides broad sharing and access to clinical data and associated biospecimens for research. The PDBP engages and collaborates with stakeholders, including the FDA, industry and nonprofit organizations, to reach common goals. Using a multifaceted approach, the NINDS PDBP is advancing biomarker discovery for PD prognosis and progression via the expansion of standardized clinical data and biosample collection in PD and related disorders, banking and distribution of samples, coordination of broad data access and new technological approaches. Coordinated and collaborative NINDS PDBP activities align with a multimodal approach to biomarker discovery required to facilitate effective drug development for the treatment of PD and related disorders

**Title:** An easily integratable behavioral system for high-throughput drug screening in zebrafish

**Authors:** ***S. L. WALKER**, D. C. CHAN, H. LIU, W. YUNG, Y. KE
Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, China

**Abstract:** A major bottleneck which limits the discovery of new neuro-active compounds for treating disorders such as Parkinson's disease or epilepsy is the duration it takes to screen said drugs which are relevant to the nervous system. While cell culture can detail toxicity and basic cellular responses of a potential drug, the model is not sophisticated enough to define the drug effects within a complex system like the brain. Individual drugs need to be tested in regards to behavior for hidden side effects and drug efficacy in order to identify active neural compounds which could treat the disorder efficiently without complicating one's health. To test the drug effects on behavior and in a high-throughput manner, we developed a behavioral system around zebrafish larvae. Zebrafishes are easy to maintain and produce large numbers of embryos, lending them particularly suitable for high-throughput drug screens. Although many drugs screens have been performed on zebrafish prior, these screens focused primarily on toxicity and basic cellular responses. To identify neural active drugs, we have developed a behavioral box which can actively test multiple plates at once and is easily integrated into a robotic system. The system utilizes an identical setup utilized for behavioral tests under the multi-photon microscope, allowing for easy and quick comparisons between a macro-view of behavior and a neural imaging view of behavior.

**Title:** Characterizing the role of ceramide in the dual cytotoxic and metabolic stimulative effects of sigma-2 receptors in SK-N-SH neuroblastoma cells

**Authors: *C. Z. LIU**, W. D. BOWEN
Mol. Pharmacol. and Physiol., Brown Univ., Providence, RI

**Abstract:** Sigma-2 receptors mediate cell survival. Sigma-2 agonists cause cell death via a variety of pathways and thus have been of interest as potential cancer therapeutics, while antagonists may have value as neuroprotective agents. Recently, a new class of sigma-2 agonists has been discovered, e.g. CM764, that do not induce cell death but that affect cellular metabolism, as shown by increased MTT reduction, increased ATP level, and HIF1α stabilization. Sigma-2 agonists modulate the sphingolipid pathway, increasing ceramide and decreasing sphingomyelin levels. Since the ceramide pathway plays both pro-survival and pro-apoptotic roles, we investigated its role in the divergent sigma-2 receptor mediated effects in human SK-N-SH neuroblastoma cells. Fumonisin B1 (10 μM), a ceramide synthase inhibitor, significantly decreased CM764-induced MTT reduction but did not affect CM572-induced cytotoxicity. This indicates that de novo ceramide synthesis may play a role in the metabolic stimulative effect. NVP 231 (1 μM), a ceramide kinase inhibitor, had no effect on either CM572-induced cell death or CM764-induced MTT reduction, indicating that ceramide-1-phosphate may not be involved. Exogenously added C6-ceramide induced dose-dependent cell death in SK-N-SH cells. However, these cells were markedly less sensitive to the pro-apoptotic effects of C6-ceramide compared to effects in other cancer cell types. C6-Ceramide induces mitochondrial depolarization. Treatment with CM572 (24 h) caused dose dependent mitochondrial depolarization, while CM764 caused less depolarization. C6-Ceramide-induced mitochondrial depolarization was only partial and more similar to that caused by CM764 as opposed to CM572, having a significant effect only at the highest concentration. This may be consistent with ceramide involvement in the metabolic stimulative effect and the relative resistance of SK-N-SH cells to the cytotoxic effects of exogenous C6-ceramide. In light of the observation that combination of C6-ceramide with cytotoxic chemotherapy agents causes additive or synergistic cancer cell death in other cancer cell types, we examined the effect of combining C6-ceramide with sigma-2 agonists. Treatment of cells with C6-ceramide (20 μM, producing ~25% cell death alone) caused an additive decrease in cell viability caused by CM572, SV119, and siramesine.

There was a synergistic increase in cytotoxicity with low dose treatments of CM572 and siramesine (3 μM) in combination with C6 ceramide. Taken together, the results suggest that ceramide may play a dual role in sigma-2 signaling, mediating metabolic effects at low concentrations and apoptosis at higher concentrations.

**Title:** Serum endocan levels are associated with large-artery atherosclerotic stroke

**Authors: *X.-P. JIN**, X.-W. HE, S.-F. KE, W.-J. HONG, Y.-Y. BAO, Y.-G. SHEN, F. ZHU, E. WANG
Dept. of Neurol., Taizhou Hospital, Wenzhou Med. Univ., Zhejiang, China

**Abstract:** Background: Accumulating evidence has suggested that endocan may play important roles in cardiovascular disease. However, no previous study has focused on its circulating levels in patients with large-artery atherosclerotic (LAA) stroke.
Methods: Serum levels of endocan in 114 patients with LAA stroke and 114 age- and gender-matched controls were measured by ELISA. Serum samples from patients were available on days 1 and 6 and in the 4th week after IS. Stroke severity was determined based on the National Institutes of Health Stroke Scale and the stroke volume. An unfavourable outcome was defined as a modified Rankin Scale score > 2 on day 90 after IS.
Results: The serum levels of endocan were significantly higher in patients with LAA stroke compared with the controls ($p = 0.001$), and after adjustment for other factors (AOR 1.553, 95 % CI 1.184-2.038, $p = 0.001$). In addition, higher endocan levels were independently associated with unfavourable outcomes on both day 1 and day 6 after IS (AOR 1.903, 95 % CI 1.115-3.248, $p = 0.018$ and AOR 2.031, 95 % CI 1.179-3.500, $p = 0.011$, respectively).
Conclusions: This study is the first to show that endocan levels are higher in patients with LAA stroke and can help in predicting the short-term unfavourable outcome.

**Abstract:** Gamma oscillations are high-frequency rhythmic activities in the brain. Gamma rhythms are observed with higher cognitive functions and are disrupted in many disorders such as Alzheimer's disease (AD), schizophrenia, autism and epilepsy. Therefore, elucidating mechanisms of gamma oscillations will lead to development of new medication for cognitive disorders. However, there are few methods to study gamma oscillations in human *in vitro*. Here we developed a new *in vitro* tool for examining gamma oscillation using human induced pluripotent stem cell (hiPSC).
Gamma oscillations are driven by fast-spiking parvalbumin positive GABAergic interneurons in mammals from rodent to human. Deficiencies of fast-spiking GABAergic interneurons are also observed in a variety of disease model mice including AD model mice. In the previous study, we reported that fast-spiking interneurons in AD model mice (PSAPP transgenic mice) were dysfunctional and characterized *in vitro* phenotypes of fast-spiking GABAergic interneurons in hippocampus slices from normal and PSAPP AD model mice. GABAergic interneurons in these slices showed kainate dependent fast-spiking activities. In AD model mice, they showed lower action potential (AP) frequency and amplitude and were reversed by a histone deacetylase inhibitor (SAHA).
Here, we generated forebrain GABAergic interneurons from hiPSCs which possessed similar phenotypes to mice fast-spiking interneurons. HiPSC-derived GABAergic interneurons showed kainate dependent fast-spiking activities which were inhibited by CNQX, a kainate receptor antagonist. These kainate receptor mediated fast-spiking activities were disrupted by Aβ42 peptides, and the disruptions induced by Aβ42 peptides were ameliorated by SAHA. These data indicated that hiPSC-derived fast-spiking GABAergic interneurons would be useful *in vitro* tools for examining pathophysiology of gamma oscillation and drug discovery.

**Title:** Multimodal MRI-based classification of the primary progressive aphasias using eigenanatomy

**Authors:** ***C. A. OLM**[1], L. H. ZHAO[2], P. A. COOK[1], C. T. MCMILLAN[3], J. C. GEE[1], M. GROSSMAN[3]
[1]Dept. of Radiology, [2]Dept. of Statistics, [3]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA

**Abstract:** Introduction: Primary progressive aphasia (PPA) is a class of neurological disorders characterized by progressive speech and language deficits, and are associated with different pathologies. As treatment trials are developed, finding reliable methods of distinguishing pathologies is becoming increasingly important. Machine learning methods help reduce the massive dimensionality of structural MRI data and have been shown to capture meaningful variance related to cognitive decline in neurodegenerative disease. We hypothesize that data driven regions of interest (ddROIs) of both gray matter (GM) and white matter (WM) are informative for classification of PPA variants.
Methods: 67 individuals with a PPA diagnosis (N=23, logopenic variant (lvPPA); N=20, nonfluect/agrammatic (naPPA); N=24, semantic (svPPA)) underwent T1-weigthed and diffusion-weighted MRI, which were used to generate cortical thickness (CT) images and fractional anisotropy (FA) images, respectively. To reduce data dimensionality, eigenanatomy

was used to find ddROIS consisting of regions of homogeneous variance, somewhat like principle component analysis, however with sparsity, non-negativity, and spatial constraints imposed. Eigenanatomy was performed on CT images to determine GM regions and FA images for WM regions. All GM and WM ddROIs were entered as predictors in a cross-validated multinomial logistic regression, wherein LASSO was used to identify the subset of ddROIs that contributed maximally to classifying participants. Each PPA phenotype was classified relative to the other two groups combined.
Results: Two ddROIs include anterior, medial, and inferior temporal cortex, with the left ddROI also extending to anterior insula, and these are reduced in svPPA. Also, a WM region consisting of portions of bilateral superior longitudinal fasciculus (SLF) is reduced in both naPPA and lvPPA relative to svPPA. naPPA displayed reduced GM relative to the other PPAs in a region encompassing much of the right frontal cortex, including the inferior frontal regions. FA in left parietal areas extending to include bilateral WM adjacent to fusiform cortex is reduced in lvPPA. Using only these 5 ddROIs, overall accuracy of 79.1% was achieved in 3-way classification.
Conclusions: ddROIs map well onto distributions of disease associated with each the PPAs: anterior-medial temporal cortex in svPPA, inferior frontal cortex in naPPA, parietal WM in lvPPA, and SLF with naPPA and lvPPA. Eigenanotomy generates ddROIs that reduce data dimensionality, are representative of different disease phenotypes, and can be used to achieve reasonable classification accuracy.

**Title:** Screening of amyloid-β aggregation inhibitors from aromatic low molecular compounds by a microliter-scale high-throughput screening system with quantam-dot nanoprobes

**Authors: *Y. ANDO**[1], K. OTA[2], I. ITO[3], H. KIKUCHI[3], Y. OSHIMA[3], Y. ENDO[2], K. UWAI[1], K. TOKURAKU[1]

[1]Div. of Sustainable and Envrn. Engin., Muroran Inst. of Technol., Muroran-shi, Japan; [2]Tohoku medical and pharmaceutical Univ., Sendai-shi, Japan; [3]Tohoku Univ., Sendai, Japan

**Abstract:** Alzheimer's disease (AD), a severe neurodegenerative disorder, accounts more than half of dementia cases. Currently, the amyloid cascade hypothesis, in which the accumulation of Aβ in the brain is the primary influence driving AD pathogenesis, is widely accepted as the molecular pathology of AD. On the basis of the hypothesis, inhibitor for Aβ aggregation may become key compounds for AD prevention and treatment. Recently, we established a microliter-scale high-throughput screening (MSHTS) system for Aβ aggregation inhibitors using quantum dot (QD) nanoprobes (Ishigaki *et al*., PLOS ONE 8, e72992, 2013). This novel system can be estimated the inhibitory activity as a half-maximal effective concentration ($EC_{50}$) at a small scale (5 μL) and high-throughput (1536-well). In this study, we screened 137 aromatic low-molecular compounds using this MSHTS system, and revealed that 15 compounds showed inhibitory activity lower than 200 μM $EC_{50}$. Interestingly, some compounds containing tropolone structure showed particularly high activity among them. The top three samples with the highest activity, TR-003 ($EC_{50}$: 6.6 ± 5.5 μM), TR-007 ($EC_{50}$: 14.9 ± 6.0 μM), and MO-009 ($EC_{50}$: 19.1 ± 5.6 μM), were higher than that of rosmarinic acid ($EC_{50}$: 20~25 μM) that is well known as an Aβ aggregation inhibitor. The results of evaluation also showed that the difference of the substituent groups strongly influence the inhibitory activities. The inhibitory activities of the active compounds containg tropolone strucutre were also confirmed by ThT assay although there are some differences between the $EC_{50}$ values determined by the MSHTS system and ThT assay. These results demonstrated that the MSHTS system is a powerful tool for screening a large compound library.

**Title:** Identification of novel circulatory microRNA signatures linked to patients with stroke

**Authors: *M. VIJAYAN**, S. KUMAR, P. REDDY
Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

**Abstract:** The purpose of our study was to determine circulatory microRNAs (miRNAs) as early detectable peripheral biomarkers in patients with stroke. To achieve our objective, we measured expression levels of miRNAs in stroke serum samples (n=34; age: 43-86 years) and healthy controls (n=11; 51-80 years). We used Illumina deep sequencing (Illumina GAIIx, ACGT101-miR v4.2, LC Sciences) analysis. Expression of selected potential candidate and unique miRNAs were further validated by SYBR green based quantitative real-time PCR assay (qRT-PCR). Target prediction of selected miRNAs was done using Targetscan and the potential targets of miRNAs were collected for GO/Pathway analysis using the DAVID functional annotation database. A total of 484,651,777 raw RNA reads were obtained in our deep sequencing analysis. Seventy percent (341,678,616) of reads were mapped for miRNAs. A total of 4,656 differentially expressed miRNAs were found in serum samples from stroke patients relative to controls. 272 miRNAs were found to be significantly differentially expressed (173 upregulated and 76 down regulated) in stroke patients. 17 most significantly deregulated miRNAs were selected for further validation. Interestingly, several previously unidentified miRNA candidates were found to be significantly differentially expressed in stroke patients relative to healthy controls. Moreover, target genes prediction of the co-expressed miRNAs and further Gene Ontology and Kyoto Encyclopedia of Genes and Genomes analyses revealed that some candidate miRNAs were involved in the regulation of the stroke event. MiRNAs identified in the present study could potentially be used for the development of novel therapeutic approaches for stroke. Further studies are necessary to better understand miRNAs-regulated stroke event.

**Title:** MRI detects the effects of Cuprizone/Rapamycin-mediated chronic demyelination and remyelination in rodent brain

**Authors: *H. BATTAPADY**[1,2], S. JOHNSON[1], L. LOOSE[1], S. LUNN[1], V. SHENOY[1], J. CHEN[2], B. TRAPP[2]
[1]Renovo Neural Inc., Cleveland, OH; [2]Cleveland Clin., Cleveland, OH

**Abstract:** Multiple sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system (CNS). MRI is extensively used for non-invasive diagnosis and monitoring progression of MS pathology in the CNS. The cuprizone-rapamycin (CR) mouse model of MS

demonstrates extensive demyelination in both white (WM) and gray matter (GM) with axonal injury; however studies looking at regional effects of chronic demyelination and remyelination in the in-vivo mouse brain are limited. In this longitudinal MRI study, using CR mouse model of reversible demyelination, we demonstrate that MRI can detect the loss and restoration of myelin in WM: corpus callosum (CC), GM: cortex, hippocampus, and deep GM structures: caudate putamen and thalamus.

Eight-week-old C57Bl/6J mice were divided into 2 groups: Controls (AM-WT) and chronically demyelinated mice treated with 12 weeks (w) of CR. 3D T2-weighted structural MRI and 3D MT-weighted MRI were acquired on a 7T Bruker system, at 12+0w, 12+3w and 12+6w of spontaneous remyelination to segment desired regions of interest and quantify myelin loss sensitive Magnetization Transfer Ratio (MTR) respectively. Immunohistochemistry was performed to quantify the density of myelin (PLP), myelinated axons (PPD), activated astrocytes (GFAP) and axonal ovoids (SMI32). All image processing was performed in-house using automated pipelines developed using AFNI, FSL and ImageJ tools.

In the WM, CC MTR significantly decreased after 12w of chronic demyelination compared to controls ($p<0.001$); after 3w and 6w of spontaneous remyelination, CC MTR significantly increased compared to the 12+0 CR mice ($p<0.01$), but was not completely restored to control levels ($p<0.001$). This data was corroborated by decreased density of myelinated axons and increased density of activated astrocytes and axonal ovoids after chronic demyelination suggesting myelin loss and axonal injury; after 6w of spontaneous remyelination, these parameters restored towards control levels. MTR in GM and deep GM regions also showed similar statistically significant results as WM suggesting that these metrics and regions may be used to study disability and cognitive impairment in this model. These myelin loss sensitive MTR-histology results are consistent with demyelination and remyelination pattern that is typically observed in these mice.

Our results show that MRI is sensitive enough to detect the regional effects of CR-mediated chronic demyelination and remyelination in the mouse brain. Moreover, these data suggest that MRI metrics can be used in preclinical studies with therapeutic interventions that aim to aid neuroprotection and remyelination in MS patients.

**Abstract:** Amyotrophic Lateral Sclerosis (ALS) is a severe adult onset neurodegenerative disorder leading to progressive paralysis and death within 2-5 years. Patients diagnosed with ALS either have a genetic mutation (familial, fALS) or the disease develops due to an unknown origin (sporadic, sALS). While the most prominent feature of the disease is death of motor neurons, oligodendrocytes and astrocytes were shown to play a crucial role in disease progression in mouse models. However, tissue from the central nervous system of human patients can only be collected after death, complicating the study of these cell types in disease progression. The new and fast reprogramming method we developed allows generating both cell types from skin biopsies of patients. We have previously shown that induced astrocytes (iAs) and oligodendrocytes from ALS patients are toxic to motor neurons. Knockdown of SOD1 prevented motor neuron toxicity in most familial and sporadic lines, with C9ORF72 mutations being the exception. Following this observation we have begun screening potential therapeutics for patients with mutations in C9ORF72. iAs were treated with multiple compounds and their effects on motor neuron survival was quantified. We are currently working with a molecule that shows high promise for this specific type of mutation. In other familial and sporadic patient iAs, the effectiveness of the same molecule appeared to be patient specific. The specificity of responses revealed patient subpopulations that may benefit from a more tailored therapeutic approach. Importantly, treatments that worked on a subset of ALS patient cells, were ineffective in others. These observations may explain why translation of therapies to clinical trial has a high failure rate in ALS. Our model system thus proves useful as a clinical screening tool to subclassify

patient populations as responders and nonresponders to a certain therapeutic approach. This underlines the power of the new method for screening of new therapeutics as well as in comparing large patient groups to identify and select adequate subpopulations for future clinical trials.

**Title:** Validation of hnRNP A1 as a novel biomarker in an early stage of Experimental Autoimmune Encephalomyelitis

**Authors: *S. LEE**[1,2], Y. SHIN[1,2], M. C. LEVIN[3,2]
[1]Univ. of Tennessee, Memphis, TN; [2]VA hospital, Memphis, TN; [3]Dept Neurol., Univ. of Tennessee Med. Group Inc, Memphis, TN

**Abstract:** The heterogeneous nuclear ribonucleoprotein (hnRNP) A1, which is expressed predominantly in the central nervous system, is involved in RNA metabolism. Dysregulation of hnRNP A1 is implicated in various neurodegenerative diseases, including multiple sclerosis (MS). Experimental autoimmune encephalomyelitis (EAE) is a well-known mouse model for human MS disease. The EAE model enabled to discover the disease mechanism and drug discovery for MS. Also, EAE mice can mimic the chronic and relapsing-remitting form of human MS.
Proteases and their inhibitors are involved in the development and progression of MS. Proteolysis plays a direct role in immune cell vasodilation, myelinolysis and damage to oligodendrocytes (OLG) and axons. Limited proteolytic events also play an important role in the regulation of the activity and expression of cytokines, chemokines, and their receptors. Therefore, proteolytic events are essential initial mediators in the development and progression of MS and EAE. In the EAE model, protease activation leads to angiogenesis that is followed by T cell infiltration event. Damaged vascular cells release exosomes containing cleaved hnRNP A1 to biological fluids such as plasma, and thus the cleaved hnRNP A1 can be used as a new biomarker in the early stage of EAE.
In this study, we report here for the first time, the stage specific (pre-onset, onset, peak and degradation) cleaved hnRNP A1 levels and patterns in plasma exosomes of the EAE mouse

model. We found that cleaved hnRNP A1 from the plasma exosome of EAE mice was found much earlier (day 5 post immunization) than disease onset (day 12). We also evaluated the drug response of FTY720 to hnRNP A1 cleavage. Identification of disease stage-specific cleaved hnRNP A1 in plasma exosomes can distinguish between prognosis and clinical subtypes, and helps to determine treatment and its effects.

**Abstract:** Parkinson's disease (PD) is a complex and heterogeneous neurodegenerative disorder. It is characterized by progressive degeneration of dopaminergic neurons in the substantia nigra and the intraneural accumulation of alpha synuclein protein. The current diagnosis of PD relies primarily on the presence of its motor symptoms. Consequently, by the time PD is diagnosed, 50-80% of the patient's dopaminergic neurons have already been lost or damaged. Thus, there is a need to develop measurable and unbiased biomarkers that can be used for early detection of PD. MicroRNAs (miRNAs) are small RNAs that regulate gene expression post-transcriptionally by binding to 3′- or 5′-untranslated regions (UTRs) of specific messenger RNAs (mRNAs). miRNAs are tissue-specific, stable, quantifiable, and easily isolated, making them ideal candidates for biomarker development. MiRNA miR-34b and miR-34c have been shown to bind at the 3′-UTR of alpha synuclein mRNA and repress alpha synuclein protein expression. They were also shown to be down-regulated in brains of PD patients. miR-7 and miR-153 also bind to

3′-UTR of alpha synuclein and down-regulate its mRNA and protein expression. Here, we evaluate miR-34b/c, miR-7, and miR-153 as potential diagnostic biomarkers for PD. 30 Patients with PD (10 newly-diagnosed and 20 advanced PD) and 8 healthy controls were recruited from the Department of Pharmacology and Clinical Neuroscience at Umeå University in Sweden. Total RNA, including miRNAs, of EDTA-treated plasma supernatant was isolated using a Qiagen miRNeasy Serum/Plasma Kit. miRNA expression of biomarker candidates was evaluated using the Taqman miRNA-specific assay. qRT-PCR was then performed in an Agilent MX3000P QPCR system. miR-7 and miR-153 did not show statistical significance in miRNA expression between PD and healthy controls. Expression of miR-34b/c was significantly lower in advanced PD when compared with newly diagnosed PD or healthy controls. Thus, miR-34b/c may be used as potential biomarkers to diagnose and track PD progression.

**Abstract:** The Implantable Multimodal Peripheral Recording and Stimulation System (IMPRESS) project aims to develop a high-density stimulating and recording microelectrode system for peripheral nerve implantation. Each year nearly 200,000 amputations occur in the United States caused mainly from vascular disease, trauma, or cancer. The loss of an upper extremity has profound psychological and physiological effects upon daily life. Prosthetic devices, such as robotic limbs, can interface with humans via electrodes implanted within remaining muscle or nerves, and in rare cases the brain to improve quality of life.
Sensory feedback enables finer control of robotic neuroprosthetic limbs. Stimulation of peripheral nervous tissue in amputees enables recapitulation of somatic perceptions such as intensity, texture, and velocity to improve cognitive control of prosthetics. Consolidating signal acquisition and stimulation within an implantable device is critical to achieve closed-loop,

naturalized control of robotic limbs. IMPRESS incorporates a next generation *hd*-TIME, an active CMOS probe embedded within a flexible polyimide substrate, for insertion into human nerve fascicles. The *high-density* transverse intrafascicular multichannel electrode (*hd*-TIME) aims to improve spatial selectivity within implanted peripheral nerves.
Implantation of peripheral microelectrodes generates an immunological foreign body response (FBR). Within the central nervous system, a chronic FBR to implanted electrodes leads to reduced or lost signal acquisition. Within the peripheral nervous system (PNS), a chronic FBR to the hd-TIME also threatens to degrade device functionality. New technologies and techniques have greatly improved our ability to perform device capture histology thus preserving the critical data at the nerve-machine interface (NMI). The ability to associate electrode functionality with specific tissue-interface sites is a critical step towards understanding and combating the FBR. Following chronic (4-week) implantation, we excised the rat sciatic nerve with mock hd-TIME to preserve the NMI between electrode sites and nerve. CLARITY techniques produced cleared nerves while maintaining device position. Light sheet fluorescence microscopy (LSFM) captured three-dimensional device-capture histological data for markers of axon fiber types, immune cells, Schwann cells, and nodes of Ranvier. These markers were quantified for each hd-TIME electrode site and for the entire implanted portion of the probe.

**Title:** Automatic surface electromyogram decomposition based on progressive fastica peel-off

**Authors: M. CHEN**[1,2], X. ZHANG[1], *P. ZHOU[3,2]
[1]Univ. of Sci. and Technol. of China, Hefei, China; [2]Guangdong Work Injury Rehabil. Ctr., GuangZhou, China; [3]PM&R, Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX

**Abstract:** Electromyogram (EMG) decomposition is the process of breaking down the multiunit EMG signal into the contributions of the underlying motor unit action potential trains (MUAPTs), which provides a powerful tool for investigation of neuromuscular control. This study presents automatic decomposition of high density surface EMG signals through a progressive FastICA peel-off (PFP) framework. By incorporating FastICA, constrained FastICA and a peel-off strategy, the PFP can progressively expand the set of motor unit spike trains

contributing to the EMG signal. A series of signal processing techniques were applied and integrated in this study to automatically implement the two tasks that often require human operator interaction during application of the PFP framework, including extraction of motor unit spike trains from FastICA outputs and reliability judgement of the extracted motor units. Based on these advances, an automatic PFP (APFP) framework was consequently developed. The decomposition performance of APFP was validated using simulated high density surface EMG signals with different motor unit numbers (30, 70, 91) and signal to noise ratios (SNRs) (20, 10, 0 dB). The results demonstrated relatively large numbers of extracted motor units and high accuracies (high F1-scores). The APFP was also evaluated with experimental surface EMG signals, and the decomposition results were comparable to those achieved from the PFP with human operator interaction. Among 111 trials of experimental surface EMG signals, the average extracted number of APFP and PFP is 13.6±5.4 and 14.1±5.0, respectively. Wherein, there are 9.8±4.7 common motor units were identified by both methods with a highly average matching rate as 97.57 ± 2.42%. The results show that the decomposition performance of APFP and PFP are highly consistent.

**Title:** Towards a framework for comparing functional magnetic resonance imaging data across scanners, vendors, and models

**Authors: *P. J. MOLFESE**[1], J. A. LEE[2], S. T. MARRETT[3], A. G. THOMAS[2], V. ROOPCHANSINGH[3], D. M. NIELSON[2], J. VARADA[3], A. DERBYSHIRE[3], P. A. BANDETTINI[1]
[1]Section on Functional Imaging Methods, [2]Data Sci. and Sharing Team, [3]Functional MRI Facility, NIMH/NIH, Bethesda, MD

**Abstract:** Neuroimaging studies are increasingly targeting diverse populations represented by different genetic, social, phenotypic, and geographical profiles (e.g. Rueckl et al., 2015), which are made more feasible through data collection at multiple sites using a mixture of equipment. These studies often involve both cognitive tasks (Gee et al., 2015; Brown et al., 2010, Yendiki et al., 2010) and/or resting state (Turner et al., 2013). Some recommendations from multi-site studies exist (FBIRN; Zou et al., 2005), and some portion of these methods have been

implemented in the recent Human Connectome Project (HCP; Van Essen et al., 2013). In this study, we collected fMRI data consisting of a rotating checkerboard stimulus on eleven participants, each imaged using four different fMRI machines with different scanner platforms (GE, Siemens), and corresponding multi-channel phased array whole-head “coils”. Data were collected using similar imaging parameters (e.g. slice number, FOV, flip angle) across all scanners. Data were analyzed in AFNI using a standard preprocessing pipeline. Comparisons of this standard pipeline to others with current “best practices” including distortion correction with blip-up/blip-down data, regression of physiological signals, smoothing to a set level of smoothing, and regressing events using ARMA were also performed (Figure 1, A). Group level analysis was conducted using a either a more traditional ANOVA (Figure 1, B), or a Linear Mixed Effects model (3dLME; Chen et al., 2013) with voxel-wise SFNR covariate (Figure 1, C). Results of these preprocessing and group level analyses are expressed in variance accounted for by the subject, scanner, and unexplained variance. The addition of each of these preprocessing and group level steps increased variance accounted for by subject, while decreasing the variance accounted for by scanner.

**Title:** Reevaluation of the form of nonlinear age-related changes in brain volume

**Authors: *D. NICHOLS**
Psychology Dept., Roanoke Col., Salem, VA

**Abstract:** It has previously been established that some aspects of the brain change volume at a fairly constant rate across the life span, i.e. linearly with respect to age, whereas other aspects of the brain change volume at different rates within different age ranges, i.e. nonlinear age-related changes. Theoretically relevant distinctions can be made between nonlinear age-related changes that switch direction, e.g. decades of size reduction followed by decades of growth, versus those that change amplitude, e.g. accelerated size reduction beginning later in life. Simulated data with known trajectories were used to compare locally-linear models of nonlinear age-related changes based on a small set of theoretically derived critical ages to smoothing spline estimations. Three particular categories of trajectories were explored - quadratic, with a change in direction across the life span; acceleration, with changes in amplitude but not direction; sigmoidal, with a period of change preceded and followed by no change in volume. Smoothing splines, which have previously been used to estimate the rate of change of individual aspects of the brain along the life span, were shown to lack the precision required to differentiate the onset of nonlinear changes less than one to two decades apart and exhibited consistent inaccuracies for non-polynomial trajectories. To demonstrate the utility of the locally-linear modeling approach, which also determines confidence intervals on the rates of change within regions of the life span, a reevaluation of published data [Fjell et al. (2013) Critical ages in the life course of the adult brain: Nonlinear subcortical aging. Neurobiol Aging 34:2239-47] was carried out for 17 aspects of MRI scans from 1100 subjects. Establishing the qualitative form of the trajectories and bounded quantitative estimates along the life span allowed for categorization of the nature of the nonlinear age-related changes for each aspect of the brain. This approach can be useful for determining distinctions between brain areas in the timing of developmental or degenerative events that influence their volume as well as making statistical comparisons between brain areas regarding their rates of change.

**Title:** Effects of dopamine depletion on signal variability and functional connectivity of resting state brain networks

**Authors: *G. SHAFIEI**, Y. ZEIGHAMI, A. DAGHER, B. MISIC
Dept. of Neurol. and Neurosurg., McGill University, Montreal Neurolog. Inst., Montreal, QC, Canada

**Abstract:** Dopaminergic projections are hypothesized to stabilize neural signaling and neural representations (Kroener et al., 2009, *PLoS One*), but their role in shaping local information processing and large-scale network interactions remains unclear. Here we investigate the effects of lowered dopamine levels on functional connectivity and signal variability of the healthy brain at rest. Acute phenylalanine and tyrosine depletion (APTD) technique was used to induce dopamine depletion in 51 healthy participants who underwent high-resolution resting-state functional MRI (fMRI). Functional data were parceled into 83 cortical and subcortical areas using the Desikan-Killiany atlas (Desikan et al., 2006, *Neuroimage*), and then further subdivided into 1015 approximately equally sized parcels (Cammoun et al., 2012, *J Neurosci Meth*). Functional connectivity was estimated as a Pearson correlation coefficient between regional time series. Sample entropy (SE) analysis was used to estimate regional signal variability by quantifying the similarity of any two sequences of data points in the fMRI time series (Richman and Moorman, 2000, *Am J Physiol Heart Circ Physiol* ). Multivariate partial least squares (PLS) analysis was used to statistically assess changes in signal variability before and after dopamine depletion (McIntosh and Lobaugh, 2004, *NeuroImage*). PLS results in a set of latent variables (LV), that are weighted combinations of experiment design (i.e. a contrast) and signal variability patterns that optimally covary with each other. We found one significant latent variable (permuted $p \approx 0$, accounting for almost 100% of covariance), capturing a pattern of increased signal variability following dopamine depletion. The pattern was spatially diffuse, but most pronounced in areas associated with the somatomotor and salience resting-state networks. Finally, changes in signal variability were concomitant with changes in functional connectivity, such that nodes with the greatest increase in signal variability following dopamine depletion also experienced the greatest decrease in functional connectivity. Our data suggest that dopamine may act to stabilize neural signaling, particularly in areas related to somatomotor function and orienting attention towards behaviorally-relevant stimuli. Moreover, dopamine-dependent signal variability is critically associated with the functional embedding of individual areas in large-scale networks.

**Abstract: Abstract:** The ability to accurately predict functional recovery upon hospital discharge and hospital length of stay (LOS) in patients with neurological injury such as traumatic brain injury (TBI), spinal cord injury (SCI) and stroke is important as it provides information that may guide clinical management, resource allocation, and patient guidance. This study presents a novel approach to predict functional improvement and LOS for patients admitted with TBI. A retrospective analysis of a database containing 409 patients with a history of TBI was provided by Casa Colina Hospital and Centers for Healthcare. We used Functional Independence Measure (FIM) scores as an index of each patients ability to complete daily activities. An advanced machine learning technique, Random Forests (RF), which uses an ensemble of learning algorithms to optimize data classification, was applied to the longitudinal inpatient data, which included features such as age, gender, rehabilitation impairment category, actual LOS and 19 subcategories of FIM scores. An RF classifier was trained to predict the LOS and the discharge FIM scores where the predicted LOS along with the features listed above were used to develop an RF regression model to predict the discharge FIM scores. The performance of the method was optimized to minimize the regression error between the predicted and actual values for both LOS and discharge FIM scores. Based on this training dataset, the RF was capable of predicting LOS with an error of less than a week and the discharge FIM scores of motor and cognitive tasks with a mean absolute error rate of 0.96 and 0.87, respectively. The regression model developed may be applied prospectively to TBI patients for further validation.

**Abstract:** Background: Quantifying effective connectivity using the Directed Transfer Function (DTF) on 1-second segments of raw clinical EEG has shown promising performance as a method for classifying conscious and unconscious states in patients undergoing anesthesia. Here, we test whether the DTF-based classification algorithm can be used as a general objective measure of consciousness, and compare its performance with a leading electrophysiological marker of consciousness - the perturbational complexity index (PCI).
Method: We reanalyzed data from an experiment in which healthy volunteers were randomly assigned to one of three forms of general anesthesia: propofol, xenon or ketamine. Spontaneous EEG was recorded from each participant before and during anesthesia, and DTF was calculated from each one-second segment of the EEG data to quantify the effective connectivity between channel pairs. From this, the state of the person was classified as either conscious or unconscious, using DTF from 1-second segments as input. The resulting classifications was compared with the subjects’ own report of experience and previously calculated PCI values from the same experiments.

Results: The DTF analysis yielded two distinct connectivity patterns, both at group and individual levels. This difference was sufficient to accurately classify the state as conscious or unconscious with 93% accuracy, compared to the participants' report of subjective experience. Specifically, the algorithm was more likely to conclude with consciousness in the awake state than during propofol and xenon anesthesia ($p<0.05$), but not during ketamine anesthesia ($p>0.05$). Finally, the DTF-based classification confidence correlates with PCI ($r^2=0.48$, $p<0.01$). Conclusion: The DTF based method seemed to be able to distinguish reliably between conscious and unconscious states in accordance with the individual's own report, and correlated well with PCI. These results provide further evidence that effective connectivity, here quantified by DTF, can be used to separate conscious from unconscious states based on spontaneous EEG activity.

**Title:** Diagnosis of autism spectrum disorder by causal connectivity strength from resting state functional magnetic resonance imaging data

**Authors: *B. HUANG**, K. ZHANG, R. S. ROMERO, J. RAMSEY, M. GLYMOUR, C. GLYMOUR
Dept. of Philosophy, Carnegie Mellon Univ., Pittsburgh, PA

**Abstract:** Diagnosing Autism Spectrum Disorder (ASD) with brain signals has received much attention in neuroscience and clinic diagnosis. It has been postulated that ASD is underpinned by atypical brain connectivity. Most analyses for neuroimaging data use correlation coefficients as a measure of brain connectivity strength to distinguish between ASD and typical control (TC). However, correlation does not directly reveal causal influences among brain regions. To identify atypical causal connections in ASD, we propose a diagnostic approach that first recovers the causal structure among brain regions and then uses the causal connectivity strength for

classification. The proposed approach is able to recover the whole causal structure including feedbacks among brain regions. We demonstrate the efficacy of the proposed methods with resting state functional magnetic resonance imaging (R-fMRI) data from the Autism Brain Imaging Data Exchange. Particularly, the R-fMRI signal is extracted from thousands of voxels clustered into regions of interest by the Automated Anatomical Labeling atlas. We choose datasets which have relatively long time period and remove unqualified data, resulting in 30 ASD subjects and 48 TCs. We use the estimated causal strength of connections as features for diagnosis, and achieve 81% out-of-sample prediction accuracy with support vector classification (SVC), which significantly improves on previously reported results. To avoid overfitting, we do feature ranking to remove uninformative features before running SVC. In addition to the causal strength, we find that the time-varying property of certain causal connection strengths may further help distinguish between ASD and TC. More specifically, the causal coefficients of certain causal relations in ASD appear to change faster than those in TC. Figure 1 shows identified causal connections which are effective for diagnosis.

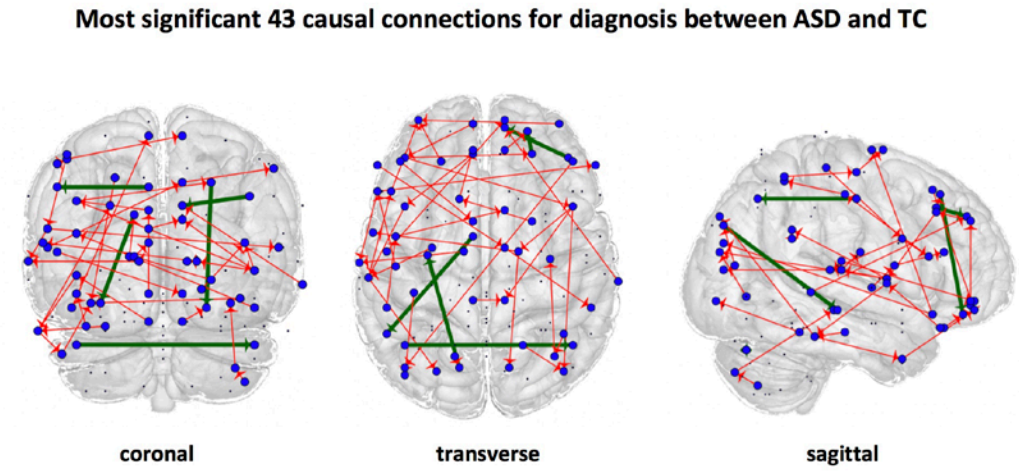

Figure 1. Coronal, transverse and sagittal views of the 43 causal connections that maximize out-of-sample prediction accuracy. Nodes represent centroids of 116 ROIs in AAL atlas. Radiological orientation. The 5 most relevant connections are in green: right midcingulate -> right angular gyrus; left superior frontal gyrus -> left superior orbital frontal gyrus; right crus 1 of cerebellum -> left crus 1 of cerebellum; left middle frontal gyrus -> left medial frontal superior gyrus; right cuneus -> right hippocampus.

**Title:** Multi-band coherence motifs for assessing network dynamical abnormalities associated with focal injury

**Authors: *S. KHANMOHAMMADI**[1], O. LAURIDO-SOTO[3], L. N. EISENMAN[3], T. T. KUMMER[3], S. CHING[2]
[1]Electrical & Systems Engineering, and Neurol., [2]Electrical and Systems Engin., Washington Univ. In St. Louis, Saint Louis, MO; [3]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

**Abstract:** Several studies suggest that a disruption of functional connectivity, i.e., statistical relationships between brain region activity, is associated with focal brain injury. However, most of these characterizations rely on a single metric, nominally the zero-lag correlation, upon which to quantify connectivity. Frequency-domain metrics such as the coherence similarly are usually limited to a particular frequency band of interest. Less emphasis has been placed on assessments of network temporal dynamics that may span multiple time-scales, thus obscuring potentially more complex network relationships. In this study, we examined time (cross-correlation) and frequency (multilayer coherence) domain dynamical abnormalities of EEG signals recorded from patients who suffered severe cerebral injury leading to coma, as well as from an uninjured control population. By aggregating both correlation and coherence matrices from several frequency bands into a single construct, we extracted multi-band motifs that characterize both the spatial location of their injury and the severity of their behavioral deficits as measured in terms of the clinical Glasgow Coma Score. We observed that the most severe behavioral deficits are associated with a pronounced decrease in slow frontal connectivity. Furthermore, our analysis reveals a lateralized, broadband increase in connectivity that is, interestingly, dominant in the hemisphere contralateral to the injury. These characterizations illustrate that focal brain injuries give rise to widespread, but systematic effects on brain network dynamics that may correlate with cognitive deficit and, in turn, enable new strategies for neuromonitoring and clinical assessment.

**Title:** Assessing approaches for estimating the electrophysiological 1/f background spectrum

**Authors: *T. DONOGHUE**[1], B. VOYTEK[1,2]
[1]Cognitive Sci., [2]Neurosciences Grad. Program, Univ. of California San Diego, La Jolla, CA

**Abstract:** Electrophysiological neural recordings have a characteristic 1/f shape in frequency space, in which the power exponentially decreases for higher frequency activity. In log-log space, this relationship is approximately linear, and can be measured by calculating the slope of the power spectral density (PSD). Measurements of this slope value, as a measure of the 1/f background, have been shown to vary. This variance can be cross-sectional—such as in aging—or within subjects across different states such as sleep wake cycles, and anesthetic conditions or even varying on a trial-by-trial basis with cognitive or perceptual state. This 1/f noise may also index disease states, including epilepsy and schizophrenia. Despite the burgeoning interest and potential applicability of examining the 1/f background, there is no clear consensus regarding the best approach for doing so. In particular, a key challenge in the characterizing 1/f dynamics is the co-existence of oscillatory 'bumps' of activity in the PSD. This oscillatory activity is not 1/f distributed, but does also vary with demographics, disease states, and behavior. It is therefore critical that methodological approaches are specific to measuring 1/f changes, and are not confounded by oscillatory changes. Here we evaluate different methodological approaches to estimating 1/f activity, using synthetic data with statistical properties mimicking neural power

spectra, in which ground truth is known. We evaluate a number of existing metrics in the literature, and also test novel approaches. Findings support that robust linear fitting procedures in log-log space, ignoring oscillatory regions, are accurate and reliable, however these approaches work best when using data-driven exclusion regions (instead of fixed ranges). Depending on the specific algorithm, and characteristics of the data, fixed-band exclusions can sometimes perform similarly, or slightly worse than, no exclusion band. Strengths and weaknesses of the various fitting procedures are discussed. We also apply these methods to existing electroencephalography (EEG) datasets of data collected from different age groups, replicating observations that 1/f as measured from the PSD of resting state data systematically varies with age. Applying best practice methods, as defined by the initial work with the synthetic data, is shown to more robustly demonstrate this relationship, using metrics that are also characterized as to their sensitivity to oscillatory confounds.

**Title:** Eeg based computation of group-level dynamic causal cortical connectivity in humans performing motor and decision making tasks

**Authors: *H. COURELLIS**[1], J. R. IVERSEN[2], D. A. PETERSON[3], G. CAUWENBERGHS[1]
[1]Bioengineering, UCSD, LA Jolla, CA; [2]Inst. for Neural Computation, UC San Diego, La Jolla, CA; [3]Salk Inst. CNL-S, La Jolla, CA

**Abstract:** Dynamic causal intracortical interactions offer a wealth of information that can be used to develop an understanding of brain functionality and quantify interaction among brain regions during the performance of cognitive tasks. Traditional analysis and evaluation of cortical electrophysiology focuses on individual brain regions or simple interactions among them but does not address spectro-temporally dynamic causal interactions between such regions. Dynamic connectivity present between different regions of the cortex can be readily interrogated in humans using a non-invasive neuroimaging modality, the electroencephalogram (EEG). We quantified spectro-temporal causal cortical connectivity dynamics at the millisecond time scale by developing a new computational methodology for processing multichannel EEG recordings. Our methodology involved the use of a group-level source localization and connectivity analysis approach. Cortical regions of interest (ROIs) were identified by clustering Independent Components across subjects into a common brain volume using both spatial and functional-activity metrics. Current source density estimation was then conducted in the identified ROIs

using a cortical boundary element model, and employing Cortically Constrained Low Resolution Electromagnetic Tomography (cLORETA), assuming cortical dipole orientations normal to the surface of the cortex. A representative current signal from each ROI was then extracted using a maximum-power selection heuristic, and causal spectrotemporal connectivity between ROIs was quantified by fitting multivariate autoregressive models to the ROI signals and computing directed transfer function-based causality measures. We applied the developed computational methodology to elucidate the cortical dynamics associated with reaching and saccading to spatial targets (RSST) (using a cognitive task performed by young adults) and to characterize the process of reward-based decision making (RBDM) through the cortical projection of sub-cortical dopaminergic basal nuclei activity (using a cognitive task performed by older adults). Analysis of connectivity dynamics in the RSST group revealed task relevant fronto-parietal communication occurring over varying frequency bands during both planning and execution of reaches and saccades. Analysis of connectivity dynamics in the RBDM group revealed that regions of the frontal cortex receiving direct input from dopaminergic subcortex, namely the Anterior Cingulate, drive activity in motor regions during decision making associated with steady-state image valuation, that is, after reward based learning has occurred.

**Abstract:** Neuroscience is experiencing an exponential growth in the ability to collect larger, more complex datasets from the human brain. Increasingly data from a single brain includes measurements made with multiple modalities, spanning functional and structural MRI data as well as electrophysiology measurements. To support reproducibility, many of these datasets are being openly shared with collaborators and the broader scientific community. These rapid developments come with new requirements for effectively managing data workflows, as well as a new set of best-practices in curating and storing data. For MRI data, a community driven effort resulted in the Brain Imaging Data Structure (BIDS), a framework for organizing data and metadata to satisfy these needs. This has now been adopted by many labs around the globe. The BIDS framework invites community involvement in shaping the specifications such that they are broadly useful and applicable. Intracranial electroencephalography (iEEG) data always have a multi-modal aspect, as data are integrated with at least a structural MRI to estimate electrode positions. While there are currently several data formats that store one iEEG dataset (including event or task information), there is no common data organization structure that allows for multi-modal integration following best-practices in data-heavy workflows. Here we propose an extension of the BIDS format to iEEG data. Our proposal is a starting point intended to spark a public discussion to adopt community standards in storing data recorded from iEEG patients, with a focus on being easy to understand and incorporate into many workflows. The BIDS format allows for the integration of iEEG with functional and structural MRI measurements in 3D or surface space and, as such, provides a standard operating procedure for storing complex multi-modal data from human subjects. BIDS also provides a common ground for data transfer within labs, between labs, and in open-data repositories. Adopting a standard will enable more complex, reproducible analyses that cut across datasets from different experiments, sites, and analysis workflows, allowing scientists to cooperate and check one another's work as they study the human brain. A link for public comment on the BIDS-iEEG specification can be found at `bit.ly/bids-ieeg-draft`.

**Title:** "Off-course" and emotional: The role of cognitive and limbic circuits during movements in humans

**Authors: *M. S. BREAULT**[1], P. SACRÉ[2], M. S. KERR[3], M. D. JOHNSON[4], J. BULACIO[5], J. GONZALEZ-MARTINEZ[5], J. T. GALE[6], S. V. SARMA[1]
[1]Biomed. Engin., [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom; [4]Biomed. Engin., Univ. of Minnesota, Minneapolis, MN; [5]Epilepsy Ctr., Cleveland Clin., Cleveland, OH; [6]Dept. of Neurosurg., Emory Univ., Atlanta, GA

**Abstract:** Nonmotor brain regions in humans are rarely studied during motor control due to their secondary, nontrivial, or even nonexistent role. Furthermore, capturing neural data from these regions can be cumbersome during movement, especially if motor regions are being probed simultaneously. However, it is important to understand what nonmotor regions encode for during movements to not only treat nonmotor neural diseases that impact movement but also to design brain-computer interfaces (BCIs) that rely solely on recordings from some of these areas. Such BCIs may provide the opportunity for patients with damaged motor cortex to regain motor control. We exploited a rare opportunity to record local field potential (LFP) activity from 680 contacts covering over 70 nonmotor structures in 9 human subjects as they executed a goal-directed reaching task using a robotic manipulandum. These subjects are medically refractory epileptic patients implanted with multiple depth electrodes for clinical purposes using the stereoelectroencephalography (SEEG) technique, which provides both high spatial and temporal resolution data. The question we set out to answer is whether or not nonmotor regions encode any path related information. To explore our relatively large data set, we developed a method that both quickly scans over all contacts, trials, and subjects and accurately extracts meaningful neural correlates of behavior. First, a behavioral signal was derived for each trial that captures modulating properties of path trajectory. That is, this signal increases or decreases when the subject's path deviates or is "off-course" from the target. Neural data was then transformed into spectrograms (time by frequency matrices) that were summarized as one-dimensional signals using singular value decomposition. These neural signals captured time periods where the spectrogram significantly modulated during trials for any frequency. Finally, the behavioral and neural signals during movement execution were cross-correlated for every trial and contact. The

top contacts with a significant number of trials with high correlations between brain and behavior signals were extracted. Preliminary results show that limbic and visual cortical areas were most highly correlated with path modulation. This suggests that when subjects move “off-course”, they see the deviation and then may emotionally react to it. Our findings provide early evidence of the important role that nonmotor regions have during motor control, suggesting that these regions should no longer be overlooked during sensorimotor control.

**Title:** Spatial filtering of high density human electrocorticography (ECoG)

**Authors:** ***J. HERMIZ**[1], N. ROGERS[1], E. KAESTNER[1], M. GANJI[1], D. R. CLEARY[1], B. CARTER[1], S. S. CASH[2], D. BARBA[1], S. DAYEH[1], E. HALGREN[1], V. GILJA[1]
[1]UCSD, La Jolla, CA; [2]Dept Neurol, Mass Genl Hosp, Boston, MA

**Abstract:** The advancement of electrophysiological neural interfaces and data acquisition systems has enabled increases in the number of electrodes. Human electrocorticography (ECoG) has the potential to see an exponential increase in sensors from 100s to 10,000s because of scalable manufacturing and integration of electronics on the neural interface substrate. With increasing sampling across space, techniques for leveraging this spatial information becomes more relevant. One important class of techniques utilized is spatial filtering. Time domain filtering is frequently used in ECoG to isolate important signals of interest such as high frequency (70 - 170 Hz) band (HFB) or remove noise (eg. DC and 60 Hz). Spatial filters have been used extensively in other domains such as array and image processing to for example

isolate sources coming from certain directions or extract relevant features from a scene. This highlights the utility of spatial filters, which may turn out to be important tools for the next generation of high density neural interfaces.
In this work, we explore a common set of spatial filters used in image processing and applied them to μECoG recordings from 2 subjects, SD007 and SD008 collected intraoperatively. The implanted surface probe has 7x8 electrodes spaced 400μm apart with a 50um diameter. Each electrode is coated with PEDOT:PSS to reduce the impedance magnitude. Classification of two stimuli types presented to the subjects were performed using HFB features and Elastic Net Logistic Regression.
We explored how spatial filters altered the classification performance. Common averaging reference (CAR), which we interpret here to be a spatial "DC" blocking filter was performed prior to the following filters: Laplacian (high pass), Laplacian of Gaussian or LoG (band pass) and Gaussian (low pass). Also, just CAR and no filtering was performed. In both, subjects, Gaussian filtering yielded maximum single channel median classification accuracy (ACC) with 70% and 73% for SD007 and SD008, respectively (note chance is 50%). For SD007, Gaussian filtering significantly outperformed the 4 other techniques, while for SD008, it outperformed all but CAR ($P < 0.01$, $n_{SD007} = 468$, $n_{SD008} = 552$, Kruskal-Wallis Test with Tukey's HSD criterion). Laplacian filtering resulted in among the lowest median ACC with 50% and 55% for SD007 and SD008. Finally, LoG produced intermediate results. This suggests that for these 2 subjects, low pass spatial filtering improves signal-to-noise ratio of HFB, while high pass filtering does the converse. Further spectral analysis of HFB and other signals of interest may shed new insights on electrophysiology measured from the cortical surface.

**Title:** Calibrating task evoked hemodynamic response of functional near infrared spectroscopy using resting state fluctuations

**Authors:** ***K. KARUNAKARAN**[1], S. GOHEL[2], A. AZEEZ[1], T. L. ALVAREZ[1], B. B. BISWAL[1]

[1]Biomed. Engin., New Jersey Inst. of Technol., East Newark, NJ; [2]Rutgers Sch. of Publ. Hlth., Newark, NJ

**Abstract: Background**: Functional MRI studies have typically used breath hold response as a measure of vascular reactivity. However, recent studies use resting state signals to calibrate task activation signal changes. The goal of this study was to utilize resting state fluctuations to calibrate task evoked response from fNIRS. **Methods**: The data were collected using TechEn fNIRS system using a wavelength of 690 and 830 nm with 10 channels over the sensorimotor cortex hand area in each hemisphere. We scanned 10 male participants (25.57±3.81) with a single session. Each session consisted of a resting scan, two trials of imaginary bilateral finger tapping (IBFT), two trials of bilateral finger tapping (BFT) and a breath holding task. The task duration was 3 min each. Preprocessing includes detrending, normalization and band-pass filtering (0.01-0.5 Hz). Average activation of a channel during task was computed using a wavelet coherence transform between the fNIRS signal and the corresponding stimulus design. Resting state fluctuation of amplitude (RSFA) was computed as the standard deviation of the rest data for 0.01-0.08Hz. Task activation measures were scaled by RSFA for each channel. A repeated measure ANOVA was performed to compare the two tasks during the two trials. **Results**: BFT task during trial #1 showed an average of 28.6 % (±7.4) greater activation compared to the IBFT task with a false discovery rate (FDR) corr-$p<0.05$ in 17 out of 20 channels. During trial #2 BFT had an average response of 9.4 % (±10.2) greater than IBFT task at $p>0.05$. No difference was observed at FDR corr-$p<0.05$ between the two trials in both tasks. Further, channel near task relevant region (post-central gyrus) greater activation in right hemisphere at FDR corr-$p<0.05$. Specifically, IBFT trial #1, IBFT trial #2 and BFT trial #2 showed 48.8% (±36.5) ,54.39% (±45.39) and 41.03% (±27.2) greater activation in the right hemisphere as compared to dominant (left) hemisphere. Lastly, correlation between RSFA and breath hold activation using bootstrapping with 1000 samples showed 18 out of 20 channels with significant negative correlation. **Conclusions**: This preliminary study using fNIRS demonstrates differences in task activation between BFT and IBFT. It also supports published results from fMRI studies applying RSFA to measure vascular reactivity. Further, the inter hemispheric differences observed after RSFA scaling suggests that resting state fluctuations may be more sensitive to underlying vasculature than breath hold response, as the latter is influenced by large vessels and subject compliance. Further investigation is required to study the effect of resting state on task activation in fNIRS.

**Abstract:** We proposed a temporal-autoencoding neural network (TANN) for the functional magnetic resonance imaging (fMRI) data analysis. Compared to conventional data-driven approaches based on a single-layer neural network such as independent component analysis (ICA), the TANN is an artificial neural network model that has a hidden layer in between the input and output layers. In each node in the hidden layer, an input value of the hidden node is transformed into an output value via a non-linear function such as a hyperbolic tangent function. Thus, the input pattern in the input layer is non-linearly transformed into the output layer via this hidden layer. Compared to a conventional autoencoder to reconstruct the input pattern in the input layer to the output pattern in the output layer via the hidden layer pattern, the TANN is well suited to the analysis of the time-series data such as fMRI since the two-consecutive fMRI volumes are modeled as the input and output patterns of the TANN. The learning rule of the weights of the TANN was derived from a minimization of mean-squared error between actual output pattern and predicted output pattern as well as the L1-norm and L2-norm regularization of the weights to prevent an overfitting to the training data. The utility of the TANN was evaluated using the fMRI data from the Human Connectome Project (HCP). Each of the fMRI volume series from the HCP motor and language fMRI runs from 50 subjects were used to train the TANN. The spatial features of the TANN (i.e., weights) and the temporal features (i.e., hidden node output) were calculated and these features were compared to those from a group ICA (GICA), a popular data-driven model for the fMRI data analysis. From the results, the correlation coefficients between the temporal features and task-related hemodynamic response functions were greater from the TANN than GICA. Thus, the TANN appeared to estimate the increased number of task-relevant spatial and temporal features than the GICA. Also, the two sets of spatial features from each of the motor and language fMRI runs seemed to be distinct from the TANN compared to the GICA models. The TANN is a novel promising data-driven approach to estimate the task-relevant spatial and temporal features of the task-fMRI and potentially useful to extract intrinsic functional networks from a resting-state fMRI as an alternative to conventional data-driven approaches for fMRI data analysis.

**Abstract:** Adaptive reasoning and problem solving represent crucial skills in increasingly information-rich working environments. The SHARP research project is a multi-institutional competitive and collaborative effort that seeks to understand the neurobiological substrates of fluid intelligence and its malleability in response to a wide variety of interventions. This research effort, across all involved institutions collected the largest dataset on the training of fluid intelligence and its possible neural correlates. To ultimately share this resources to all researchers, a repository has been created to hold this data (https://sharp.bidmc.harvard.edu). We have hosted this data using the XNAT data repository infrastructure. This infrastructure has been extended to fit the data elements of interest, including EEG, quantitative phenotypical information, cognitive assessment and MR imaging data. At present data includes over 500 research participants, and over 800 imaging sessions. API data access is available for researcher direct access to data elements. Sample API analysis scripts are available through the repository. This repository offers a valuable resource for studies investigating the flexibility of fluid intelligence.

**Abstract: INTRODUCTION**
Neuroanatomical variation can be accounted for by three factors: genetics, shared and unique environment. The genetic component is defined as heritability. Studies have investigated the heritability of regional cortical volumes [Baare *et al.*, 2001]; however volume can be fractionated into surface area (SA) and cortical thickness (CT) while both measures have independent genetic basis [Panizzon *et al.*, 2009]. Here, we used region of interest (ROI) and vertex-wise measures of SA and CT to compare regional heritability estimates. This can help us identify neuroimaging endophenotypes in imaging-genetics studies.
**METHODS**
•**Database:** 757 healthy subjects (twin and non-twin siblings; age: 22-37 years) with magnetic resonance imaging scans from the Human Connectome Project [Van Essen *et al.*, 2013] were used.
•**Image processing:** CIVET 1.1.12 pipeline [Lyttelton *et al.*, 2007] was used to measure CT and SA. In the vertex-wise approach SA and CT is measured at each vertex. In the ROI approach the Anatomical Automatic Labeling atlas [AAL, Tzourio-Mazoyer *et al.*, 2002] is used to calculate the average CT and SA within defined regions. Images were manually quality controlled.
•**Heritability calculations:** OpenMx [Neale et al., 2015] was used to calculate heritability for CT and SA after adjusting for sex, age and ipsilateral total brain SA or average CT. Heritability for CT and SA was estimated using a vertex-wise and an ROI approach based on average CT and total SA of AAL parcellations. In the vertex-wise approach heritability was averaged within AAL atlas regions.
**RESULTS**

Heritability estimates of CT and SA were lower when accounting for ipsilateral brain average CT or total SA. In both approaches, calcarine fissure had the highest SA heritability (ROI: 44%, vertex-wise: 50%) and posterior cingulate gyrus had the highest CT heritability (ROI: 50%, vertex-wise 40%). Many vertices had heritability measures of zero as well as smaller regions within the ROI approach (ex: heschl's gyrus).

**CONCLUSION**

Global measures (total brain SA and average CT) partly account for regional SA and CT. Variability in spatial averaging errors associated with regional size may make obtaining estimates of CT and SA in smaller regions difficult. This can cause the heritability model to fail when the assumption that monozygotic twin correlation of a trait should be equal to or greater than dizygotic twins is not met, resulting in heritability estimates of zero. Therefore it is important to identify which approach is best suited based on the research hypothesis and the size of the regions being investigated in heritability analysis.

**Title:** Retrospective Functional MRI: Expanding translational imaging to the clinical domain

**Authors: *F. A. PROVENZANO**[1], X. FENG[2], S. A. SMALL[1]
[1]Dept. of Neurol., [2]Taub Inst., Columbia Univ., New York, NY

**Abstract:** Introduction: Measurements of cerebral function can be obtained using non-invasive imaging techniques across species. Concordant measures are crucial for accurate comparison in both disease states and animal models. Given the ubiquity of various types of brain imaging it would be beneficial for researchers to focus not only on the novelty of new methods to yield underlying neuronal function but to explore the undiscovered utility of the swaths of existing clinical scans. Fortuitously, one commonly acquired clinical scan shares the same protocol of an existing research functional MRI scan: T1-weighted MRI prior to and after contrast agent injection. In this study, we attempt to test whether functional information (in this case, relative cerebral blood volume (CBV) measurements) can be obtained from clinically acquired scans where contrast agent was ordered. Methods: Steady-state exogenous contrast cerebral blood volume (ssCBV) scans are generated from the subtracted difference of T1-weighted scans after an intravenous bolus injection of gadolinium compared to a scan prior to the injection. Simulated receiver-gain setting variations (which are almost always present on clinical scans) are applied to

existing non-corrected, research obtained scans. Brain tissue classes are extracted from simulated scan's pre-contrast image (gray matter, white matter and cerebrospinal fluid) and examined in a maximum likelihood manner to adjust the scaling (which, when corrected, should be as close to 1 as possible). Results: 20 pairs of pre-contrast scans and correctly scaled post contrast Fast Field Echo (FFE) scans we 3.0T MRI scans were used in the simulation. WM was found to be the most predictable scaling parameter alone (with an estimated correction mean of 1.000±0.0094), and WM/GM/CSF performed the worst. Conclusion: This method demonstrates the feasibility of generating ssCBV scans from clinical scanners using WM segmentation as an internal fiducial. This opens up the possibility of generating functional imaging on previously non-functional MRI, and the possibility of quantifying and mapping retrospective neuronal function.

**Abstract:** Structural white matter connections are thought to facilitate integration of neural information across functionally segregated systems. Recent studies have demonstrated that changes in the balance between segregation and integration in brain networks can be tracked by time-resolved functional connectivity derived from resting-state functional magnetic resonance imaging (rs-fMRI) data and that transitions between segregated and integrated network states are related to human behavior. However, how these two network states relate to the underlying structural connectivity is largely unknown. To obtain a better understanding of structural substrates for these network states, we investigated how structure-function relationships change with the transition between segregated and integrated network states in the human brain, using structural connectivity derived from diffusion tractography and time-resolved functional connectivity as measured by rs-fMRI, both of which were obtained from public neuroimaging databases. We found that the similarity of edge weights between structural and functional connectivity was greater in the integrated state, especially at edges linking the default mode and the dorsal attention networks. We also demonstrated that the similarity of network partitions into modules, evaluated between structural and functional connectivity, increased and the density of direct structural connections within modules in functional networks was elevated during the integrated state. These results suggest that, when functional connectivity exhibited an integrated network topology, structural and functional connectivity networks were more closely linked to each other and direct structural connections mediated a larger proportion of neural communication within functional modules. Our findings point out the possibility of significant contributions of structural connections to integrative neural processes underlying human behavior.

**Title:** Changes in spike sorting technique affect the apparent fraction of neuronal responses

**Authors: *P. N. STEINMETZ**
Nakamoto Brain Res. Inst., Tempe, AZ

**Abstract:** Prior studies of detecting single neuron firing in human intracranial recordings have focused on how to accurately isolate the activity of single neurons in electrically noisy signals. The quality of isolation has been judged by how often simulated action potentials corresponding to a single neuron are detected amidst the activity of other simulated neurons and background noise.
In an actual experiment, however, it is normally changes of neuronal firing rate correlated with experimental variables, such as the identity of an object shown in a picture or recollection of an word, which are of primary interest. Given the normal tradeoff between sensitivity and specificity in detecting a signal, such as a neuron firing, in the presence of noise, it is unclear method for detecting action potentials will be best for detecting the changes in neuronal firing rate which are of primary experimental interest.
To determine how well changes in neuronal firing rate can be detected in human intracranial single neuron recordings, I simulated 150 3 second trials during which the firing of neurons was at a background rate for the first 2 seconds and a response rate during the last 1 second. The simulations also contained background noise designed to emulate the noise observed in human single neuron recordings. Simulated single neuron activity was first isolated using either the Brain Modeling Laboratory (BML) standard technique or using the program WaveClus. Differences between the rate of firing in a background interval and stimulation interval were detected using a Wilcoxon signed rank test. The ability to detect changes in firing was quantified as the p-value of the signed rank test.
These simulations reveal two primary results. Firstly, when the ratio of the firing rate during stimulation to that during background firing is increased or decreased from 1, the likelihood of detecting a change in firing initially increases, as expected. However, for ratios of firing above 20, the likelihood for detecting the change actually decreases. Thus both very low and very high ratios of stimulated firing to background firing become difficult to accurately detect.
Secondly, when the threshold for spike detection is lowered using either sorting technique, BML or WaveClust, the primary effect is to detect additional putative clusters of neuronal activity which have no relationship to simulated changes in neuronal firing.
Both of these results suggest that the choice of spike sorting techniques and parameters used for isolating single neuron activity may affect the apparent distribution of neuronal responses to experimental stimuli and impact the overall conclusions which can be drawn from a study.

**Abstract:** This exploratory study demonstrates the suitability and adequacy of a Local Mutual Information (LMI) to estimating the dynamics of cross-frequency coupling (CFC) in brain electrophysiological signals. In tonic or transient CFC, concurrent activity streams in distinct frequency ranges interact. A particular form of CFC, phase-amplitude coupling (PAC), has raised interest given the growing amount of evidence of its potential role in brain information processing under healthy and pathological conditions. Although several methods have been proposed for PAC estimation, few have addressed estimation of the event-related temporal evolution of PAC, and these typically require a large number of experimental trials to return a robust estimate. Here we explore the use of information-theoretic measures to estimate PAC based on local Mutual Information (LMI). The proposed method is applied to a set of simulated phase-amplitude modulated signals in which differents waveforms are used to shape the coupling to mimic stimulus-induced activations in typical electroencephalographic experiments. We show that the LMI approach can successfully recover the temporal dynamics of the simulated coupling from a relatively small number of trials. Finally, we apply the same approach to an event-related human electrocorticographic (ECoG) data set that exhibits strong and physiologically plausible PAC, showing that the new LMI-based PAC approach may be useful for modeling real data in event-related paradigms.
