Title: Permanent whisker removal reduces the expression of calcium-related proteins, disrupts hippocampal neurogenesis, and affects spatial memory

Authors: *O. GONZALEZ-PEREZ, N. IBARRA-CASTANEDA, V. LOPEZ-VIRGEN, J. GUZMAN-MUNIZ, N. MOY-LOPEZ
Psicologia/University of Colima, Colima, Mexico

Abstract: Facial vibrissae, commonly known as whiskers, are the main sensitive tactile system in rodents. Whisker stimulation triggers neuronal activity that promotes neural plasticity in the barrel cortex and helps create spatial maps in the adult hippocampus. Therefore, the neuronal activity of the barrel cortex possibly regulates hippocampal neurogenesis. To assess whether tactile information from facial whiskers may modulate hippocampal neurogenesis, we permanently eliminated whiskers in CD1 male mice and analyzed the effects in cellular composition, molecular expression and memory processing in the adult hippocampus. Our data indicated that the permanent deprivation of whiskers reduced in 4-fold the expression of c-Fos (a calcium-dependent immediate early gene) in cornu ammonis subfields (CA1, CA2 and CA3) and dentate gyrus. A significant reduction in the expression of calcium-binding protein calbindin-D_{28k} was also observed in granule cells of the dentate gyrus. Notably, calbindin and c-Fos reduction was linked to a dramatic decrease in proliferation and cell survival of neural precursor cells in the subgranular zone, which ultimately reduced the number of NeuN+ mature neurons generated after whisker elimination. These abnormalities in the neurogenic process coincide with a significant impairment of spatial memory and navigation skills. This is the first evidence indicating that tactile inputs from vibrissal follicles strongly modify the expression of calcium-related proteins in the dentate gyrus, disrupt different aspects of hippocampal neurogenesis, and support the notion that spatial memory and navigation skills strongly require tactile information in hippocampus.

Title: Nutrient-sensing pathways in ageing models of hippocampal progenitor cells

Authors: *C. DE LUCIA[1], T. MURPHY[1], C. STEVES[2], R. DOBSON[3], S. THURET[1]
[1]Basic and Clin. Neruoscience, [2]Twin Res. & Genet. Epidemiology, [3]Biostatistics & Hlth. Informatics, King's Col. London, London, United Kingdom

Abstract: Ageing is associated with changes in cellular and molecular processes including the alteration of stem cell pools. In particular, biological and functional changes observed in ageing neural stem cells (NSCs), are linked to age-related cognitive decline. Recently, the systemic environment has been shown to alter both NSC regulation and age-related cognitive decline. Interestingly, a well-documented and naturally occurring way of altering the composition of the systemic environment is through diet and nutrition. Studies have found an overabundance of nutrients to be detrimental for human and animal health; the presence of specific nutrients as well as the overall increase in calorie or protein intake was shown to overstimulate conserved molecular pathways and to reduce lifespan. Conversely, dietary restriction was found to be the most efficient way of extending an organism's lifespan. In this study, we examined nutrient sensing pathways in relation to their function on NSC and ageing. We focus on the Sirtuin, mTOR and Insulin / Insulin like growth factor-1 pathways. We used a human hippocampal progenitor cell line (HPCs) and employed pharmacological interventions and increasing passage number to induce, and measure ageing phenotypes. A semi-automated imaging platform was used for the quantification of NSC differentiation by using cellular markers for neuronal progenitors (DCX) and immature neurons (Map2) and machine learning was employed to measure morphological changes. Candidate gene selection was preformed through literature search and validated by qPCR to measure gene expression alterations within our model. Finally, we investigated the association of SNP variants within these candidate genes with lifestyle and cognition using 1633 participants from the adult longitudinal population-based TwinsUK cohort (n= 12 000). Our data suggests this novel ageing model induces changes in the expression levels of several key nutrient sensing genes (*FOXO3A, NAMPT, PTEN, GRB10* and *MTOR*) and alterations in neuronal morphology reminiscent of ageing phenotypes. We believe this assay has great potential to investigate NSC ageing and could be employed to validate existing pathways, uncover new targets and test novel therapies.

Title: Multiple neonatal anesthesia exposures suppress neuronal proliferation in the adult rodent hippocampus

Authors: *R. MAKARYUS[1], M. YU[1], K. CHEN[2], M. BOYD[2], G. ENIKOLOPOV[1]
[1]Stony Brook Med., Stony Brook, NY; [2]Stony Brook Univ., Stony Brook, NY

Abstract: Background: We recently found in rodents that multiple anesthesia exposures caused a greater decrease in a neuronal marker over the course of neuronal development compared to a single exposure of the same cumulative duration. This was further evidenced by more severe behavioral deficits in adult rodents with such exposures. Given the persistence of effects in adult rodents, we sought to investigate the effects of neonatal anesthesia on neurogenesis in the adult hippocampus. Methods: On postnatal day 5 (P5), rats were divided into three groups: single exposed (receiving 6h of sevoflurane exposure on P7), multiple exposed (receiving 2h of exposures on P5, 7, and 10), and unexposed. All were injected with IdU and CldU on P30 and P60, respectively. Behavioral testing was performed from P30-45 using open field testing (OFT), novel object recognition (NOR) testing, and Barnes Maze testing, with a small subset in each group not undergoing behavioral testing. Perfusion fixation was performed on P60 for histological analysis, staining for IdU, CldU, and Dcx. Results: The multiple exposed group had the most severe behavioral changes, specifically in NOR and OFT. Histological analysis of the dentate gyrus revealed a decrease in number of IdU-positive and CldU-positive cells in the multiple exposed group (Fig 1A). Of note, behavioral testing increased the number of double-labeled (IdU^+CldU^+) cells in the multiple exposed group, and the vast majority of these double labeled cells were not Dcx^+ (Fig 1B). Discussion: We have shown that the multiple exposed group had the greatest changes in behavior. This is directly correlated with a decrease in neuronal cell proliferation at P30 and P60, evidenced by the changes in IdU^+ and $CldU^+$ cell populations, respectively. Interestingly, most double labeled cells in the dentate gyrus were not Dcx^+, indicating that they were not neurons. The increase of these cells in multiple exposed with behavioral testing compared to those without behavioral testing may indicate an increase in glial cell proliferation related to the enriched environment provided by such testing.

Figure 1 – Effects on Neuronal Stem Cells

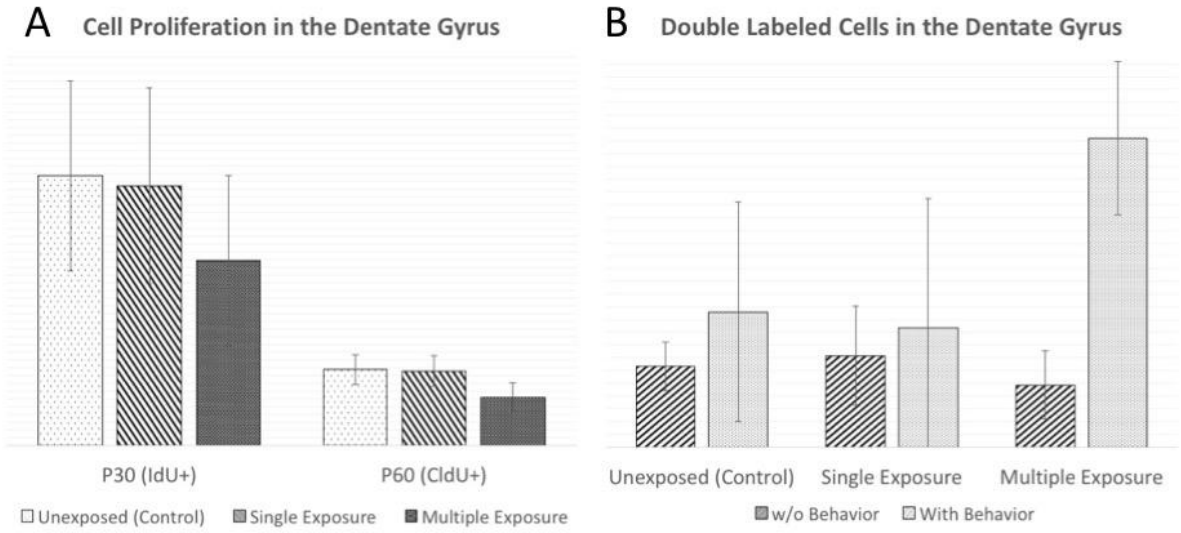

Fig 1. (A) Cell proliferation at P30 as determined by IdU+ cells, and P60 determined by CldU+ cells, demonstrating that multiple neonatal anesthesia exposures causes a decrease in cell proliferation even in the adult rodent brain. (B) Double labeled (IdU+,CldU+) cells are highest in the multiple exposed group that had behavioral testing. These were determined to be non-neuronal cells, possibly indicating an increase in glial cells in response to being in an enriched environment after neonatal anesthesia neurotoxicity.

Title: Age and experience-dependent hippocampal neurogenesis is regulated by sphingosine 1-phosphate

Authors: *A. P. CHEN[1,2], G. W. KIRSCHEN[2,3], J. SCHRANDT[3], A. AHAMAD[4], N. U. SCHWARTZ[1], L. M. OBEID[5], C. MAO[5], S. GE[4]

Abstract: The rate of adult hippocampal neurogenesis is well known to decline rapidly with advancing age, and to increase in response to experiences such as environmental enrichment. Understanding the regulatory mechanisms controlling this process, which remain poorly characterized, may aid in the development of novel strategies to target age-related decline in hippocampal neurogenesis, and consequent impairments in memory function. Pathways related to cell growth and energy metabolism are likely important in the age-related neurogenesis decline, yet signaling pathways implicated have not been fully elucidated. Further, it is not known how neurogenesis may be regulated from cues originating from outside of the central nervous system. We hypothesized that bioactive lipid signaling through sphingosine 1-phosphate, important for proliferation and survival of non-neuronal cells throughout the body and shown to be present and active in the brain of adult mice, may influence adult hippocampal neurogenesis. We made the surprising discovery that environmental enrichment, known to potently increase adult hippocampal neurogenesis, sharply decreased circulating blood S1P levels. To test the causal relation between S1P and neurogenesis, we used two independent transgenic mouse models that exhibit limited S1P production, and found that both exhibited heightened neurogenesis. Together, our findings implicate the S1P pathway in basal and activity-dependent neurogenesis, and implicate a potential therapeutic target to promote or restore neurogenesis associated with aging or disease.

Title: Hippocampal neurogenesis induced by single or multiple sessions of thalamic electrical stimulation

Authors: *F. CHAMAA[1], Z. NAHAS[3], N. E. SAADE[4], W. ABOU-KHEIR[2]
[1]Anatomy, Cell Biol. and Physiological Sci., [2]American Univ. of Beirut, Beirut, Lebanon; [3]Dept.

of Psychiatry, Univ. of Minnesota, Minneapolis, MN; [4]American Univ. of Beirut, Beirut, Lebanon

Abstract: Background: Deep brain stimulation (DBS) has provided substantial clinical benefit for a variety of movement disorders. It is still unknown how DBS alters neural activity to induce beneficial outcomes. One area of interest is to investigate a possible role for modulation of adult hippocampal neurogenesis in mediating DBS effects. The hippocampus is a structural and functional component of the limbic system and contains a neurogenic niche of neural stem/progenitor cells in the subgranular zone (SGZ) of the dentate gyrus (DG). It possesses extensive interconnections with the anteromedial thalamic nucleus (AMN) proposing that stimulation to the AMN conveys physiological fluctuations in the hippocampus and possibly elicits neurogenesis.
Objective: The aim of the study is to examine the effect of single as well as multiple sessions of AMN electrical stimulation in modulating stem/progenitor cell proliferation at early stages and track their fate at later stages.
Methods: Adult male Sprague-Dawley rats received either single or multiple unilateral electrical stimulation in the right AMN. Electrodes were implanted without current delivery in sham groups. Another control group, for selective site stimulation, received electrical stimulation in the ventral posterolateral thalamic nucleus (VPL) that has no established direct projections to the hippocampus. All
groups received 3 injections (66mg/Kg/injection) of 5'-bromo-2'-deoxyuridine (BrdU) and were euthanized on two time points. Early stages of neurogenesis were examined at 7 days post-surgery and the late stages after 4 weeks. The BrdU positive cells in the dentate gyrus (DG) of the hippocampus were counted. Double labeling of BrdU with NeuN was examined. The Exploratory Behavior test was performed using a Y-maze to detect for enriched hippocampal skills following stimulation.
Results: Single AMN electrical stimulation was marked by a 2-fold increase in proliferation of neural stem/progenitor cells in the ipsilateral DG at 7 days and translated into a 1.8-fold increase in hippocampal neurogenesis at 4 weeks. Multiple sessions of electrical simulation further increased hippocampal neurogenesis to 3-folds higher than the sham at 4 weeks. The Y-maze test showed that single electrical stimulation to the AMN enhanced exploratory behavior at 4 weeks while it was detected at the earlier 7 days-time point in multiple sessions of stimulation.
Conclusions: The current study presents an increase in hippocampal neurogenesis in response to single or multiple sessions of electrical stimulation. It also reveals a translational behavioral enhancement of hippocampal-related skills following stimulation.

Title: Mode of action of memantine on adult hippocampal neurogenesis

Authors: *S. ITAMAN[1], O. PODGORNY[1], G. N. ENIKOLOPOV[2]
[2]Ctr. for Developmental Genet., [1]Stony Brook Univ., Stony Brook, NY

Abstract: Adult hippocampal neurogenesis can be altered by various endogenous and exogenous stimuli. Both an increase and a decrease in production of new neurons can arise as a result of several distinct scenarios, with the stimuli impacting various subpopulations of neural stem and progenitor cells and various steps of the stem cells' division/differentiation cascade. Memantine, a non-competitive NMDA receptor antagonist used clinically to treat symptoms of Alzheimer's disease, can increase the division of progenitors and production of new neurons in the adult brain. However, its basic mode of action is unknown. In particular, it is not known whether it activates stem cells, their progeny (or both), whether it targets division of neuronal progenitors or their elimination, and whether it induces symmetric division of stem cells, increases the number of divisions of already activated stem cells, or augments activation and recruitment of quiescent stem cells into the cell cycle. Conventional analysis methods of neurogenesis do not distinguish between these scenarios. We developed new experimental paradigms based on double- and triple S phase labeling and phenotyping stem and progenitor cells, which allow fine analysis of the division and fate of stem cells and their progeny. Our results provide a blueprint for the analysis of stem cell maintenance and division. These methods indicate that memantine induces increased production of new neurons in the hippocampus of adult mice by increasing the rate of de novo activation of hippocampal neural stem cells.

Title: Postnatal neurogenesis after cardiopulmonary bypass in a juvenile porcine model

Authors: C. LEONETTI[1], Z. DHARI[3], L. KOROTCOVA[2], *R. A. JONAS[2], N. ISHIBASHI[4]
[1]Ctr. for Neurosci. Res., [2]Children's Natl. Med. Ctr., Washington, DC; [3]Neurosci., Children's Natl. Hosp., Washington, DC; [4]Children's Natl. Heart Inst. and Ctr. for Neurosci. Res., Children’s Natl. Hlth. Syst., Washington, DC

Abstract: Impairments in higher-order cognitive and behavioral function are widely observed in children after cardiac surgery with cardiopulmonary bypass (CPB). The subventricular zone (SVZ) in the postnatal/adult brain is the region where most neural stem/progenitor cells (NSPC) originate. Recent studies suggest that the SVZ plays an important role in neocortical growth of the gyrencephalic frontal lobe during postnatal life. However, the effect of CPB-induced insults on postnatal SVZ neurogenesis is largely unexplored and poorly understood. The aim of our study is to determine SVZ neurogenic activity after CPB using a porcine survival model. Piglets were randomly assigned to control group and severe-CPB insult group (reproducing CPB-induced systemic inflammation and ischemia-reperfusion injury). To assess SVZ neurogenic activity, we performed immunohistochemistry and quantified NSPCs and neuroblasts with antibodies directed against Sox2, GFAP and doublecortin. The SVZ was divided into 3 tiers as previously described in the human SVZ and into ventral (V-SVZ) and dorsolateral regions (DL-SVZ). Severe-CPB resulted in a significant reduction of $GFAP^+$ processes length and $Sox2^+$ layer thickness in tier-1 of DL-SVZ. On the other hand, there was no difference in $Sox2^+$ cell number in other tiers. Moreover, the number of neuroblasts in the DL-SVZ was remarkably reduced in severe-CPB group. Recent studies have demonstrated that neuroblasts form migration chains moving tangentially through the SVZ and appear as clusters on coronal sections. Although there was no difference in the number of these clusters we found a significant decrease in their surface area after severe-CPB insult, indicating a disruption of neuroblast migration. Furthermore, 4 weeks after severe-CPB we continued to observe a significant reduction of $Sox2^+$ layer thickness in tier-1 of DL-SVZ. Collectively, our results demonstrate that severe-CPB

reduces neurogenesis up to 4 weeks after insult. Our preliminary data demonstrate prolonged impairments in the NSPC pool following severe-CPB insult. The impact is confined to the dorso-lateral region which is the most active part of the SVZ under normal conditions. Our results consistently showed reduced neurogenic activity and suggest disruption of neuroblast migration towards the frontal cortex after severe-CPB insult. The frontal cortex is the region responsible for a wide range of higher-order cognitive functions; our study therefore provides novel insights into cellular mechanisms underlying complex neurological impairments in children with congenital heart disease.

Title: Social isolation stress alters the expression of hippocampal neurogenesis in adolescent animals prenatally exposed to alcohol

Authors: *S. L. BAGLOT[1,2], P. UBI[1], E. MORGAN[1], S. E. LIEBLICH[2], W. YU[1], J. WEINBERG[1], L. A. M. GALEA[2]
[1]Cell. and Physiological Sci., The Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Fetal alcohol spectrum disorders encompass a wide range of deficits following prenatal alcohol exposure (PAE), including central nervous system abnormalities. Of particular importance, PAE alters the development and functioning of the hippocampus. The hippocampus, a brain area sensitive to the teratogenic effects of alcohol, is unique because it possesses the ability to form new neurons (i.e. neurogenesis) into adulthood. Hippocampal neurogenesis has been implicated in stress regulation, emotional behaviour, and learning and memory. It is well known that both PAE and exposure to chronic stress produce changes in hippocampal neurogenesis across the lifespan. Further, many of the effects of PAE are altered or exacerbated

by chronic stress exposure. However, little research has looked at the combinatorial effects of PAE and chronic stress on hippocampal neurogenesis in adolescence. Adolescence is an extremely important maturation period that often involves exposure to chronic stress, especially social stressors. Animal models have shown that hippocampal neurogenesis is sensitive to social isolation stress in adulthood, but that these alterations are different in males and females. Thus, the goal of this study is to look at the unique and/or interactive effects of PAE and social isolation stress on hippocampal neurogenesis during late adolescence in male and female rats. Utilizing an animal model, male and female offspring from control, pair-fed, and ethanol exposed dams were examined in adolescence. Half the animals from each prenatal condition were exposed to social isolation stress from postnatal day 35 for 10 continuous days. On the last day of stress exposure animals were perfused and brains removed. Rat hippocampi were sectioned and immunohistochemically processed for the endogenous protein doublecortin (DCX), a marker for immature neurons. As expected, social isolation stress resulted in decreased density of DCX expression (reduced immature neurons) in the dorsal dentate gyrus in control animals. Interestingly, the effect of social isolation stress was absent in PAE animals. In fact, following social isolation stress, PAE animals actually expressed increased DCX density compared to controls. Analysis of cell morphology similarly revealed alterations following stress and PAE. Taken together, our results suggest that PAE animals respond differently to social isolation stress in adolescence. Importantly, these differential neurogenic changes may underlie some of the common cognitive, emotional, and behavioural deficits seen in animal models of PAE, as well as in individuals exposed to alcohol *in utero.*

Abstract: 3D visualization of dividing cells in the whole brain could facilitate the analysis of neurogenesis, increase its accuracy, and reveal new functional patterns of stem cell division. We developed whole-mount click-reaction technique (WM-CLICK) which allows detecting the population of dividing cells using with 5-ethynyl-2'-deoxyuridine (EdU) and fluorescent azide, with and further reconstruction of the 3D maps of EdU-labeled cells in the whole brain. We now used WM-CLICK as well as our new algorithms for rapid processing and comparison of multiple brain samples to analyze the 3D patterns of cell division in the brains of adult animals which were treated with saline or memantine (50 mg/kg) daily for 5 days and analyzed 2 h after injecting EdU injection at the last day of experiment. The images of whole stained brain were registered to each other and then averaged group images were created and compared. This analysis revealed several areas of the adult brain where memantine had particularly strong effect on cell division, with high densities of EdU+ cells found in the CA and DG regions of the hippocampus, subcallosal zone, olfactory bulb, and piriform cortex.

Title: Adult neurogenesis in turtles increases when they learn a visual discrim

Authors: *A. S. POWERS
Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Adult neurogenesis occurs throughout the telencephalon in turtles, and it is increased by exercise or an enriched environment, as in the hippocampus of mammals. Another factor that has been shown to influence adult neurogenesis in mammals is learning, and in this experiment we studied the effects of visual discrimination learning on adult neurogenesis in painted turtles (*Chrysemys* picta).
The experiment had 4 groups, which were run in a discrimination box with a response key and a food magazine that delivered beef baby food. All animals were trained to press the response key for food and then two groups were given 3 injections of BrdU (50 mg/kg) over one week. One group (Acquisition, n=6) was then trained to criterion on a visual discrimination between vertical

and horizontal lines while they continued to receive 6 more BrdU injections over the next two weeks. The second group (Control, n=5) was housed throughout this time in their home cage with no discrimination training. The other two groups were trained to criterion on the horizontal-vertical discrimination *before* being given BrdU injections for one week, and then they were tested on retention (Retention, n=6) or reversal of the discrimination they had learned (Reversal, n=5) while receiving 2 more weeks of BrdU injections. Turtles were euthanized 6 weeks after the first BrdU injection, and the brains were treated for BrdU immunohistochemistry. We counted the number of new cells in the telencephalon in each group.
Only the Acquisition group, which learned the discrimination while receiving BrdU, showed an increase in new cells in the brain. The other groups did not differ from the Controls. This finding suggests that, in turtles, neurogenesis is facilitated when animals have to learn a new task but not when they remember one already learned, even if the memory task requires them to learn a reversal of the previous learning. The result is consistent with studies in mammals that show an increase in neurogenesis when animals learn a new task and suggest that a facilitative role for learning in adult neurogenesis may have been present in the common ancestor of both groups, the stem amniotes.

Title: Antioxidant (aox) mediated allteration incalbindin expression within cerebellar purkinje cells of rat pups exposed to sodium arsenite

Authors: *P. DHAR[1], P. KUMAR[2], P. KAUSHAL[3]
[1]Anat., All India Inst. of Med. Sci., New Delhi, India; [2]Anat., AIIMS, New Delhi, India; [3]Anat., All India Institue of Med. Sci., New Delhi, India

Abstract: Calbindin D28k (CB), a member of calcium-binding protein (CaBP) superfamily, plays important role in regulation of calcium homeostasis in the cells. In the cerebellum, most of the Purkinje cells express calbindin-D28k as well as parvalbumin, whereas basket, stellate and Golgi cells express parvalbumin alone. Purkinje cells play a crucial role in motor learning especially during the developmental period. Heavy metal toxicity could reduce expression of these CaBPs, thereby inducing aberrations in the developing cells. Arsenic toxicity is a matter of global concern and consumption of water contaminated with *iAs* is the major source of exposure

to *iAs*. Morbidity and mortality induced by *iAs* exposure is prevalent in endemic areas all over the globe.
We studied Calbindin D28k expression in the cerebellum of rat pups subjected to sodium arsenite ($NaAsO_2$) exposure. Also, any modulation in the expression of these proteins, following anti-oxidant (AOX) supplementation, was determined.
Mother-reared Wistar rat pups were divided into control and experimental groups. $NaAsO_2$ alone or along with AOXs (ALA and Curcumin) was administered by intraperitoneal (i.p.) route from postnatal day (PND) 1 to 21 to experimental groups. Pups receiving distilled water/ethanol/DMSO served as the controls. On PND 22, the animals were perfusion fixed. Immunohistochemical localization of Calbindin D28k (CB) was carried out on parasaggital cerebellar sections (25 µm) using mouse monoclonal antibodies. The morphological features and morphometric parameters (linear density and perikaryal area (Pa)) of immunoreactive (IR) Purkinje cells were determined using NIS-Elements AR software attached to Nikon E 600 microscope fitted with Digital Camera Head DS-Fi1.
Preliminary observations revealed decrease in Purkinje cell density and cell area in *iAs* alone treated animals as compared to controls. However, these parameters were comparable amongst control and AOX supplemented groups.

Title: Age-mediated effects of short-term environmental enrichment on neuroplasticity

Authors: *K. CHANDLER[1], H. DOSSO[1], L. LAIRD[2], C. A. RUDYK[1], N. SALMASO[1]
[1]Neurosci., [2]Carleton Univ., Ottawa, ON, Canada

Abstract: Early in telencephalic development, neural stem cells are born in the ventricular zone and migrate through the cortex before differentiating into neurons and glia. Adult neurogenesis, however, is limited to specific niches in the brain: the dentate gyrus of the hippocampus (DG) and the subventricular zone (SVZ). The proliferation and differentiation potential of these neural stem cells is plastic and shows changes across states and in response to environmental manipulations. It has previously been shown that short-term environmental enrichment (Enr)

increases cognitive abilities on the Morris Water Maze and is sufficient to increase the proliferation of the GFAP+ stem cell pool in juvenile mice. However, in adults, longer-term Enr protocols are typically used to induce behavioural and functional recovery and few studies have examined the effects of short-term Enr in adults. We hypothesized that in conjunction with previous research, short-term Enr will be sufficient to induce an increase in cognitive abilities and in neural stem cell potential in juveniles, but that these changes will be attenuated in adults. To achieve this, we exposed juvenile (P35) and adult (P90) male C57 wildtype mice to two weeks Enr (including physical, social and cognitive enrichment), and examined cognitive behaviour as well as the potential of SVZ and DG NSCs in vitro using neurosphere assays. We also examined changes in doublecortin, SOX2, GFAP and synaptic protein levels to assess age-induced changes in neuroplasticity in response to short-term Enr. As hypothesized, we found that the short-term Enr increased learning and memory in juvenile mice, but not in the adult mice. These changes were paralleled by an increase in proliferation of the stem cell pool in juveniles that was less pronounced in adults, together suggesting an age-related decrease in NSC potential and plasticity in response to short-term environmental manipulations.

Title: The effects of androgen deprivation therapy on the adult hippocampal neurogenesis and cognition in mice

Authors: *T. ALKAM, K. A. ATKINSON, 91766, J. JO, J. CHAN, E. SMITH, R. N. PECHNICK
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Among the various therapeutic approaches, androgen deprivation therapy (ADT) is a well-established treatment for prostate cancer. Its goal is to lower levels of testosterone, the main factor driving the progression of prostate cancer. Although this treatment strategy can slow disease progression, patients receiving ADT show significant declines in executive functioning, spatial reasoning, spatial abilities and working memory. At the present time, however, little is known regarding the fundamental mechanisms underlying ADT-induced impairment of cognition. We hypothesize that the cognitive impairment observed in prostate cancer patients

following ADT is due to treatment-induced reduction in hippocampal neurogenesis. In this study, in order to assess neuronal survival, the number of BrdU-positive cells and percentage of BrdU-positive cells that co-express NeuN, a marker of mature neurons was determined in the dentate gyrus of mice using immunofluorescent double-staining and confocal microscopy. Proliferation was assessed by counting the number of Ki-67-positive cells and percentage of Ki-67-positive cells that co-express nestin (a marker of proliferating neural progenitors) and doublecortin (DCX), a protein expressed in immature neurons (i.e., neuroblasts). We found that ADT, using either surgical or pharmacological castration (i.e., the androgen receptor antagonist flutamide or down-regulating the secretion of gonadotropins using leuprolide), affected both neuronal proliferation and survival. In addition, the effects of ADT on learning and memory were determined using open field activity, Y-maze, Barnes maze, and novel object recognition tests. The results of the present study might lead to the development of an animal model to help understand the pathophysiological processes underlying ADT in humans. (Supported by USAMRMC PC150494).

Title: Do new neurons affect motivation in a barrier T-maze task?

Authors: *K. B. HUNTZICKER[1], R.-M. KARLSSON[2], H. A. CAMERON[3]
[1]Neuroplasticity Br., Natl. Inst. of Mental Hlth., Bethesda, MD; [2]NIMH, Natl. Inst. of Hlth. (NIH), Bethesda, MD; [3]NIMH, NIH, Bethesda, MD

Abstract: Adult neurogenesis in the hippocampus has long been implicated in neural mechanisms for complex learning. Through the use of a transgenic rat model expressing herpes simplex virus thymidine kinase (HSV-TK) under the glial fibrillary acidic protein (GFAP) promoter, our lab can study the behavioral effects of pharmacogenetic ablation of adult neurogenesis. Previous studies from our lab have found that GFAP-TK rats treated with valganciclovir to eliminate adult neurogenesis show decreased motivation for weak rewards when compared with wild-type controls in two operant tasks that require high effort. To determine whether this difference stems from an aversive response to the uncertainty inherent to the progressive ratio and effort-based reward tasks or solely from a lack of motivation, we used a

barrier T-maze task to assess motivation when both effort level and reward outcome are certain. This paradigm employs a two-armed T-maze to compel animals to choose between a high-reward arm known to contain several sucrose pellets and a low-reward arm with fewer pellets. The addition of physical barriers of varying heights modulates the amount of effort that rats must expend to receive a reward, essentially forcing a decision between high-effort/high-reward and low-effort/low-reward outcomes. Results showed that GFAP-TK rats and wild-type controls behaved similarly with a high reward ratio (5:1), with both groups choosing the high-reward arm in more than 80 percent of trials, even when it required climbing a very high barrier. Ongoing studies will determine whether this behavior persists in the presence of a lower reward ratio and more evenly matched choices. If not, this would suggest that decreased motivation in rats lacking adult neurogenesis is unrelated to uncertainty about whether rewards will be earned. However, if GFAP-TK rats and wild-type rats continue to perform similarly in the T-maze task, this finding would suggest that GFAP-TK rats exhibit a differential response to reward motivation specifically in the presence of uncertainty, suggesting a role for adult neurogenesis in the cost-benefit analysis required for the execution of complex reward-seeking behaviors.

Title: Actions of a novel glucocorticoid in the neonatal rat brain

Authors: *E. M. BARGERSTOCK[1], J. D. JAUMOTTE[2], S. G. WENDELL[3], D. B. DEFRANCO[3]
[1]Pharmacol. and Chem. Biol., Univ. of Pittsburgh, Mc Kees Rocks, PA; [2]Neurol., [3]Pharmacol. and Chem. Biol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Bronchopulmonary dysplasia (BPD) remains a significant complication of prematurity, particularly extremely preterm infants. Its management often includes the administration of systemic glucocorticoids (sGC), mainly dexamethasone. However, sGC therapy carries significant concerns for not only short-term systemic side effects, but also detrimental impact on long-term neurodevelopment and structural brain development. As such, there remains a need for a GC therapy that will have the desired anti-inflammatory effect on neonatal lungs, but which would not produce negative systemic side effects seen with

dexamethasone. Ciclesonide is a new generation inhaled sGC currently used in children for asthma management. It is a prodrug activated by lower airway carboxylesterases and demonstrates low systemic bioavailability and rapid metabolism outside of the lungs, which allows for the avoidance of systemic side effects, in addition to equivalent efficacy to current sGC therapies. We hypothesized that exposure to ciclesonide will have limited detrimental effects on white matter in neonatal rat brain relative to dexamethasone due to its limited conversion in brain tissue to its active compound des-ciclesonide. Our study compared the effects of ciclesonide on myelin formation and astrogliosis via myelin basic protein (MBP) immunofluorescence and Western blot analysis, to those of dexamethasone, which has previously been shown to cause such abnormalities. We also assessed the pharmacokinetics of the conversion of ciclesonide to des-ciclesonide in various tissues in rat neonates via LC/MS/MS analysis. These studies provide an important step in examining the efficacy and impact on structural brain development, as well as brain and systemic pharmacokinetics, of ciclesonide in order to potentially establish its position as a superior alternative to dexamethasone. Development of an alternative and superior sGC therapy to dexamethasone in the management of BPD would present a significant clinical advancement in the treatment of extremely preterm infants.

Title: Neonatal phlebotomy-induced anemia, PIA, in developing mice increases expression of immune response genes in the hippocampus and is associated with behavioral and social deficits

Authors: *T. MATVEEVA[1], G. SINGH[2], T. GISSLEN[3], P. V. TRAN[4], J. C. GEWIRTZ[5], M. GEORGIEFF[3]
[1]Psychology, [2]Univ. of Minnesota, Minneapolis, MN; [3]Pediatrics, Univ. of Minnesota, MINNEAPOLIS, MN; [4]Dept. of Pediatrics, Univ. of Minnesota, Minneapolis, MN; [5]Dept Psychology, Univ. of Minnesota Dept. of Psychology, Minneapolis, MN

Abstract: Background: Anemia is common in premature infants and is exacerbated by repeated phlebotomy for lab analyses. The behavioral consequences of infant phlebotomy remain understudied. vidence in humans suggests that the degree of anemia commonly tolerated in the NICU can negatively affect neurodevelopment, potentially through dysregulation of inflammatory pathways.

Objective: Determine the short-term effects of PIA on the hippocampal transcriptome and investigate long-term cognitive and social deficits in neonatal PIA mice.
Design/Methods: PIA was induced in mice by phlebotomizing 5.3 µL blood/g body weight twice daily through the facial vein beginning at postnatal day (P) 3 to target hematocrits (Hct) of 25% or18%, respectively. Thereafter, blood was drawn once daily (3.5µL/g) to maintain those hematocrit levels until P14. Non-phlebotomized pups served as controls. RNA isolated from P14 PIA and control hippocampus was sequenced and processed using EdgeR package to identify differentially expressed genes ((DGE, [FC] $\geq$ 1.5, P $\leq$ 0.05). DGEs were analyzed using Ingenuity Pathway Analysis (IPA) to uncover altered signaling pathways and functional gene networks. The formerly anemic and control mice were also assessed behaviorally using the NOR test and the Three-Chambered Sociability/Social Novelty Task immediately after recovery at P17-P21 and then again at $\geq$P120.
Results: 217 DEGs were identified from 18,380 sequenced genes. IPA analysis revealed multiple altered gene networks indicating an increased inflammatory response via NFATC2 and decreased estrogen receptor (ESR1) signaling. 18% Hct mice showed novelty aversion, while 25% Hct mice were indifferent to object novelty. Conversely controls spent more time exploring a novel object than a familiar one. During the Three-Chambered Sociability/Social Novelty task, both 25% and 18% Hct mice showed social novelty aversion, while 25% Hct animals also revealed deficits in sociability.
Conclusion(s): Neonatal PIA in mice similar to that of human premature infants displayed deficits in novelty-related exploration and social behavior. These effects could be related to increased inflammation and decreased estrogen receptor signaling- processes providing safeguards against injurious events in the neonatal period.

Title: Mild traumatic brain injury in the mouse results in transient increase of neurogenesis but sustained survival of newborn neurons

Authors: *K. L. CLARK[1,2], S. YUN[1,2], H. E. METHENY[1], A. S. COHEN[1,2], A. J. EISCH[1,2]
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The majority of the 2.8 million traumatic brain injuries (TBIs) that occur annually in the US are classified as mild. Mild TBIs (mTBIs) can induce long-lasting impairment in memory and attention. Contextual memory is disrupted after mTBI, and is critically dependent on adult dentate gyrus neurogenesis. There are conflicting results about how TBI affects neurogenesis, with very little work examining the impact of a mild injury. Here we utilized a mouse model of mTBI and defined its influence on the dynamic process of adult hippocampal neurogenesis. Male C57BL/6J mice (6-8 weeks) received either sham surgery or mTBI via lateral fluid percussion injury (LFPI), and dentate gyrus neurogenesis was measured via stereology at early (3 days post-injury, dpi), intermediate (7 dpi), and late (31 dpi) time points. Mice received a single injection of BrdU (150mg/kg i.p.) 3 dpi to label proliferating cells. Brains from the early time point were collected 2 hours post-BrdU and assessed for indices of dentate gyrus neurogenesis: proliferation (BrdU+ and Ki67+ cells in subgranular zone [SGZ] of granule cell layer [GCL]) and immature neurons (doublecortin [DCX]+ cells in SGZ and GCL). Brains from the intermediate and late time points were collected 4 days and 4 weeks post-BrdU, respectively, and assessed for proliferation (Ki67+ cells), immature neurons (DCX+ cells), and survival and fate of newly-born neurons (BrdU+ cell number and phenotype). At the early time point, LFPI mice had ~50% more Ki67+ SGZ cells relative to sham mice, but the same number of DCX+ SGZ/GCL cells as sham mice. In contrast, at the intermediate time point, LFPI mice had ~30% more DCX+ SGZ/GCL cells than sham mice. At the late time point, Ki67+ and DCX+ cell numbers were the same between LFPI and sham mice, but LFPI mice had ~70% more BrdU+ SGZ cells than sham mice. Our current hypothesis is that these data suggest a transient increase in proliferation of neural precursor cells shortly after LFPI, which may relate to the subsequent transient increase in immature neurons and to a bolus of adult-born granule cell neurons that persist 1 month post-injury. Ongoing work is testing this hypothesis with additional immunohistochemical analyses (early and late timepoints: dentate gyrus GCL volume; intermediate: Ki67 and BrdU cell numbers, late: phenotype of BrdU+ cells; all time points: indices of glial activation), and exploring how these cells influence hippocampal physiology and function on both the circuit and behavioral level.

Title: Oxycodone in the female rat: Development of an oral self-administration protocol and effects on infant behavior and communication

Authors: *G. ZANNI, M. J. DESALLE, A. A. DOUGHER, J. CHANDAR, H. M. DEUTSCH, G. A. BARR, A. J. EISCH

Abstract: The use and misuse of prescription and other opiates during pregnancy in the US has increased 5-fold in the past 10 years. Indeed, from 2000-2012, 22,000 newborn infants in the U.S. were diagnosed with Neonatal Abstinence Syndrome (NAS, also called Neonatal Opiate Withdrawal Syndrome, or NOWS), which is marked by severe irritability and neurobehavioral complications. Little is known about the long-term consequences of oxycodone exposure. Here we explore the effects of gestational and early postnatal exposure to oxycodone using our newly-developed preclinical model of oxycodone self-administration and NAS. Adult female Long Evans rats received oxycodone in drinking water before, during, and after pregnancy and readily drank oxycodone (0.06-0.12 mg/ml), even when unadulterated water was available. Intake averaged about 10/mg/kg/day. Maternal liquid intake and body weight were measured daily, and the following measurements/behaviors were recorded in offspring from postnatal day 2 (P2) to P14: plantar thermal test, negative geotaxis, pivoting, olfactory spatial navigation, righting, cliff avoidance, and maternal separation-induced ultrasonic vocalizations. Oxycodone was detected in the serum of mothers and pups and there were no differences in the number of pups/litter, litter weight, or pup weight over time relative to pups of mothers that received water only. Compared to control pups, oxycodone exposed pups had longer latency to remove a paw in the plantar thermal test on P2. Together with detectable oxycodone in the serum of P0 pups and mothers, these data show oxycodone received via placenta and lactation has a functional effect in P2 pups. The analgesia was transient, though, as it was not evident in P14 litters. Oxycodone-exposed and control pups had similar performance on many of the tests (P3-P13), including motor coordination, cliff avoidance, righting time, and olfactory spatial learning. However, P7 oxycodone-exposed pups had reduced pivoting relative to control pups. Female but not male oxycodone-exposed rat pups vocalized more before and after reunion with their mother (P8) suggesting potential differences in attachment and social communication,. These data suggest prenatal exposure to opioids has a transient analgesic effect, a mild locomotor effect, and a sex-dependent effect on “emotional”-like behavior. We are currently employing this novel translational rat model for a longitudinal analysis of the effects of oxycodone on brain and behavior in both mothers and offspring, including hippocampal neurogenesis.

Title: GABAergic entorhinal cortex control of hippocampal function in stress-related behavior: Cellular and circuitry mechanisms

Authors: *S. YUN[1], R. P. REYNOLDS[2], M. SUAREZ[2], A. D. GIBSON[2], M. J. DESALLE[2], A. J. EISCH[2,1]
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]The Children's Hosp. of Philadelphia Res. Inst., Philadelphia, PA

Abstract: Major Depressive Disorder is marked by dysregulated hippocampal circuitry in both humans and rodent models, and antidepressant treatments, like pharamceutical and electroconvulsive therapies, ameliorate these hippocampal changes. From such work, a promising framework for discovery of new antidepressants has emerged: find treatments that "recalibrate" depression-linked dysfunctional neural circuits and behavior. Indeed, other approaches to "stimulate" neural circuits–such as deep brain stimulation (DBS)–have been successful in reversing depression-related symptoms and neuropathology, particularly in the hippocampus. In the context of depression, it is notable DBS has only been targeted to non-hippocampal brain regions, such as the nucleus accumbens and subcallosal cingulate. While direct stimulation of the hippocampus has generally negative effects, we recently showed chronic stimulation of the glutamatergic input from the entorhinal cortex [Ent] to the hippocampal dentate gyrus (DG) is antidepressive and improves fear memory. In addition to glutamateric projections, the Ent also hosts GABAergic interneurons that, despite their name, project to the hippocampus and contribute to network activity and function (i.e. memory). However, it is unknown if Ent GABAergic hippocampal-projecting neurons regulate depressive-like behaviors. Here we used chemogenetics and DREADD technology to control the excitability of efferent

GABAergic neurons via AAV-DIO-hM3Dq infusion into the Ent of either Somatostatin (SST)- or Parvalbumin (PV)-cre transgenic mice and examine the impact on social avoidance induces by chronic social defeat stress. Stimulation of Ent–CA1/CA3 projecting GABAergic neurons (SST+ or PV+ cells) shows longer total immobile time in FST after chronic restraint stress, implying depressive-like behaviors. In contrast, stimulation of Ent–DG projecting GABAergic neurons (SST+ cells) shows shorten total immobile time in FST. Given our interesting data, we are currently examining DG dysfunction-related depressive-like processes (e.g. pattern separation, social and non-social approach behavior, neurogenesis) after stimulation of SST+ Ent–DG projecting GABAergic neurons after chronic stress. Also, we are examining neuroanatomical and neuron functional complexity of Ent GABAergic interneuron via monosynaptic tracing techniques and in vivo Ca2+ imaging. Our study will reveal Ent–hippocampus projecting GABAergic interneurons circuit has broad implications for understanding pathological condition of depression and manipulating for depression treatment.

Title: Impaired BDNF-TrkB signaling in human Angelman syndrome neurons

Authors: *E. S. LEVINE, J. J. FINK
Neurosci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Individuals with a deletion of chromosome 15q11-q13 suffer from Angelman syndrome (AS), a neurogenetic developmental disorder characterized by intellectual disability, motor ataxia, autistic features, absent speech, and seizures. The specific gene that is responsible for AS encodes the ubiquitin protein ligase E3A (UBE3A). The expression of this gene in neurons is imprinted (silenced) on the paternal allele, and expression in neurons is only from the maternal allele. Thus, deletion or mutation of the maternal UBE3A gene cause a complete loss of Ube3A protein in neurons. However, the specific Ube3A targets and downstream signaling mechanisms underlying AS pathophysiology are unknown. Using neurons differentiated from patient-specific induced pluripotent stem cell (iPSC) lines, we have recently identified a cellular

phenotype in AS neurons that includes impaired maturation of resting membrane potential and action potential firing, along with decreases in spontaneous synaptic activity, synaptic plasticity, and dendritic complexity. In the present work, we explored whether disruption of signaling by brain-derived neurotrophic factor (BDNF), acting through the trkB receptor, is responsible for aspects of this phenotype. BDNF is a member of the neurotrophin gene family that plays well-established roles in neuronal differentiation and development as well as modulation of synaptic structure and function. Interestingly, BDNF-trkB signaling was recently shown to be disrupted in AS mice. In iPSC-derived neurons from control subjects, we find that removal of exogenous BDNF, along with blocking endogenous BDNF signaling, impaired maturation of resting membrane potential, action potential firing, and spontaneous synaptic activity, mimicking the phenotype of AS neurons. Preventing BDNF signaling in AS neurons, on the other hand, did not cause any further impairment. We also monitored acute responses to BDNF via electrophysiology and calcium imaging. BDNF application resulted in increased synaptic activity and action potential firing in control neurons, but failed to do so in AS neurons. Taken together, these results suggest that AS neurons are unresponsive to BDNF, which may account for the immature phenotype of AS neurons. Ongoing studies are examining whether disruptions in BDNF signaling are responsible for deficits in NMDA receptor-dependent synaptic plasticity in AS neurons. This approach sets the stage for identifying novel therapeutic targets for treatment of AS and related disorders.

Title: Effect of altered glucose levels on the activity of human Dup 15q syndrome neurons

Authors: *M. ELAMIN, T. M. ROBINSON, J. J. FINK, E. S. LEVINE
Neurosci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Chromosome 15q11-q13 duplication syndrome (Dup15q) is a neurodevelopmental disorder caused by duplication of the maternal copy of this region of the long arm of chromosome 15. Affected children typically present with autistic behavior, epileptic seizures, and a wide range of intellectual and motor disabilities. We are using neurons derived from induced pluripotent stem cell (iPSC) lines from Dup15q patients and unaffected controls to

identify cellular phenotypes related to the underlying pathophysiology. We have recently identified differences in excitability and synaptic transmission between Dup15q neurons and unaffected controls over the course of *in vitro* development. In addition, several studies have reported mitochondrial dysfunction and metabolic irregularities in individuals with Dup15q that could contribute to the underlying pathophysiology. However, cells studied *in vitro* are typically grown in supra-physiological levels of glucose, which by itself could cause mitochondrial dysfunction, thereby obscuring physiological differences between control and Dup15q-derived neurons. Furthermore, Dup15q neurons could be more sensitive to elevated glucose levels if they have mitochondrial dysfunction, or alternatively, mitochondrial dysfunction may mask the effects of altered glucose levels. The present studies were designed to compare neuronal and synaptic activity of iPSC-derived neurons from Dup15q patients and unaffected controls under a range of glucose levels. We found that, in control cells, 48 hours of incubation with 3 mM glucose increased spontaneous synaptic activity and increased action potential amplitude compared to incubation with normal culture media (25 mM glucose). In contrast, neurons derived from Dup15q individuals had higher baseline synaptic activity compared to controls in normal culture media (25 mM), consistent with our previous results, but were unaffected by lowering glucose levels. In a parallel set of experiments, we are examining spontaneous action potential firing and neuronal synchrony using population calcium imaging. Preliminary results suggest that the availability of energy substrates can significantly modulate neuronal activity and support the existence of underlying metabolic abnormalities in Dup15q-derived neurons.

Abstract: Neural progenitor cells (NPCs) play a vital role in early brain development by acting as an intermediate proliferative cell type in the pathway from pluripotent stem cells to fully functional neurons and glia. NPC dysfunction has been linked to several neurodevelopmental disorders, including schizophrenia, autism, and Zika (ZIKV) Congenital Syndrome. Our understanding of these brain diseases has been greatly improved by advancements in *in vitro* stem cell-derived NPC model systems, which usually take anywhere from 14-50 days to generate using conventional methods. Here, we describe human Stem cell-derived Ngn2-accelerated Progenitor cells (SNaPs), which are produced using a novel 48 hour induction protocol. Large quantities of highly pure SNaPs that express several canonical transcript and protein markers of human NPCs can be manufactured in a fraction of the time required for standard techniques. SNaPs are proliferative, multipotent, and able to self-aggregate into neurospheres under low attachment conditions. Importantly, SNaPs are susceptible to ZIKV infection and viral-mediated cell death, while also being able to support active replication of this virus. Furthermore, ZIKV infection elicits an antiviral response in SNaPs that is similar to that found in human patients, and can also inhibit neurosphere development and outgrowth. Given the efficiency of the SNaP system, we were also able to perform a first-of-its-kind whole genome CRISPR-Cas9 screen to identify genetic factors that confer resistance to ZIKV-induced cell death. Together, our findings support the use of SNaPs for the rapid 2-D and 3-D modeling of ZIKV neuropathogenesis in developing human neural cell types.

Abstract: CDKL5 deficiency disorder (CDD) is a rare X-linked epileptic encephalopathy caused by *de novo* mutations in the cyclin-dependent kinase-like 5 (*CDKL5*) gene located on the X-chromosome (Xp22). Pathogenic mutations in *CDKL5* lead to CDD and causes early onset of seizures, developmental delay, and intellectual disability. To date, there is still limited understanding of CDD and how *CDKL5* deficiency affects brain function. Recently, reactivation of the inactive X-chromosome containing the silenced, healthy CDKL5 in neurons has become an attractive therapeutic strategy to treat CDD. However, due to males having only one *CDKL5* gene, patients with a hemizygous *CDKL5* variants would not be candidates for this therapeutic approach. Our goal was to model a pathogenic *CDKL5* variant in male induced pluripotent stem cells (iPSC) and to generate a lentivirus encoding healthy *CDKL5* as a potential avenue to restore *CDKL5* levels. The CDKL5 mutation (Arg178Gln) was knocked into male iPSC using CRISPR Cas9-mediated HDR to generate a hemizygous *CDKL5* pluripotent cell model. This variant has been reported to be pathogenic and common in male and female CDD patients. CDD iPSCs were isolated through serial dilution to obtain purified cell population containing the CDD variant as assessed using Kompetitive Allele-Specific PCR (KASP). CDD iPSCs were then differentiated into neuronal-like cells for quantification of *CDKL5* expression level. CDD neurons were used as a model to assess the restoration of normal *CDKL5* levels *in vitro* following lentiviral transduction. Our CDD-models and lentivirus could potentially be contributed to future development of CDD therapeutic treatments for both males and females.

Title: Understanding neurological disease by utilizing high-throughput assays and CRISPR KO iPSC-derived cell types as an approach to functional genomic studies

Authors: *J. A. DIZON, E. WILLEMS, C. REVANKAR, X. LIANG, D. PIPER
Res. and Develop., Thermo Fisher Scientific Inc Carlsbad, Carlsbad, CA

Abstract: Induced pluripotent stem cells (iPSCs) can be differentiated into numerous cell types and provide useful tools to create translatable neuronal assay systems, effective for both *in vitro*

disease modeling and drug discovery efforts. The advent of CRISPR/Cas9 genome editing platforms has expanded methods to study genetic defects in disease by enabling the introduction of genetic changes in iPSCs, which can subsequently be differentiated to the affected cell type. Although CRISPR/Cas9 mediated genome editing in iPSCs is the optimal approach to study disease-specific genetic defects, genome editing during or after differentiation would support high-throughput functional genomics screens using targeting panels such as the LentiArray CRISPR libraries to understand the biology of neuronal development or to identify novel targets associated with a particular disease. To facilitate LentiArray CRISPR screening in hiPSC-derived cell types, we generated an iPSC line that stably expresses the Cas9 nuclease. We have established proof-of-concept that these LentiArray tools can efficiently edit the genome of Cas9 hiPSC-derived neuronal progenitors, which suggests that this approach will support high-throughput functional genomic screens in disease-relevant neuronal models. Furthermore, we have developed a series of high content imaging and excitability assays to specifically study disease-relevant cellular phenotypes in progenitors or neuronal cells. After delivery of tools, Cas9 iPSC-derived progenitors and neurons can then be tested in a high throughput fashion for changes in cell health, neurite outgrowth, calcium influx and variations in channel activity, and/or electrophysiological changes. By combining the LentiArray CRISPR system with hiPSC-derived neuronal progenitors or neurons and these high-throughput assays, we have built a functional genomics platform that enables the discovery of novel genetic targets and/or drug leads that could ultimately result in therapies for neurobiological diseases.

Title: Neurons derived from human induced pluripotent stem cells as a viable alternative to rodents' embryonic primary neurons for safety and drug discovery studies

Authors: *P. KITCHENER[1], D. HESS[2], F. SIMON[1]
[1]Fluofarma, Pessac, France; [2]Ncardia, Cologne, Germany

Abstract: In vitro models for drug discovery or safety screening need to be relevant for particular pathological or physiological contexts and have high levels of reproducibility in order

to repeatedly obtain valuable results. The easiest starting materials are cancer cell lines, which are widely used in neuroscience literature for simple screening and are handled with standard procedures. A major drawback, however, is that these cells lack many of the key neuronal features, such as spontaneous neurite outgrowth and the ability to form functional neuronal networks that respond to neuronal pharmacology. While more delicate to obtain and use, primary neurons classically obtained from rodents are a tool of choice to study most of neuronal biology in vitro. They are good tools for measuring neurotoxicity and pathophysiological modeling, however, obtaining these cells is labor intensive and time consuming, requiring the sacrifice of a number of embryos. Additionally a specific subpopulation of interest may be poorly represented as exemplified by primary dopaminergic neurons. Three iPSC derived neuronal types from two different providers were evaluated in different assays where primary rodent neurons where used. CNS.4U® cells (Ncardia) represent a highly physiological in vitro co-culture model of diverse Human neurons and astrocytes. Peri.4U® cells (Ncardia) are peripheral neurons. iCell DOPA® (Cellular Dynamics International) are Human dopaminergic neurons. These postmitotic ready to use neurons suppress the need for long and delicate expansion and differentiation steps and provide a short path to initiating neuronal cultures. Each of these cells responds to particular needs in terms of neuronal types, that may not otherwise be obtained as Human neurons for reasonable throughput experiments. We show that optimized experimental conditions to perform live content neurite outgrowth assays, endpoint immunofluorescent labeling and high throughput intracellular calcium measurements, allow for the measuring of neurotoxicity and neuronal network functionality in different physiological and pathological contexts such as in epilepsy (CNS.4U), Parkinson's disease (iCell DOPA) and peripheral neuropathy (Peri.4U). Comparisons with similar data obtained in rodent primary neurons can demonstrate the relevance of the tested Human iPSC-derived neuronal cells with added workability and species relevance for Human medicine. Therefore, while not only reducing the effort involved in using primary neurons obtained from rodents, iPSC-derived neurons, used in adapted experimental paradigms have good validity as models for neurotoxicity and drug discovery studies.

Title: Transplantation and functional integration of human stem cell derived 3D forebrain spheroids into the rodent cortex

Authors: *O. REVAH, T. A. KAHN, N. SAKAI, J. ANDERSEN, J. R. HUGUENARD, S. P. PASCA
Stanford Univ., Palo Alto, CA

Abstract: Three-dimensional human brain region-specific organoids or spheroids derived from pluripotent stem cells hold great potential for studying development and modeling brain disease. However, these in vitro cultures do not receive physiological input from other brain regions, do not generally include immune cells and are not vascularized. Here, we have developed a method of transplanting and integrating forebrain spheroids into the cerebral cortex of rats. We show that forebrain spheroids integrate anatomically and functionally, become vascularized and send long-distance projections. We use state-of- the-art live imaging, electrophysiological and calcium imaging techniques to systematically investigate the morphology and function of the human neural graft. This platform can provide novel insights into maturation and circuit integration of neurons and can be used to model human neuropsychiatric disease.

Program, Sch. of Medicine,, UNAM, Mexico City, Mexico; [4]Dept. of Psychology,, The Univ. of Texas Austin., Austin Texas, TX

Abstract: Glioblastoma multiforme (GBM) is the most common and aggressive primary malignant brain tumor in adults [1]. Despite advances in treatment, GBM has an extremely poor prognosis [1, 2]. Studies indicate that tumors located close to the lateral ventricles (LV) have higher proliferative rates, invasive capacity, and potential of multifocal recurrence at distant areas of the brain [3-7]. The explanation of this phenomenon remains controversial. However,

recent theories propose that tumors are originated from a subpopulation of cells called brain tumor initiating cells (BTICs), which are similar to the neural progenitor cells (NPCs) found at the subventricular zone that lines the LV [8-11]. BTICs have self-renewing and multipotent characteristics, critical for tumor growth and maintenance [8-11]. These malignant capabilities could be increased when BTICs are in close relationship with the LV components: the cerebrospinal fluid (CSF) and the neurogenic niche located at the SVZ [3, 12]. Therefore, we studied the migration and proliferation effects of human BTICs after CSF stimulation. To this end, we divided the study into two subsets. First, 15,000 GBM cells were grown *in vitro* and stimulated with cancer CSF, non-cancer CSF, or control conditions for 48h diluted in 1:200 with base media. We evaluated cell viability using Alamar blue assay, and performed western blot and immunocytochemistry against Ki67 and Nestin. To determine cell migration, cells were plated on a glass bottom culture dish; groups were established as described above and evaluated by time-lapse video microscopy for 30 hours and further analyzed using Matlab. Second, we used an *in vivo* model in which both female and male nude mice were implanted with luciferase-labeled GBM cells in suspension with human cancer or non-cancer CSF in a hydrogel as vehicle (n=8 per group). Tumor growth was followed with bioluminescence imaging. 14 days post tumor implantation, mice were euthanized and brains were stained with H&E and immunohistochemistry against for Ki67. We found that *in vitro* stimulation with cancer CSF increases proliferation of GBM cells, as we obtained higher growth rates and greater concentrations of Ki67 and Nestin. Results correlated with the *in vivo* studies, as animals receiving cancer CSF presented with greater tumor size and Ki67 proliferation index. Regarding cell migration, we did not find differences in the *in vitro* migration assays. Taken together, this study provides direct evidence proving that cancer CSF could have a direct effect on tumor growth. Understanding the interaction of brain tumors and CSF may lead to new therapeutic strategies that will target the CSF components in GBM patients.

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by a focal loss of dopaminergic (DA) neurons the substantia nigra pars compacta (SNpc). The establishment of patient derived pluripotent stem cells (iPSCs) (Takahashi et al. 2007) and their efficient conversion into DA neurons (Kriks et al. 2011) (Chambers et al. 2009) fueled the possibilities for disease modeling and its implication in development and screening of novel drugs up to implementation of cell transplantation therapies. Human iPSCs can be differentiated into DA neurons and support the study of neurological diseases in vitro. However, current neuronal differentiation protocols lack the ability to produce a homogeneous population of midbrain DA neurons. So far, this has not limited positive outcomes of functional recovery in preclinical studies (Daadi et al. 2012; Peng et al. 2014; Hallett et al. 2015) as transplantation often occurs at neural stem cell state (Qiu et al. 2017). However, it still represents an important limitation with regard to predictive and translational application for in vitro models of PD.
To overcome this limitation, we have used the CRISPR/Cas9 system to generate human iPSC lines engineered in the tyrosine hydroxylase (TH) gene, a marker of DA neurons. The iPSC lines carry an enhanced GFP reporter knocked-into frame with the TH gene and under the control of its own promoter to allow expression together with TH during in vitro differentiation. We confirmed the accurate integration of the fluorescent protein reporter in the cell lines with ddPCR and fluorescent in-situ hybridization. With ddPCR we confirmed the simultaneous expression of TH and eGFP mRNA. The co-localization of the two proteins was confirmed via co-immunostaining using primary antibodies specific for TH and eGFP respectively. In addition, upon differentiation into DA neurons of the genetically engineered TH-eGFP hiPSCs, the endogenous eGFP reporter expression was clearly recognizable using flow cytometric analysis as early as 25 days in vitro. These results give promising perspective into the possibility of isolating this subpopulation and thereby obtaining a pure DA cell population. In conclusion, we provide a novel cellular model to study PD phenotypes in vitro, allowing to focus functional studies and screening of novel drugs for the treatment of PD. Moreover, we implement a platform that can be applied to any other cell model of neurodegeneration.

Abstract: Establishing specific cell lineages from human induced Pluripotent Stem Cells (hiPSCs) is vital for cell therapy approaches in regenerative medicine, particularly for neurodegenerative disorders. While neural precursors have been induced from hiPSCs, the establishment of hiPSCs-derived human neural stem cells (hiNSCs), with characteristics that match fetal hNSCs and abide by cGMP standards, thus allowing clinical applications, has not been described. We generated hiNSCs by a virus-free technique, whose properties recapitulate those of the clinical grade hNSCs successfully used in an ALS phase I clinical trial. *Ex-vivo*, hiNSCs critically depend on exogenous mitogens for stable self-renewal and amplification and spontaneously differentiate into astrocytes, oligodendrocytes and neurons upon their removal. In the brain of immunodeficient mice, hiNSCs engraft and differentiate into neurons and glia, without tumor formation. These findings now warrant the establishment of clinical-grade, autologous and continuous hiNSC lines for clinical trials in neurological diseases.
We have expanded our previous results and successfully applied the same neuralization protocol to iPSCs derived from patients affected by genetic neurological diseases. These hiNSCs lines reproduce in vitro disease-related features such as altered neuronal differentiation and trophic

factors expression, thus representing a potential tool to study new therapies for uncurable devastating pathologies.

Abstract: Induced pluripotent stem cells (iPSCs) have been globally recognized as a multipurpose research tool for modeling diseases, developing and screening potential drugs, and implementing cell transplantation therapies to support regenerative medicine. The ability to differentiate human iPSCs into any cell type, including dopaminergic neurons, supports the study of neurological diseases in vitro. The emergence of genome editing tools, such as the CRISPR/Cas9 system, allows diseases to be modeled at the genetic level and studied at the cellular level. However, genetic mimicking of disease has been difficult due to challenges in developing neuronal assays that demonstrate cellular and genetic phenotypes for Parkinson's disease. Here, we describe the generation of clonal CRISPR-edited iPSCs to model Parkinson's disease and demonstrate several cellular phenotypes in neuronal assays associated with the disease.. Through use of an iPSC line that stably expresses the Cas9 protein, we obtained highly efficient editing in targets relevant for Parkinson's disease and obtained single edited iPSC clones that were isolated through the combination of an optimized cell sorting method and expansion of as single cell clones with reagents that support improved single cell survival. We then generated dopaminergic neurons from our clonal CRISPR-edited iPSCs using our PSC Dopaminergic Neuron Differentiation Kit, which generate neurons that express tyrosine hydroxylase (TH) indicative of dopaminergic neurons. Neurite outgrowth assays with these dopaminergic neurons indicated phenotypes typical of Parkinson's disease. Dopaminergic neurons derived from the disease models generated were more sensitive to neurotoxic

compounds as shown in neurite length and apoptosis assays, which again exhibited a disease-like phenotype. In addition, we observed that target selective genes associated with Parkinson's disease are exclusively affected in iPSC lines with mutations introduced in the respective target. In summary, we describe our genome editing platform to reliably produce clonal gene-edited iPSCs that can be used as cellular models to study neurodegenerative disease phenotypes in vitro. This genome editing workflow can be used to mimic these human diseases or revert disease mutations, and will support significant insights into neurodegenerative diseases at the genetic and cellular level.

Title: Intrinsic differences between cranial and spinal motor neurons as a route to ALS gene therapy

Authors: *D. E. IANNITELLI[1], D. AN[1], E. O. MAZZONI[1,2]
[1]Dept. of Biol., [2]Neurosci. Inst., New York Univ., New York, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is marked by progressive degeneration of motor neurons resulting in near total paralysis. While in familial forms of ALS all cells in the body carry associated mutations, a subset of cranial motor neurons (CrMN) resist degeneration better than spinal motor neurons (SpMN), allowing patients to retain eye movements until late disease stages. Therefore, the gene regulatory program triggered during embryonic development in CrMNs allows them to later resist neurodegeneration better than SpMNs. The nature of the intrinsic resistance of this subpopulation of motor neurons to degeneration is not understood and

represents an under-exploited area of ALS research that will lead to a better understanding of the disease mechanism and the development of new therapeutic strategies. Direct comparison of sensitive and resistant MNs is hindered by challenges in extracting and culturing sufficient numbers of CrMNs from tissue. We overcome this hurdle by employing a stem cell-based platform wherein we program both types of motor neurons from embryonic stem cells. Expression of the NIL (Ngn2-Isl1-Lhx3) and NIP (Ngn2-Isl1-Phox2a) transcription factor cassettes induce (i) iSpMNs and iCrMNs respectively. To test their response to ALS toxicity, we established isogenic inducible lines to program iSpMNs and iCrMNs expressing hSOD1 with ALS-related mutations which induce protein misfolding. Thus, taking advantage of our ability to generate both iSpMNs and iCrMNs from mouse embryonic stem cells at high efficiency and model ALS-associated mutations *in vitro*, our goal is to understand the molecular nature of differential sensitivity to neurodegeneration ALS. Immunostaining shows that iCrMNs accumulate less p62-positive aggregates than iSpMNs, differentially modeling an early symptomatic feature of ALS. Inhibition of the proteasome gives the opposite result, suggesting that iCrMNs rely more on proteasome function than iSpMNs to prevent protein aggregation. To determine whether differences in how iCrMNs and iSpMNs prevent protein aggregation extend to how they cope with proteostasis stress, we treated iCrMNs and iSpMNs with CPA. We found that iCMrNs survive better than iSpMNs to chemically induced proteostasis stress. With an *in vitro* platform in hand to model ALS pathology in iCrMNs and iSpMNs, we want to investigate if Phox2a expression (the master regulator of CMN fate) will be sufficient to 1. induce the gene regulatory network which confers resistance to CrMNs and 2. protect SpMNs from ALS stress. These findings will be used to determine if conferring CrMN attributes to SpMNs is sufficient to protect SpMNs from ALS-related degeneration.

Title: Multiplication of the SNCA locus exacerbates neuronal nuclear aging in hiPSC-derived neuronal models of Parkinson’s and dementia with Lewy bodies

Authors: *O. CHIBA-FALEK, L. TAGLIAFIERRO, M. E. ZAMORA
Duke Med., Durham, NC

Abstract: Overexpression of alpha-synuclein gene (*SNCA*) has been implicated in the etiology of synucleinopathies, such as Parkinson's (PD) and dementia with Lewy bodies (DLB). However, the mechanisms that mediate the pathogenic role of *SNCA* overexpression in synucleinopathies remain to be fully elucidated. Human induced Pluripotent Stem Cell (hiPSC) models advanced the field, however, age is critical in the etiology of synucleinopathies and hiPSC-derived models represent rejuvenated neurons which are not fully suitable to model age-related diseases. We developed a new approach to induce aging in hiPSC-derived neurons to further the understanding of the genetic etiologies and molecular mechanisms that are commonly perturbed in synucleinopathies, and those that may underlie the heterogeneity amongst the different diseases in this group. Using hiPSC from a patient with *SNCA*-triplication and a control, we applied the new protocol to generate *isogenic* hiPSC-derived aged dopaminergic and cholinergic neurons, that model PD and DLB, respectively. We characterized age-related phenotypes of the nuclear architecture, specifically markers for heterochromatin organization and nuclear envelope structure. In addition, we evaluated features of the alpha-synuclein aggregation including, aggregates distribution, size, number and confirmation. The hiPSC-derived aged neurons recapitulated aging-features, demonstrating that our protocol is fully suitable for studying late-onset neurodegenerative diseases. The *SNCA*-triplication neurons exhibited advanced-aging signatures of nuclear architecture and chromatin organization already at the juvenile-stage, suggesting that *SNCA* overexpression exacerbates nuclear aging. The aged *SNCA*-triplication dopaminergic neurons showed increased number of alpha-synuclein aggregates per-cell compared to the *isogenic* juvenile neurons. However, the effect of age on the number of aggregates was not observed for the cholinergic neurons. The aggregates in the cholinergic neurons presented a diffuse conformation, while aggregates in the dopaminergic neurons appeared more defined with a punctuate structure. In conclusion, we described a link between *SNCA* overexpression and neuronal nuclear architecture features of aging. We suggest that wild-type *SNCA* functions in pathways related to neuronal nuclear organization, and that *SNCA* overexpression exacerbates nuclear aging and by that contribute to synucleinopathies. Moreover, the interplay between aging and *SNCA* overexpression have a differential phenotypic effect on different neuronal types, providing new insights into the heterogeneity in synucleinopathies.

Title: Modeling PICALM Alzheimer's disease variants in human iPSC-derived cells

Authors: *E. J. LAWSON[1], Z. DAI[1], X. XIE[1], S. A. BAZZI[1], A. P. SAGARE[1], Z. ZHAO[1], R. E. TANZI[2], B. V. ZLOKOVIC[1]
[1]Physiol. and Neurosci., USC, Los Angeles, CA; [2]Massachusetts Gen Hosp, Harvard Med. Sch., Charlestown, MA

Abstract: PICALM is abundantly expressed in neurons and brain capillaries in the human brain, playing an essential role in regulating neuronal function and providing a major pathway for amyloid-beta clearance *in vivo* across the blood-brain barrier. Impaired transvascular and/or paravascular clearance of Amyloid-beta across the BBB contributes to an accumulation of Aβ, accelerating neurovascular and neuronal dysfunction in the Alzheimer's Disease brain. Our research has shown that PICALM is required for Aβ endocytosis and trafficking across the BBB through endocytosis via the LRP1 receptor. Moreover, diminished PICALM levels in the brain endothelium are associated with increased neuronal vulnerability to Aβ species resulting in neuronal dysfunction and, concurrently, neurodegeneration. Several PICALM variants have been identified to influence neuronal toxicity *in vivo*. Using CRISPR/CAS9 genome editing technology, we explored the protective *PICALM* SNP *rs3851179*^{A} and the risk *rs3851179*^{G} variants. We successfully generated iPSC lines homologous for allelic variants of *PICALM* SNP *rs3851179* which were further differentiated into neurons, microglia, and endothelial cells. We confirmed by western blot analysis higher PICALM expression in iPSC-derived neurons and endothelial cells carrying protective *rs3851179*^{A} alleles than those carrying non-protective *rs3851179*^{G} alleles. Neurons carrying protective or non-protective alleles of PICALM can be functionally compared throughout differentiation in 3D and 2D *in vitro* models. Interestingly, neurons generated from iPSCs with the protective *rs3851179*^{A} were less vulnerable to Aβ toxicity. By generating *in vitro* models with neurons, microglia, and endothelial cells derived from human iPSCs with other allelic variants of PICALM, we can explore the fundamental characteristics of AD pathology as it relates to PICALM expression.

Title: Efficient derivation of distinct dopaminergic neuronal subpopulations from mouse and human pluripotent stem cells

Authors: P. GARCAO, E. MOLES-GARCIA, T. OOSTERVEEN, C. SOLEILHAVOUP, K. PATRICK, *L. PANMAN
Med. Res. Council, Leicester, United Kingdom

Abstract: Midbrain dopaminergic (mDN) neurons constitute a highly diverse neuronal population controlling important brain functions, such as motor action, cognition, motivation, reward and emotions. These neurons can be broadly subdivided into two major anatomically and functionally groups, which form the substantia nigra (SN) and ventral tegmental area (VTA). The SN neurons innervate the dorsal/lateral striatum and are critical for controlling motor functions, while neurons within the VTA innervating cortical and limbic areas of the forebrain are primarily associated with emotional behaviours. SN dopaminergic neurons selectively degenerate in Parkinson's disease, while the neighbouring VTA neurons remain relatively unaffected despite the commonalities in developmental origin and gene expression profile. Pluripotent stem (PS) cells offer important opportunities for disease modelling and cell replacement therapy. However, it is important that cell types of the desired identity are generated. Parkinson's disease (PD) is the second most common neurodegenerative disease, which is caused by the selective degeneration of SN dopaminergic neurons located in the ventral midbrain. Despite the commonalities in gene expression and developmental origin, dopaminergic neurons within the VTA remain relatively spared in PD. Access to enriched cultures of these distinct dopaminergic subpopulationsSN will offer important opportunities for disease modelling and cell replacement studiesmodelling Parkinson's disease. Although, dopaminergic neurons have been efficiently generated from embryonic stem (ES) cells, it is unclear how enriched cultures of either SN or VTA subpopulations can be obtained. We have established novel mouse and human embryonic stem (ES) cell differentiation protocol that results in the generation of dopaminergic cultures highly enriched for SN neurons. The SN enriched cultures display the predicted sensitivity to mitochondrial toxicity, which is not observed in cultures mainly consisting of VTA neurons. In addition, applying our differentiation protocol to a PD patient specific iPS cell line resulted in increased levels of alpha-synuclein selectively in SN enriched cultures. Altogether our platform provides us with a model system that can be used to model PD disease and to get novel insight into the selective vulnerability of SN neurons.

Title: Stem Cell derived human central nervous system lineages and models of neurodegenerative diseases

Authors: *M. CARNA, V. POZO DEVOTO, M. FEOLE, V. LACOVICH, G. STOKIN
Translational Neurosci. and Aging Res. Group, Intl. Clin. Res. Ctr. FNUSA-ICRC, Brno, Czech Republic

Abstract: To date, different protocols have been published to differentiate human stem cells into neuronal and glial lineages. Current protocols of human stem cell drive differentiation towards a specific CNS lineage at the expense of the others. However, efficiency of target cell generation varies widely, characterization of cells profile and functionality differs between studies, which leads to highly variable protocols outcomes. Recent evidence indicates that differentiation of CNS cell lineages requires intimate exchange of growth and transcription factors between differentiating cells. Cell to cell communication is essential for coordination of cellular events, better development and homeostasis. To test whether NSCs can be differentiated into comparable amount of fully differentiated CNS cell lineages, namely neurons, astrocytes and oligodendrocytes, a novel protocol was developed to allow for exchange of all necessary factors and optimal maturation of cells. The medium was designed to mimic brain-like serum-free environment to test cells interactions and functionality. We find that this newly designed system exhibits comparable gene and protein expression patterns characteristics for mature CNS cell lineages. The optimal stem cell differentiation into the target cell type was confirmed by demonstrating appropriate morphology lineage specific markers. The function of cells was characterized by their electrophysiological properties, which regulate cell specific activities. The new protocol significantly improved glutamate responsive calcium transients in astrocytes and enhanced glutamate uptake; adequately supported neuronal activity exhibited by increased density of synapsin-immunoreactive punctae in culture, but moreover robustly promoted myelination confirmed by significant MBP immunoreactive cell bodies ensheathing axons. PCR array gene analyses uncovered cell-type specific secreted factors regulating differentiation process. Additionally, RNAseq of single cell-types was performed in order to discover unique regulatory pathways participating on the specific cell features. The novel 2D *in-vitro* model allows for optimal maturation and physiological function of human stem cell derived neurons, astrocytes and oligodendrocytes. It is a powerful tool which enables to investigate the

neurobiological impact of glial cells on neuronal differentiation and development and to study human neurological diseases *in-vitro.*

Univ. Sch. of Life Dent. at Tokyo, Tokyo, Japan; [6]Keio Univ., Yokohama, Kanagawa, Japan

Abstract: Human dental pulp stem cells (hDPSCs) that can be obtained from deciduous or permanent teeth are notable stem cells. The hDPSCs are capable of differentiation into osteogenic, adipogenic, and also neurogenic cells and have proliferation ability (Tamaki et al., 2013). However, characteristics of these derived cells are decided as only static ones by using immunochemistry not functional ones. We, therefore, investigate the functional characteristics of the neuron-like cells derived from hDPSCs by using several fluorescent imaging techniques. We obtained hDPSCs from the cell bank of The Nippon Dental University School of Life Dentistry. In the specific neurogenic culture condition, hDPSCs differentiated into neuron-like cells. We introduced fluo-4 (calcium ion indicator) to these cells at 0, 7, 14, 21, 28 days after differentiation, and observed calcium mobilization before and after the application of several chemicals (glutamate, ATP, and high-KCl). We observed 4 types of hDPSC-derived neuron-like cells characterized by calcium responses; induction of calcium transient after glutamate application, calcium transient after ATP application, calcium oscillation after ATP application, and calcium transient after high-KCl application. In addition, calcium response was also obtained by stimulation with veratridine, an activator of voltage-dependent Na+ channel. After calcium imaging experiment, we identified each cell types (neurons or astrocytes) by immunostaining using the antibodies against glial fiber acidic protein (GFAP) as glial maker and βIII-tubulin as neuron marker, and characterized each cells with specific 4 types of calcium responses. The cells with calcium mobilization by the application of KCl showed intense immunoreactivity to βIII-

tubulin compared with that of GFAP. Regarding the localization site, strong positive reaction of βIII-tubulin was obtained in the cell processes and GFAP in the cell bodies. This results suggested that βIII-tubulin is involved in processes elongation.

Title: Generation of cholinergic neurons in hPSC-derived organoids

Authors: *K.-H. FANG, F. YUAN, X.-Y. TANG, Y. HU, M. XU, Y. LIU
Nanjing Med. Univ., Jiangsu, China

Abstract: Cholinergic neurons play essential roles in regulating learning and memory, which mainly originate from medial ganglionic eminence (MGE). Current available protocols to generate cholinergic neurons are relied on 2D culture system, which is unaccessible for long term culture. This study is aiming at exploring a high efficiency method for differentiating cholinergic neuron in human pluripotent stem cell-derived basal forebrain (BF) organoids. With the combination of XAV939 (Wnt pathway inhibitor) and Purmorphamine (Shh signaling activator), we generate human BF organoids with ventricular and sub-ventricular structures which express MGE marker NKX2.1. To further promote the differentiation of cholinergic neurons, we treat the BF organoids with NGF (nerve growth factor). After two weeks, cholinergic neurons are determined in the BF organoids. Then we transplanted BF organoids into SCID mice basal forebrain. After 3 months, numerous $ChAT^+$ human neurons were tested in the mice brain, and a great mount of human neurites were observed in the cortex. The results of this study demonstrated XAV939/purmorphamine/NGF medium could generate human cholinergic neurons in BF organoids, and grafted human neurons could survived and have long projections in mice brain.

Title: A GEFS+ SCN1A mutation causes cell type-specific and temperature-dependent defects in neurons derived from isogenic hiPSC pairs

Authors: *Y. XIE[1], N. N. NG[1], O. S. SAFRINA[1], C. M. RAMOS[1], K. C. ESS[2], P. H. SCHWARTZ[3], D. K. O'DOWD[1]

Abstract: Approximately 50 missense mutations in *SCN1A*, a gene that encodes the alpha subunit of the Nav1.1 voltage-gated sodium channel, are associated with genetic epilepsy with febrile seizures plus (GEFS+). Mechanisms of how specific *SCN1A* mutations alter neuronal activity and result in seizures are still obscure. To address this question we are assessing the functional properties of neurons differentiated from two pairs of isogenic human iPSC lines: 1) a patient line with K1270T *SCN1A* mutation (GEFS+), and an isogenic corrected line by removing the K1270T mutation using CRISPR/Cas9 editing; 2) a control (unaffected sibling of GEFS+ patient) and isogenic mutant line by introducing the K1270T mutation using CRISPR/Cas9 editing. Isogenic iPSCs were patterned into functional neuronal cultures that consist of 65% excitatory neurons and 35% inhibitory neurons. Electrophysiological analysis of inhibitory neurons 21-24 days post plating showed that the *SCN1A* K1270T mutation, in both genetic backgrounds, causes a reduction in neuronal sodium current density and evoked firing rate at room temperature. Excitatory neurons also exhibited reduced sodium current density but the evoked firing rate was not altered, giving rise to hyperexcitability of the neural network. To investigate the underlying temperature-dependent changes, we are now evaluating the neuronal activity in isogenic hiPSC lines at elevated temperatures, in both excitatory and inhibitory neurons. Preliminary data suggest that the K1270T *SCN1A* mutation results in temperature-dependent depolarized shift of action potential rheobase selectively in inhibitory neurons. This isogenic hiPSC model will be very beneficial to deciphering the links between *SCN1A* mutations and the impact on febrile seizures and epileptic disorders, facilitating the development of personalized anti-seizure medications and improved therapies.

Title: Loss-of-function mutation in inositol monophosphatase 1 (IMPA1) causes severe intellectual disability and schizophrenia-like/bipolar-like behaviors: A human model to study inositol pathway

Authors: *T. FIGUEIREDO[1,2], G. KOBAYASHI[1], D. MOREIRA[1], D. OLIVEIRA[1], E. GOULART[1], A. MENDES[2], F. KOK[1], S. SANTOS[3], R. Y. CHO[4], C. MARCHETTO[2], F. H. GAGE[2], M. ZATZ[1]
[1]Biosci. Inst., Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Salk Inst., La Jolla, CA; [3]State Univ. of Paraiba, Campina Grande, Brazil; [4]Psychiatry, Baylor Col. of Med., Houston, TX

Abstract: Inositol monophosphatase 1 is the critical enzyme for the recovery of the inositol cycle, and it is key for both the de novo synthesis of inositol and the recycling of inositol polyphosphates. The phospoinositol metabolism pathway is involved in normal physiological conditions, such as insulin and PI3K/Akt signaling, endocytosis, vesicle trafficking, exocytosis, cell migration, proliferation, apoptosis, neurotransmitter release, hormone secretion and in maintaining the state of homeostasis for second messengers. Thus, dysfunctions of the inositol cycle have been implicated in a variety of human diseases, including developmental defects, cancer, diabetes and neurological diseases. IMPA1 is thought to have an important role in the mechanism of bipolar disorder (BD), because in therapeutic concentrations, lithium, the main pharmacological treatment for BD, it is an uncompetitive inhibitor of this enzyme. Despite its many physiological functions, no human disease had been attributed to a malfunction of this protein. We identified a new homozygous 5 bp duplication (c.489_483dupGGGCT) in *IMPA1*, leading to a frameshift (p.Ser165Trpfs*10) mutation, in a large consanguineous family with severe intellectual disability and disruptive behaviors from a geographically isolated location in Northeastern Brazil (Figueiredo et al., 2016). Recently, we investigated resting EEG data from

30 participants (17 non-carriers (NC), 9 heterozygotes (HT) and 4 homozygotes (HM). We found disturbances in frontal theta and more global alpha band disturbances in individuals with homozygous *IMPA1* mutation. Interestingly, homozygote IMPA1$^{-/-}$ mice die *in utero*. To gain further insights on IMPA1 function in human cells, we developed induced pluripotent stem cell lines (iPSCs) from three HM, one HT, and two NC individuals from the same family. Using anti-IMPA1 polyclonal antibody we observed expression of IMPA1 in iPSCs from family control individuals and no expression in homozygotes, because of a premature stop codon generated by the frameshift mutation in both alleles. We are currently expanding these studies to patient-derived neuronal cell lines in order to clearly elucidate the mechanisms by which impairment of IMPA1 can alter signaling pathways leading to the development of mental dysfunctions and to correlate with *in vivo* measures of brain activity and cognitive capacity aiming to better understand the pathway from genetic variants to abnormal behavior.

Title: new methods for studying network activity in human induced-pluripotent stem cell (ipsc) derived neural cultures for modeling diseases

Authors: *K. PADMANABHAN[1], C. MARCHETTO[2], R. SANTOS[4], F. H. GAGE[3]
[1]Neurosci., Univ. of Rochester, Rochester, NY; [3]LOG-G, [2]Salk Inst., La Jolla, CA; [4]Inst. of Psychiatry and Neurosci. of Paris, INSERM U894 - Univ. Paris Descartes, Paris, France

Abstract: Neuron cultures derived from induced-Pluripotent Stem Cells (iPSC) are rapidly being used to model circuits *in vitro*. In these cultures, electrophysiological recordings of populations of neurons has been used to understand how structure influences network dynamics, and the ways in which diseases processes disrupt these networks and consequently alter activity. While methods that use mean firing rate or degrees of synchrony can help to identify differences in networks, they are often insensitive to the complexity of single neuron dynamics and the higher

order interactions between neurons that underlie many principles of computation *in vivo*. One of the major challenges for studying the activity of populations of neurons, both *in vitro* and *in vivo* is that the number of possible network states scales exponentially with the number of neurons recorded. In this regard, the benefit *In vitro* recording methods offer in terms of allowing for the monitoring of large numbers of neurons at high temporal precision, carries with it the consequence of requiring new statistical and computational methods for describing patterns of activity. To address this challenge, we recorded large populations of iPSC-derived neurons *in vitro,* and then developed approaches to classify and studying network activity. First, we describe strategies for characterizing the spike count statistics of populations of cells, including estimating the entropy of the circuit (a measure of structure). Following this, we use these methods to describe the network topology that generates specific patterns of dynamics. We show that our method can identify differences in circuit structure, for instance the effect of network size and connectivity in generating different kinds of dynamics. Importantly, our methods could serve as a platform for interrogating how different neurological and psychiatric disorders alter network activity.

Title: Altered neural calcium signaling in human iPSC-derived cortical organoids with cytomegalovirus infection

Authors: *A. D. EBERT[1], A. JOHNSON[2], S. L. SISON[1], S. S. TERHUNE[3]
[1]Cell Biology, Neurobiology, and Anat., [2]Dept. of Obstetrics and Gynecology, [3]Dept. of Microbiology and Immunology, and Biomed. Engin., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Human cytomegalovirus (HCMV) is a beta herpesvirus that upon infection during pregnancy can cause severe congenital birth defects including microcephaly, vision loss, and hearing loss. Currently, no approved treatment options exist for managing in utero infections. Our previous work showed that the antiviral compound maribavir (MBV) decreases HCMV infection in undifferentiated human induced pluripotent stem cell (iPSC) derived neural progenitor cells (NPCs) and allowed progression to early steps in differentiation. However, it remains to be determined whether MBV-treated NPCs can differentiate into functional glutamatergic neurons and astrocytes. Here we evaluated the impact of infection on calcium signaling using cultured NPCs as well as in three-dimensional iPSC-derived cortical organoids.

Functional changes were quantified using live-cell ratiometric imaging measuring intracellular calcium changes following stimulation of purinergic and voltage-gated channels with ATP and KCl, respectively. In the absence of infection, acutely plated NPC populations exhibited increasing percentages of ATP-responsive astrocytes and KCl-responsive neurons over time in culture consistent with maturation. Following infection using GFP-expressing HCMV, NPCs exhibited reduced baseline calcium levels and were unresponsive when evaluated 5 days post infection. In contrast, addition of MBV resulted in reduced numbers of GFP-positive cells, and the GFP-negative cells within the population exhibited normal ATP- and KCl-responsive signaling. To extend these studies, we used early and late stage multicellular iPSC-derived cortical organoids. We first confirmed proper differentiation and laminar organization within uninfected organoids. Upon HCMV infection, we observed GFP-expressing cells within the tissues regardless of the developmental stage. MBV treatment reduced the numbers of GFP-expressing cells, and the GFP-negative cells exhibited more normal ATP- and KCl-responsive signaling. Our studies demonstrate that HCMV infection significantly impairs neuronal and glial function. Moreover, our data indicate that MBV-mediated inhibition of HCMV infection allows NPCs within a complex population to develop into functional glutamatergic neurons and astrocytes.

Abstract: Human mutations in the sodium-activated Slack potassium channel, also known as KCNT1, produce intractable early childhood epilepsy with very severe intellectual disability. In heterologous systems, mutant channels are functional but produce higher amplitude currents than

wild type channels. This has presented a quandary because Slack channels are highly expressed in many neuronal types including excitatory pyramidal cells in the cortex. Ordinarily, increases in potassium currents that are relatively voltage-independent such as Slack are expected to reduce rather than enhance excitability. There have, however, been no studies to determine whether these mutations produce increased Slack currents in neurons (as opposed to transfected cell lines or oocytes), nor any studies of the effects of such increases on neuronal excitability. Using human neurons derived from IPS cells and engineered to have an epilepsy-associated KCNT1 mutation, we now show that the introduction of a disease-causing mutation strikingly increases neuronal sodium-activated potassium currents despite similar expression levels. We find that this results in more rapid repolarization of action potentials and a larger afterhyperpolarization following each spike. As a result, neurons bearing the mutant channel fire many more action potentials in response to depolarizing stimuli. In networks of neurons in vitro, the enhanced Slack currents produce more intense bursts of action potentials and increase overall firing rates. Our findings provide new insights into the biological role of Slack channels in the regulation of neuronal excitability and provide very clear new therapeutic opportunities for the treatment of these devastating diseases.

Title: Brian organoid-based approach to the pathogenesis of ketamine-induced neurodevelopmental disorders

Authors: *C. XU[1], L. JIANG[2]
[1]Shanghai Jiaotong Univ. Sch. of Med., Shanghai City, China; [2]Dept. of Anesthesiol. and Surgical Intensive Care Unit, Xinhua Hospital, Shanghai Jiaotong Univ. Sch. of Med., Shanghai, China

Abstract: The repeated or lengthy use of general anesthetic and sedation drugs in pregnant women during their third trimester potentially affects the development of children's brain and is mandated as “black box warnings” by the U.S. Food and Drug Administration. Although animal studies demonstrated clearly that prolonged exposure to ketamine leads to histological and

functional disorders on brain development, the extrapolation of preclinical research to human is still insufficient for providing bases for clinical treatment, which highlights the need for a better model of developing human brain. In recent years, human pluripotent stem cell (hPSC)-derived three-dimensional organoid culture system, termed brain organoid, has been developed to recapitulate features of human brain development and help to study mechanisms of human brain diseases. We applied hPSC-derived brain organoids to mimic human brain development and investigate the influence of ketamine on germinal zone organization, neurogenesis, gene expression and the distinct primate-specific outer radial glia cell layer by immunostaining, quantification PCR and RNA sequencing. Our preliminary results suggest dramatic effects of ketamine on brain organoid growth, neural apoptosis and survival in 24- hours, which is both dose- and time- dependent as well. Human brain organoids provide an efficient way to evaluate the influence of ketamine on human neural development. Extrapolating these hPSC-derived findings to guide clinical use of ketamine and even other general anesthetic drugs in pregnant patients would be more necessary, compared with studies based merely on animal models.

Title: Neuroinflammation could be associated with autism risk increase in infants born with congenital Zika syndrome

Authors: *P. BELTRÃO-BRAGA[1], C. M. Y. OHKI[2], F. B. R. RUSSO[1], P. E. C. LEITE[3], V. V. LINDEN[2]
[1]USP, Sao Paulo, Brazil; [2]Univ. of São Paulo, São Paulo, Brazil; [3]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Zika virus is associated with congenital malformations, including microcephaly, leading to a congenital syndrome (CZS), which affected hundreds of newborns in Brazil. Autism Spectrum Disorders (ASD) is a neurodevelopmental disorder characterized by communication and social impairment, also associated with restricted and repetitive patterns of behavior. Epidemiological and animal model studies have implicated both environmental factors and genetics in ASD etiology, which affects approximately 1% of worldwide population. The literature concerning viral maternal infections during gestation and ASD risk is still inconclusive. Induced pluripotent stem cells (iPSC) have been successfully generated modeling human neurological disorders, including ASD and CZS. Here we investigated the effects of Zika virus in astrocytes and neurons derived from iPSC and its possible correlation with autism. We found

that Zika virus-infected astrocytes trigger a cytokine profile compatible with neuroinflammation. It includes IL6, IL17 and TNFa, which increased levels are related to ASD. Besides, we investigated the effect of Zika virus infection in neurogenesis and synaptogenesis. We found that Zika causes an impairment in functional synapses in neurons, revealing that children infected during embryogenesis could produce defective neurons, reflecting in cognitive impairment. Actually, children born with CZS during Brazilian outbreak are around 2/3 years old and some of them have been already diagnosed as presenting autistic clinical phenotype. Our results revealed that CZS display a neuroinflammation cytokine profile comparable with the one found in ASD individuals, as well as a significant decrease in synaptic gene and protein expression levels. Altogether, such data could be associated with the increased risk for ASD in children born with CZS.

Abstract: Heterozygous loss-of-function mutations in *GRIN2B*, a subunit of the NMDA receptor, cause intellectual disability and language impairment. We developed clonal models of *GRIN2B* deletion and loss-of-function mutations in a region coding for the glutamate-binding domain in human cells, and generated neurons from a patient harbouring a missense mutation in the same domain. Transcriptome analysis revealed extensive increases in genes associated with cell proliferation and decreases in genes associated with neuron differentiation, a result

supported by extensive protein analyses. Using electrophysiology and calcium imaging, we demonstrate that NMDA receptors are present on neural progenitor cells, and that human mutations in *GRIN2B* can impair calcium influx and membrane depolarization even in a presumed undifferentiated cell state, highlighting an important role for non-synaptic NMDA receptors. It may be this function, in part, which underlies the neurological disease observed in patients with *GRIN2B* mutations.

Title: Biogenesis of sonic hedgehog in the developing brain

Authors: *A. RIVELL[1], P. J. YAO[1], M. P. MATTSON[1], R. S. PETRALIA[2], Y.-X. WANG[2]
[1]Natl. Inst. on Aging, Baltimore, MD; [2]Advanced Imaging Core, NIDCD/NIH, Bethesda, MD

Abstract: In addition to patterning embryonic neural tubes, the Sonic Hedgehog (Shh) signaling pathway continues to have functions in the post-embryonic brain including the development and plasticity of neurons. We have previously found that the Shh pathway receptor Patched and transducer Smoothened are situated in the dendritic spines and shafts of hippocampal neurons. We have also found that activation of the Shh signaling pathway stimulates the growth of axons and presynaptic terminals in hippocampal neurons. In this study, we investigate the production and biogenesis of Shh. We begin by examining Shh mRNA and protein levels in developing brains and hippocampal neurons. We then examine potential regulatory factors that affect global Shh levels. Using antibodies that react with either the N-terminus or C-terminus of Shh, we compare the levels as well as subcellular distributions of different Shh protein species. The findings of our study provide a necessary step towards a full understanding of Shh signaling in brain functions. Title: Growth cone turning on soft-substrate environments requires paxillin-drebrin interaction

Authors: *C. CHEN, R.-S. LIN, T.-Y. CHANG, P.-L. CHENG
Inst. of Mol. Biol. Academia Sinica, Taipei, Taiwan

Abstract: Soft tissue environments have profound effects on axon guidance and growth. However, the molecular mechanisms that underlie growth cone responsiveness to guidance factors on soft substrate are still unclear. Here we found that soft substrate (0.1 kPa) promotes BDNF-induced growth cone turning via modulating the paxillin-associated structural dynamics of hippocampal neurons. By using MALDI-TOF MS and immunoprecipitation, we identified an actin-microtubule crosslinking protein-drebrin as one of the paxillin interacting proteins in embryonic brain lysates. On soft substrate, paxillin associated with drebrin and co-localized at growth cone T-zone. When cells asymmetrically exposed to the guidance factor, i.e., BDNF, their growth cones exhibited significantly larger turning angles with a higher degree of drebrin-paxillin co-localization on 0.1 kPa soft substrates as compared with on glass. Down regulation of drebrin expression by siRNA approach resulted in a reduction in the distribution of paxillin on T-zone. Ectopic expression of a paxillin variant, which has lost drebrin interactions, led to reduced turning responses of growth cone to BDNF-coated stripes on soft substrates. Together, these findings suggest that growth cone response to BDNF on 0.1 soft substrate requires paxillin association with drebrin.

Title: Guiding retinal ganglion cell axons to brain visual centres: Is Pax6 the key molecule?

Authors: *L. SOUNDARARAJAN[1], V. MEERA[1], S. SURYA[1], R. ANN PAUL[1], S. PARVATHY[1], B. BASU[1], A. BHATTACHARJEE[2], N. M. ABRAHAM[2], J. JAMES[1]

Abstract: Intra-retinal axonal guidance is a complex process involving a number of axonal guidance genes that direct the nascent axons of retinal ganglion cells (RGCs) to fasciculate together to reach the optic disc. It is known that Pax6 is a key molecule for RGC genesis but its expression persists in RGCs after they are formed. We were curious to understand why the expression of Pax6 persists in the RGCs during late retinogenesis. Hence, we hypothesize that it could possibly be involved in axonal guidance after RGC fate specification. To understand the role of Pax6 in axonal guidance, we perturbed Pax6 expression in retinal explant culture and also we conditionally knocked out (cKO) Pax6 in the mice retina during the period of axon formation. Down regulation of Pax6 with siRNA in E16 retinal explants showed a significant reduction in RGC axonal growth and fasciculation. We further substantiated our results by knocking out Pax6 in E15.5 mice retina. Here, we have observed a decrease in the number of RGCs, amacrine cells, horizontal cells and photoreceptors which were confirmed by Brn3, Ap2-alpha, calbindin, and recoverin staining, respectively. Analysis of $Pax6^{+/+}$ (control) and $Pax6^{-/-}$ (knocked out at E15.5) retinal flatmounts showed a significant alteration in the axonal guidance and fasciculation in $Pax6^{-/-}$ retina compared to the control. To further understand axonal guidance molecules that Pax6 could be regulating, we performed ChIP-seq with Pax6 antibody and identified a number of axonal guidance genes that are regulated by Pax6. Out of which, the prominent ones were *EphB1* and *Sema5B*. The interaction and regulation of EphB1 and Sema5B by Pax6 was further confirmed with luciferase and qRT-PCR analyses. These findings highlight a novel role for Pax6 in the intra-retinal axonal guidance by regulating key guidance molecules. Our results could have far reaching consequences at a later stage where, it could be mimicked to guide the axons of RGCs transplanted to replace degenerating RGCs in conditions such as glaucoma.

Title: PlexinA1 is crucial for the midline crossing of callosal axons during corpus callosum development in BALB/c mice

Authors: *M. HOSSAIN[1], T. ITO[2], T. TSUZUKI[1], F. IMAIZUMI[1], I. TAKAHASHI[1], T. NEGISHI[1], K. YUKAWA[1]
[1]Dept. of Physiol., Meijo Univ., Aichi, Japan; [2]Aichi Med. Univ., Nagakute, Japan

Abstract: The corpus callosum (CC) is the biggest commissural tract that connects the right and left hemispheres of the brain. In the mouse cortical midline during CC development, the guidepost structures emerge and express axon guidance molecules including semaphorins to instruct neurons about the proper direction of axonal elongation toward and across the midline. Neuropilin 1 (Npn1), a high affinity receptor for class 3 semaphorins, localized on the cingulate pioneers has a crucial role in the midline crossing of the pioneer axons through the interactions with semaphorins like Sema3C. However, it remains unproved which type of Plexin receptor actually functions as a component of Npn1-containing receptor complex during the midline crossing of cingulate pioneering neurons. To examine if PlexinA1 is crucially involved in CC development, CC phenotype was examined in PlexinA1-deficinet mice at postnatal day 0.5 (P0.5) under the BALB/c genetic background. All of the PlexinA1-deficinet mice at P0.5 showed partial or complete agenesis of CC (partial; 6 of 13, complete; 7 of 13 mice). To address the role of PlexinA1 in CC development, we examined the localization of PlexinA1, Npn1, Sema3A, Sema3C and calretinin (CR) by immunohistochemistry (IHC) with brain sections from wild-type (WT) and the mutant mice at embryonic day 15.5 to 17.5 (E15.5-17.5). The IHC revealed the expression of PlexinA1 on the dorsal side of callosal axons crossing the cortical midline at E17.5. The IHC confirmed the expression of Sema3A following the gradient from lateral to midline and the specific localization of both Sema3C and CR in the guideposts such as subcallosal sling. Coimmunoprecipitation assay demonstrated the direct association of PlexinA1 and Npn1 at the stage of CC development. To examine the role of PlexinA1 in the midline crossing of callosal axons, the extension of callosal axons across the midline was traced by both IHC of Npn1 and DiI anterograde axonal tracing. Both methods showed that the incidence in midline crossing of callosal axons at E17.5 was significantly lower in PlexinA1-deficient brain as compared with WT. The results indicate the crucial involvement of PlexinA1 in the midline crossing of callosal axons during CC development in BALB/c mice. To test if PlexinA1 could act as a functional receptor mediating Sema3A repulsive and Sema3C attractive activity, we are planning to conduct an axon guidance assay using explants derived from embryonic cingulate gyrus.

Title: Nerve growth factor induces mitochondria fission that is required for axon branching

Authors: *L. ARMIJO WEINGART[1], A. KETSCHEK[2], R. SAINATH[2], A. PACHECO[2], G. GALLO[2]
[2]Shriner Hosp. Pediatric Res. Ctr., [1]Temple Univ., Philadelphia, PA

Abstract: Mitochondria have emerged as major determinants of the sites of axon branching. We report that NGF treatment decreases the length and increases the number of axonal mitochondria along chicken sensory axons in vitro by 15 min of acute treatment, indicative of fission. Consistently, live imaging of mitochondria following 5-10 minutes of NGF treatment revealed increased rates of mitochondria fission. By 15 min post-treatment NGF established a persistent new steady state of mitochondria length and number, an effect that was reversed following NGF withdraw. BDNF and NT3 similarly decreased the length and increased the number of axonal mitochondria. Pharmacological and peptide-mediated inhibition, and dominant negative expression of dynamin related protein 1 (Drp1), a required component of mitochondria fission, blocked NGF induced fission and axon branching. *In ovo* expression of dominant negative Drp1 decreased the number of branches along sensory axons extending in the spinal cord. Live imaging of eYFP-Drp1 revealed accumulation at sites of mitochondria fission and NGF increased the formation of Drp1 accumulations. NGF promoted phosphorylation of Drp1 at the activating site S616 trough Erk activation independently of the PI3K pathway. Inhibition of ERK signaling also blocked the effect of NGF on mitochondria fission, branching and Drp1 accumulation along mitochondria. PI3K activity is required for branching and its inhibition blocked fission but not phosphorylation of Drp1. Furthermore, live imaging revealed that axonal actin patches, which we have previously shown are driven by PI3K signaling, co-localize with sites of mitochondria fission. Inhibition of actin polymerization using Latrunculin-A blocked the effect of NGF on mitochondria fission and Drp1 accumulation. Pharmacological inhibition of the actin nucleating Arp2/3 complex also blocked the effect of NGF on mitochondria length and number. Finally, inhibition of fission blocked the effect of NGF on the intra-axonal synthesis of cortactin, a required and mitochondria-dependent component of branching, and the subsequent increase in axonal actin dynamics. Collectively, these observations unveil a novel biological action of neurotrophins; the regulation of mitochondria fission and setting of steady state

mitochondrial length and number in axons. Given the multitude of roles played by neurotrophins in the nervous system these observations are expected to have broad implications. This work was supported by the NIH NS078030/ NS095471.

Title: Controlling nerve growth using an electric field induced indirectly in transparent conductive substrates

Authors: *A. M. RAJNICEK[1], Z. ZHAO[1], J. MORAL-VICO[2], A. CRUZ[2], C. MCCAIG[1], N. CASAN-PASTOR[2]
[1]Univ. Aberdeen, Aberdeen, United Kingdom; [2]CSIC, Campus de la Univ. Autonoma de Barcelona, Barcelona, Spain

Abstract: Rationale:
Innovative neurostimulation therapies, including those for brain and spinal injury, require improved electrode materials, such as poly(3,4-ethylenedioxythiophene) (PEDOT) polymers or IrOx mixed ionic-electronic conductors. Little is known about how the electrochemical changes they undergo during stimulation influence nerve growth.
Method:
We performed time lapse microscopy of amphibian neurons growing on transparent films of electronic (metal) conductors and electronic-ionic conductors (conductive polymers and semiconducting oxides) prepared in house. Materials were not connected directly to the power supply but an electric dipole was created wirelessly within them by electrodes connected to the culture medium in which the materials were immersed.
Results:
Without electrical stimulation neurons grew well on films of gold, platinum, PEDOT-polystyrene sulfonate (PEDOT-PSS), IrOx and the mixed oxide (Ir-Ti)Ox but successful growth

was not related directly to surface texture or hydrophilicity. Electrical stimulation induced a dipole in all conductive materials but neurons responded differently to electronic conductors and mixed-valence mixed-ionic conductors. Electrical stimulation slowed, but steered neurite extension to the imposed cathode on gold but not on platinum. The rate and cathodally-directed neurite growth on PEDOT-PSS resembled that on glass, but on IrOx and (Ir-Ti)Ox neurites grew faster and in random directions.
Conclusions:
Our data suggest that electrochemical changes induced in these materials indirectly controlled neurite growth speed and direction selectively. Evidence that the electric dipole induced in conductive materials was sufficient to control nerve growth will impact CNS neuroregenerative electrotherapies that exploit wireless stimulation of implanted material arrays, with additional implications for situations (e.g. retina) where transparency is required.

Title: Birthdate and muscle target in chick oculomotor axons

Authors: *J. P. SCHWARTZ[1], B. M. BJORKE[2]
[1]Carleton Col., Northfield, MN; [2]Biol. Dept., Carelton Col., Northfield, MN

Abstract: Early in neural development, oculomotor neurons send axons into peripheral tissue to innervate four of the six extraocular muscles: the dorsal, ventral, and medial recti, and the ventral oblique. These axons generate the oculomotor nerve (nIII). We previously found that nIII displays a complex innervation pattern where motor axons first form a plexus with extraocular muscle precursors prior to muscle formation. The nerve-muscle precursor interaction is critical in regulating axon growth and nerve branching. We are currently interested in further characterizing this interaction by examining how motor pools are represented within the plexus. The first goal of our study is to determine whether motor neuron birthdate reproducibility predicts muscle choice. This would suggest that motor pools are presorted prior to axon outgrowth, plexus formation and muscle development. Motor pools in the chick oculomotor nucleus are divided into distinct sub-nuclei in the adult. Previous research demonstrates that motor neuron birthdate drives the organization of these sub-nuclei, but it is unclear whether motor pools can be reproducibly labeled based on birthdate alone. To answer this question, we are labeling early-born motor neurons with GFP, and late-born neurons with RFP introduced by

in ovo electroporation and examining subsequent muscle innervation. By using birth-date to identify motor pools we hope to characterize how motor pools sort within the nerve-muscle plexus prior to muscle innervation.

Title: Early trigeminal ganglion afferents enter the cerebellum before the purkinje cells are born and target the nuclear transitory zone

Authors: *H. MARZBAN[1], M. RAHIMI-BALAEI[2], R. HAWKES[3]
[1]Dept. of Human Anat. and Cell Sci., [2]Human Anat. and Cell Sci., Univ. of Manitoba, Winnipeg, MB, Canada; [3]Cell Biol. and Anat., Univ. of Calgary, Calgary, AB, Canada

Abstract: In the standard model for the development of climbing and mossy afferent pathways to the cerebellum the ingrowing axons target the embryonic Purkinje cell somata (around embryonic ages (E)13-E16 in mice). In this report we describe a novel earlier stage in afferent development. Immunostaining for a neurofilament-associated antigen (NAA) reveals the early axon distributions with remarkable clarity. By using a combination of DiI axon tract tracing, analysis of *neurogenin1* null mice, which do not develop trigeminal ganglia, and mouse embryos maintained *in vitro*, we show that the first axons to innervate the cerebellar primordium as early as E9 are direct projections from the trigeminal ganglia. Therefore, early trigeminal projections are *in situ* before the Purkinje cells are born. Double immunostaining for NAA and markers of the different domains in the cerebellar primordium reveal that afferents first target the nuclear transitory zone (E9-E10), and only later (E10-E11) are axons, either collateral projections from the trigeminal ganglia or a new afferent source (e.g., vestibular ganglia), seen in the Purkinje cell plate.

Title: Core PCP proteins direct peripheral axon guidance in the developing cochlea through a non-autonomous signaling mechanism

Authors: *M. R. DEANS[1,2], S. R. GHIMIRE[2]
[1]Surgery, [2]Neurobio. & Anat., Univ. of Utah, Salt Lake City, UT

Abstract: Neural circuit assembly is critically dependent upon dynamic axon pathfinding events that enable individual growth cones to accurately navigate the developing nervous system and form synaptic contacts in the correct target areas with the correct synaptic partners. The commissural axons of the neural tube have emerged as a preeminent model for studying these events because their growth cones sequentially respond to axon guidance molecules and morphogen gradients as they project towards and cross the ventral midline, and subsequently turn to extend anteriorly. In this model Planar Cell Polarity (PCP) signaling in the growth cone allows commissural axons to turn 90 degrees and extend anteriorly in response to an increasing Wnt gradient. We have characterized a similar 90 degree turning event in the developing cochlea that is required for TypeII Spiral ganglion neurons (SGN2) to extend peripheral axons that innervate the three rows of outer hair cells. SGN2s are thought to contribute to important feedback circuitry that provides neuroprotection in extreme noise, perhaps by acting as nociceptors. SGN2 peripheral axon turning in the cochlea is also dependent upon PCP signaling and in mutant mice lacking the core PCP gene *Vangl2*, these peripheral axons frequently turn incorrectly and project towards the cochlear apex rather than the cochlear base. Similar errors occur in other PCP mutants including *CELSR1* KO mice suggesting a role for the non-canonical Wnt-signaling pathway in SGN2 turning. Using a *Vangl2* CKO line and a series of Cre drivers to further restrict *Vangl2* gene deletion to either neurons or the cochlear duct, we demonstrate that VANGL2 functions in a non-cell autonomous manner and is not required in the growth cone for turning. This is remarkably different from commissural axons where VANGL2 and PCP signaling have been documented in the growth cone. We further demonstrate that VANGL2 and CELSR1 are asymmetrically distributed at the intercellular boundaries between cochlear supporting cells. At this location, the polarized distribution of these proteins is oriented parallel to the short axis of the cochlea and perpendicular to the polarized distribution of core PCP proteins in hair cells which are oriented parallel to the long axis. As the SGN2 peripheral axons pass between cochlear supporting cells before turning, VANGL2 is strategically located at this

intercellular junction to act as an axon guidance cue. While these experiments are focused on developmental processes guiding cochlear innervation, core PCP proteins are broadly expressed throughout the developing nervous system and may direct other axon guidance events through similar mechanisms.

Title: The E3 ligase SIAH regulates ubiquitination and degradation of Akt3

Authors: *B.-S. KIM[1,2], H. KO[1,2], J.-Y. AHN[1,2]
[1]Sungkyunkwan Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Single Cell Network Res. Center, Sungkyunkwan Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Besides its role in neuronal survival, Akt signaling is an important regulator of neural development including axonal growth and branching. However, the mechanism for coordination of Akt activity and the distinctive function of Akt isoforms in the brain development presents a challenge. Here we report the identification of SIAH1 as a novel E3 ubiquitin ligase that preferentially regulates ubiquitin-dependent degradation of the Akt3. SIAH1 most strongly interacts with Akt3 among Akt isoforms and facilitates ubiquitination and subsequent degradation of active Akt3. Notably, during differentiation of hippocampal neurons in culture, Akt3 is abundant in l axonal shaft but not branching point or tips where SIAH1 is prominently present. Depletion of SIAH1 enhanced Akt3 levels in the soma and axonal tips, promoting axon growth and multiple branching. These findings demonstrate that Siah serves as elective ubiquitin ligase that mediates ubiquitin-dependent degradation of Akt3 isoform and would regulate Akt3 turnover in the brain.

Title: Transcription factor c-Jun regulates perineuronal inflammatory activation in dorsal root ganglia following peripheral nerve injury

Authors: *Y. OH
Brain Sci., Ajou Univ., Gyeonggi-do, Korea, Republic of

Abstract: Although regeneration capacity of CNS axons is very limited, peripheral nerve axons readily regenerate, allowing recovery of function after injury. As such, adult dorsal root ganglion (DRG) neurons are able to regenerate axons robustly after sciatic nerve injury (SNI) accompanied by upregulation of numerous regeneration-associated genes (RAGs). Using CCL2-deficient mice, we previously demonstrated that a chemokine molecule CCL2, expressed in DRG neurons following SNI, plays a critical role in the activation of perineuronal inflammatory reactions that lead to enhanced axon regeneration capacity. Intriguingly, c-Jun, one of the RAGs, was persistently activated in CCL2-deficient DRG neurons. This finding prompted us to hypothesize that c-Jun could act in an upstream pathway to induce perineuronal inflammatory reactions supporting the enhanced axon regeneration capacity. Luciferase assay showed that c-Jun overexpression markedly increased transcriptional activity of CCL2. Chromatin immunoprecipitation assay confirmed binding of c-Jun to the promoter region of CCL2 gene following SNI. To examine a functional role of c-Jun expressed in DRG neurons, we established a mouse line in which c-Jun is conditionally deleted only in neural lineage cells by crossing the c-Jun floxed line with the nestin-cre mice. Cultured DRGs neurons deficient of c-Jun could not enhance the extent of neurite outgrowth in response to SNI *in vivo* as robustly as wild type DRG neurons. Consistent with this finding, upregulation of RAGs such as ATF3 and GAP-43 following SNI was substantially attenuated in c-Jun deficient mice. Perineuronal activation of macrophages was significantly reduced in DRGs of c-Jun deficient mice compared to those of c-Jun floxed animals without cre-recombinase. These results suggest that c-Jun is necessary for the activation of perineuronal macrophages by regulating transcription of CCL2 following peripheral nerve injury.

Title: Disruption of neural circuitry in the mouse model of pediatric dysphagia

Authors: *Z. MOTAHARI[1], A. S. POPRATILOFF[1,2,3], S. A. MOODY[1,2], A. S. LAMANTIA[1,2]
[1]Anat. and Cell Biol., George Washington Univ., Washington, DC; [2]Inst. for Neurosci., Washington, DC; [3]Nanofabrication and Imaging Ctr., Washington, DC

Abstract: Pediatric dysphagia, feeding and swallowing difficulty, is seen in 35% to 80% of children with neurodevelopmental disorders. Its consequences include malnutrition, acute choking, and food aspiration leading to nasal, middle ear, and lung infections. We defined the *LgDel* 22q11.2 Deletion Syndrome mouse as a dysphagia model. In *LgDel*, several cranial nerves essential for feeding and swallowing develop aberrantly. The trigeminal nerve (CnV), which provides sensory innervation to the face and oral cavity and motor innervation to muscles of mastication, is particularly compromised due to disrupted retinoic acid (RA)-mediated anterior-posterior hindbrain patterning. *LgDel* CnV sensory and motor neurons, as well as the neural crest that constitutes most of the cranial mesenchyme through which these axons grow, arise from RA "posteriorized" rhombomeres. This patterning change could render CnV neurons unable to extend
axons appropriately, due either to disrupted neuronal identity or altered extrinsic guidance. We labeled individual CnV axons via small tracer injections in living E11.5 embryos of several genotypes and prepared these embryos as whole mounts for confocal 3D imaging, which resolves compromised pathfinding of single axons that likely would be missed in histological sections. An initial assessment of fasciculation using dual fluorophore tracer injections did not show significant distinctions in *LgDel* versus WT axon segregation or mixing. However, *LgDel* CNV axons, despite reaching targets shared with WT, branch, loop, and sprout aberrantly at significantly higher frequencies than WT (p£0.01). The numbers of phenotypes/axon (p£0.01) and loops/axon (p£0.001) were significantly higher in *LgDel*. Consistent with our previous data, these *LgDel* CnV single axon phenotypes are rescued by diminishing RA signaling genetically. As predicted,
individual CnV axons*Tbx1*$^{+/-}$ embryos, a 22q11deleted gene responsible for Cn IX/X abnormality, exhibited a normal morphology as those observed in WT CnV. We are now analyzing other heterozygous and homozygous mutations in other single 22q11-deleted genes to assess their potential contributions to these CnV axon growth and guidance phenotypes.

Together, the axon trajectory phenotypes associated *LgDel* and other genotypes indicates 22q11 gene deletion disrupts axon guidance and alters construction of key sensory and motor circuits for feeding and swallowing in an RA-dependent manner, independent of *Tbx1*, perhaps contributing to perinatal dysphagia.

Abstract: *Objectives:* In laboratory animals, the axon guidance molecule receptor, DCC, directs the neural connectivity of corticospinal and commissural fibers, influencing the coordination of motor behaviors. Here, we investigated these potential effects in humans. Members of a large four-generational family were tested, two-thirds of whom carry a *DCC* mutation and exhibit mirror movements, involuntary contralateral responses that mirror voluntary unilateral actions. We hypothesized that the *DCC* mutation carriers with mirror movements would have the following features: an ipsilateral corticospinal tract, greater ipsilateral motor activations, reduced interhemispheric inhibition, and decreased *DCC* mRNA expression. *DCC* mutation carriers without mirror movements, it was predicted, would express fewer of these features.
Methods: The participants (n=52) were 13 *DCC* mutation carriers with mirror movements, 7

DCC mutation carriers without mirror movements, 13 relatives without the mutation or mirror movements, and 19 unrelated healthy volunteers. The multimodal approach comprised transcranial magnetic stimulation, task and resting state functional magnetic resonance imaging, diffusion tensor imaging, and quantitative real time polymerase chain reaction.
Results: DCC mutation carriers with mirror movements exhibited a functional ipsilateral corticospinal tract, diminished interhemispheric inhibition, greater ipsilateral motor responses, and reduced *DCC* mRNA expression. In comparison, both groups of *DCC* mutation carriers displayed lower resting state functional connectivity between the left and right primary motor cortex and reduced white matter integrity in the corpus callosum.
Conclusions: Diverse connectivity abnormalities were identified in mutation carriers with and without mirror movements, but corticospinal effects and decreased peripheral *DCC* mRNA were unique to those with the mirror movement phenotype.

Title: Antioxidants and autism: Teacher perceptions of behavior change

Authors: *A. SADEK[1], L. S. BERK[2], K. MAINESS[3], N. S. DAHER[2]
[1]Allied Hlth. Studies, Loma Linda Univ. Sch. of Allied Hlth. Prof, Loma Linda, CA; [2]Allied Hlth. Studies, [3]Communication Sci. and Disorders, Loma Linda Univ. Sch. of Allied Hlth. Professions, Loma Linda, CA

Abstract: Children with Autism Spectrum Disorder (ASD) demonstrate a physiological imbalance between free radicals and antioxidants, also referred to as oxidative stress. Oxidative stress is linked to the pathogenesis of this neurocognitive disorder. Children with ASD tend to demonstrate maladaptive behaviors that hinder their participation in activities of daily living. The purpose of this pilot study was to examine the effects of consuming high antioxidant cacao on behavior of children with ASD as measured by teacher perceptions.
This was a 4-week pre-test post-test clinical trial (NCT 03195465). Participants with ASD consumed 4 squares of the dark chocolate twice per day which had a composition of 70% cacao

and 30% organic cane sugar and total antioxidant concentration of 8,320 mmol/100 grams. The two behavioral outcome measures, the *Aberrant Behavior Checklist- 2nd Edition* and the *Autism Spectrum Rating Scale*, were completed by the child's teacher at baseline and end of week four. Twelve participants (9 males, 3 females, mean age of 10.9 ±3.9 years) completed the study. Significant improvements were noted on the Autism Spectrum Rating Scales of Social/Communication (p=0.03, η^2=0.79), Unusual Behaviors (p=0.02, η^2=0.70), and Self-Regulation (p=0.04, η^2=0.59). No significant changes were noted on any of the Aberrant Behavior Checklist-2 subscales (p>.05). Results from this study support existing literature on the benefits of antioxidants in improving social communication, unusual behaviors, and self-regulation behaviors of children with ASD. Further randomized controlled trials are deemed necessary to expand on the validity of these findings.

Table 1 Median (min, max) Scores for ABC-2 and ASRS over time

Scale	Baseline	Four weeks	p value* (η^2)
ABC-2			
Irritability	5.0 (0,31)	6.0 (0,28)	0.27 (0.18)
Social Withdrawal	13.5 (1,33)	9.0 (0,32)	0.48 (0.13)
Stereotypic Behavior	2.5 (0,15)	3.0 (0,15)	0.61 (0.05)
Hyperactivity/Noncompliance	10.5 (1,36)	8.0 (0,43)	0.20 (0.13)
Inappropriate Speech	1.0 (0,9)	0.5 (0,9)	0.59 (0.04)
ASRS			
Social/Communication	63.0 (55,82)	58.5 (47,82)	0.03 (0.79)
Unusual Behaviors	66.5 (58,85)	60.5 (53,81)	0.02 (0. 70)
Self-Regulation	61.0 (51,80)	58.0 (43,83)	0.04 (0.59)
Total of all 3 Subscales T Score	69.5 (62,79)	59.0 (52,79)	0.007 (1.4)

Title: Report of a parents survey of medical cannabis use in treatment autism

Authors: *G. M. LEWITUS, B. YELLIN, A. DAR, S. IMBERMAN, P. BERMAN, D. MEIRI
Fac. of Biol., Technion, Haifa, Israel

Abstract: Autism spectrum disorder (ASD) is a group of neuro-developmental disabilities which are characterized by impairments in communication, social interaction, behavioral control, and emotional instability. In Israel, individual with ASD with sever aggressive behavior can get license for medical cannabis from specialized physicians. However, there is no treatment guidelines for the use of cannabis and caregiver use trial and error to find the right dosage and strains of cannabis that is most effective for them.
This naturalistic follow-up study follow 66 individuals with ASD who were legally prescribed medical cannabis in Israel. In-house caregiver-specific surveys were administered to track behavioral-specific treatment progress. The cannabinoid compositions of the cannabis used by the participants were analyzed.
We found that cannabis use reduced aggressive behavior and improved sleeping quality but had negligible effects on repetitive behaviors. Few participants reported exacerbations in abnormal behavior. Moreover, differences in cannabis treatment response depended on sex as cannabis treatments were reported to be more effective in male participants. In addition, the cannabis products that were used were not all equally effective in reducing abnormal behaviors. Purified cannabidiol (CBD) was the least effective in reducing aggressive behaviors compared to whole extracts from high-CBD Cannabis plants.
Our observations suggest that cannabis products produced from high-CBD Cannabis plants may be considered as a potential therapy for ASD individuals specifically to reduce aggressive behaviors.

Abstract: Introduction. Autism Spectrum Disorder (ADS) is a neuropsychiatric condition characterized by severe deficits in emotional and social functioning, which is a critical component in their quality of life. Although the study of social cognition and its neural correlates in ASD has received considerable interest in recent years, few works have addressed a fundamental aspect of human interaction such as social emotions (i.e. those that are triggered by the presence or interaction with others). In this study, we aim to fill that gap by exploring how ASD patients experience envy and Schadenfreude (pleasure at others' misfortune), two social emotions that constitute counter-empathic responses and therefore can negatively impact interpersonal relationships. Methods. We administered a novel ecological paradigm to 15 adults with ASD and 15 healthy controls (HC) matched in age, gender, IQ and level of education. Subjects had to read short sentences describing different fortunate and unfortunate events that happened to different characters, and rate how much envy and pleasure they felt, respectively. We used SPSS to compare the performance between patients and HC in the task. Additionally, we obtained magnetic resonance imaging recordings from all subjects. Using MATLAB and SPM, we performed voxel-based morphometry to explore the neuroanatomical correlates of envy and Schadenfreude in ADS. Results. Behaviorally, ASD patients reported significantly lower levels of envy and Schadenfreude as compared to HC. VBM analysis revealed a positive

correlation between levels of Schadenfreude and gray matter volume of middle-frontal and parietal regions. Envy did not correlate with any structure. Discussion. This is the first study that explored the neuroanatomical correlates of envy and Schadenfreude in ASD. We found that patients with ASD had a difficulty in feeling those social emotions. Moreover, the experience of Schadenfreude was associated with fronto-parietal hubs, structures previously implicated in mentalizing processes and in ASD symptoms. The study of complex social emotions through ecological paradigms that resemble real-life situations is critical to better understand some of the core deficits of ASD. This findings may help the development of new assessment and intervention strategies to improve the patients' quality of life.

Title: Design and use of an ipad application to improvide reading and writing in children with autism

Authors: *R. AGUILAR, L. I. GARCIA, G. CORIA, R. TOLEDO, M. HERNANDEZ, J. MANZO
Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstract: Autism is a neurobiological disorder that is mainly expressed during the first 3 postnatal years, and includes impairment in social communication and social interaction, as well as repetitive activity. Accordingly, it is important for patients diagnosed as autistic, to be exposed to different therapies or contexts that facilitate the development of social and communication skills. Herein, we show the effects of an iPad application we developed to help reading-writing skills of autistic kids. Accordingly, the application was used for 20-min twice a week during one year. The results indicated that there were positive effects in reading and writing in ten out of ten kids of different age observed in Xalapa, Veracruz, Mexico. All of them were capable of recognize their written name, and also wrote and read it. They also recognized, read and wrote the name of 90% of family members, and also words related to emotions, body parts, and activities (e.g. sleep, eat, sweep, etc.) These results allow us to conclude that this iPad application (LEA) can be used as a complement in therapy to enhance the development of reading-writing skills in autistic kids.

Title: Evaluation of naringenin & its surface modified nanocarriers as neurotherapeutic in autism spectrum disorders (asd)

Authors: *R. BHANDARI, A. KUHAD, 160014, J. PALIWAL, 160014
Panjab Univ., Chandigarh, India

Abstract: Aim of the study was to investigate pharmacotherapeutic potential of Naringenin and its brain targeted nanoformulations in Autism Spectrum Disorders (ASD). ASD like phenotype was induced by infusion of 1M Propanoic acid into anterior portion of lateral ventricle in rats. Naringenin (25, 50 and 100 mg/kg), uncoated and coated (glutathione & tween 80) naringenin loaded poly (lactic-co-glycolic acid) (PLGA) nanoparticles (25 mg/kg) and minocycline (50 mg/kg) were administered orally for 28 days. Neurobehavioural, biochemical, blood brain barrier permeability, TNF-α, MMP-9, HSP-70 and P-glycoprotein tests were performed. Naringenin and its nanoparticles significantly restored behavioural and biochemical deficits in ASD phenotype. Glutathione and tween 80 coated nanoparticles enhanced brain delivery of NGN by inhibition of P-glycoprotein. Naringenin (100 mg/kg) and its nanocarriers (25 mg/kg) demonstrated pharmacological efficacy comparable to minocycline (50 mg/kg). Naringenin and its coated nanocarriers have strong clinical potential as an adjunct neurotherapeutic moiety in attenuating neuropsychopathology associated with ASD. ***Keywords:*** Autism spectrum disorders (ASD), naringenin, neurobehavioural, naringenin loaded PLGA nanoparticles, glutathione (GSH), tween 80

Title: Improvement of cardiorespiratory parameters following music stimulation in children with autism

Authors: L. NUÑEZ-ARCOS[1], I. FERNANDEZ-LECHUGA[1], P. CARRILLO[2], R. TOLEDO[2], *M. HERNANDEZ[3], J. MANZO[2]
[1]Doctorado en Investigaciones Cerebrales, Xalapa, Mexico; [2]Univ. Veracruzana, Xalapa, Ver. Mexico, Mexico; [3]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstract: Autism spectrum disorder is an alteration of neurodevelopment becoming visible in children about 2-3 years of age. Basic behavioral manifestations of the disorder are social isolation, language impairment, and motor problems. However, there are further manifestations related to autonomic dysfunctions modifying anxiety, stress, mood changes, and hyperactivity in response to sensory stimuli, that become manifested in cardiorespiratory alterations. On the other hand, it is known that music stimulation is an external variable with the potency to modify the cardiorespiratory function. A number of experiments have shown that Mozart's K448 Sonata is highly effective to trigger such benefit responses. Therefore, in this study we use this sonata for musical stimulation of 9 children with autism from 5 to 12 years of age. Auditory stimulation was delivered through headphones during 5 min, twice a week for a year, and with a volume at the lower threshold for tolerance of music of each child. Previous to music stimulation, an intelligent wristband was placed to the child (Bracelet 37º; 37 Degree Technology, Shanghai), that took cardiac and respiratory frequency and blood pressure during the stimulation period and send data via Bluetooth to an app in a cell phone. Data showed that cardiac frequency becomes reduced with music stimulation but return to altered values when the stimulus is not applied continuously (when the kid did not come to the test for holidays or other reason). High blood pressure was reduced to normal values even if the child was absent for some tests, but it was unchanged in children with normal blood pressure. The respiratory frequency did not show any modification. Thus, results show that music stimulation is effective in the long term to modify to normal values some cardiorespiratory parameters, what could be a response of physiological changes that deserve to be studied in further studies.

Title: Increased skin sensibility induced by different sensory stimuli in kids with autism

Authors: A. FERNANDEZ-LECHUGA[1], L. NUÑEZ-ARCOS[1], P. CARRILLO[2], L. I. GARCIA[2], G. A. CORIA-AVILA[2], *J. MANZO[2]
[1]Doctorado Inv. Cerebrales, Xalapa, Mexico; [2]Univ. Veracruzana, Xalapa, Ver. Mexico, Mexico

Abstract: Autism spectrum disorder is an alteration of neurodevelopment becoming visible in children about 2-3 years of age. Basic behavioral manifestations of the disorder are social isolation, language impairment, and motor problems. However, there are further manifestations related to sensory perception that is now also considered as a diagnosis criterion. Tactile stimulation is almost unknown, notwithstanding it is known that an appropriate perception is critical for the activities in everyday life. Thus, with the aim to modify alterations in tactile sensitivity of autistic kids, in this work we applied as therapy two sensory stimuli to 6 kids from 5 to 12 years old. The used stimuli were bubble paper and a skin massager twice a week for a year. A carpet of 2x2 m of bubble paper was placed on the floor and tests consisted in each kid walking in socks for 2 min trying to burst the bubbles. A handheld massager (HoMedics) was used to stimulate the skin with a 2 level of intensity for 2 min on the arm and face. Following stimuli, the sensitivity threshold was obtained by using Von Frey Fibers on the same areas, as kids kept their eyes closed indicating perception by pointing with a finger the stimulated area. Results showed that as therapy was applied consecutively every kid was able to perceive smaller fibers. Thus, here we showed that an enriched sensory stimulation of autistic children modifies cutaneous sensitivity, suggesting an improved perception of the general environment.

Title: Cerebrospinal fluid vasopressin, diagnostic classification, and symptom severity in children with autism

Authors: *O. OZTAN[1], J. P. GARNER[1], S. PARTAP[1], E. H. SHERR[2], A. Y. HARDAN[1], C. A. FARMER[3], A. THURM[3], S. E. SWEDO[3], K. J. PARKER[1]
[1]Stanford Univ., Stanford, CA; [2]UCSF, San Francisco, CA; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Background
Autism is a brain disorder characterized by core social deficits and the presence of restricted, repetitive behaviors. Progress in understanding and treating autism has been hindered by the extraordinary difficulty in obtaining brain-relevant tissues [e.g., cerebrospinal fluid (CSF)] from children by which to study disease biology more directly. Here we bridge this critical gap in knowledge by testing whether CSF concentrations of the "social" neuropeptides arginine vasopressin (AVP) and oxytocin (OXT) differentiate cases and controls and are associated with symptom severity in the largest pediatric cohort studied for this purpose to date.
Methods and Findings
Children with autism were diagnosed based on clinical criteria which was confirmed with research diagnostic methods. All participants (N=72: 48 males, 24 females, aged 1.5 to 9 years, matched 1:1 on sex and age) underwent lumbar puncture; CSF neuropeptide concentrations were quantified using established enzyme immunoassays. CSF AVP concentration was significantly lower in the autism compared to control group ($F_{1,66}$=14.20; P=0.0004). CSF AVP concentration also significantly differentiated individual cases and controls (Likelihood Ratio Chi-Square=15.14; P<0.0001). Specifically, across the range of observed CSF AVP concentrations, the likelihood of autism increased over 1000-fold, corresponding to nearly a 500-fold increase in risk with each 10-fold decrease in CSF AVP concentration. Lower CSF AVP concentration also

predicted greater overall symptom severity ($F_{1,27}$=4.878; P=0.0359) on the Autism Diagnostic Observation Schedule Calibrated Severity Score (ADOS-CSS). Further analyses revealed that this was driven by social ($F_{1,27}$=7.708; P=0.0099), but not repetitive ($F_{1,27}$=0.0274; P=0.8698), symptoms on the ADOS Social Affect-CSS and Restricted and Repetitive Behaviors-CSS, respectively. Finally,
these findings were more pronounced in males than in females with autism, and were specific to AVP, as no evidence implicating the structurally related neuropeptide OXT was found.

Conclusions

These findings highlight the value of performing CSF-focused biomarker research in individuals with autism. As prior preclinical research has shown that AVP (rather than OXT) preferentially regulates social behavior in male mammals, these data also suggest that brain-related AVP signaling deficits may be particularly relevant to better understanding the male-biased risk for, and symptom presentation in, autism. Finally, although preliminary, these findings suggest that AVP may be a promising CSF indicator of, and potential therapeutic agent for, autism's social deficits.

Title: Effect of different types of distractors over selective attention in children diagnosed with autism spectrum disorders

Authors: *P. A. BATIZ FLORES[1], S. MENESES-ORTEGA[2]
[1]Inst. de Neurociencias - Univ. de Guadal, Guadalajara, Mexico; [2]Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Autism Spectrum Disorder (ASD) is usually detected in the first years after birth and is maintained throughout life. Children diagnosed with ASD present social interaction difficulties, communication deficits, stereotyped and repetitive behaviors, difficulties processing and recognizing social stimuli, and sensory alterations. These abnormalities in processing sensory stimuli are present in 87% of the cases. Apparently, these deficits are not related to alterations in primary sensory processing, but rather to the systems involved in relevant stimuli selection and inhibition processes associated to interference control. It has been proposed that

selective attention is one of the main cognitive alterations in ASD. Two alternatives have been proposed about the type of attention alterations that patients with ASD may present: First, it has been proposed that children with ASD over focus their attention on specific stimuli or traits; on the other hand, other authors have proposed that they have a wide attentional beam that allows them to perceive stimuli far from the attention focus. The objective of the present study was to evaluate the effect of social and nonsocial distractors over detection of visual stimuli. We also assessed performance on an Attentional Network Task (ANT).
For this, we evaluated 15 children diagnosed with ASD (ages 6-12) and compared their performance with that of children with normal development. Groups were paired by IQ and school grade.
Participants performed two tasks: a task of detecting visual stimuli in which they were presented with distraction stimuli in the periphery of the focus of attention (social and non-social), and the Attentional Network Task (ANT). Results showed that children with ASD diagnosis have higher reaction times on conditions when social distractors appear, compared to when they are presented with nonsocial distractors, also, error percentage was significantly higher in ASD group compared to control group. In addition, we found significative differences in ANT performance; both groups had higher reaction time rates when incongruent distractors were presented, however, the ASD group showed significantly lower correct answers percentage than the control group. No group was benefited by spatial or temporal cues. We conclude that social stimuli do interfere with selective attention processes of children with ASD diagnosis. Results on the ANT could mean poor functioning on executive control attention network on ASD diagnosed children.

Title: The effect of difference of autism-spectrum quotient scores on role adaptation in interpersonal motor coordination

Authors: *K. MUKAI[1], A. MIURA[1], K. KUDO[2], S. TSUTSUI[3]
[1]Dept. of Life Sci., [2]Grad. Sch. of Interdisciplinary Information Studies, The Univ. of Tokyo, Tokyo, Japan; [3]The Fac. of Wellness, Tokai Gakuen Univ., Aichi, Japan

Abstract: It has been suggested that the difference in social skills between two persons affects role adaptation (leading or following role) in rhythmic interpersonal motor coordination. We investigated this by using interpersonal motor coordination task that required participants to

perform a rhythmic movement featuring an interpersonal relative phase pattern 90° without verbal communication. They were required to decide two roles during the task and continued the task until they were able to create the relative phase of 90° stably. Social skill was assessed by the Autism-spectrum Quotient (AQ), and then we computed the ratio of AQ scores between the members of each pair. Pairs whose social skills differed greater (pairs with smaller AQ ratio) finished the task early, and the role was adapted early. On the other hand, pairs whose social skills were similar (pairs with greater AQ ratio) finished the task late, and the role was switched more often than in the early pairs. We examined the effect of the difference of the AQ ratio on the performance of the task (i.e., the number of trials until the pairs finished the task) by mediation analysis. The results showed that pairs with a smaller AQ ratio difference in social skills had a smaller number of role switching, and that the pairs with a smaller number of role switching were able to finish the interpersonal motor coordination task earlier. A bias-corrected bootstrap confidence interval that was calculated for the indirect effect using 10,000 bootstrap samples lay entirely above zero, which provides evidence of an indirect effect of the AQ ratio on the number of trials through the mediator (i.e., number of role switching). The direct effect of the AQ ratio on the number of trials was not significant. We confirmed that the difference in social skills between two persons affected the performance of interpersonal motor coordination task in terms of role adaption.

Title: Autism diagnosis using rewards experiments task-based functional-mri

Authors: *M. ALI[1], O. DEKHIL[2], A. SHALABY[2], R. KEYNTON[2], M. GHAZAL[2], A. EL BAZ[2], G. N. BARNES[3]
[2]Bioengineering, [1]Univ. of Louisville, Louisville, KY; [3]Dept Neurol, Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Introduction: Autism Spectrum Disorder (ASD) is a neuro-developmental disorder. The main goal of using the task-based functional MRI in ASD is to localize task-evoked blood oxygen level-dependent (BOLD) effects in the brain and subsequently, to analyze those effects in order to find anatomical areas of activation related to that specific task. In this work, we adopt the monetary reward experiment for monitoring the activation areas in the brains of both ASD

and control subjects in response to a specific task. In this task, physicians asked the participants to press a button to classify dichotomous categories of images. These images were displayed to them during the experiment, and subsequently, a monetary feedback was provided. **Materials and Methods:** We used 20 subjects and 3T MRI was used to acquire this data. We have covered the whole cerebral volume through 180 functional images which lasted for 6 minutes. 5 seconds were the duration for each trial, where the subject was exposed to the images for approximately 2 seconds. The feedback, then, was displayed for 1.25 sec, and finally a rest period of approximately 1.75 sec occurs between trials. We applied preprocessing algorithms on each volumes. GLM was used to model The BOLD activation change during the feedback display, then we conducted (using SPM package) a one regressor describing the feedback event timing and a first group analysis. We have analyzed the brain's Brodmann areas (BAs) to reach a diagnosis decision on local areas, to move to the idea of personalized medicine. Every brain voxel is then mapped to certain BA. We have used Autoencoder-based classifier (AE) for space reduction and learning the most significant features. We extracted features from every BA and fed them to the AE. A local decision per area is made which indicates the significance of this BA. Finally, we fused all local decisions to have a final diagnosis. **Experimental Results:** We have locally analyzed every BA of all the 94 BAs and have fused them to obtain a global diagnosis decision. We achieved global accuracy of 90%. In addition to the global diagnosis, visualized local analysis is provided. We will show multipe different cases of ASD, where BAs of the cortices of subjects are color-coded according to the strength of association of each area with ASD. The two maps are different, which emphasizes the idea of personalized medicine that is the ultimate goal of our group. **Conclusion:** A novel CAD system for autism diagnosis by adopting functional task-based fMRI information is proposed. Our system provided local analysis for brain areas, which can allocate subjects on the autism spectrum and help to deliver personalized treatments to individuals with autism.

Title: Cortical surface architecture endophenotype and correlates of clinical diagnosis of autism spectrum disorder

Authors: *Y. AOKI[1], B. YAMAGATA[2], T. ITAHASHI[1], J. FUJINO[1], H. OHTA[1], O. TAKASHIO[3], M. NAKAMURA[1], N. KATO[1], M. MIMURA[2], R.-I. HASHIMOTO[1,4]
[1]Med. Inst. of Developmental Disabilities Res., Showa Univesity, Tokyo, Japan; [2]Dept. of Neuropsychiatry, Keio Univ. Sch. of Med., Tokyo, Japan; [3]Showa Univ., Tokyo, Japan; [4]Tokyo Metropolitan Univ., Tokyo, Japan

Abstract: Identifying endophenotype and neural correlates for a diagnosis of autism spectrum disorder (ASD) is particularly important because of its complex genetic influence. Focusing on the cortical volume and three surface-based parameters, cortical thickness (CT), fractal dimension (FD), and sulcal depth (SD), we aimed to identify a pattern of ASD endophenotype and neural correlates for the clinical diagnosis. Enrolling 30 people with ASD endophenotype (15 people with ASD and 15 of their unaffected siblings) and 30 people without (15 pairs of TD siblings), sparse logistic regression with a leave-one-pair-out cross-validation showed high accuracy for identification of the ASD endophenotype (73.3%), which is more evident in SD compared with other parameters. Focusing on SD, a bootstrapping analysis accounting for a difference in SD between typical siblings showed substantially large difference between individuals with ASD and their unaffected siblings in seven out of 34 regions-of-interest. These regions includeinclude left bank of superior temporal sulcus (<0.01 percentile), right pars triangularis, banks superior temporal sulcus, medial orbitofrontal cortex, precentral gyrus (<0.01 percentile). Mean SD values in three of these regions were correlated with ASD severity. Intriguingly, both endophenotype and clinical diagnosis emphasize the social brain but they did not completely match. These findings suggest that ASD endophenotype emerges as SD and the neural correlates for the clinical diagnosis can be dissociable from the endophenotype.

Title: Adolescents and young adult with autism spectrum disorder show specific impairments in cognition

Authors: *R. M. GEDDERT[1], M. K. KRUG[1], V. P. REINHARDT[1], J. P. HOGEVEEN[1], E. FERRER[2], M. SOLOMON[1]

[1]Dept. of Psychiatry and Behavioral Sci., Univ. of California, Davis, Sacramento, CA; [2]Dept. of Psychology, Univ. of California, Davis, Davis, CA

Abstract: Adolescents with autism spectrum disorder (ASD) exhibit impairments in cognitive control (Solomon et al., 2008; Solomon et al., 2009; Solomon et al., 2017). To further investigate the development of these deficits from adolescence to young adulthood, we recruited 88 participants with typical development (TYP) and 88 age and gender matched individuals (age 12-22) with ASD, who were assessed using gold standard ASD diagnostic measures including the Autism Diagnostic Observation Schedule (ADOS-2). Participants completed the NIH Toolbox Cognition Battery (NTCB). The NTCB is a well validated measure of cognition, consisting of measures of cognitive flexibility (Dimensional Change Card Sorting; DCCS), inhibitory control (Flanker), episodic memory (Picture Sequence Memory; PSM), list-sorting working memory (LSWM), processing speed (Pattern Comparison Processing Speed; PCPS), and language skills (Vocabulary; PV; Oral Reading Test; ORT; Akshoomoff et al., 2014). More generally, Flanker, DCCS, PSM, LSWM and PCPS are considered measures of fluid intelligence, while PV and ORT are measures of crystallized intelligence. The ASD group performed significantly worse on the Flanker (F = 38.17, p < .001), DCCS (F =37.27, p < .001), PCPS (F = 30.91, p < .001), PSM (F = 8.04, p = .005) and ORT (F = 5.121, p = .025) tasks when covarying full scale IQ. The groups were not significantly different in LSWM or PV. Stepwise discriminant function analysis was used to examine the combination of NTCB variables that best predicted diagnosis. The overall chi-square test was significant (Wilks lambda = 0.636, Chi-Square = 69.139, df = 4, Canonical Correlation = 0.603, p < .001). The function extracted consisted of DCCS, PCPS, Flanker and PSM, and accounted for 37% of the variance in each group's cognitive performance on the NTCB. These results indicate that the cognitive profile of individuals with ASD is characterized by weaknesses in measures of fluid reasoning, specifically impairments in flexibility, processing speed, inhibition, and episodic memory while crystallized abilities are largely intact. Lastly, we explored how age relates to performance and group differences. Though Flanker, PV and ORT performance was positively correlated with increasing age, diagnosis did not significantly impact growth on any measure. Collection of longitudinal data in the future will allow for a more robust investigation of the developmental trajectories of cognition in ASD. Future analyses will also examine how these relate to clinical symptoms, functional outcomes and the connectivity of neural networks.

Title: Exploring the relationship between prosodic control and social skills in children with and without ASD

Authors: *N. SCHEERER[1], J. A. JONES[2], G. IAROCCI[1]
[1]Psychology, Simon Fraser Univ., Burnaby, BC, Canada; [2]Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: The ability to communicate thoughts, ideas, and emotions is integral to social development. We know this in part because of conditions such as autism spectrum disorder (ASD), where early social communicative deficits (e.g., joint attention) are predictive of later language deficits. As children develop, speech becomes the dominant form of social communication, as it allows complex ideas and emotions to be conveyed between individuals. Social aspects of speech production, such as prosody (e.g., vocal pitch), must be carefully regulated to accurately express information about the emotionality, excitability, and intent of the speaker. Thus, a child may acquire fluent, even excellent speech articulation, but their social communication may be compromised due to poor prosodic control. The objective of the current study is to gain a better understanding of how auditory information is used to regulate the prosodic aspects of speech in children and adults with and without ASD. Furthermore, this research aims to explore the relationship between the prosodic control of speech, or more specifically the control of vocal pitch, and social communication abilities. In this study participants with and without ASD produced vocalizations while being exposed to frequency altered auditory feedback. The size, timing, and variability of participants' responses to the frequency altered feedback were measured. The multidimensional social competence scale was also used to assess social communication abilities. Results indicate that both participants with and without ASD produced compensatory vocal responses to the auditory feedback manipulation. Specifically, vocal responses in the altered auditory feedback condition were significantly larger than vocal responses in the unaltered auditory feedback condition. Vocal response magnitudes were also found to differ across participants with and without ASD. These results represent a key step in the understanding of how atypicalities in the mechanisms supporting speech production may manifest in social-communication deficits, as well as broader social competence, and vice versa. Thus, these findings will establish important benchmarks for researchers studying auditory processing, speech development, and speech perception and production, while also uncovering the relations between these processes and social communication outcomes. This research has the potential to facilitate early detection of speech deficits and communication disorders that interfere with social adaptation across the lifespan.

Title: Communicative misalignment in autism spectrum disorder

Authors: *I. TONI[1], H. WADGE[2], R. BREWER[3], G. BIRD[4], A. STOLK[5]
[1]Donders Inst., Nijmegen, Netherlands; [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Dept. of Psychology, Royal Holloway, Univ. of London, London, United Kingdom; [4]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [5]Knight Lab., Helen Wills Neurosci. Institute, UC Berkeley, Berkeley, CA

Abstract: Autism spectrum disorder (ASD) is diagnosed on the basis of communicative impairments observed in everyday social interactions. While individuals with ASD show remarkable proficiency on lab tests of social cognition, face-to-face interaction proves problematic and has been associated with biases in processing biological and multimodal linguistic cues. Here, we provide empirical evidence characterizing a specific cognitive challenge raised by interpersonal communication in people with ASD, which persists even in environments stripped of those biases and in the presence of neurotypical social motivation and cognitive flexibility. During online, experimentally-controlled interactions, both adults with ASD (N=22) and neurotypical adults (N=30) spontaneously generated novel and intelligible non-verbal communicative behaviors toward their interaction partners. Furthermore, both groups showed a similar propensity for modifying their behavior when misunderstandings arose. However, communicative success was lower when individuals with ASD interacted with other individuals both on and off the spectrum. This impairment was proportional to the misalignment between the meanings of the communicative behaviors used by pair members across successive interactions. Individuals on the spectrum struggled to converge on single shared behaviors with their interaction partners, particularly when resolving the referential ambiguity of a behavior required interpersonal coordination. These findings illustrate the importance of considering human communication as a solution to a conceptual alignment challenge, and how ineffective the evolutionarily anomalous human communicative system is without this special interactional ingredient.

Title: Gesture processing and production in autism spectrum disorder

Authors: *E. FOURIE[1,2], E. R. PALSER[1,6,7], J. J. POKORNY[1], M. NEFF[3,4], S. M. RIVERA[1,2,5]
[1]Ctr. for Mind and Brain, Univ. of California Davis, Davis, CA; [2]Dept. of Psychology, [3]Dept. of Computer Sci., [4]Dept. of Cinema and Digital Media, Univ. of California, Davis, Davis, CA; [5]MIND Inst., Univ. of California, Davis, Sacramento, CA; [6]Clinical, Educational and Hlth. Psychology, [7]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Individuals with autism spectrum disorder (ASD) show impairments in nonverbal communication, including diminished gesturing and difficulties with imitation, which may be explained by a deficit in processing biological motion (BM). This study examined whether this BM deficit is reflected in atypical neural activity when observing gestures and investigated the relationship between activation during gesture observation and quality of gesture production in a group of children and adolescents with ASD and typically developing (TD) controls, ages 9 to 15. During the fMRI task, participants (19 ASD, 17 TD) viewed animations (created by applying digitalized motion capture of actions performed by an actor to a 3D human model) of both functional pantomimes (e.g. driving) and communicative gestures (e.g. waving), which were computationally manipulated to vary in the amount of movement, from subtle to exaggerated. Gesture production was assessed using a charade-style paradigm, in which participants enacted a series of 15 familiar actions (e.g. brush teeth), which were double-coded by blind raters for quality of specific components (e.g. limb movement, hand posture). In whole brain analyses, both groups showed activation of the motion-sensitive area MT+. The TD group showed an additional cluster of activity in left premotor cortex. In both groups, communicative gestures elicited greater activity than functional ones, suggesting higher processing demand for actions with communicative intent. In a 3-way ANOVA (movement x type x group) of peak values extracted from left and right MT+ for each condition, there was a main effect of movement ($p < .01$), such that the most overt gestures elicited greater activity than midlevel, but not subtle gestures, indicating increased processing for both the most subtle and overt gestures. Left MT+ also showed a movement x type x group interaction ($p < .01$), where activation differed based on movement for communicative gestures in the TD group and for functional gestures in the ASD group. Compared with TD individuals, MT+ in ASD appears to be less sensitive to changes in

movement intensity of communicative gestures.In a subset of participants who completed both fMRI and behavioral sessions (8 ASD, 11 TD), we performed correlations between MT+ activity and gesture performance. Activity in the L MT+ was positively correlated with performance score in the TD group ($r = .65$, $p < .05$) but not in the ASD group ($r = .08$, $p = .86$). These results suggest that in typical development, increased neural processing of gestures is associated with better gesture production, and that dysfunction in the BM system in ASD may disrupt development of gesturing abilities.

Title: Quantifying fine motor dependencies in autism spectrum disorder

Authors: *T. F. QUATIERI[1], J. O'ROURKE[2], L. NOWINSKI[2], D. HANNON[1], A. LAMMERT[1], J. WILLIAMSON[1], E. THIRY[1], J. PALMER[1], C. STAMM[2], M. MODY[2], C. MCDOUGLE[2]
[1]MIT Lincoln Lab., Lexington, MA; [2]MGH Lurie Ctr. for Autism, Lexington, MA

Abstract: Autism Spectrum Disorder (ASD) is a prevalent neurodevelopmental disorder that often results in the co-occurrence of impairment of fine sensorimotor systems, as for example in comorbid deficits in manual-motor skills and speech production (Mody et al., 2017). Yet there is little quantitative understanding of these complex dependencies. An essential hypothesis in our work is that estimation of coordination across sensorimotor impairments, through advanced correlation and modeling methods, can improve objectivity and accuracy of detecting and tracking the ASD state. Toward our objective of a quantitative understanding of fine-motor dependencies, we designed and pilot-tested a non-intrusive platform capturing audio, video, and hand movement, with protocols involving vocal and facial expression plus hand writing, drawing, and tracing. While administering the speech and face protocol through an iPad display via Apple Airplay by the clinician, high-quality audio and video are recorded with an acoustic microphone and a HD camera. For hand movement, displacement, velocity and pressure are measured through our custom-designed, web-based iPad application. The speech protocol consists of a phonetically-balanced short paragraph, a diadochokinetic sequence, sustained vowels, and response to questions. The face protocol involves mimicking facial expression with

and without emotion labels, while the hand dexterity component involves writing word descriptions of objects, drawing geometric shapes, and tracing templates. MIT and MGH IRB approvals were obtained and data collection of 10 controls and 10 ASD subjects is planned for mid-May. Subjects are 6-12 years of age, verbal, and able to read the simple paragraph in the speech protocol. Speech measures include phoneme- and articulatory-based features reflecting fine neuromotor timing and coordination, while facial measures reflect neuromotor coordination across muscle groups, effective in detecting various neurological conditions (Quatieri et al., 2017). Temporal aspects of hand motion and pressure, also reflecting timing and coordination, are extracted. Correlation analysis of these features across the three modalities, and their use in detecting ASD, will be presented at the conference.

Title: Similarities in limbic system connectivity at resting state in autism and social anxiety disorder

Authors: *A. KIRKPATRICK[1], L. ANTEZANA[2], C. BROWN[2], N. LY[2], M. MAURIN[2], J. VOYACK[2], J. RICHEY[2], M. COFFMAN[2]
[1]Blacksburg, VA; [2]Virginia Tech., Blacksburg, VA

Abstract: Background: The limbic system (LS) is associated with the regulation of fear (Anad et. al 2005). Brain connectivity within the LS at rest is hypothesized to correlate with anxiety (Mucci et. al, 2018) and hyperconnectivity with subcortical regions has characterized social anxiety disorder (SAD; Arnold et. al, 2014). However, no studies have examined connectivity transdiagnostically in individuals with comorbid Autism Spectrum Disorder (ASD+SAD), and it is not known whether individuals with ASD+SAD show similar patterns of connectivity in the LS compared to those without ASD. **Objectives:** To elucidate heterogeneous patterns of LS connectivity in SAD across adolescents with varying degrees of social impairment. Specifically, we used a graph theory approach, Group Iterative Multiple Model Estimation (GIMME) with community detection on fMRI resting state data to examine whether LS connectivity can

robustly differentiate SAD, ASD+SAD, and controls (CON). Secondary analyses examine the relationship between the LS and measures of social anxiety. **Hypotheses**: We predict that individuals with ASD+SAD will share similar neural profiles within the LS, but that these profiles will be separate from SAD alone and from CON participants. It is also hypothesized that scores on measures of social anxiety will be distinct among diagnostic classifications. **Methods:** 20 children with each ASD+SAD, SAD only, and CON adolescents participated in this study (N=60). Participants were matched on age (M=15.19) and FSIQ (M=108.38). Diagnoses were confirmed with semi-structured clinical interviews. fMRI data were collected on a 3T TIMTrio. Functional regions of the LS were identified via Neurosynth and included: bilateral amygdala, thalamus, anterior cingulate cortex, and bilateral orbitalfrontal cortex. GIMME was used with resting state data from each subject. Subsequently, a community detection algorithm was used to identify subgroups characterized by LS connectivity patterns (Gates et al., 2014). Social anxiety was measured via self-report with the Leibowitz Social Anxiety Scale-Child Adolescent (LSAS-CA). **Results:** Analyses in progress define subgroups based on LS functioning. Additional analyses will reveal relationships between social anxiety and LS connectivity. Preliminary results on the LSAS-CA suggest significant group differences in social anxiety (p >0.001), such that CON had less anxiety than ASD (p = 0.030) and SAD (p *>* 0.001). **Conclusions:** The results will highlight the similarities in network activity in adolescents with anxiety and comorbid ASD. Going forward these findings have an influence on treatment of SAD and SAD+ASD.

Title: Detecting visual-motor challenges in autism using a robotically guided drawing task

Authors: *A. H. MASON[1], M. ZINN[2], G. SUBRAMANI[2], A. FISHER[3], S. JACQUOT[3], B. TRAVERS[4]
[1]Kinesiology, Univ. of Wisconsin - Madison, Madison, WI; [2]Mechanical Engin., [3]Occup. Therapy, [4]Kinesiology & Occup. Therapy, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Background: Children with autism spectrum disorder (ASD) struggle with motor impairments, and these motor impairments have been found to predict difficulties with independent living skills and the severity of core social communication impairments. Motor skill therapy may offer an effective but under-utilized approach to improve skills of children with ASD. However, individuals with ASD have a unique motor learning style that necessitates consistency in presentation, which is difficult for a human therapist to enact with fidelity. To address this, we aim to develop a robotically-guided motor skill intervention paradigm for the treatment of children with ASD. As the first step, we set out to determine whether the robot could accurately detect performance differences between children with ASD and children with typical development (TD). **Objective**: Use a robotically guided drawing task to examine drawing and motor performance under varying visual-motor conditions in children with ASD compared to children with TD. **Methods**: 20 children with ASD and 20 children with TD (10-12 years old) completed the robotically guided drawing tasks, in which they used the robotic arm to draw shapes on a computer screen mounted below a glass table. Participants drew 4 different shapes (circle, square, star, and hexagon) under 3 visual-motor conditions (tracing the shape, copying the shape from a model presented on a horizontal screen, and copying the shape from a model presented on a vertical screen). Kinematic data from the hand, arm, and torso were collected, and participants completed standardized motor and autism assessments. **Results**: Hierarchical linear modeling (using the nested structure of the data) examined the root mean squared error of the drawn shape compared to the model as a function of the condition and diagnostic group. A significant interaction between condition and group emerged (p = .02). Groups performed almost identically in the tracing condition but differed in the horizontal and vertical copying conditions. **Conclusions**: The robotically-guided drawing task was able to detect motor performance differences in children with ASD compared to children with TD, particularly when the to-be-copied shape was out of the line of vision during drawing. This finding is consistent with previous findings of atypical visual motor integration in ASD and indicates that many children with ASD may benefit from an intervention aimed at enhancing visual motor integration during motor tasks. Future analyses will examine the kinematic data and predictors of individual differences that may inform personalization of the robotically guided motor intervention.

Abstract: Recent theoretical work suggests that certain behaviors displayed by individuals with an autism spectrum disorder (ASD) reflect a diminished ability to use contextual information to interpret current sensory information. Here we tested this hypothesis experimentally by evaluating contextual learning in ASD and typically developing (TD) adolescent peers by manipulating context across multiple sessions. Participants viewed a computer screen divided into four quadrants, and were asked to search for a visual target (the letter "C") amongst letters "I" and "F", and to report the quadrant in which the target was located using a button box. A total of 9 sessions of ~300 trials/session were completed by each participant. Unbeknownst to the participants, contextual information about the target location was manipulated across sessions by co-varying the number of I's in a quadrant and the probability of the target being present in that quadrant. In the first three and last three sessions, the number of letter I's in a quadrant was informative (context present), whereas in the middle three sessions, there was no contextual relationship between the I's and target location (no context). Search time as a function of the proportion of informative cues in the target quadrant was used as a measure of contextual learning. We found that the performance of TD participants modulated strongly and quickly with the contextual changes. In contrast, the ASD participants showed impaired contextual learning and greater heterogeneity in their learning profiles. Cluster analysis of the search time data revealed two distinct groups of ASD learning profiles. The first group resembled the TD learning profile in the magnitude of contextual learning, but when the context was turned off, they showed a one session delay in disengaging from the context learned in the first three sessions. The search times of the second ASD group did not modulate with context, indicating that they did not learn the embedded context. The performance of this group could instead be explained by a greater subjective saliency of low-level visual features of the search field. These results provide experimental evidence for at least two distinct contextual learning profiles within the autism spectrum, and have practical implications for the development of individualized treatments and educational approaches to maximize behavioral therapy gains.

Title: Classification of autism spectrum disorder improves with addition of motor and sensory components to the research domain criteria (RDoC) framework

Authors: *L. A. HARRISON, E. KILROY, C. BUTERA, C. ZEISLER, L. AZIZ-ZADEH
USC, Los Angeles, CA

Abstract: The National Institute of Health's Research Domain Criteria (RDoC) is a multi-level research framework for investigating mental disorders. While not diagnostic, it aims to describe where individuals fall on a spectrum of health in terms of biological and psychological dysfunction in five domains: (1) negative and (2) positive valence systems, (3) cognitive systems, (4) social processes, and (5) arousal and regulatory systems. Notably, the RDoC framework is currently lacking a motor functioning domain, despite growing evidence of the role motor functioning has been observed to play in various disorders, including autism spectrum disorder (ASD) and schizophrenia. To test the utility of adding a motor and/or sensory domains to the RDoC framework in order to characterize individuals with ASD, we attempted to use machine learning to classify individuals with ASD according to various psychological measures that (1) map onto current RDoC domains (positive and negative affect from the PANAS; anxiety severity from the CASI-Anx; ADHD symptomatology from the Conners; identification, communication, and externalizing of affect from the Alexithymia scale for children; empathy from the IRI; affect recognition and theory of mind from the NEPSY; and arousal from the PH-C, then (2) onto indices of both motor (coordination from the DCDQ; postural praxis from the SIPT) and sensory functioning (for different sensory categories from the SenSor); then (3) using both traditional RDoC and sensorimotor measures combined. In a group of 35 children (16 diagnosed with ASD), a support vector machine-based decoder using current RDoC domains classified children with ASD versus neurotypical controls with 85.7% classification accuracy. Motor measures alone were largely successful, with 74.3% classification accuracy. The addition of sensory processing to the motor measure improved classification accuracy to 85.7%, supporting the inclusion of sensory processing measures as well as motor measures. RDoC classification improved with sensory measures added (88.6% accuracy) and even more with motor measures added (91.4% accuracy). The combined use of all three - current RDoC, motor, and sensory measures - matched the accuracy of RDoC plus motor measures (91.4% accuracy). This suggests that all components work together to capture the heterogeneity of functioning in

our ASD sample. These results support the utility of adding both motor and sensory domains to the RDoC framework for characterizing ASD.

Title: Monkey see monkey do: Decreased spontaneous entrainment to rhythmical movement in children with autism

Authors: B. TUNCGENC[1,2], *S. H. MOSTOFSKY[3]
[1]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Kennedy Krieger Inst., Baltimore, MD; [3]Neurology/Developmental Cognitive Neurol., Kennedy Krieger Institute, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: During social interactions, typically developing children (TDC) and adults spontaneously entrain their movement rhythm to others and such synchronization facilitates prosociality and bonding. To explore these links in autism spectrum disorders (ASD) –a neurodevelopmental disorder marked by social interaction and motor imitation deficits– we examined motor entrainment to external visual rhythms in the absence of any instruction to do so.
Hypothesis 1: Children with ASD will show less motor entrainment than TDC.
Hypothesis 2: Among children with ASD lesser motor entrainment will correlate with autism severity in Autism Diagnostic Observation Scale.
Preliminary data includes thirteen 8-12 year-olds (9 ASD, 4 TDC) matched on IQ. In the study, children moved their arms in a certain way to "collect food for the monkey in the video" while the monkey character moved in time to 3 prefixed speeds: 0.75Hz, 1Hz, 1.25Hz in three 90 sec rounds (counterbalanced). To ensure all children could move to these speeds a final round was played in which children purposely tried to synchronize with the monkey. We recorded children's movements using Microsoft Kinect Xbox interface, obtained xyz coordinates using iPi Motion Capture software and calculated periodograms on MATLAB. To analyze entrainment levels, we assessed the difference between the children's movement frequency and the stimulus frequency.
No group effect on peak frequencies was found in the elicited round; hence all children could

perform the speeds presented. In line with Hypothesis 1, frequency difference scores showed less entrainment to the stimuli in children with ASD than in TDC (Fig 1, $p < .0001$). Analyses of mean power at +/-10% of stimulus frequency further supported Hypothesis 1 revealing that TDC moved more consistently and distinctly at the stimulus frequency than children with ASD ($p < .0001$). As per Hypothesis 2 higher autism severity was correlated with lesser entrainment ($r = -.69$, $t(7) = -2.53$, $p = .04$). Overall, our findings support spontaneous motor entrainment to visual rhythms as a biomarker for diagnosis and treatment of ASD.

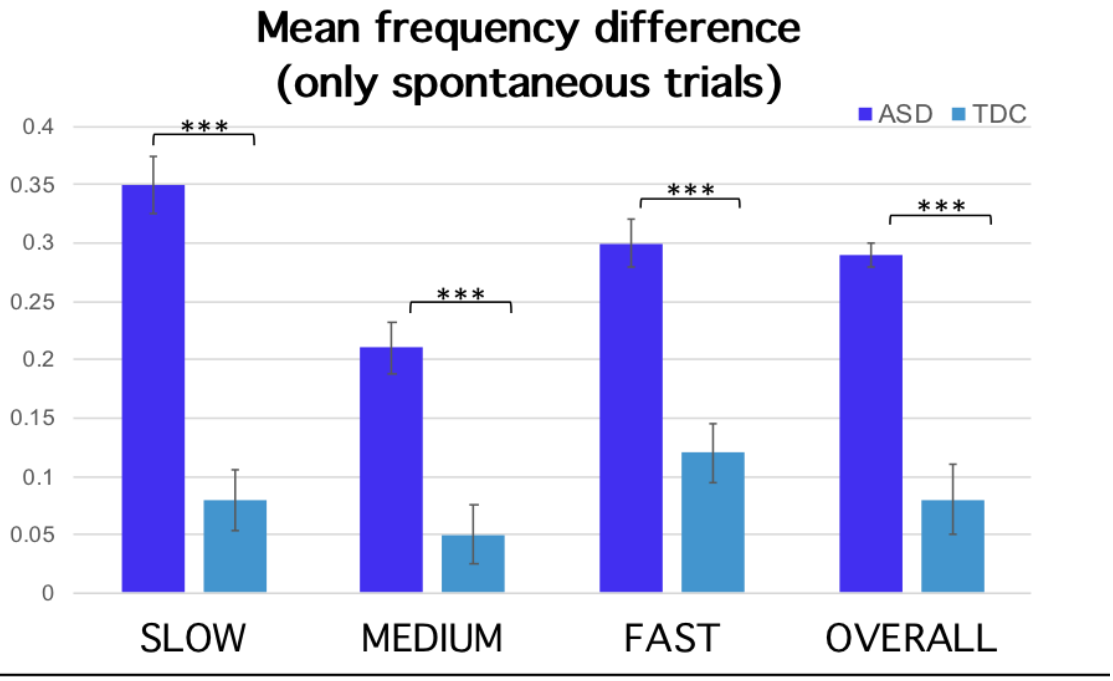

Fig 1. Mean frequency difference scores for ASD and TDC, with lower values indicating better entrainment with the stimulus.

Title: Acoustic properties of early life ultrasonic vocalizations are altered in the valproic acid rat model of autism

Authors: *M. L. MCNAIR[1], T. M. HENNESSEY[2], C. E. BARRETT[4], H. WALUM[3], D. RAINNIE[3]
[1]Yale Univ., New Haven, CT; [2]Neurosci., [3]Emory Univ., Atlanta, GA; [4]Dept. of Psych. and Beh. Disorders, Emory Univ., Atlanta, GA

Abstract: Background: Early vocalizations and infant voice quality have been a research focus for early detection of autism spectrum disorder (ASD). Studies have examined social and behavioral impairments in animal models of ASD, though few have assessed parallel communication deficits or analyzed acoustic patterns of ultrasonic vocalizations (USVs) in rat models of ASD.
Objectives: This study investigated potential developmental differences in early life vocalizations between valproic acid (VPA)-exposed and control rat pups. We hypothesized that VPA-exposed pups would exhibit developmental delays in USV communication, emitting fewer USVs and expressing stunted acoustic development that mirrors the pre-speech delays seen in high risk, pre-ASD children.
Methods: Dams (VPA n=22, control n=20) received oral gavage of 500 mg/kg VPA or saline on embryonic days 11, 12, and 13. Five-minute recordings of VPA-exposed (n=54–74) and control (n=51– 75) pups in isolation were collected on postnatal days (P) 7, P11, and P14 using Sonotrack USV recording equipment. We examined USV number, duration, frequency, and structure at each postnatal day, emphasizing a comprehensive examination of acoustic property development within the VPA ASD model.
Results: VPA pups, compared to controls, called less on P7 (t_{150}=4.31, p<0.001) and P11 (t_{139}=2.88, p<0.005) but showed no difference in number of calls on P14 (t_{103}=0.56, p>0.05). VPA pups emitted more high frequency USVs. A three-way interaction was found between treatment, age, and frequency bin ($F_{8, 3230}$=6.0, p<0.001). Post hoc ANOVAs showed an interaction between treatment and frequency bin at P7 ($F_{8,1177}$=7.18, p<0.001), P11 ($F_{8,1112}$=13.08, p<0.001), and P14 ($F_{8,824}$=4.89, p<0.001). VPA pups showed a differential distribution of USV structure at P7 ($F_{1,35}$=864.81, p<0.05). Post hoc analysis revealed an interaction between treatment and call type in males for Short ($t_{10.41}$=2.35, p<0.05), Flat ($t_{16.47}$=2.78, p<0.05), Up ($t_{10.99}$=2.19, p<0.05), and Down structures ($t_{10.63}$=3.95, p<0.01), but only Short structures ($t_{8.41}$=2.93, p<0.05) in females. While prenatal VPA exposure did not alter USV duration, the pattern of duration changed from P7 to P11 to P14 for both VPA and controls.
Conclusions: Prenatal exposure to VPA alters early life vocalizations and may alter communication development in rat pups. These USV abnormalities may decrease functionality, differentially impact maternal behavior, and serve as a potential predictive factor of future ASD-like symptoms. Our study emphasizes a more complex analysis of USVs and supports using early life vocalizations as a potential form of early detection in both models and humans.

Title: Age- and sex-specificity of deficits in the Pcdh10 mouse model relevant to autism

Authors: *S. L. FERRI[1,2], H. DOW[3], E. S. BRODKIN[3], T. ABEL[1,2]
[1]Dept. of Mol. Physiol. and Biophysics, [2]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA; [3]Univ. of PA Sch. of Med., Philadelphia, PA

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects nearly five times as many males as females. The protocadherin 10 gene (*PCDH10*) has been linked to ASD and is highly expressed in the amygdala and striatum. It encodes for an activity-dependent cell adhesion molecule involved in dendritic spine development. We previously reported that juvenile male mice (28-32 d) heterozygous for a deletion of *Pcdh10* ($Pcdh10^{+/-}$) exhibit deficits in a social approach task. Recently, we found that these deficits are ameliorated in adults (60-90 d), a phenomenon of social improvement also observed in individuals with autism. However, the cognitive deficits we have recently observed, in both contextual and cued fear conditioning, are present before and after puberty. These behavioral impairments, as well as amygdalar abnormalities we previously reported, including decreased expression of NMDAR and increased spine density, are observed in males only. Future studies will address the mechanisms involved in the age- and sex-specificity of the social and cognitive deficits.

Title: Sensorimotor gating and social behavior in adolescent ratsexposed to poly i:c maternal immune activation at mid-gestation

Authors: *F. HADDAD[1], L. LU[2], C. DE OLIVEIRA[2], S. SCHMID[2]
[1]Neurosci. Program, Dept. of Anat. and Biol., [2]Dept. of Anat. and Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Maternal infection during pregnancy is associated with an increased risk of neurodevelopmental disorders such as autism spectrum disorder (ASD) and schizophrenia in the offspring. Interestingly, the association of multiple infections with similar disorders points to a common underlying mechanism for infection's effects on brain development. Results from rodent research have shown that a pathogen-free immune response during pregnancy is sufficient to cause symptoms linked to ASD and schizophrenia in the offspring, and that behavioral changes mainly manifest in adulthood. We used polyinosinic:polycytidylic acid (poly I:C) maternal immune activation (MIA) at Gestation Days (GD) 9.5 or 14.5 to more specifically describe the sensorimotor gating phenotype of the poly I:C model and investigate whether this phenotype is associated with aberrant social behavior in Sprague Dawley rats during adolescence and adulthood. Sensorimotor processes were measured through open field locomotor activity in addition to habituation and multimodal (auditory and visual) prepulse inhibition (PPI) of the acoustic startle response, while social novelty preference was measured in the three-chamber test. Results from MIA-exposed offspring show GD and sex-specific effects of MIA on startle reactivity, visual PPI and locomotor activity but no impairment in habituation of startle and social novelty preference. These results extend on past MIA studies, particularly in the specific characterization of PPI deficits across different stimuli.

Title: The kynurenine pathway: A link between prenatal inflammation and disruption of offspring behavior in mice

Authors: *D. S. COELHO, A. TRAN, J. O'CONNOR
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San A, San Antonio, TX

Abstract: Infection and inflammation during pregnancy are risk factors for neurodevelopmental disorders such as autism. In rodent models, maternal immune activation (MIA) causes phenotypes in offspring that resemble many features of this human disorder, but the pathogenic mechanisms remain unclear. Inflammatory cytokines can upregulate the tryptophan metabolizing enzyme indoleamine 2,3-dioxygenase (IDO) which increases kynurenine metabolite levels, and experimentally increasing kynurenine levels of pregnant dams causes developmental consequences in the offspring. Therefore, we hypothesized that MIA-induced upregulation of IDO during gestation is a pathogenic mechanism by which fetal neurodevelopment is disrupted and autism-like phenotypes develop. Pregnant female IDO-/- mice or control C57BL/6J mice were administered 20 mg/kg polyinosinic:polycytidylic acid (PIC) or saline i.p. on gestational day 12.5. At post-natal day 7, isolation-induced ultrasonic vocalizations were recorded from pups after a brief separation from their dams. WT-MIA offspring exhibit decreased the number of vocalizations when compared to WT-Saline pups. IDO -/- animals did not exhibit a PIC-induced decrease in vocalization. Preliminary analysis of sound spectrograms shows that WT-PIC offspring display differences in the vocalization repertoire when compared to WT-saline pups characterized by fewer downward syllables and increased two-syllables. Repetitive/stereotypic behavior was also assessed, and IDO-/- offspring of PIC treated dams exhibited less repetitive grooming than WT pups of WT-PIC dams. Our data suggest that IDO plays a role in the development of communication deficits and repetitive behavior in the MIA model.

Title: Deficits in learning are common across multiple mouse models of autism

Authors: *J. F. LYNCH, III[1], T. ABEL[1], T. NICKL-JOCKSCHAT[1], N. M. GRISSOM[2], S. E. MCKEE[3], H. SCHOCH[5], L. WALSH[4], T. M. REYES[6]

California Irvine, Irvine, CA; [6]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Autism Spectrum Disorders (ASDs) are a set of neurodevelopmental disorders that cover a wide range of symptoms. The overall prevalence of ASDs continues to increase and is 4 times more common in males than females. Given the role of striatal and cortical deficits in ASDs and the large discrepancy in prevalence rates, the current experiments will assess different genetic mouse models in distinct learning and memory paradigms. The mouse models may include 16p11.2 microdeletion animals, which is the most common genetic link with ASD, CNTNAP2 knockout animals, and Shank3b knockout animals. All models will be trained in several distinct behavioral paradigms including operant conditioning, fear conditioning, social activity, and novel object recognition. Preliminary data suggests deficits in mutant mice in reward learning procedures and potentially reduced motivation as measured by a progressive ratio task. Overall, these preliminary findings suggest impaired goal-directed learning in males of 3 different ASD-linked genotype mouse models. Continuing work will demonstrate the depth and breadth of the deficits seen in mutants across behavioral procedures and tasks. Determining the mechanisms for these dysfunctions and understanding the sex-specific nature of these deficits are promising avenues for developing specific, targeted therapeutics for ASDs and other neurodevelopmental disorders.

Title: Fluoxetine alleviates effects of stress in pregnant mice but increases repetitive behaviors and reduces hippocampal synaptic plasticity in adult male and female offspring

Authors: *A. L. ARZUAGA[1], M. E. RAGOZZINO[2,3], J. LARSON[3,4]
[1]Dept. of Biol. Sci., [2]Dept. of Psychology, [3]Lab. of Integrative Neurosci., [4]Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Autism spectrum disorder (ASD) is characterized by social and communication impairments as well as restricted and repetitive behaviors (RRBs). RRBs can be exhibited as stereotyped motor behaviors or reduced behavioral flexibility. The increased prevalence of ASD

in recent decades and the heterogeneity of symptom severity may arise from a complex interaction of environmental and genetic risk factors that induce alterations in synaptic function. The present study investigated in C57BL/6 (B6) mice examined whether restraint stress and/or treatment with selective serotonin reuptake inhibitor (SSRI) in pregnant females affects self-grooming behavior, behavioral flexibility, and/or hippocampal synaptic plasticity in male and female offspring. Pregnant female mice were subjected to chronic restraint stress from gestational days 4-18 (three daily 30-minute sessions) and/or administered fluoxetine (0.3mg/kg/day) on days 8-18. Offspring were tested as young adults (7 weeks of age) on self-grooming behavior and learning to inhibit a prepotent response in a spatial discrimination task. Offspring were also tested for alterations in long-term potentiation (LTP) induced by theta burst stimulation (TBS) of Schaffer-commissural synapses in hippocampal slices. The results indicate that restraint stress reduces preference for sucrose reward and suppresses weight gain in pregnant dams; these effects were reversed by fluoxetine. However, combined maternal stress and prenatal SSRI exposure increased self-grooming in both male and female offspring. These offspring also exhibited impaired behavioral flexibility in a spatial discrimination test. LTP in hippocampal field CA1 was reduced in offspring of dams subjected to restraint stress, SSRI exposure, or both treatments, relative to offspring of non-stressed, vehicle-treated dams. The findings suggest that restraint stress, which may model depression, combined with SSRI treatment during pregnancy increases RRBs and reduces hippocampal synaptic plasticity in adult offspring. Understanding the mechanisms by which maternal stress and SSRI exposure during pregnancy affect brain development in offspring is critical for better comprehension of ASD pathophysiology and may lead to the development of more effective treatments.

Title: Effect of gluten on social behavior in rats

Authors: *P. MICHENER[1], S. N. MYERS[2], R. A. RICHARDSON[2], O. M. FAHR[2], I. M. NORTH[3], M. L. FEIGEN[2], T. R. SCHACHTMAN[2]
[1]Psychology, [2]Univ. of Missouri, Columbia, MO; [3]Psychological Sci., Univ. of Missouri-Columbia, Columbia, MO

Abstract: Previous research has shown that a gluten-free diet can have an effect on symptom reduction in children with autism spectrum disorder (ASD) (Knivsberg, Reichelt, Høien, & Nødland, 2003; Pennesi & Klein, 2012). Pennesi and Klein (2012) found that strict adherence to

a gluten-free diet for children with ASD led to an increase in social behaviors and a decrease in unusual, stereotyped behaviors compared to children who did not strictly adhere to the diet. In addition, the longer that the diet was implemented, the greater were the change in symptoms. Knivsberg et al. (2003) also found that after a 1-year gluten-free diet intervention, children with ASD on a gluten-free diet showed significant improvement in social behavior and unusual behaviors over a control group. These improvements included improved communication and social interaction and decreased isolation and stereotypic behaviors. The present experiment therefore was an exploratory experiment designed to examine social behaviors in male Sprague-Dawley rats that were on either a gluten-free (n = 2) or a high-gluten (n = 4) diet for 7 weeks. The rats were approximately 3 months old at the time of testing. The rats were placed into a plastic apparatus divided into two halves, with one half containing a clear plastic container with a nontarget rat underneath. Each target rat experienced a 3 min trial, and time spent in both the empty half and the half of the apparatus with the nontarget rat were recorded, as well as approach behaviors to the nontarget rat. The results showed that the high-gluten diet rats approached the nontarget rat significantly more times than the gluten-free rats. There were no differences between time spent in each side of the apparatus for the two groups; however, there was a slight tendency for gluten-free rats to spend more time on the nontarget side of the apparatus. These findings are inconsistent with the literature on children with ASD and gluten-free diets and the effects on social behavior. However, there were a total of 6 rats used in the present study, and the rats used were not a model of ASD. More data collection is anticipated.

Title: HuD regulates the biogenesis of synaptic plasticity and development-related circular RNAs

Authors: *M. DELL'ORCO, N. I. PERRONE-BIZZOZERO
Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: The neuronal RNA-binding protein (RBP) HuD is involved in multiple steps of neuronal differentiation from neurogenesis to axonal and dendritic development and remodeling.

Post-transcriptional regulation of genes involved in neuronal development and plasticity is particularly relevant in neurons. RBPs not only bind to mRNAs but also interact with circular RNAs (circRNAs), a class of non-coding RNAs generated by pre-mRNA back-splicing. Due to their high expression in synaptic terminals, circRNAs are likely to be involved in neuroplasticity. Different RBPs control circRNAs production (e.g., MBL, QKI, ADAR1) or bind to circRNAs (e.g., FMRP, EIF4AIII, HuR). This study was aimed at exploring whether HuD regulation of circRNAs levels may be linked to synaptic plasticity and neuronal development. HuD controls target RNA's fate by binding to Adenylate-Uridylate Rich Elements (ARE). Using bioinformatics analyses, we searched for ARE sequences in all mouse circRNAs and found consensus HuD binding motifs in about 29%. By RNA immunoprecipitation (RIP) followed by circRNA arrays, we identified over 600 circRNAs bound by HuD. Pathways analysis showed an enrichment of HuD targeted circRNAs in genes regulating synapse density and central nervous system development (15.8%), neurites growth (14.3%), congenital brain malformations and dendrites morphogenesis (10.5%). To test whether HuD interactions with circRNAs could lead to changes in their levels, we analyzed differentially expressed circRNAs in HuD overexpressor (HuD_{OE}) and HuD KO (*Elavl4* $^{-/-}$) mice compared to wild type (WT) mice. Cross-correlations analyses of circRNAs altered in HuD_{OE} and *Elavl4* $^{-/-}$ revealed that HuD selectively regulates circRNAs deriving from neurogenesis and plasticity-related genes within the same biological pathways identified in the HuD RIP. These include: *Brwd1* and *Foxp1*, associated with neurodevelopment disorders and autism; *Ntrk3* neurotrophic receptor kinase; *Map1a* involved in neuronal development and regeneration; *Dock10* regulating dendritic spines morphogenesis; *Magi1* and *Lppr4*, members of the Plasticity Related Genes (PRGs) and membrane-associated guanylate kinases (MAGUKs) families respectively, controlling synaptic development and linked to psychiatric disorders. Interestingly, the linear counterparts of some of these circRNAs, such as *Brwd1*, *Foxp1* and *Ntrk3*, are listed in the ARE gene database (ARED) and likely targeted by HuD. Collectively these data suggest that HuD interactions with circRNAs regulates their biogenesis, and that the ensuing changes in HuD-targeted circRNAs and mRNAs may be related to altered neurogenesis and neuroplasticity.

Title: RNA binding proteins and circular RNAs are linked to nucleus accumbens gene expression changes during environmental enrichment following prolonged abstinence from cocaine self-administration

Authors: *N. PERRONE-BIZZOZERO[1], M. DELL'ORCO[1], G. L. POWELL[2], A. VANNAN[3], R. J. OLIVER, JR[5], S. SEKAR[6], W. S. LIANG[7], J. L. NEISEWANDER[4]

Inst., Phoenix, AZ; [7]Translational Genomics, Phoenix, AZ

Abstract: Aberrant neuroadaptative changes during the establishment of drug addiction are thought to involve alterations in post-transcriptional mechanisms controlling neuroplasticity in specific neural circuits. Multiple RNA binding proteins (RPBs), including neuronal HuD, have been previously associated with substance use disorders (SUD). Not only are HuD and many of its targets listed in the Knowledgebase of Addiction related genes (KARG) database, but HuD levels are also altered after cocaine exposure. Previous work by our group has shown that increased cocaine seeking after prolonged abstinence following cocaine-self administration is attenuated by environmental enrichment (EE); and that these changes in behavior are linked to changes in the expression of specific genes. RNA-seq analysis of gene expression in the nucleus accumbens (NAc) of EE animals compared to an isolated group, after 21 days of cocaine abstinence, demonstrated that differentially expressed genes are enriched in pathways involved in nervous system development; particularly synaptic transmission, neuronal differentiation, and axonogenesis. In this study, we aimed to explore whether HuD interaction with circular RNAs (circRNAs) could regulate gene expression during EE-induced neuroplasticity. CircRNAs are not only likely involved in synaptic plasticity and neurodevelopment, but also contain numerous consensus regulatory sequences for RBPs and microRNAs. Bioinformatics analyses from the same RNA-seq data identified several circRNAs that were linked to EE. Concurrently, analysis of circRNAs bound by HuD (see Dell'Orco et al, associated poster) showed that about 18% were derived from genes in KARG. Furthermore, using circRNA array data from HuD knock-out (KO) versus wild type mice, we were able to confirm that HuD also altered target circRNA expression. The set of genes that were targets of HuD or differentially expressed in HuD KOs were then compared with genes whose expression correlated with lever presses in the EE group. Specifically, we found that 87 of the circRNAs that were significantly downregulated in HuD KO mice and 49 of the bound circRNAs were associated with the EE gene set. These common genes belong to the same biological pathways that regulate synaptic plasticity and neuronal development. These analyses allowed us to generate a list of possible circRNAs targeted by HuD whose levels are altered during neuroadaptive processes induced by EE. Uncovering HuD regulation of circRNAs levels linked to the effect of EE on cocaine seeking can potentially reveal therapeutic targets to reduce drug craving and relapse.

Title: Chronic prenatal interleukin-17 is sufficient to cause sex-specific ASD-phenotypes in a mouse model

Authors: *S. B. GUMUSOGLU[1], A. S. CHILUKURI[1], S. HAIDER[2], B. W. HING[3], H. E. STEVENS[3]
[2]Biol., [3]Psychiatry, [1]Univ. of Iowa, Iowa City, IA

Abstract: Background: Studies in both humans and animal models have implicated interleukin-17 (IL-17) as a key pro-inflammatory cytokine in multiple psychiatric disorders and neurodevelopmental processes, respectively. In humans, both increased activity of Th17 lymphocytes and elevated blood levels of IL-17A have been linked to ASD and its severity. In animals, studies have implicated IL-17A signaling as being necessary for the offspring effects of viral infection during pregnancy, including behavioral phenotypes related to ASD. Offspring effects of chronic prenatal IL-17 exposure, however, have not been evaluated.
Method: C57BL/6 dams were chronically administered IL-17 (25ng/hr) via subcutaneous osmotic minipump (Alzet) throughout pregnancy. Some offspring tissues were collected at embryonic day 18 (E18), and some in adulthood. RNA-sequencing (Illumina HiSeq 4000) was performed on sexed, neocortical tissues across two lanes (approx. depth/lane: 15000). Gene-wise data analyses were conducted using Kallisto (used sequence based bias correction) and Sleuth. E18 and adult tissues were also analyzed for morphology via unbiased stereology and optical fractionator (StereoInvestigator). Behavior was assessed [three-chamber social task, open field, elevated plus maze, prepulse inhibition (Anymaze, SDI Lab)] in adult offspring.
Results: RNA-seq results demonstrated that there were significant, sex-specific changes to E18 neocortical gene expression with IL-17 exposure across four litters per group (320 genes were differentially expressed in males and none in females; n=4,4 per group, per sex). These altered transcripts were significantly enriched for ASD-related genes (37 matched ASD-related genes from the Simons Foundation Autism Research Initiative genes database). IL-17 male and female offspring had lower body weight at E18, as did males as adults. E18 males had smaller neocortical volume at E18 and as adults (total cell and neuronal density were unchanged). Additionally, IL-17 offspring exhibited male-specific social approach deficits and reduced anxiety-like behavior, though locomotor and sensorimotor gating behaviors were unaltered.
Conclusions: We report here that chronic IL-17 exposure during gestation was sufficient to result in ASD-like phenotypes in male offspring, including altered embryonic and adult neocortical size, embryonic neocortical gene expression signatures, and adult behavior. This echoes the male

bias and some altered cortical development and behavioral findings in the human ASD literature, suggesting that chronic prenatal IL-17 may serve as a robust ASD model and be a factor in altered neurodevelopment.

Title: Investigation of Foxp2 function in layer 6 corticothalamic neurons

Authors: *M. CO[1], A. KULKARNI[1], N. USUI[2], M. HARPER[1], G. KONOPKA[1]
[1]Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Grad. Sch. of Med., Osaka Univ., Osaka, Japan

Abstract: Humans rely on language to convey information and form social bonds, but the neurobiology underlying this ability remains largely uncharacterized. One of few genes known to play a role in speech and language is *FOXP2*, which encodes a transcription factor expressed in the brain from development into adulthood. In the cortex, a brain region essential for language and cognition, layer 6 corticothalamic neurons comprise the major *Foxp2*-expressing cell type, yet few studies have investigated its function in these cells. Thus, we aimed to identify Foxp2-driven gene expression networks and neuronal functions in layer 6 corticothalamic neurons. Using single-cell RNA-seq of these neurons in mice lacking cortical *Foxp2*, we identified gene expression alterations related to neuromodulatory signaling. Furthermore, while mice lacking cortical *Foxp2* show normal cortical morphology and emit normal vocalizations throughout their lifespan, they display behaviors suggesting cognitive inflexibility. Altogether our data show that Foxp2 may promote gene expression programs in corticothalamic neurons that underlie cognitive functions beyond innate vocalization abilities. Understanding the cortical role of *Foxp2* will provide insights into language circuitry and the etiology of language-disrupting disorders of cognition.

Title: USP9X missense variants associated with neurodevelopmental disorders disrupt signalling pathways critical to brain development

Authors: *L. JOLLY[1], #. THE USP9X NEURODEVELOPMENTAL DISORDER CONSORTIUM[1], B. V. JOHNSON[1], R. SHARMA[1], T. KLEEFSTRA[2], T. BURNE[3], S. WOOD[4], T. PIERSON[5], M. PIPER[6], J. GECZ[1]

Ctr., Los Angeles, CA; [6]Sch. of Biomed. Sciences, Univ. of Queensland, Brisbane, Australia

Abstract: Variants in the X-linked gene USP9X have been associated with intellectual disability (ID) in both males and females. Nineteen mutations causing haploinsufficiency of USP9X in females with ID, congenital malformations and recognisable brain abnormalities have been reported. In males, only three missense mutations associated with ID had been reported, and another two associated with seizures, and as such the involvement of USP9X in male ID remained less certain. Here we report an additional 12 likely pathogenic USP9X missense variants in male ID cases, and an additional 25 variants of unknown significance for which in-silico prediction and allelic frequency data align well with pathogenicity. We describe an expanded phenotypic spectrum associated with USP9X missense mutations in males in which speech delay, hypotonia, seizures, autistic behaviour, aggressiveness and visual impairment were frequent. We also resolve a severe learning and memory deficit in our USP9X knockout mouse highlighting its utility to understand mechanisms of patient pathology. As a deubiquitylating enzyme, USP9X protects its substrates from proteasomal degradation. We previously reported altered levels of multiple USP9X substrates which regulate neurodevelopmental signalling pathways in embryonic brains of USP9X knockout mice. Furthermore, we show these pathways including mTOR, WNT, NOTCH and TGFβ are disrupted. We now identify several key substrates including SMURF1 and RAPTOR are also depleted in a panel of patient-derived fibroblast cells lines, with associated disruption to their respective signalling pathways TGFβ and mTOR. Collectively, our data demonstrate the involvement of USP9X in male ID and other

neurodevelopmental disorders, and identify mechanisms of pathogenesis centred on disrupted signalling pathways critical to normal brain development.

Abstract: Considerable evidence suggests loss of function mutations in the chromatin remodeler, *CHD2*, contribute to a broad spectrum of human neurodevelopmental disorders. However, it is unknown how *CHD2* mutations lead to impaired brain function. Here we report mice with heterozygous mutations in *Chd2* exhibit deficits in neuronal proliferation and a shift in neuronal excitability that included divergent changes in excitatory and inhibitory synaptic function. Further *in vivo* experiments show $Chd2^{+/-}$ mice displayed aberrant cortical rhythmogenesis and severe deficits in long-term memory, consistent with phenotypes observed in humans. We identified broad, age-dependent transcriptional changes in $Chd2^{+/-}$ mice, including alterations in neurogenesis, synaptic transmission and disease-related genes. We replicated our results in a second, independent cohort of mice with *Chd2* haploinsufficiency only in inhibitory interneurons and are now evaluating interneuron-based rescue experiments designed specifically for $Chd2^{+/-}$. Our results demonstrate a critical role for *Chd2* in neurodevelopment and provide initial insight into how *Chd2* haploinsufficiency leads to aberrant cortical network function and impaired memory.

Title: Late stage embryonic disruption of Dnmt3a activity in pyramidal neurons alters glutamatergic transmission in frontal cortex

Authors: *A. PINTO-DUARTE[1], J. LI[2], C.-Y. LAI[1], C. LUO[4], J. LUCERO[1], T. J. SEJNOWSKI[1], E. A. MUKAMEL[2], S. B. POWELL[3], J. R. ECKER[4,5], M. M. BEHRENS[1]

Abstract: DNA methylation is critical for regulating gene expression and establishing cell-type specificity. It occurs mainly in a cytosine-guanine (CG)-dinucleotide context, but brain tissue also contains a substantial amount of non-CG methylation (mCH). The accumulation of mCH depends on Dnmt3a, a *de novo* methyltransferase, whose levels peak at a time of intense synaptogenesis and neuronal maturation - the second postnatal week in mice. The dysregulation of Dnmt3a activity might, therefore, play an important role in the pathophysiology of neurodevelopmental disorders, such as autism or schizophrenia.
Previously, using a pyramidal-cell specific *Dnmt3a* knockout mouse, in which the conditional deletion occurs during the late embryonic stage (around embryonic day E15), we showed that the disruption of Dnmt3a activity caused the differential expression of nearly 1,000 genes in the medial prefrontal cortex (mPFC), a significant fraction of which were synapse or morphology related. Consistently, these mice presented sustained neurodevelopmental disease-related phenotypes, such as impaired working memory and sociability.
Our current results suggest two levels at which neural physiology might be compromised by the disruption of *Dnmt3a* expression. Firstly, we found that *Dnmt3a*-deficient pyramidal neurons in the mPFC were significantly hypoexcitable. Secondly, we observed a tendency for a greater variability in the amplitude of miniature excitatory postsynaptic currents onto those neurons, indicating possible impairments in the postsynaptic element.
In light of these findings, the detailed morphological and physiological analysis of the synapses,

which is currently underway, will further help understanding how Dnmt3a dysfunction might be involved in the molecular underpinnings of neurodevelopmental disorders.

Title: Dysfunction of RNA-binding protein Sfpq causes long-gene transcriptopathy in the brain

Authors: *A. TAKEUCHI, K. IIDA, M. HAGIWARA
Dept. of Anat. and Developmental Biol., Grad. Sch. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: From an evolutionary perspective, the pre-mRNA transcripts of vertebrates are comparatively expanded, and in mammals, genes preferentially expressed in the brain have significantly longer introns. Longer genes present a novel problem with respect to fulfilment of gene-length transcription and evidence suggests that dysregulation of long genes is a mechanism underlying neurodegenerative and psychiatric disorders, such as amyotrophic lateral sclerosis (ALS), frontotemporal lobar degeneration (FTLD), autism spectrum disorder (ASD), or Rett Syndrome. These observations have yielded the hypothesis that some neurodegenerative and psychiatric diseases are in fact “long-gene diseases” or “long genopathies.” Yet, it has remained unclear what mechanism specifically regulates long genes to ensure their long-distance transcription. Here, we report the discovery that RNA-binding protein Sfpq is a critical factor for maintaining transcriptional elongation of long genes (Takeuchi et al., *Cell Reports 2018*).
In mouse embryos, Sfpq was robustly expressed in the whole central nervous system including the spinal cord. In the cerebral cortex, Sfpq was specifically expressed in naïve cortical plate, where newly generated neurons are maturing, suggesting its crucial functions for the development of cerebrocortical neurons. Genome wide binding mapping using *in vivo*

crosslinking and immunoprecipitation (CLIP) indicated that Sfpq co-transcriptionally bound to the target pre-mRNAs. Loss of *Sfpq* dramatically reduced the expression of pre-mRNAs >100 kbp in length, which we have termed “long-gene transcriptopathy”. Mechanistically, we demonstrated that Sfpq is required for sustaining long-gene transcription by RNA polymerase II through mediating interaction of cyclin-dependent kinase 9 with the elongation complex. Phenotypically, *Sfpq* disruption caused neuronal apoptosis in developing mouse brains. Expression analysis of Sfpq-regulated genes revealed specific downregulation of developmentally essential neuronal genes longer than 100 kbp in *Sfpq*-disrupted brains; those genes are enriched in associations with neurodegenerative and psychiatric diseases. The identified molecular machinery yields directions for targeted investigations of association between long-gene transcriptopathy and neuronal diseases.

Title: Perturbation of overall activity of mTOR pathway in mouse model of focal cortical dysplasia

Authors: *J. KIM[1], S. BAEK[2]
[1]Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of; [2]Div. of Integrative Biosci. and Biotech., Pohang university of Sci. of Technol., Pohang, Korea, Republic of

Abstract: Focal cortical dysplasia (FCD) is neurodevelopmental disorder associated with drug-resistant epilepsy. Histopathological spectrum of FCD is broad, including cortical dyslamination in the absence or presence of significant cellular defects, FCD Type I and Type II respectively. Somatic mutations in mTOR pathway genes such as *MTOR, TSC1* and *TSC2* have been found in FCD type II however, a clear genotype-phenotype correlation has not been established to explain FCD type I. In this study, we found that the severity of developmental defects is associated with the overall activity of the mTOR pathway. In developing mouse brain, ectopic overexpression of gain-of-function mutations in the components of upstream mTOR pathway caused cortical dyslamination and cellular defects seen in FCD type II, whereas expression of wildtypes caused cortical dyslamination only. We now aim to characterize transcriptional profiles to reveal the

molecular mechanisms underlying phenotypic differences caused by the perturbation of overall activity of mTOR pathway.

Title: FOXP1 regulates cell-type specific molecular pathways and function within striatal projection neurons

Authors: *A. ANDERSON, A. KULKARNI, S. CAVALIER, J. GIBSON, G. KONOPKA
Neurosci., UT Southwestern, Dallas, TX

Abstract: *De novo*, loss-of-function mutations in the transcription factor *FOXP1* are among a handful of significant, recurrently-hit genes found in autism spectrum disorder (ASD). We previously reported that a *Foxp1* haploinsufficient mouse model (*Foxp1*$^{+/-}$) not only exhibited brain-region selective impairments within the striatum, but cell-type specific deficits particularly within dopamine 2 receptor (D2) expressing spiny projection neurons (SPNs). We therefore hypothesized that Foxp1 might govern striatal molecular pathways at risk in ASD, particularly within D2 SPNs. To test this, we deleted *Foxp1* from either D1, D2, or both neuronal populations in mice and used a combination of single-cell RNA-sequencing (scRNA-seq), physiological, and behavioral assays to better understand the cell-type specific mechanisms regulated by Foxp1 during striatal development. We found that Foxp1 is crucial for specifying a subset of D2 SPNs and D2 SPNs that remained are hyperexcitable with loss of Foxp1. Using scRNA-seq, we then identified the cell-type specific targets of Foxp1 and found that genes encoding KCN-family potassium channels were downregulated specifically in D2 SPNs. We also found evidence for cell-type specific alterations in striosome-matrix compartmentalization with loss of Foxp1 in D1 neurons. In addition, non-cell autonomous changes occurred with deletion of *Foxp1* in D2 SPNs specifically, including changes in local parvalbumin and calretinin positive interneuron populations. We connect these molecular findings to cell-type specific deficits in motor and limbic system-associated behaviors, including motor-learning, ultrasonic vocalizations, and fear conditioning. These results offer novels insights into the cell-type specific molecular pathways

regulated by Foxp1 during striatal development and provide the first evidence that Foxp1 specifies a subpopulation of D2 SPNs.

Title: Role of Sirt2 in oligodendrogenesis in white matter after neonatal hypoxia

Authors: *B. JABLONSKA, L.-J. CHEW, M. REIBNER, V. GALLO
Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington, DC

Abstract: Diffuse white matter injury (DWMI) is a major form of brain injury, which results in chronic neurological and behavioral disabilities in prematurely born infants, including a broad spectrum of cognitive and learning disabilities until young adulthood. Using a mouse model of neonatal hypoxia, we have previously demonstrated delayed oligodendrocyte (OL) maturation in white matter controlled by the $p27^{Kip1}$/Foxo1 pathway. Since Sirt2 is implicated in OL maturation, we determined whether neonatal hypoxia altered Sirt2 expression and function in white matter. We found that hypoxia reduced Sirt2 expression and the number of $Sirt2^+$ cells in white matter. The number of $Sirt2^+Olig2^+$ cells decreased after hypoxia, but $NG2^+Sirt2^+$ cells remained unchanged, indicating that hypoxia may affect Sirt2 primarily in mature OLs. Indeed, we observed a significant reduction of Sirt2 expression in mature $CC1^+$ and CNP^+ oligodendrocytes after hypoxia. Since Sirt2 siRNA treatment of cultured OL progenitor cells (OPCs) reduced percentages of $Olig2^+$, $GalC^+$, and $O4^+$ cells, it is likely that hypoxia-induced decrease in Sirt2 prevents OL differentiation. To uncover possible molecular mechanisms underlying OL dysmaturation mediated by Sirt2 changes, we investigated the $p27^{Kip1}$/FoxO pathway using immunoprecipitation. We found that the Sirt2/FoxO1 complex and deacetylated FoxO1 were reduced by hypoxia. Conversely, hypoxia enhanced formation of the Sirt2/FoxO3a complex, but reduced deacetylated FoxO3a levels. Since FoxO1 deacetylation regulates its activity, these changes induced by hypoxia suggest that reduced Sirt2-mediated deacetylation of FoxO1 reduces $p27^{Kip1}$ expression in injured white matter. These findings demonstrate that the functional involvement of Sirt2 may provide a link between enhanced OPC proliferation and delayed OL maturation in hypoxia-induced white matter damage.

Title: Neonatal death of conventional adenylyl cyclase 3 knockout pups

Authors: *M. R. STROBEL[1], R. LEBEL[2], X. CHEN[3]
[1]Univ. of New Hampshire, Dover, NH; [3]Dept. of Molecular, Cell. and Biomed. Sci., [2]Univ. of New Hampshire, Durham, NH

Abstract: Primary cilia are microtubule-based organelles found on most mammalian cells, which function as signaling hubs for many physiological functions including sensation and development. Type III adenylyl cyclase (AC3) is highly expressed in olfactory cilia and neuronal primary cilia in the brain. While AC3 in olfactory cilia is known to mediate olfactory signal transduction, its function in primary cilia in the brain and other tissues remains unclear. An AC3 conventional knockout (KO) mouse line in C57Bl/6 background has been developed. We observed that most homozygous AC3 KO pups die within hours of birth (neonatal death). To identify the cause of neonatal death and to investigate if AC3 play a role in embryonic development E19 and P0 KO mice were compared to wildtype littermates and no differences in size or external morphological deformities were observed. P0 mice were sectioned and stained to look for possible internal malformations such as short rib thoracic dysplasia or other deformities but no gross defects were found and brain structures were almost identical between KOs and WTs. AC3 KO pups do not display cyanosis or pulmonary hypoplasia either, indicating normal pulmonary development. However, AC3 KO pups did not present milk spots in the belly and lacked movement coordination. We conclude that the neonatal death of AC3 KO pups is caused by lack of nourishment due to loss of smell, but not by AC3 ablation in other tissues.

Sch. of Med., Hamamatsu, Japan; [10]Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: Trio-based whole exome sequencing identified two *de novo* heterozygous missense mutations (c.1449T>C/p.(Leu500Pro) and c.1436A>T/p.(Asn479Ile)) in *PHACTR1*, encoding a scaffold molecule critical for the regulation of protein phosphatase 1 (PP1) and actin cytoskeleton, in unrelated Japanese individuals with West syndrome (infantile spasms with intellectual disability (ID)). We then examined the role of *Phactr1* in the development of mouse cerebral cortex and pathophysiological significance of these two mutations and another (c.1561C>T/p.(Arg521Cys), which had been reported in an undiagnosed ID patient. Immunoprecipitation analyses revealed that actin-binding activity of PHACTR1 was impaired by the p.Leu500Pro and p.Asn479Ile mutations while the p.Arg521Cys mutant exhibited reduced binding to PP1. Acute knockdown of *Phactr1* with *in utero* electroporation caused defects in cortical neuron migration and dendritic arbor formation during corticogenesis. Notably, these phenotypes were rescued by an RNAi-resistant Phactr1, but not by the mutants. Forced expression of the mutants *per se* also exhibited aberrant phenotypes in neuronal migration. These results suggest dominant negative effects of the mutant allele. In addition, electrophysiological analyses revealed abnormal synaptic properties in *Phactr1*-deficient excitatory cortical neurons. Taken together, *PHACTR1* abnormalities were found to cause West syndrome probably due to morphological and functional defects in cortical neurons during brain development.

Title: A genetic screen by transposon-mediated somatic mutagenesis in the mouse brain identifies genes associated with malformations of cortical development

Authors: *I.-L. LU, J.-W. TSAI
Inst. of Brain Sci., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Malformations of cortical development (MCDs) are heterogeneous neurodevelopmental disorders that often result in epilepsy and developmental delays in children. However, many genetic mutations involved in MCD pathogenesis remain unidentified. To identify new genes potentially involved in cortical development and the pathogenesis of MCDs, we took advantage of forward genetic screening by somatic mutagenesis during brain development. Here we developed a genetic screening paradigm by combining somatic mutagenesis with *in utero* electroporation in the developing mouse cortex. We identified 33 potential MCD genes, several genes have been previously implicated in neuronal development and disorders. Consistent with the screening results, functional disruption of these genes by RNA interference or using CRISPR/Cas9 causes alterations in the distribution of cortical neurons that resemble human cortical dysplasia. To verify potential clinical relevance of these candidate genes, we analyzed somatic mutations in brain tissue from patients with focal cortical dysplasia and found mutations enriched in these candidate genes. These results demonstrate that the approach is able to identify potential novel genes involved in cortical development and MCD pathogenesis.

Title: Mouse B3glct knockout a new model for hydrocephalus

Authors: *J. GOTO[1], P. SHULTZ[1], R. C. GRADY[2], C. SHULA[1], D. C. CAMERON[2], F. T. MANGANO[1], R. S. HALTIWANGER[3], B. C. HOLDENER[2]
[1]Cincinnati Children's Hosp., Cincinnati, OH; [2]Stony Brook Univ., Stony Brook, NY; [3]Univ. of Georgia, Athens, GA

Abstract: Hydrocephalus is a life-threatening condition characterized by the excessive buildup of cerebrospinal fluid (CSF) in the cerebral ventricles. The development of excessive CSF can result from impaired CSF flow, immoderate production of CSF, or inabilities to reabsorb the CSF. Hydrocephalus affects one out of every 1,000 babies that are born and is the most common reason for children to have brain surgery. A better understanding of the CSF flow and factors that impair flow is needed to develop alternative treatment plans for more positive outcomes. CSF flow traditionally has been described as unidirectional from the lateral ventricles to the third ventricle, into the fourth ventricle, and finally along the subarachnoid space until the CSF is reabsorbed. Recent studies proposed additional CSF absorption sites, including nasal lymphatics and glymphatic pathways, but the molecular and cellular mechanisms involved in the development of CSF circulation system remained largely unknown.
Peters plus syndrome is caused by recessive loss-of-function mutations in *B3GLCT* (beta 3-glucosyltransferase) and is characterized by Peter's anomaly of the eye, craniofacial defects, shortening of the long bones and digits, and intellectual disabilities. *B3GLCT* mutations were also identified in late gestation fetuses with cleft-palate, eye abnormalities and structural brain disfigurements such as hypoplasia, Dandy-Walker malformation, and hydrocephalus. Here, we report the abnormal CSF flow pattern of the *B3glct* knockout mutant mice, a new mouse model with hydrocephalus phenotype. We examined the neural expression pattern of the *B3glct* gene in LacZ reporter allele inserted in the *B3glct* gene to identify the responsible cell types for the hydrocephalus phenotype. B3GLCT functions in *O*-glycosylation of 49 target proteins that have thrombospondin type 1 repeats (TSRs) with the consensus site C-X_{2-3}(S/T)C. Recent studies provide evidence that the B3GLCT-mediated modification accelerates folding of the native protein, suggesting that the neurological abnormalities in Peters plus syndrome result from defects in folding or function of one or more B3GLCT targets. Candidates include but are not limited to F-Spondin, Sco-spondin, SEMA5A, and SEMA5B.

Title: Dysregulation of mTORC2, but not mTORC1, underlies the neurophysiological and behavior abnormalities in Pten-deficient mouse model of ASD and epilepsy

Authors: *C.-J. CHEN[1], M. SGRITTA[1], J. MAYS[1], J. NOEBELS[2], M. COSTA-MATTIOLI[1]
[1]Dept of Neurosci., [2]Dept of Neurol., Baylor Col. of Med., Houston, TX

Abstract: The mechanistic target of rapamycin (mTOR) acts as a highly conserved signaling hub that integrates neuronal activity and a variety of synaptic inputs. Mutations in phosphatase and tensin homolog (*Pten*) leads to hyperactivation of both mTOR complex 1 and mTOR complex 2, and is associated with Autism Spectrum Disorder (ASD) and epilepsy. Chronic rapamycin treatment has been shown to inhibit both mTORC1 and mTORC2 and rescue neuronal and behavioral phenotypes in Pten-deficient mice. However, the individual contribution of mTOR complexes to the molecular, behavioral and neurophysiological abnormalities associated with Pten deficiency remains unknown. Here, we discovered that each mTOR complex differentially contributes to different aspects of ASD and seizures. Conditional *Pten* forebrain neuron knockout (*Pten* fb-KO) mice show enlarged brain size, ASD-like behaviors (including social and cognitive deficits as well as repetitive behaviors), increased neuronal excitability, seizure activity, and early mortality due to terminal seizure. Interestingly, genetic inhibition of mTORC1(*Pten;Raptor* fb-dKO) only restores normal brain size in *Pten* fb-KO. Genetic inhibition of mTORC2(*Pten;Rictor* fb-dKO) along, however, is able to rescue seizure and prolong survival of *Pten* fb-KO mice. Normal neuronal excitability, social behavior, and cognitive function are also restored in *Pten;Rictor* fb-dKO, but not in *Pten;Raptor* fb-dKO. We further showed that while the expression of glycolytic enzymes and glycolysis metabolites levels are increased in *Pten* fb-KO and *Pten;Raptor* fb-dKO brain, the restoration of in neuronal function in *Pten;Rictor*fb-dKO mice is accompanied by normalized glucose metabolism in the brain. Our findings not only provide new insight of understanding the molecular mechanism underlying brain mTORopatheis, but but alsohold promise for new specific mTORC2-based treatments for ASD, epilepsy, and related neurodevelopmental disorders in which mTOR function is dysregulated.

Title: Optogenetic stimulation of the subthalamic nucleus reduces repetitive behavior in C58 mice

Authors: *A. M. MUEHLMANN[1], L. CURRY-POCHY[1], J. HART[1], M. SMELTZER[2], E. G. KRAUSE[3], M. H. LEWIS[1]

Abstract: Restricted, repetitive behavior represents a range of responses including stereotyped movements, compulsions, and rituals that are diagnostic for autism spectrum disorders (ASD) and common in other neurodevelopmental and psychiatric disorders. Despite its clinical importance, effective medications for repetitive behavior are lacking. This is due to our rudimentary understanding of the relevant neural circuitry mediating such behavior. Identifying discrete neural pathways controlling repetitive behaviors is key to determining the precise neurobiological pathology and developing effective treatments. We use mouse models of repetitive behavior to accomplish these aims, including C58 mice that show very high rates of repetitive behavior in a laboratory environment. Our prior work using C58 mice revealed decreased neuronal activation and reduced dendritic spine density in the subthalamic nucleus. The overall goal of this project was to determine if reversing this hypoactivation through optogenetic stimulation could reduce repetitive behavior. Using this approach, we expressed channelrhodopsin (ChR2; pAAV-CaMKIIa-hChR2(H134R)-EYFP) or control virus (pAAV-CaMKIIa-EYFP) bilaterally in the subthalamic nucleus of C58 mice. The stimulation used was 10 ms pulses of 473 nm light at 40 Hz for five seconds on and ten seconds off. In ChR2-injected mice, repetitive behavior counts were equal to control mice when laser light was off (10 sec blocks). During photoactivation (5 sec blocks) repetitive behavior was significantly reduced relative to laser off in the ChR2 group and relative to the laser on in the control virus group. Other, non-repetitive, behaviors were not affected by photoactivation of the subthalamic nucleus. We are currently evaluating the widespread effect of the subthalamic nucleus stimulation on large-scale brain networks, as measured by BOLD signal changes, using optogenetic fMRI (ofMRI). These data will also be presented.

Title: Altered inhibitory synaptic plasticity in the Neuroligin3-R451C mouse model of autism

Authors: *E. PETRINI, S. H. STANCHEVA, F. COLACI, L. MANNINO, A. BARBERIS
Inst. Italiano di Tecnologia, Genoa, Italy

Abstract: Autistic Spectrum Disorder (ASD) has been associated to genetic alterations of proteins that are crucial for the synaptic function such as Neuroligin 3 (NLGN3), a postsynaptic adhesion molecule, which binds to its presynaptic partner Neurexin at both excitatory and inhibitory synapses.
This study explores the R451C mutation on NLGN3 -found in autistic siblings- as a molecular determinant of ASD. We aim at assessing how this mutation affects the structure and function of inhibitory synapses and alters synaptic plasticity in a characterized transgenic mouse model of ASD, the $NLGN3^{R451C}$ knock-in (KI) mouse. We found that the $NLGN3^{R451C}$ protein was much less expressed at the neuronal surface and was significantly more mobile at GABAergic synapses as compared to WT conditions. Also surface synaptic GABAARs were more mobile in KI than in WT neurons. However, the immunoreactivity of the scaffold protein gephyrin and of GABAAR at synapses as well as the amplitude of inhibitory synaptic currents were comparable in WT and KI neurons, indicating that in basal conditions the higher lateral mobility of synaptic $NLGN3^{R451C}$ and GABAAR did not result in significant changes in the postsynaptic organization and function.
Next, we probed WT and KI neurons for the expression of postsynaptic inhibitory long term potentiation (iLTP) induced by a chemical protocol. As expected, upon iLTP induction, neurons from WT animals exhibited a significant increase in synaptic gephyrin along with the accumulation and the immobilization of GABAAR at synapses, leading to a persistent potentiation of the IPSCs amplitude as compared to control treatment. During iLTP we also observed enhanced stabilization of NLGN3 at GABAergic synapses in WT neurons. On the contrary, neurons from KI animals did not respond to the chemical stimulation, leaving the synaptic abundance of GABAAR and gephyrin as well as the amplitude of inhibitory synaptic currents comparable to controls. In line with this, in KI neurons the higher lateral diffusion of GABAAR and $NLGN3^{R451C}$ at inhibitory synapses observed in basal conditions persisted after

the chemical stimulation. Overall those results suggest that in NLGN3 KI neurons the altered stability of the molecular components of inhibitory synapses entail functional consequences only when major synaptic reorganizations are required, such as during synaptic plasticity. Those findings may shed light on how the $NLGN3^{R451C}$ mutation may unbalance the coordination of inhibitory and excitatory synaptic plasticity.

Title: Defects in sensory information processing in the neocortex in a mouse model for fragile x syndrome — from ion channels to cell types and circuits

Authors: *A. A. FRICK[1], A. A. BHASKARAN[2], G. BONY[3], K. LE CORF[2], R. PROVILLE[2]

Abstract: Sensory hypersensitivity is a common aspect of fragile x syndrome, and of autism spectrum disorder (ASD) in general. In spite of the prevalence of this phenotype there is a paucity of studies examining sensory information processing defects in animal models of ASD. We investigated sensory information processing in the neocortex of $Fmr1^{-/y}$ mice both at the network and cellular level using different tactile modalities, and a variety of methodologies. We present data illustrating that cellular and synaptic phenotypes depend on the particular cell-types within and across layers (layers 2/3 and 5). We also investigated the correction of aberrant cellular and synaptic properties by targeting a specific ion channel in these neocortical circuits — either using systemic delivery or direct neocortical application of the drug. In conclusion, our study contributes to an understanding of the role of cell diversity in neocortical function in both the normal and diseased brain. In addition, it lends further support for the importance of targeting neuronal excitability as a suitable approach for pharmacological correction of autism related neocortical defects.

Title: Developmental mechanisms of sebaceous nevus syndrome caused by dysregulation of RAS/MAPK pathway

Authors: *Y. KIM[1], S. BAEK[2]
[1]Pohang Univ. of Sci. and Technol., Pohang-si, Korea, Republic of; [2]Div. of Integrative Biosci. and Biotech. (IBB), Dept. of Life Sci., Pohang Univ. of Sci. and Technology(POSTECH), Pohang-si, Korea, Republic of

Abstract: Sebaceous nevus syndrome is a neurocutaneous disorder that shows neurological symptoms such as epilepsy, mental retardation, cerebral defect and ocular abnormality with the skin lesion called nevus sebaceous. Recently, it has been reported that sebaceous nevus syndrome is caused by somatic mutation of KRAS and HRAS during development. Interestingly, other neurodevelopmental conditions that are associated with genetic mutations in the components of RAS/MAPK pathway also show characteristic neurological symptoms including mental retardation, epilepsy, seizures, and learning disability which may explained by perturbation of RAS/MAPK pathway. We found that the mis-activation of RAS/MAPK pathway resulted in neurological defects associated with sebaceous nevus syndrome. Activation of RAS/MAPK pathway by ectopic over-expression of KRAS p.G12D in developing mouse brain caused defective neuronal migration. Using human embryonic stem cell-derived neuronal progenitor cells, we aim to characterize the gene expression profile that may explain the underlying molecular mechanisms of neurological defects caused by the mis-regulation of RAS/MAPK pathway.

Title: Sex differences in microglia-neural signaling and learning following early-life immune activation in the juvenile rat

Authors: *B. OSBORNE, J. M. SCHWARZ
Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Developmental disorders associated with learning deficits including Autism, ADHD, and developmental disorders have been linked to early-life immune activation, and notably, are male-biased. Microglia are the primary immune cells of the brain and are in constant communication with neurons, thus, activation of microglia can significantly influence the function of surrounding neurons. Recent evidence indicates that microglia-neuron signaling is also necessary for the proper formation of neural circuits that support learning during early brain development. We found that immune activation with lipopolysaccharide (LPS; 100ug/ml/kg) on postnatal day (P) 21 produces sex-dependent deficits in the *emergence* of hippocampal-dependent learning on P24 in rats. We examined gene expression in the hippocampus at 2-, 4-, 8-, and 24-hr following immune activation and found sex differences in the expression of inflammatory molecules including IL-1β in the hippocampus. Additionally, males, but not females, have a persistent decrease in brain derived neurotrophic factor expression starting 4hr post-LPS that persists until 24hr. Finally, we found that males, but not females, have a significant increase in the expression of C3, an immune molecule that tags synapses for phagocytic elimination, at 24hr. Currently, we are examining whether we can rescue learning deficits on P24 by treating males and females with the microglia inhibitor minocycline; however, we have found a sex difference in the effectiveness of minocycline such that minocycline effectively inhibits IL-1β production in males, but is not as effective in females. We also found that minocycline restores BDNF levels in males treated with LPS back to levels seen in control males. Finally, we examined whether LPS on P21 alters microglia phagocytosis of synapses in the hippocampus and whether measures of neuronal morphology and spine density are altered on P24. These results will be discussed. Our data suggest that changes in microglia-neural communication may be a mechanism underlying sex differences in the vulnerability to the emergence of developmental learning disorders following early-life immune activation and that LPS may cause lasting changes in microglia-neural communication in the hippocampus.

Title: Subtype-specific sensitivity of NMDA receptors to neuropsychiatric lupus autoantibodies

Authors: *K. CHAN[1], C. KOWAL[3], B. DIAMOND[3], L. P. WOLLMUTH[2]
[2]Neurobiol & Behavior, [1]Stony Brook Univ., Stony Brook, NY; [3]Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: Systemic lupus erythematosus (SLE) is an autoimmune inflammatory disease where patients may develop perturbations in neurological and psychiatric function, leading to neuropsychiatric SLE (NPSLE). A subset of these patients produce anti-dsDNA antibodies (DNRAbs) that cross-react with the NMDA receptor. NMDA receptors are glutamate-gated ion channels that are essential for excitatory signaling in the nervous system. They are obligate heterotetramers, typically composed of two GluN1 subunits and two GluN2 subunits. DNRAbs mediate synaptic dysfunction, cognitive impairment, and excitotoxicity through NMDA receptor activity, largely in the hippocampus. The two major GluN2 subunits in the hippocampus are GluN2A and GluN2B and DNRAbs bind to both GluN2A and GluN2B-containing NMDA receptors. Nevertheless, the specific effect of DNRAbs on NMDA receptors and which NMDA receptor subunits are targeted remain elusive. A major function of synaptic NMDA receptors is to convert synaptically released glutamate into an electrical signal by opening of its associated ion channel, a property called ion channel gating. Here, we show that DNRAbs exert subunit-specific effects on NMDA receptor gating. At a moderate concentration (patient titers), DNRAbs increase peak amplitude of glutamate-induced currents only in GluN2A-containing receptors but not GluN2B-containing receptors. Using high-resolution single channel recordings, we show that DNRAbs increase the mean open probability (P_o) and mean open time (MOT) of GluN2A-containing receptors, but not in those containing GluN2B, suggesting that DNRAbs stabilize GluN2A-containing receptors in the open state. In the hippocampus, NMDA receptors are typically tri-heteromeric, containing both GluN2A and GluN2B subunits. We find that DNRAbs potentiate GluN2A/GluN2B tri-heteromeric receptors, suggesting that GluN2A confers dominance of antibody susceptibility to NMDA receptors. Our data supports *in vivo* findings of GluN2A-containing NMDA receptors being the primary target of excitotoxicity from DNRAbs.

Taken together, these findings suggest that targeted therapies for NPSLE patients to improve neurocognitive function should be directed towards GluN2A.

Title: Characterisation of intrinsic and synaptic properties of hippocampal CA1 pyramidal neurons in Grin2a$^{+/-}$ and Grin2a$^{-/-}$ rats

Authors: *F. YASMIN, S. A. BOOKER, R. LOUREIRO, K. F. M. MARWICK, G. E. HARDINGHAM, P. C. KIND, D. J. WYLLIE
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: *N*-methyl-D-aspartate receptors (NMDARs) are ionotropic glutamate receptors that play pivotal physiological roles during development and maturation of the central nervous system (CNS). In the mammalian forebrain, the predominant NMDAR composition is a diheteromeric assembly of two GluN1 with either two GluN2A or two GluN2B subunits or a triheteromeric assembly of GluN1 and GluN2A and GluN2B subunits. The identity of GluN2 subunits in a NMDAR is a major determinant of its kinetic behavior with GluN1/2A and GluN1/2A/2B NMDARs having faster deactivation rates than those exhibited by GluN1/2B NMDARs. As such, loss or reduced expression of either GluN2A or GluN2B subunits will change the kinetic profile of NMDAR populations. Indeed, altered functional properties of NMDARs is considered to underlie the CNS dysfunction observed in individuals carrying mutations in either *GRIN2A* or *GRIN2B* (the genes encoding GluN2A and GluN2B, respectively). We have employed CRISPR/Cas9 gene editing methods to generate a genetically modified rat in which the *Grin2a* gene is deleted in order to investigate the influence of the GluN2A subunit in determining excitability and synaptic properties in CA1 hippocampal pyramidal neurons.
CA1 pyramidal neurons from P27-34 *Grin2a*$^{-/-}$ rats show an increase in the slope of the action potential frequency versus injected current (F/I plot) compared to *Grin2a*$^{+/+}$ controls but otherwise have unaltered intrinsic physiology. We also find that dendritic branch complexity,

assessed by 3-dimesional cell reconstruction and Sholl analysis, is reduced in *Grin2a*$^{-/-}$ rats. Loss of expression of GluN2A results in slowing of the NMDAR component of EPSCs as would be predicted if EPSCs were mediated by NMDARs with a greater GluN2B content (*Grin2a*$^{+/+}$: 104.33±5.74 ms, n=12; *Grin2a*$^{+/-}$: 140.58±13.19 ms, n=17; *Grin2a*$^{-/-}$: 186.59±10.2 ms, n=14). We also find that the frequency of mEPSCs is reduced in *Grin2a*$^{-/-}$ rats (*Grin2a*$^{+/+}$: 2.47±0.17 Hz, n=8; *Grin2a*$^{+/-}$: 1.59±0.33 Hz, n=10; *Grin2a*$^{-/-}$: 1.38±0.23 Hz, n=9). However, mEPSC amplitudes remain unaffected by the loss of GluN2A expression. Subthreshold EPSP summation and probability of action potential firing at different frequencies of Schaffer collateral stimulation (2, 5, 10, 20 and 50 Hz) appear unchanged by GluN2A reduction or deletion. Thus, while slower EPSCs are observed, EPSPs summate similarly in *Grin2a*$^{+/+}$, *Grin2a*$^{+/-}$ and *Grin2a*$^{-/-}$ CA1 pyramidal cells.

Title: Site of action of brain neurosteroid, pregnenolone sulfate, at the N-methyl-D-aspartate receptor

Authors: *L. .-. VYKLICKY JR[1], B. KRAUSOVA[2], B. KYSILOV[2], J. CERNY[2], V. VYKLICKY[2], M. LADISLAV[2], T. SMAJKALOVA[2], H. CHODOUNSKA[3], E. KUDOVA[3]

Abstract: N-methyl-D-aspartate receptors (NMDARs) play a key role in excitatory synaptic transmission, and their dysfunction underlies some neurological and psychiatric disorders. Receptor hypofunction has been implicated in autism, schizophrenia, and various forms of intellectual disability, and compounds with a positive allosteric effect at NMDARs may have a beneficial effect in these diseases. The aim of this study was to characterize the site of action for pregnenolone sulfate (PES), an endogenous neurosteroid that has a positive allosteric effect at NMDARs. We have used patch-clamp technique to study PES effect at recombinant

GluN1/GluN2B receptors. Our results show that PES did not compensate for the diminution of NMDAR responses induced by cholesterol depletion, indicating that cholesterol and PES potentiation are mediated by distinct sites. Dose-response analysis of the positive allosteric effect of PE-S at NMDAR indicates that at biologically relevant concentrations the steroid exists in micelle form and together with the effect of methyl-γ-cyclodextrin indicates that the steroid acts at the NMDAR transmembrane domain. The steroid positive allosteric effect was observed only for PES added from the extracellular, not from the intracellular site. To identify the PES site, we sequentially replaced amino acid residues at the outer segment of the transmembrane helices M1 and M4 of both the GluN1 and GluN2B subunits. Single alanine substitution mutations included: GluN1(Q559A to V572A; T809A to V825A) and GluN2B(S555A to I568A; D814A to A830T). Relative effect of PES (100 μM) varied considerably from that found for the wild type receptors (104 ± 4 %; *n* = 158) and mutated receptors (spanning from inhibition 33 ± 2 % (*n* = 7) for GluN1/GluN2B(M824A) to augmented potentiation 507 ± 112 % (*n* = 4) for GluN1/GluN2B(G815A)). The effect of PES at GluN1/GluN2B(D816A; Y823A; and M824A) receptors was significantly reduced compared to WT and at GluN1(G815A; M818A; and G822A)/GluN2B receptors was significantly increased compared to WT. Electrophysiological results together with computational methods indicate that PES binds to the cavity between the M1 and M4 membrane domains of the GluN2B subunit of the closed conformation of the channel. Following receptor activation M1/M4 helices rearrange, including the steroid binding site - this explains why the effect of PE-S is disuse-dependent. Together our study has identified a novel site at the NMDAR by which endogenous neurosteroid PE-S augments the activity of the receptor.

Title: GluN2D-containing NMDARs modulate the excitatory activity of CRF neurons within the BNST and influence changes in anxiety and depressive-like behaviors

Authors: *G. J. SALIMANDO[1], T. A. WILLS[2], A. J. BAUCUM II[3], D. G. WINDER[1]
[1]Vanderbilt Univ., Nashville, TN; [2]Dept. of Cell Biol. and Anat., LSUHSC, New Orleans, LA; [3]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: The bed nucleus of the stria terminalis (BNST) is a key regulator of affective stimuli. Previously, our lab has shown that disrupting glutamatergic signaling in the BNST via the ablation or inhibition of N-methyl-d-aspartate receptors (NMDARs) containing the GluN2B subunit alters regional synaptic plasticity and produces an antidepressant-like phenotype in mice. Using a proteomic screen of GluN2B-associated proteins, we identified GluN2D as another NMDAR subunit expressed in the BNST. GluN2D is a less well-studied NMDAR subunit with unique biophysical properties and a more restricted distribution in the CNS. Thus, we assessed the behaviors of GluN2D knockout mice in a variety of tasks designed to assess affective states. Interestingly, GluN2D KO mice exhibited a phenotypic profile across the elevated zero maze, open field and forced swim tests consistent with increased anxiety- and depressive-like behaviors, opposite to the phenotype of BNST-GluN2B knockouts. In addition to behavioral analyses, we have begun to assess the contribution of GluN2D to circuit activity in the BNST. We find that short-term plasticity (STP) is significantly reduced in GluN2D knockout animals compared to wildtype controls. Whole cell electrophysiological analysis of BNST neurons, however, showed no significant differences in the amplitude or frequency of spontaneous excitatory post synaptic currents (EPSC) or in evoked NMDAR EPSC kinetics between knockouts and wildtypes. We hypothesized that the changes we observed in both behavior and BNST plasticity could be due to altered signaling in select populations of BNST neurons that express high levels of GluN2D. Using RNAscope® fluorescent *in situ* hybridization, we found that GluN2D mRNA is highly co-localized with the neuropeptide corticotropin releasing factor (CRF, ~70-75% co-localization) in the BNST. To determine if GluN2D deletion on BNST-CRF neurons altered their excitatory activity, we crossed GluN2D knockout mice into a CRF-IRES-Cre/ROSA (Ai9) reporter line in order to interrogate these cells. CRF cells in GluN2D knockouts show increased spontaneous EPSC amplitude, and a subset of these cells also showed increased spontaneous EPSC frequency. Evoked NMDAR currents in GluN2D KO BNST-CRF cells also showed more rapid decay kinetics compared to GluN2D wildtype CRF cells, suggesting that GluN2D-containing NMDARs may play a role in regulating CRF signaling in the BNST. These changes in CRF cell activity may also underlie the behavioral phenotypes we and other have observed in the GluN2D KO mouse line.

Title: GluN3 containing triheteromeric NMDA receptor subunit interactions in the rat medial entorhinal area

Authors: *S. BEESLEY, S. S. KUMAR
Florida State Univ., Tallahassee, FL

Abstract: The subunit composition of native NMDA receptors (NMDARs) in the brain is not precisely known. Recent work from our lab has provided electrophysiological / pharmacological evidence for the expression of GluN3-containing triheteromeric (t-) NMDARs, comprising of one or more subunits from each of the three gene families (GluN1-GluN3), in excitatory layer 3 pyramidal neurons of the medial entorhinal area (MEA). The MEA is implicated in the pathophysiology of Temporal Lobe Epilepsy. Given the paucity of subunit specific pharmacological tools with which to query subunit composition of native receptors, we devised a cell biology approach to determining NMDAR subunit interactions within membrane-bound fractions of tissue excised from the MEA for immunoblotting and co-immunoprecipitation work. Using this approach we validated the expression of GluN3A containing t-NMDARs within the MEA, and the putative co-expression of GluN1/GluN2-containing diheteromeric (d-) NMDARs in these neurons. Based on our results, we propose co-expression of GluN1/GluN3A/GluN2B containing t-NMDARs along with $(GluN1/GluN2A)_2$–containing d-NMDARs in these neurons. Given the unique properties of GluN3-containing t-NMDARs, including enhanced Ca^{2+} permeability, these findings would facilitate the development of novel inhibitors which could curtail excitability of the MEA and prevent Ca^{2+} induced excitotoxicity and cell death of neurons that mediates temporal lobe epileptogenesis.

Title: Sorting Nexin 27 controls the exocytosis of NMDA receptors

Authors: *V. ANGGONO[1,2], T. WANG[1,2], X. YU[1,2], M. VIEIRA[4], X. L. H. YONG[1,2], S. E. JANG[1,2], B. M. COLLINS[1,3], K. W. ROCHE[4]

Abstract: Sorting nexin (SNX) is a family of cytoplasmic and membrane proteins commonly involved in the endosomal trafficking of surface receptors. SNX27 is the only sorting nexin to contain a postsynaptic density 95/discs large/zona occuldens (PDZ) domain, and is playing an important role in mediating PDZ-dependent endosomal sorting and recycling of cargo molecules to the plasma membrane. Mutations of *SNX27* gene is linked to intellectual disability, epilepsy and growth retardation. Mice lacking SNX27 display impairments in glutamatergic neurotransmission and long-term potentiation, as well as deficits in learning and memory. Previous studies have attributed synaptic dysfunction in SNX27 knockout mice to impairment in the trafficking of AMPA-type glutamate receptors. However, our recent finding found no evidence for direct interaction between SNX27 with AMPA receptor subunits. Instead, we found that SNX27 PDZ domain directly interacts with subunits of NMDA receptors and that this interaction is regulated by the phosphorylation of NMDA receptor near the carboxy-terminal PDZ ligands. Here, we report that SNX27 regulates the forward trafficking of GluN2A subunit of NMDA receptors in cultured hippocampal neurons. Overexpression of SNX27 upregulates surface expression GluN2A under basal conditions. In contrast, loss of SNX27 function abolishes activity-dependent insertion of GluN2A to the plasma membrane. Our results suggest that SNX27 plays a critical role in synaptic plasticity by enhancing the surface insertion of GluN2A-containing NMDA receptors during synaptic potentiation.

Title: Facilitation of synaptic, but not extrasynaptic, NMDA Currents CA1 pyramidal neurons by adenosine A_{2A} receptors in young adult rats

Abstract: N-methyl-*D*-aspartate receptors (NMDAR) are calcium permeable ionotropic glutamate receptors that play pivotal roles in synaptogenesis, experience-dependent synaptic remodelling and for the induction of long-lasting changes in synaptic efficiency, as it is the case for several forms of synaptic plasticity. However, NMDARs also play a key role in neurodegeneration. The dual role of NMDAR is related to receptor location relative to the synapse, the synaptic NMDARs being mostly involved in synaptic plasticity while the extrasynaptic NMDARs are linked to neurotoxicity. Regulatory mechanisms that control NMDAR activity at specific membrane locations are therefore of particular importance and their knowledge relevant for strategies aiming to favour the balance towards neuronal survival and shape synaptic functioning. Adenosine is an endogenous neuromodulator and through membrane receptors of the A_{2A} subtype (A_{2A}Rs) can also influence both synaptic plasticity and neuronal death. We now evaluated the influence of adenosine A_{2A}Rs upon NMDAR discriminating between modulation of synaptic *versus* extrasynaptic receptors. Whole-cell patch-clamp recordings were obtained to evaluate NMDAR actions on CA1 pyramidal neurons of young adult (6-10 weeks) male Wistar rat hippocampus. Activation of adenosine A_{2A}Rs with CGS21680 (30nM) consistently facilitated chemical-evoked NMDAR-currents (NMDA-PSCs) and afferent-evoked NMDA-currents (NMDA-EPSCs), an action prevented by an A_{2A}R antagonist (SCH58261, 100nM) and a PKA inhibitor, H-89 (1µM). These actions were predominantly postsynaptically-mediated since there was no change in NMDA-EPSCs paired-pulse ratio (PPR). A_{2A}R actions were lost in the presence of an open-channel NMDAR blocker, MK-801 (10µM), but persisted in the presence of memantine, at a concentration (10µM) known to preferentially block extrasynaptic NMDARs. These results show that A_{2A}Rs exert a positive modulatory effect over synaptic, but not extrasynaptic NMDARs in CA1 neurons and therefore under non-pathological conditions may contribute to shift the dual role of NMDARs towards enhancement of synaptic plasticity.

Title: Zinc transporter ZnT1 regulates zinc inhibition of NMDARs

Authors: *R. F. KRALL[1], A. MOUTAL[2], R. KHANNA[2], M. HERSHFINKEL[3], E. AIZENMAN[1], T. TZOUNOPOULOS[1]
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Col. of Med. Univ. of Arizona, Tucson, AZ; [3]Ben-Gurion Univ. of the Negev, Beer Sheva, Israel

Abstract: Synaptically released zinc modulates glutamatergic neurotransmission in a large number of brain regions, including neocortex, hippocampus and the dorsal cochlear nucleus (DCN), an auditory brainstem nucleus. Synaptic zinc is loaded into presynaptic vesicles by the transporter ZnT3 and released with activity. In the DCN, synaptically released zinc inhibits postsynaptic NMDARs and AMPARs. ZnT3 knockout mice, which lack synaptic zinc, show zinc-mediated inhibition of NMDARs at high frequency of stimulation, indicating that other transporters regulating extracellular zinc levels may contribute to the zinc-mediated inhibition of NMDARs. Consistent with this hypothesis, ZnT1, a plasma membrane-localized transporter that extrudes zinc from the cytoplasm, binds to the C-terminal domain of the highly zinc sensitive GluN2A subunit of the NMDAR. We hypothesized that through this association, ZnT1 regulates NMDAR inhibition by increasing zinc levels in the extracellular milieu surrounding NMDARs. We found that ZnT1 RNA expression *in vitro* increased developmentally, paralleling the expression profile of GluN2A. To test whether the ZnT1/NMDAR coupling regulates receptor function, we developed a peptide that competitively interferes with ZnT1-GluN2A association. The peptide sequence was identified by using a far-Western screen to determine the sequence of the C-terminal domain of GluN2A with the highest affinity for ZnT1. The peptide effectively displaced ZnT1 from Glun2A in our cultured neurons in a proximity ligation assay. In addition, this peptide, but not its scramble control, completely abolished endogenous zinc inhibition of NMDARs in rat cortical neurons *in vitro*. This effect was specific for NMDARs, as the peptide treatment reduced endogenous zinc inhibition of NMDAR-mediated synaptic currents in DCN slices, without influencing zinc-mediated inhibition of AMPAR-mediated responses. Finally, the peptide did not affect the IC50 of exogenously applied zinc of NMDA-induced whole cell currents in neurons and in CHO cells expressing GluN1/GluN2A-containing receptors, suggesting that it does not affect either the binding or the direct inhibition of zinc inhibition of NMDARs. These results suggest that ZnT1 regulates local extracellular zinc levels and zinc inhibition of NMDARs.

Title: Neuromophological characterization of CA1 pyramidal cells expressing chimeric NMDAR GluN2 subunits: Changes during hippocampal development

Authors: *M. J. KEITH[1], J. REEVES[2], D. CHEN[2], R. E. KEITH[2], T. DUMAS[2]
[1]Neurosci., Northern Virginia Community Col., Fairfax Station, VA; [2]Psychology, George Mason Univ., Fairfax, VA

Abstract: N-methyl-D-aspartate receptors (NMDARs) are key regulators of dendritic growth. NMDAR composition changes throughout development in that GluN2B subunits are replaced by GluN2A subunits at roughly three weeks of age. Dysfunction of this process is known to impact activity-dependent synaptic plasticity and cognitive development and is believed to be involved in autism spectrum disorders. Calcium conductance through NMDARs [regulated by amino(A)-terminus and transmembrane domains (TMDs)] and intracellular signaling (regulated by carboxy(C)-terminus) are known to impact functional and structural synaptic plasticity. It remains unknown how these separate functional properties independently affect dendritic morphology. To determine the separate influences of NMDAR subunit regions on dendritic development, we constructed GluN2 chimeras and generated two transgenic mouse lines. One mouse line expresses the A-terminus and TMDs of GluN2A fused to C-terminus of GluN2B (termed ABc) and, vice versa, the other mouse line expresses the A-terminus and TMDs of GluN2B fused to C-terminus of GluN2A (termed BAc). Transcription was regulated by the TET-off expression system with tetracycline transactivator protein (tTA) expression under control of the CaMKII minimal promoter. tTA expression was seen in many forebrain regions, but predominantly in hippocampal pyramidal cells in area CA1. We measured neuromorphological characteristics of hippocampal CA1 pyramidal neurons in two postnatal periods: P17-P19, and P22-P24, by utilizing Thy-1 GFP fluorescence methods, confocal microscopy, and Neurolucida tracing. Our findings revealed that ABc animals appear to show reduced spine density at P17-P19 than BAc and WT animals. This suggests that ABc animals may go through synaptic pruning earlier than wildtypes due to the presence of the amino(A)-terminus and TM regions. In contrast to the ABc animals, the BAc animals appear to express greater synaptogenesis at P17-P19, possibly due to a prolonged development period compared to ABc and WT animals. The BAc animals express shorter than average branch length at P17-P19. This may be explained by prolonged development as mentioned previously. Also, the ABc animals have a longer average branch length in the P22-P24 age group suggesting that the GluN2B carboxy tail could be affecting growth factors following hippocampal maturation. This study furthers understanding of how NMDAR regions and their separate properties facilitate developmental changes, yielding insight into neurodevelopmental disorders.

Title: Discovery of a novel antagonist selective for GluN2A-containing NMDA receptors

Authors: S. SIMAVORIAN, T. LOVENBERG, *R. NEFF
Neurosci. Drug Discovery, Janssen Res. and Develop. La Jolla, San Diego, CA

Abstract: The discovery of NMDA modulators has long been a priority for both basic scientific investigation as well as for potential therapeutic purposes in many neurological and psychiatric diseases. Despite extensive efforts identification of compounds selective for GluN2A has proven difficult. Recent advances in the field, however, have generated tools and information that have facilitated new avenues of investigation. Specifically, the identification of GluN2A selective compounds and publication of the key structural determinants of their interactions with the channel have enabled virtual interrogation of ligand binding sites. Here, we report the discovery of a GluN2A selective antagonist that was identified in a *in silico* screen of the GluN2A glutamate binding site. The potency of this compound is right-shifted in the presence of increasing concentrations of glutamate. In addition, the molecule exhibits selectivity for antagonism of GluN2A over GluN2B, C, & D. Thus, we provide an additional tool for the targeted study of GluN2A function.

Title: Ketamine trapping inside of NMDA channels affects spiking dynamics in Hodgkin-Huxley-like models

Authors: *M. M. KOWALSKI, M. M. MCCARTHY, N. KOPELL
Dept. of Mathematics and Statistics, Boston Univ., Boston, MA

Abstract: One of the most abundant ionotropic receptors for glutamate, the NMDA receptor, has received increased attention in recent years due to its fundamental role in synaptic plasticity, its dysfunction in the pathology of schizophrenia, and the prominent antidepressant, hallucinatory, and anesthetic effects induced by its direct channel blocker ketamine. At rest, closed NMDA channels trap physiologically available magnesium ions, which are expelled from the receptor during depolarization to make way for inward ion flow. Ketamine is believed to block NMDA receptors in a similar way to magnesium, but with higher affinity and higher net trapping, such that its negative effects on transmembrane currents persist for several seconds after application of glutamate to voltage-clamped cells. Previous studies report that high-dose ketamine anesthesia produces bursts of gamma oscillations in the EEG that appear regularly every 5-10 seconds and decay in frequency in a stereotypical fashion before disappearing completely for a couple of seconds. One possible explanation for the duration and frequency decay of these gamma epochs could be that high neural activity at the beginning of each burst facilitates ketamine entry into open NMDA channels, leading to progressive trapping and, in turn, periodic slowing and shutdown of the gamma-generating network. Given the complicated binding and trapping kinetics of ketamine, numerical network simulations are uniquely positioned to investigate this potential link, but all contemporary conductance-based models vastly reduce the complexity of NMDA kinetics by assuming instantaneous channel block. We thus incorporate a multiple-state, experimentally supported kinetic scheme of NMDA magnesium block into a Hodgkin-Huxley model of a single cell. We assume that ketamine acts via the same kinetic scheme as magnesium, but adjust for its higher affinity and trapping by increasing the rate constant of block. We find that, at the single-cell level, this significantly reduces excitability and produces a progressive decay in firing rate that can lead to complete shutdown of spike generation if the rate constant of block is set at a sufficiently high value. In the kinetic scheme we employ, this shutdown is partially driven by locking of the receptor into a distinct, desensitized state that requires a complete pause in input to recover the firing properties of the cell. We discuss the impact of extended trapping and blocking of NMDA receptors in the context of ketamine action on cortical network dynamics.

Title: Control astrocyte proliferation through manipulating NMDA receptor signaling in mouse brain

Authors: *Y. GENG[1], C. FU[1], Q. WANG[1], J. KAMINKER[2], M. H. SHENG[2], Y. CHEN[1]
[1]IRCBC, SIOC, Chinese Acad. of Sci., Shanghai, China; [2]Neurosci. Res., Genentech, South San Francisco, CA

Abstract: Astrocytic abnormality, such as alterations in its population, occurs in many brain diseases, but the underlying mechanisms are poorly understood. Particularly there is lack of tools to manipulate astrocyte proliferation to address the significance of alterations in its population. We report that astrocyte proliferation is bi-directionally regulated by neuronal activity via NMDA receptor (NMDAR) signaling in neurons. Using whole genome mRNA profiling, we found that a set of cell cycle-related genes were altered by prolonged treatment of hippocampal cultures with NMDAR antagonist AP5. These cell cycle-related genes were expressed in astrocytes rather than neurons. Consistent with this, NMDAR inhibition suppressed astrocyte proliferation, whereas NMDAR potentiation with a novel pharmacological tool promoted astrocyte proliferation *in vitro* and *in vivo*. In summary, we identified a mechanism regulating astrocyte proliferation and provided methods to manipulate it. These will be useful tools to study the functional significance of astrocyte.

Title: Synaptic network dysfunction in neurological disorders: Understanding the impact of rare genetic variants of NMDAR subunits in autism-spectrum disorders and epilepsy

Authors: *M. M. VIEIRA[1], S. LIU[2], K. W. ROCHE[3]
[1]NINDS, Building 35, Bethesda, MD; [2]GeneDx, Gaithersburg, MD; [3]RBU/NINDS, NIH, Bethesda, MD

Abstract: Neurological disorders, including autism-spectrum disorders (ASDs) and epilepsy (EPI) are highly prevalent, complex syndromes, with genetic and environmental components. Intensive research efforts have been made to identify the causative genes. Notably, selective clusters of genes with copy number variations and rare variants have been identified. One such cluster is the synaptic protein network, which suggests that proteins related to synaptic function and activity may be dysfunctional in these pathologies. One of the recurrently affected genes in ASDs is *GRIN2B*, which encodes for GluN2B, a subunit of N-methyl-D-aspartate receptors (NMDARs). Indeed, many rare variants of GluN2B have been identified in ASD probands. The GluN2A subunit, on the other hand, is commonly identified in patients with EPI. This suggests that NMDAR dysfunction may be relevant for these neurological disorders.
We screened a variety of rare variants within the C-terminal domain (CTD) of GluN2A/B subunits and their effects on receptor function, spine density, and on the molecular complex associated with the receptors. Because the NMDAR CTDs mediate protein-protein interactions with synaptic scaffolds and signaling molecules, these variants might disrupt coupling NMDAR activity to downstream pathways.
We observed that GluN2B rare variants identified in ASD patients caused dramatic changes on NMDAR and AMPAR surface expression, spine density, and the interaction with post-synaptic proteins. To assess the implications of these defects observed in primary cultures, we generated an animal model of one of these rare variants, S1413L. Our results demonstrate that indeed this rare variant of GluN2B results in defects in the post-synaptic network. We observed that the PSD fraction of the mouse hippocampus had reduced levels of the NMDAR subunits as well as MAGUKs and CaMKII. In the cortical PSD fractions, we did not detect such differences relative to WT animals. Interestingly, our GluN2A rare variants, that were identified in EPI patients, also showed reduced spine density. This effect implies a common mechanism of dysfunction underlying both ASD syndromes and EPI.
Overall, our work supports a model in which dysfunction of the synaptic protein complex underlies defects seen in ASD and EPI. Elucidating these mechanisms will pave the way to the development of novel therapeutic strategies for these disorders.

Title: Neurobeachin-mediated regulation of NMDA receptors and PSD-95 family members

Authors: *E. FINGLETON[1], K. W. ROCHE[2]
[1]NINDS, [2]RBU/NINDS, NIH, Bethesda, MD

Abstract: The PSD-95 family of scaffolding proteins regulate N-Methyl-D-Aspartate receptors (NMDARs), which play a key role in canonical forms of Long Term Potentiation (LTP). NMDARs are also key molecular players in neurological development and disease: over the course of development, NMDAR trafficking and expression patterns at the synapse versus extrasynaptic areas are dynamic and give rise to plasticity. PSD-95, among other scaffolding proteins, mediates NMDAR stability at the synapse. Neurobeachin, an autism candidate gene, is a known NMDAR interactor and regulator of spine dynamics. Neurobeachin has been shown to regulate the surface expression of several synaptic proteins, including NMDARs, and is thought to do so by facilitating local recycling. However, neurobeachin's role in shaping synaptic protein populations remains poorly understood. In the current study, we investigate the interaction between neurobeachin and PSD-95 family members. We virally transduce cortical neurons with shRNA to knock down neurobeachin expression and probe the role neurobeachin plays at the synapse throughout development. We find that neurobeachin differentially regulates synaptic expression of PSD-95 compared to other synaptic proteins. Furthermore, we find regulation of synaptic NMDARs by neurobeachin is developmentally-regulated and subunit-dependent.

Title: Non-ionotropic signaling through presynaptic NMDA receptors promotes neurotransmitter release in the developing retinotectal system

Authors: *M. VAN HORN, V. HIGENELL, E. S. RUTHAZER
Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada

Abstract: The NMDA receptor plays an important role in activity-dependent plasticity mechanisms underlying neural circuit formation. Recent experiments have reported NMDA receptor expression on presynaptic, as well as postsynaptic terminals. Presynaptic NMDA receptors (preNMDARs) have been found to modulate transmitter release and are essential for many forms of plasticity. Here we found evidence of preNMDARs on retinal ganglion cells (RGCs) in the *Xenopus laevis* tadpole visual system. Application of NMDA produced Ca^{2+} transients in RGC axon terminals separated from their somata, suggesting the presence of presynaptic NMDARs on RGC axons. Using whole cell electrophysiology, under postsynaptic NMDAR blockade, bath application of NMDAR antagonists, particularly targeting GluN2B-containing receptors, decreased miniature excitatory postsynaptic current (mEPSC) frequency. Moreover, the NMDAR antagonist APV resulted in a significant increase in paired -pulse ratios. These results suggest a presynaptic contribution of NMDARs to neurotransmission in the developing optic tectum. Interestingly, raising the animals in MK801, to block Ca^{2+} influx through the ion channel of the NMDARs, did not prevent the APV-induced decrease in mEPSC frequency, suggesting that presynaptic NMDARs in the optic tectum can signal non-ionotropically to regulate synaptic release. Taken together, these results suggest that NMDARs in RGCs modulate glutamate release via mechanisms both dependent and independent of Ca^{2+} influx through the ion channel.

Abstract: N-methyl-D-aspartate receptors (NMDARs) are ionotropic glutamate receptors that are critical for learning, memory and development. NMDARs are also involved in numerous diseases. In many pathological conditions NMDARs can become overactive and further disease progression. Molecules that inhibit NMDARs have been examined for their therapeutic potential in cases of pathological NMDAR overactivity. NMDAR inhibitors that act through an “open channel block” mechanism have shown significant therapeutic utility. Open channel blockers can enter the open NMDAR channel and bind there, preventing current flow. Memantine is an open channel blocker that is used to treat Alzheimer’s disease and shows promise in treating many other disorders. In addition to open channel block, memantine inhibits NMDARs through a second mechanism initially thought to involve memantine binding to NMDARs at a “superficial” site external to the pore. However, our recent data suggest that this second mechanism of inhibition involves accumulation of memantine in the membrane, followed by memantine transit from the membrane to the channel blocking site (membrane-to-channel inhibition, MCI). We further investigated MCI using whole-cell recordings from tsA201 cells transfected to express NMDAR subunits. Although very little uncharged memantine is present at physiological pH, experiments in which we varied pH suggest that the uncharged form of memantine is critical for MCI. The lack of MCI in experiments with a permanently charged trimethyl derivative of memantine also supports the importance of uncharged memantine in MCI. We used molecular modeling to predict a hydrophobic path through which memantine can travel during MCI, and examined the effects on MCI of mutating residues that line the putative hydrophobic path. We also discovered that numerous NMDAR channel blocking drugs in addition to memantine exhibit MCI. These data suggest a previously unexamined route of drug access to the NMDAR pore.

Title: Expression of GluN2C subunit in parvalbumin positive neurons and astrocytes: Relevance to schizophrenia

Authors: *P. J. GANDHI, G. SHELKAR, R. PAVULURI, J. LIU, S. DRAVID
Pharmacol., Creighton Univ. Sch. Of Med., Omaha, NE

Abstract: Functional deficit in NMDA-receptors on parvalbumin (PV)-positive neurons is central to the pathophysiology of schizophrenia. Despite the proposed relationship of GluN2C-expressing PV-interneurons to the NMDA receptor hypofunction hypothesis in schizophrenia, the precise expression pattern of GluN2C subunit remains unknown. Using a novel EGFP reporter model, we found the expression of EGFP (GluN2C) with PV positive neurons in nucleus reticularis of the thalamus, globus pallidus externa and interna, ventral pallidum and substantia nigra. Interestingly, EGFP (GluN2C) showed co-localization with the astrocytic marker in the striatum, cortex, hippocampus and amygdala but not with PV positive neurons. GluN2C was found to be enriched in several thalamic relay nuclei including first order and higher order nuclei. We also studied the behavioral effect of GluN2C and GluN2D ablation on pure C57BL/6N mouse strain. GluN2D knockout mouse exhibited hypo-locomotion and anxiety-like behavior. Increase in startle response was found for GluN2C heterozygous, GluN2D heterozygous and GluN2D knockout (KO) while no significant difference in prepulse inhibition (PPI) was observed. We also found that CIQ, a selective positive allosteric modulator for GluN2C/GluN2D subunit, reversed the MK801 induced impairment in PPI in GluN2C wildtype and heterozygous mice but not in GluN2C KO mice. Furthermore, we observed that GluN2C KO mice but not GluN2D KO mice were less sensitive to phencyclidine-induced hyperlocomotion, a model of psychosis. Together, these results identify a unique expression pattern of GluN2C subunit in neuronal and non-neuronal cell population. It also demonstrates that GluN2C rather than GluN2D may underlie phencyclidine-induced hyperlocomotion and facilitation of GluN2C subunit may reverse the schizophrenic phenotypes.

Abstract: N-methyl-D-aspartate receptors (NMDARs) are ionotropic glutamate receptors expressed at nearly all excitatory vertebrate synapses. NMDAR-mediated Ca^{2+} influx is essential for many critical neuronal functions and plays key roles in synaptogenesis, plasticity, dendritic integration, and cell survival. NMDAR dysfunction is implicated in nervous system pathologies such as neurodegenerative diseases, epilepsy, and cell death following stroke and ischemia. Thus, drugs targeting NMDARs are of great clinical interest. NMDAR channel blockers, antagonists that impede ion flux through NMDARs by physically occluding the channel, have shown significant therapeutic utility. Two of the most well-characterized and widely used NMDAR channel blockers are memantine (Mem) and ketamine (Ket). Despite sharing similar affinities, binding kinetics, and overlapping binding sites, Mem and Ket possess wildly divergent clinical profiles. Recent work from our lab has revealed substantial differences in how Mem and Ket act on NMDARs. Mem and Ket differentially augment NMDAR desensitization, with Mem enhancing Ca^{2+}-dependent desensitization of GluN2A-containing NMDARs. Here we test the hypothesis that the differential ability of Mem and Ket to augment NMDAR desensitization is due to differences in their interactions with the NMDAR channel. We used molecular simulations in which Mem and Ket were docked to our atomistic GluN1/N2A transmembrane domain (TMD) model to identify residues that differentially contribute to Mem and Ket binding. We then mutated channel residues predicted to specifically interact with Mem and examined effects on Mem and Ket potency. Whole-cell recordings from tsA201 cells transfected to express NMDARs revealed a mutation in the GluN2A TMD that altered Mem potency without affecting Ket potency, as predicted by our simulations. Strikingly, the mutation also powerfully enhanced NMDAR desensitization, suggesting that residues located in the Mem binding site are involved in the conformational changes associated with NMDAR desensitization. These experiments provide evidence that Mem and Ket interact with distinct NMDAR channel residues involved in NMDAR desensitization.

Abstract: N-methyl-D-aspartate receptors (NMDARs) are ionotropic ligand-gated glutamate receptors that mediate a slow, Ca^{2+}-permeable component of synaptic transmission that is critical for brain development and function, different forms of learning and memory, and cognition. NMDARs are obligate heterotetramers made up of two GluN1 subunits and two GluN2 subunits from four different genes (GluN2A-D). Hypofunction of NMDAR activity is hypothesized to play a role in multiple neurological diseases including schizophrenia, which has driven interest in the discovery of drug-like small molecule positive allosteric modulators (PAMs) of NMDAR function. Here, we describe modifications to the tetrahydroisoquinoline scaffold of GluN2C/GluN2D-selective PAMs that expands their activity to include actions at GluN2A- and GluN2B-containing di- and triheteromeric receptors. This series (EU-1180-55) was active at all NMDAR subtypes in transfected HEK cells. However, separation of EU-1180-55 into (*S*) and (*R*) enantiomers, revealed enantiomer-specific actions on NMDARs that contained different GluN2 subunits. Specifically, (*S*)- EU-1180-55 showed pan-potentiation whereas (*R*)- EU-1180-55 was only active at GluN2C- and GluN2D-containing NMDARs. We exploited our triheteromeric expression system in *Xenopus laevis* oocytes, which utilizes masking of endoplasmic reticulum retention signals for control of subunit stoichiommetry, to evaluate the actions of compounds on different triheteromeric receptors. Evaluation of the actions of these two enantiomers on GluN1/2A/2B, GluN1/2A/2C, GluN1/2A/2D, GluN1/2B/2C, and GluN1/2B/2D triheteromeric receptors revealed unique pharmacological properties (n=5 oocytes from 2-3 frogs). Furthermore, we observed enantiomer-specific modulation of the NMDAR-component of evoked EPSCs at the CA3-CA1 synapse from mouse hippocampal slices. (*S*)-EU-1180-55 significantly prolonged the weighted decay time constant by 1.36-fold when compared to (*R*)- EU-1180-55 (1.18-fold) or vehicle (1.04-fold, one-way ANOVA, $p<0.001$, Tukey post hoc, N=8 cells). In summary, evaluation of the effects of (*S*)- and (*R*)- EU-1180-55 on triheteromeric NMDARs revealed a novel pharmacological profile that may be useful to probe the role of NMDARs comprised of different subunits in circuit function.

Title: Grin2a knockout promotes hyperexcitability in the mouse hippocampus: A model to understand epileptic activity in grin2a lof variants

Authors: *C. R. CAMP, S. F. TRAYNELIS
Emory Univ., Atlanta, GA

Abstract: N-methyl-D-aspartate receptors (NMDARs) are ionotropic ligand-gated glutamate receptors responsible for mediating a slow, Ca2+ permeable component of fast excitatory neurotransmission. These receptors are critical for neuronal development, learning and memory, and general cognition. Although there is high selective pressure against variation in regions of the *GRIN* genes essential for receptor function, numerous variants have been identified in patients with a range of neurological disorders. Among the four GluN2-subunits (GluN2A-D), variants within the GluN2A subunit are most commonly associated with epilepsy. Particularly interesting are the *GRIN2A* loss-of-function (LOF) mutations, which make up 67% (14/21) of currently identified *GRIN2A* variants and present an epileptic phenotype. This finding suggests that hypofunction of GluN2A results in compensatory mechanism(s) that promote hyperexcitability. To study these LOF mutants, we have used a *Grin2a*-knockout (KO) mouse model. Mouse hippocampal brain slices were studied using whole-cell patch clamp and extracellular field recordings. Slices were exposed to elevated levels of extracellular potassium that can generate spontaneous epileptiform activity. All *Grin2a*-KO brain slices (N = 3 animals/5

slices) showed spontaneous interictal field bursts originating in the CA3 region and propagating to the CA1 region of the hippocampus in 7.0 mM extracellular potassium. By contrast, no wild-type (WT) slices showed epileptiform activity (N = 3 animals/3 slices). Additionally, *Grin2A*-KO mice display an increased inhibitory tone, measured by an increased frequency of spontaneous inhibitory postsynaptic currents and a large gabazine-sensitive current, onto CA1 pyramidal cells when compared to WT. A better mechanistic understanding of how the loss of GluN2A activity impacts neuronal development and promotes these compensatory changes may allow novel therapeutics to be identified that can be used to treat patients with LOF *GRIN2A* mutations.

Abstract: *N*-methyl-*D*-aspartate receptors (NMDARs) are excitatory ligand-gated ion channels that play critical roles in CNS. Many studies on NMDARs have been performed on diheteromeric receptors containing 2 GluN1 and 2 identical GluN2 subunits. Four genes encode GluN2 subunits (GluN2A-D), and most neurons express 2 or more GluN2 subunits. Multiple lines of evidence suggest that some native NMDARs are triheteromeric assemblies of 2 GluN1 and 2 different GluN2 subunits. However, there are a few studies of the functional properties for triheteromeric NMDARs due difficulties in expressing triheteromeric NMDARs in heterologous systems without also co-expressing diheteromeric NMDARs. We developed a strategy that utilizes masking of endoplasmic reticulum retention signals to express triheteromeric NMDARs with two different GluN2 subunits, allowing evaluation of their properties. We have successfully utilized this strategy to express triheteromeric GluN1/2A/2B, GluN1/2A/2C, GluN1/2A/2D,

GluN1/2B/2C, and GluN1/2B/2D combinations by optimizing the amount of cRNA injected into oocytes and the post-injection incubation time. We also developed control experiments to estimate the percentage of the current response arising from diheteromeric NMDARs that might reach the cell surface despite the absence of masking of the ER retention signal. This was done by introducing two agonist binding site mutations to each GluN2 subunit that eliminate glutamate binding. These mutations, referred to as RK+TI, are inserted in each GluN2 subunit to act as controls for escaped diheteromeric receptors. We measured the "escape current" as a fraction of the total triheteromeric current for all combinations (*n=5*). Because we observed substantial escape current when GluN2A or GluN2B were expressed with GluN2C or GluN2D (nearly 10% in oocytes), we developed an approach to further reduce escape current, thereby increasing the fractional current response accounted for by triheteromeric receptors. To do this we introduced the N624K pore mutation into GluN2C or GluN2D subunits. When GluN1/2A/2D(NK) was expressed in the presence of 0.1-1.0 mM Mg^{2+}, there was virtually no detectable escape current. Similar results were found for GluN1/2A/2C(NK), GluN1/2B/2C(NK), and GluN1/2B/2D(NK). The reduced escape current allowed accurate pharmacological characterization of triheteromeric NMDARs, which typically showed altered EC_{50} values for agonists, endogenous ions, and allosteric modulators compared to diheteromeric receptors. This work advances our ability to study triheteromeric NMDARs with reduced contribution from diheteromeric receptors.

Abstract: NMDA receptors (NMDARs) are important mediators of synaptic plasticity and memory. Native NMDARs consist of two GluN1 subunits with two GluN2A-D subunits, and possibly GluN3. The GRIN1 gene, which encodes GluN1 has 8 splice variants whereas the GRIN2s are unspliced. The functional roles for various GluN2 subunits in synaptic physiology have been well characterized but the biological functions of GRIN1 splice variants remain unknown in physiological contexts. Here, we examined the role of alternative splicing of GluN1 exon 5, which encodes the N1 cassette. We generated mice lacking exon 5 (GluN1a) or compulsorily expressing this exon (Glun1b). Here we show that GluN1a and GluN1b mice are viable, develop normally and have normal basal synaptic transmission at CA3-CA1 synapses of the hippocampus. The presence or absence of exon 5 did not change the input-output relationship of basal synaptic transmission. There were no significant differences between wild-type, GluN1a or GluN1b mice in their ratio of NMDAR- to AMPAR-mediated excitatory postsynaptic currents (EPSCs) nor in their paired-pulse ratio (PPR) of fEPSPs. Current-voltage relationship (I-V) of NMDARs does not change by exon 5 splicing, suggesting NMDAR channel function was not altered. However, we found that theta burst stimulation (TBS)-induced long-term potentiation (LTP) was significantly lower in hippocampal CA1 slices taken from GluN1b mice ($125.48 \pm 4.60\%$ n=10, $p<0.05$ vs WT or GluN1a) compared to slices taken from either wild-type ($150.39 \pm 4.61\%$, n=19) or GluN1a mice ($147.95 \pm 5.39\%$). In contrast, slices from GluN1a mice had significantly stronger LTP when induced by 20Hz stimulation versus GluN1b or wild-type slices ($148.03 \pm 2.86\%$ n=6 for GluN1a, $p<0.05$ vs WT or GluN1b; $130.15 \pm 1.64\%$ n=9 for WT; $130.02 \pm 2.26\%$ n=8 for GluN1b). Additionally, GluN1b mice had reduced learning and memory performance in the Morris-water maze test compared with wild-type mice while GluN1a mice performed better than wild-type mice. Together, these data show that splicing of exon 5 modulates LTP strength, and learning and memory behavior in mice. We have thus defined for the first time a biological function for alternative splicing of GluN1 in vivo.

Title: GluN1 N1-cassette regulates glycine-primed internalization and NMDA channel activity in hippocampal CA1 pyramidal neurons

Authors: *V. RAJANI, H. LI, A. S. SENGAR, D. CHUNG, L. HAN, M. W. SALTER
Neurosciences & Mental Hlth., The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: N-methyl-D-aspartate receptors (NMDARs) are a subtype of ionotropic glutamate receptors that play a central role in numerous physiological and pathological conditions of the central nervous system. NMDARs are assembled as tetramers composed of two GluN1 subunits and two of four possible GluN2 subunits. NMDARs are activated upon simultaneous binding of co-agonists glycine and glutamate to the GluN1 and GluN2 subunits, respectively. We reported previously that glycine (30μM-1mM) initiates a signaling event that primes the receptors for dynamin-dependent endocytosis upon addition of glutamate (*Nature* 2003). Here we show that glycine-primed internalization of recombinant NMDARs expressed in HEK293 cells is prevented by the presence of alternatively spliced exon 5 (N1 cassette) in GluN1. Western blot of co-immunoprecipitation revealed that glycine stimulation significantly increased the association of endocytosis adaptor protein AP-2 with recombinant NMDA receptors expressing exon 5-lacking (GluN1a) but not exon 5-containing (GluN1b) subunits. Secondly, high glycine did not induce the progressive, ~50% reduction in NMDAR-mediated current in HEK-293 cells expressing GluN1b subunits that we observed with cells expressing GluN1a subunits. To determine the role of alternative splicing of the N-terminal exon in neurons, we generated mice lacking exon 5 or compulsorily expressing this exon. In hippocampal slices from GluN1a mice, pretreatment with a high glycine concentration produced a subsequent and sustained decline in NMDAR-mediated synaptic currents (68.1±5.2 of baseline, n=13, $p<0.05$). However, in slices from GluN1b mice, NMDAR-mediated synaptic currents fully recovered to baseline levels (95.0 ± 6.5, n=7, p=0.22). Our results indicate that exon 5-lacking NMDA receptors are permissive to glycine primed internalization, while exon 5-containing NMDA receptors are not. This differential mechanism may regulate cell surface expression of NMDARs in neurons. Our findings suggest that GluN1a-NMDARs at synapses in the hippocampal pyramidal neurons may be primed for internalization by glycine, leading to the depression of NMDAR synaptic transmission.

Title: Phosphorylation of GluA1-S845 regulates clathrin-mediated endocytosis of AMPA receptors

Authors: *M. F. SATHLER[1,2], L. KHATRI[3], R. KUBRUSLY[4], S. KIM[2], E. ZIFF[3]
[1]Fort Collins, CO; [2]Biomed. Sci., Colorado State Univ., Fort Collins, CO; [3]Biochem. and Mol. Pharmacol., NYU Sch. of Med., New York, NY; [4]Physiol. and Pharmacolgy, Univ. Federal Fluminense, Niteroi, Brazil

Abstract: Introduction: During scaling-up, AMPARs accumulate at synapses, restoring synaptic strength. In most scaling-up protocols, GluA2-lacking AMPA receptors accumulate selectively at the synapse, despite the fact that the great majority of AMPARs are GluA1/2 heteromers. Although it has been shown that GluA1 S845 phosphorylation reduces endocytosis, the molecular basis for regulation of GluA1 endocytosis is not well understood. **Objective:** To study how GluA1 S845 phosphorylation regulates clathrin-mediated endocytosis during neuron activity. **Methods:** Cortical neurons were obtained from E18 Sprague-Dawley rat embryos and cultured as mixed cultures for immunofluorescence and co-immunoprecipitation, after 48h with TTX or chemical LTP induction. Membrane fraction of Sprague-Dawley rat whole brain was used for the GST pull-down assay. Unpaired two-tailed Student's t-tests were used in single comparisons. For multiple comparisons, we used one-way analysis of variance (ANOVA) followed by Fisher's least significant difference (LSD) test to determine statistical significance. P value < 0.05 was considered statistically significant. **Results:** Previous results from the group have shown that 48h TTX treatment increases GluA1 S845 phosphorylation (Kim and Ziff, 2014). 48h TTX treatment reduces GluA1 endocytosis (CTL=1; TTX=0.63±0.02) and increases surface expression (CTL=1; TTX=1.17±0.04). Blockage of dynamin with 25 µM Dynole increases binding of clathrin adaptor AP2 to GluA1 (CTL=1; DYN=1.46±0.13). 48h TTX treatment reduces B-Adaptin binding to GluA1 (CTL=1; TTX=0.43±0.11). Induction of chemical LTP increases phosphorylation of GluA1 S845 (CTL=1; cLTP=5.55±0.84) and decreases B-Adaptin binding to GluA1 (CTL=1; cLTP=0.24±0.08). GST pull-down assay show less binding of GluA1 to the S845D phosphomutant (GLUA1=1; S845D=0.31±0.06). **Conclusion:** TTX treatment for 48 hours, a well stablished scaling up protocol, diminishes GluA1 endocytosis rate and the binding of β-Adaptin, a subunit of the AP2 adaptor, to GluA1. GluA1 S845 phosphorylation decreases the binding of AP2 to the CTD of this AMPA receptor subunit, unveiling a mechanism of phosphorylation-regulated clathrin-mediated endocytosis of GluA1. **References**: Kim S, Ziff EB (2014) Calcineurin Mediates Synaptic Scaling Via Synaptic Trafficking of Ca2+-Permeable AMPA Receptors. Title: Photoactive unnatural amino acids reveal functional modules of the AMPA receptor membrane domain

Authors: *A. POSHTIBAN[1], M. H. POULSEN[2], V. GHISI[1], A. PLESTED[3]
[1]Leibniz-Institute For Mol. Pharmacol. (FMP), Berlin, Germany; [2]Univ. of Copenhage, Copenhagen, Denmark; [3]Biology, Cell. Biophysics, Humboldt Univ. zu Berlin, Berlin, Germany

Abstract: Ionotropic glutamate receptors (iGluRs) are ligand gated ion channels, which are fundamental for normal brain function and are proposed to be involved in numerous central nervous system (CNS) diseases. Consequently, considerable efforts have been dedicated to study the function of iGluRs. However, despite recent progress in resolving their structural architecture and dynamics, but current methods lack specificity in the membrane domain. Here, we present an optogenetic approach with the goal of elucidating receptor dynamics mediated by specific AMPA-type iGluRs. This method involves site-specific incorporation of unnatural amino acid (UAA) photo-crosslinkers by unnatural mutagenesis. Thus, we create photo-controllable AMPA receptors that can be regulated with high spatiotemporal precision, using light as the orthogonal input signal. We introduced the UAAs p-benzoyl-L-phenylalanine (BzF) and p-azido-L-phenylalanine (AzF) at individual sites throughout the transmembrane domain (TMD) of AMPA receptor subunits. Recordings of outside-out patches from HEK cells in combination with synchronised exposure to UV light via epi-illumination led to a range of effects on channel activity, from fast inhibition to potentiation. One of the most striking UV effects arose from the F579 site harbouring AzFin the base of the M2 re-entrant helix, which showed complex changes in receptor kinetics after crosslinking AzF upon UV illumination.Entry to desensitzation was reduced but the desensitized state also became more stable. These results suggest a distinct role of the M2 segment in channel gating, beyond its canonical role in ion selectivity

Title: Role of synaptic plasticity in AMPA receptor intracellular trafficking

Authors: *F. COUSSEN[1], E. HANGEN[2], F. CORDELIÈRES[3], J. PETERSEN[2], D. CHOQUET[4]
[1]Interdisciplinary Inst. of Neurosci. (IINS), Bordeaux Cedex, France; [2]Interdisciplinary Inst. for Neurosci., Bordeaux, France; [3]Bordeaux Imaging Ctr., Bordeaux, France; [4]UMR 5297 CNRS Univ. Bordeaux, Bordeaux Cedex, France

Abstract: Abundance of AMPA receptors (AMPARs) at the synapse is essential for the establishment and maintenance of synaptic function. Their synaptic localization is dependent on a highly dynamic exocytosis, endocytosis and plasma membrane mobility events. Our hypothesis is that synaptic localization of AMPARs is also regulated by their intracellular trafficking at basal state and during LTP. However, AMPARs post-ER trafficking toward the plasma membrane still remains poorly understood because of the lack of appropriate biological and imaging tools. Using a new biochemical tool combined with photonic live imaging, we controlled and followed the dynamic secretion of tagged GluA1 containing receptors in cultured rat hippocampal neurons and characterize AMPAR intracellular transport. These analyzes are performed in basal condition, during induction of LTP and 20-50 min after LTP. Finally we have studied the impact of GluA1 phosphorylation on its transport by expressing phospho-mimetic mutants known to be phosphorylated during synaptic plasticity.

Title: APP phosphorylation and internalization regulates synaptic removal of AMPARs

Authors: *S. N. GARCIA DUBAR[1], D. CASTELLANO[1], M. ABDEL-GHANI[1], A. SCHNEEWEIS[1], E. ANDRE[1], S. VICINI[2], D. T. PAK[3]

Abstract: Alzheimer's disease (AD), characterized by progressive cognitive impairment and neuronal cell death, is the most common neurodegenerative disorder. The initiating step in AD pathogenesis is considered to be the accumulation of amyloid beta (Aβ), a proteolytic cleavage product of amyloid precursor protein (APP) Thus, understanding the regulation of APP processing is critically important. Aβ production is known to be responsive to synaptic activity levels, and we have recently identified polo-like kinase (Plk) 2 as a novel molecular mechanism underlying synaptic activity-dependent production of Aβ. We identified two sites in the APP cytosolic tail (Thr668/Ser675) that were directly phosphorylated by Plk2 and regulated APP internalization as well as amyloidogenic processing. Here, we aimed to test the hypothesis that phosphorylation of APP by Plk2 at these residues governs the intertwined processes of APP internalization, production of Aβ, and synaptic removal of AMPARs. Hippocampal neurons from embryonic Sprague-Dawley rats were cultured and plated on poly-D-lysine coated glass coverslips. At DIV 19 neurons were transfected by Lipofectamine 2000 with constructs expressing either APP WT or APP-2A-HSP (Thr668/Ser675 sites mutated to nonphosphorylatable alanines). Forty-eight hours after transfection, the neurons were subjected to patch clamp electrophysiological analyses. Current clamp recordings from these neurons showed the occurrence of spontaneous paroxysmal depolarizing shift occurring at the frequency of ~1.9 Hz. AMPAR mEPSCs were recorded in the presence of 1 μm TTX and 25 μM bicuculline and morphological analysis of neuronal population subtypes was performed as described (Lee et al., Neuron 2013). In morphologically identified CA3 pyramidal neurons transfected with APP-2A-HSP, mEPSCs peak amplitude was significantly larger (-18.24±2.159 pA, mean±SEM) than in neurons transfected with APP-WT (-12.58±1.396 pA). No change was observed in mEPSC frequency or decay time. Our results support the hypothesis that APP phosphorylation and internalization regulates synaptic removal of AMPARs. Further

characterization of different APP phosphosite mutations under various synaptic plasticity paradigms will be presented. We propose that dysregulations in these mechanisms may contribute to synaptic deficits and disease progression in AD.

Title: Subunit-specific regulation of synaptic AMPARs by $step_{61}$

Authors: *S. WON[1], S. INCONTRO[3], Y. LI[1], R. A. NICOLL[4], K. W. ROCHE[2]
[1]NINDS, [2]RBU/NINDS, NIH, Bethesda, MD; [4]Dept Cell & Mol Pharmacol, [3]UCSF, San Francisco, CA

Abstract: AMPA receptors (AMPARs) are ionotropic glutamate receptors that mediate fast excitatory neurotransmission and are expressed throughout the central nervous system. AMPARs are composed of four subunits (GluA1-4), which combine to form tetramers, mostly heteromeric. In addition, AMPAR modulation is a critical mechanism that underlies many forms of synaptic plasticity. The precise regulation of AMPAR expression, trafficking, and localization is critical for proper neuronal function. Phosphorylation, a posttranslational modification, regulates surface and synaptic expression of AMPARs. The S/T phosphorylation of AMPARs has been well studied, whereas there are fewer studies on the role of tyrosine phosphorylation of AMPARs. It has been reported that tyrosine phosphorylation by Src family kinases regulates AMPAR trafficking by inhibiting endocytosis. Striatal-enriched protein tyrosine phosphatase (STEP) is a brain-specific protein tyrosine phosphatase. STEP has splice variants: $STEP_{61}$, $STEP_{46}$, $STEP_{38}$, and $STEP_{20}$. All variants are expressed in the striatum, whereas $STEP_{61}$ is only expressed in cortex and hippocampus. $STEP_{61}$ regulates a variety of synaptic proteins such as ERK 1/2, p38, Fyn, and Pyk2 kinases via dephosphorylation at regulatory tyrosine residues within their activation region, thereby inactivating them. $STEP_{61}$ also regulates NMDARs. In the case of GluN2B, $STEP_{61}$ dephosphorylates Y1472 in its endocytic motif and facilitates the internalization of GluN2B-containing NMDARs. To better understand the effect of $STEP_{61}$ on other receptors and synaptic proteins, we used mass spectrometry to identify the $STEP_{61}$ interactome using mouse cortex and hippocampus. We identified a number of known interactors

such as GluN2B, PSD-95, and Fyn, but also novel ones including the GluA2 subunit of AMPARs. Interestingly, the synaptic expression of the AMPAR subunit GluA2 and 3 are increased in STEP knockout mouse brain and knock-down of STEP increases AMPAR-mediated synaptic currents. Our findings demonstrate a differential effect of $STEP_{61}$ on NMDAR vs. AMPAR. In both cases, $STEP_{61}$ dephosphorylates receptors but there is an extrasynaptic effect on NMDARs. Therefore, we report a comprehensive list of $STEP_{61}$ binding partners, including AMPARs, and reveal a critical role for $STEP_{61}$ in regulating synaptic AMPARs.

Title: Regulation of AMPA receptor stability and trafficking by acetylation in Alzheimer's disease

Authors: *M. O'CONNOR[1], Y.-P. SHENTU[2], G. WANG[1], Y. ZHANG[1], R. LIU[2], H.-Y. MAN[1]

Abstract: AMPA receptors (AMPARs) mediate fast excitatory synaptic transmission. Regulation of AMPAR trafficking and surface expression is crucial for synaptic plasticity and brain functions such as learning and memory. Disruption in AMPAR postsynaptic surface expression can result in dysfunctional synaptic activity and ultimately impairments in brain function. We have recently reported that AMPARs are subject to lysine acetylation on GluA1 C-terminals. This post translational modification competes with ubiquitination, leading to increased stability by antagonizing receptor internalization and degradation. Here we show that p300 is the acetyltransferase responsible for this modification. In cultured hippocampal neurons, overexpression of p300 or activation of endogenous p300 results in an increase in AMPAR acetylation levels. This increase in GluA1 acetylation also results in an increase in both total and surface expression of AMPARs. We find that application of Aβ to neurons causes a reduction in AMPAR acetylation. Post-mortem brain tissue from Alzheimer’s Disease (AD) patients show a significant reduction in GluA1 acetylation and an increase in GluA1 ubiquitination compared

with age matched healthy controls. Consistently, an increase in acetylation of GluA1 ameliorates the Aβ-induced removal of AMPARs from the cell surface. Overexpression of acetylation-mimetic GluA1 (GluA1-4KQ) reduces Aβ-induced changes in GluA1 internalization and turnover. Likewise, overexpression of p300 in the presence of Aβ reduced the GluA1 internalization and degradation. These findings indicate that p300 functions as the acetyltransferase responsible for the lysine acetylation on AMPARs. AMPAR acetylation likely plays a key role in the aberrant alterations in AMPAR distribution and dynamics in AD.

Title: Claudins: A novel group of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) auxiliary proteins and a stepping stone to understanding transmembrane AMPAR regulatory protein function

Authors: *S. OBST[1,2,3], S. HAERING[1], A. KUZULU[1,4], M. HOLLMANN[1]

Abstract: Ionotropic glutamate receptors (iGluRs) are responsible for the majority of excitatory signal transmission throughout the central nervous system (CNS). Especially AMPA receptors (AMPARs) play an important role in fast signal transmission but are also crucial for the onset of learning mechanisms in the brain.
The group of transmembrane AMPAR regulatory proteins (TARPs) support AMPARs by interacting with them and modulating their functional properties. We recently identified the family of claudins, which show high structural homology to TARPs and were formerly only known to be involved in assembling tight junctions, as potential candidates for a new class of modulatory proteins of iGluRs and AMPARs in particular[1].
We now investigated additional claudins, co-expressed with the AMPAR GluA1(Q)flip from *in vitro*-transcribed cRNA injected into *Xenopus laevis* oocytes. Two-electrode voltage clamp was used to measure glutamate- and glutamate-trichlormethiazide-(TCM)-induced whole cell currents. Five to seven oocytes per condition and day were measured in at least three different oocyte batches, normalized to the mean current response of the receptor alone, and then pooled and statistically analyzed.

We identified another functionally interacting claudin that in oocytes shows a 10-fold higher modulation than the weakly modulating claudins 20 and 24 investigated before.[1] We also present screening data of the modulatory function of 24 mammalian claudins for homomeric GluA2(Q)flip and GluA2(R)flip receptors. Via domain exchange mutations and point mutations we investigated the mechanism of interaction and current modulation that might be shared between TARPs and modulatory claudins. A shared mechanism was expected due to their similar structure in, e.g., the transmembrane domain 4 (TMD 4) or the extracellular loop between TMD 3 and the extracellular β-sheet 5, which have been reported to be critical for TARP modulation.[2] Differences in structure, such as in the extracellular loop between β-sheets 1 & 2, shed light on the much more efficient modulatory properties of TARPs. These structural and functional similarities as well as the distinct differences between these two groups of proteins depict claudins as a stepping stone in the evolution of auxiliary protein modulatory function.

Title: Subunit organization in heteromeric AMPA receptors - Rules and functional consequences

Authors: *I. H. GREGER, H. HO, O. CAIS, B. HERGUEDAS, J. F. WATSON, B. KOHEGYI
MRC LMB, Cambridge, United Kingdom

Abstract: AMPA-type glutamate receptors (AMPARs) mediate the majority of fast excitatory neurotransmission in the brain. They belong to the ionotropic glutamate receptor (iGluR) family, consisting of four subfamily members that comprise tetrameric cation channels.
iGluRs predominantly assembly as heteromers – NMDA-type receptors (NMDARs) are strict (obligatory) heteromers, whereas AMPARs are preferential heteromers but they can also form homomers. The two subunit pairs in a tetramer are conformationally distinct in all three major iGluR subfamilies, with a pore proximal (A/C) chain pair and a pore-distal (B/D) pair. The B/D chains are believed to exert a greater force on the channel gate upon agonist-triggered channel

opening than the A/C pair. In NMDARs, GluN1 subunits occupy the A/C position and GluN2 subunits the B/D slots. This division of labour is expected to also pose constraints on the organization of AMPAR hetero-tetramers. However, current data on AMPAR subunit organization are conflicting. Here we present a series of functional and structural data investigating the architecture and organization of AMPAR heteromers and their consequence on receptor signalling in recombinant cells and at synapses of CA1 hippocampal neurons.

Abstract: The vast majority of excitatory neurotransmission is mediated by AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors. The functional receptor exists as a tetramer, either homomers or heteromers, from a repertoire of 4 different subunits, GluA1 - GluA4. It is well known that glutamate is a neurotoxin and it is proposed that overactivation of ionotropic glutamate receptors may underlie many neurodegenerative disorders such as ischemic stroke, epilepsy, Parkinson's and dementia, amongst others. Enhancement of AMPA receptor activation by, for example, BDNF, has been proposed to have beneficial effects of learning and memory and has potential therapeutic value in the treatment of depression, Huntington's and Parkinson's diseases. We have used GluA2 receptors expressed in HEK cells on 3 different automated patch clamp systems recording from either 1, 8 or 384 cells simultaneously. We have compared the glutamate EC_{50} obtained on the different platforms and found that they are similar, ranging from approximately 30 - 70 µM. Responses to glutamate were reproducible using a concentration of 30 or 100 µM, GluA2 could be repetitively activated at least 3 or more times, making the assay suitable for pharmacological characterization. Using pharmacological agents we could either inhibit or enhance the glutamate elicited responses. The inhibitor, CNQX, blocked glutamate responses mediated by GluA2 with an IC_{50} of 600 nM using a glutamate concentration of 100 µM and the concentration response curve for CNQX was dependent on the glutamate concentration. The potentiator, LY404187, was pre-incubated prior to co-application

with 100 µM glutamate giving an EC_{50} of around 500 nM. In addition to GluA2 expressed in HEK cells, we also recorded glutamatergic-enriched cortical neurons derived from induced pluripotent stem cells on an automated patch clamp platform. In these neurons we recorded NaV currents which could be blocked by low concentrations of TTX with an IC_{50} of 12 nM. In addition, glutamate responses were recorded which were potentiated by LY404187.

Abstract: Brain function and plasticity relies on the tight regulation of the stoichiometry of neurotransmitter receptors and other proteins at synapses. While the molecular mechanisms controlling synaptic incorporation of glutamate receptors are well described, what controls their removal from synapses remains to be found. Here we show that the complement-related transmembrane protein SUSD4 controls synaptic transmission and plasticity of excitatory synapses by tethering ubiquitin ligases of the HECT family and regulating AMPA receptor

turnover. SUSD4 is highly expressed in neurons during postnatal development, a time of intense synaptogenesis and synapse maturation. Affinity purification followed by mass spectrometry revealed that E3 ubiquitin ligases of the NEDD4 family bind to the cytoplasmic tail of SUSD4. Morphological analysis of *Susd4* knockout mice showed no deficit in excitatory synaptogenesis in cerebellar Purkinje cells. However, invalidation of *Susd4* led to increased transmission at Climbing Fiber/Purkinje Cell synapses, lack of climbing fiber-dependent Parallel Fiber long-term depression and facilitation of Parallel fiber long-term potentiation in *Susd4* knockout mice. This phenotype was accompanied by a deficit in motor coordination learning. Immunolabeling experiments and miniature EPSC analysis showed increased and more homogeneous GluA2 levels in Purkinje cells synapses in *Susd4* knockout mice when compared to controls, suggesting that SUSD4 is a tether for the machinery controlling GLUA2 degradation. This chaperone function in targeting HECT ubiquitin ligases could be a general mechanism allowing precise spatiotemporal control of the turnover of specific target proteins in cells.

Title: The phosphatase PTP-3/LAR regulates transport of AMPARs in the nematode *C. elegans*

Authors: *D. PIERCE[1], B. PULFORD[1], F. J. HOERNDLI[2]
[2]CVMBS, [1]Colorado State Univ., Fort Collins, CO

Abstract: Normal cognition is dependent on AMPAR (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor) trafficking, which includes local synaptic trafficking and long-distance transport. Previous work has shown a critical role for the phosphatase leukocyte common antigen-related protein (LAR), in regulating the trafficking of AMPARs to synapses. LAR activity is mediated by a member of the LAR protein tyrosine phosphatase-interacting protein family, Liprin-α. These studies have shown that the localization of LAR to synaptic spines is dependent upon the degradation of Liprin-α by Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII). However, despite this knowledge we do not know how LAR regulates AMPAR transport. One of our previous studies has shown that kinesin-mediated transport of

AMPARs is controlled by CaMKII. This suggests that LAR might be a downstream target of CaMKII in AMPAR transport regulation. This study aims to identify the function of LAR in long-distance AMPAR transport. Specifically, it will define the site of action of LAR on AMPAR trafficking as well as its role in the CaMKII signaling cascade regulating long-distance transport of synaptic AMPARs. We have previously established an imaging platform enabling the tracking and manipulation of *in vivo* AMPAR transport in real-time using the transparent model *C. elegans*. Here we combine this imaging approach using fluorescently labeled GLR-1 (GluA1 homologue) and genetic analyses to study the role of LAR in long-distance AMPAR transport *in vivo*. First, we measured synaptic SEP::mCherry::GLR-1 at proximal and distal synapses and found that synaptic GLR-1 were decreased at proximal synapses, but increased at distal synapses in LAR loss-of-function mutants. Next, we used time-lapse confocal imaging combined with photobleaching to track transport of single GLR-1 containing vesicles. LAR mutants display decreased transport of single vesicles. Lastly, we used fluorescence recovery after photobleaching (FRAP) and show that LAR mutants have decreased delivery of GLR-1 to synapses. Furthermore, LAR mutants exhibited a decrease in spontaneous reversals, a behavior dependent on functional synaptic GLR-1. Taken together, our results show a critical role of LAR in long-distance synaptic AMPAR transport. However, these results still leave some questions unanswered, for example: how does LAR interact with CaMKII in GLR-1 transport regulation? To better understand this, we will combine *in vivo* transport, LAR structure function analysis and CaMKII genetic epistasis analyses.

Abstract: Glutamatergic AMPA receptors (AMPARs) are abundant neurotransmitter receptors in the brain which are tightly regulated by a diverse array of synaptic auxiliary proteins. One AMPAR auxiliary protein whose precise function in the brain remains largely unknown is cornichon homolog-3 (CNIH3). Prior studies of cornichon homologs predominately focus on CNIH2, but a recent genome-wide association study (GWAS) of heroin users identifies single nucleotide polymorphisms (SNPs) in *CNIH3* correlated with protective effects against opioid dependence independent of *CNIH2*. Based on prior studies of CNIH3's effect on AMPAR activity and new evidence that CNIH3 may play a unique role in higher order behaviors, we hypothesize that CNIH3 regulates AMPAR-dependent memory and learning behavior through maintenance of AMPAR interactions with additional regulatory proteins and synaptic activity mediating synaptic morphology. To investigate the specific function of CNIH3, we use a C57BL/6 knock-down (KD) mouse line from the Knockout Mouse Project. *CNIH3* KD animals express 60% less *CNIH3* than wild-type (WT) and *CNIH3* expression is highest in the hippocampus. No compensatory overexpression of *CNIH2* is observed in the KD genotypes. To determine the effects of *CNIH3* KD on AMPAR levels at the synaptic membrane, hippocampal post-synaptic density (PSD) fractions of 6-8-week-old male and female mice are analyzed via western blot analysis. AMPAR subunit levels are not quantifiably changed at the PSD between genotypes, but a significant reduction in the excitatory scaffolding protein PSD-95 is observed in *CNIH3* KD females compared to WT. To investigate potential changes due to *CNIH3* KD in AMPAR protein interactions, co-immunoprecipitation assays targeting AMPAR subunits are performed to measure interactions with additional auxiliary proteins. To assess changes in synaptic integrity that may result from reduced PSD-95 at the synapse, dendritic spine density and morphology are compared between genotypes. Future studies will investigate the behavioral effects of *CNIH3* KD on memory and learning in a Barnes Maze assay, where animal performance is dependent on hippocampal AMPAR function. Sex differences in CNIH3 function are not reported in the present literature, making the discovery of a possible sex-difference in the effects of *CNIH3* KD an important subject for future investigation. Once we understand the cellular mechanisms of hippocampal CNIH3 responsible for mediating behavioral outcomes, we plan to investigate how *CNIH3* SNPs found in the human heroin users can mediate a protective effect on opioid dependence.

Title: Different molecular species of alpha-synuclein produce distinct effects on synaptic vesicle trafficking *in vivo*

Authors: *A. T. MEDEIROS[1], J. B. SANDERSON[2], H. JIANG[2], D. J. SELKOE[3], T. BARTELS[2], J. R. MORGAN[1]

Abstract: α-Synuclein is a 14 kDa presynaptic protein that normally regulates synaptic vesicle (SV) trafficking. Although the native forms of α-synuclein are debated, there is strong evidence that neurons generate both monomeric and multimeric α-synuclein under physiological conditions. Altering the balance of these normal molecular species of α-synuclein leads to its aggregation and contributes to neurodegenerative processes in Parkinson's disease (PD), dementia with Lewy bodies (DLB), and other synucleinopathies. Yet how each molecular species of α-synuclein affects synapses and impacts SV trafficking is not understood. We have started to address this by acutely introducing different forms of α-synuclein directly into lamprey giant reticulospinal synapses and determining the effects on SV trafficking. Using detailed ultrastructural analyses, we previously showed that both monomeric and dimeric recombinant α-synuclein severely impaired clathrin-mediated synaptic vesicle recycling. However, while the recombinant α-synuclein monomers inhibited clathrin uncoating, dimeric recombinant α-synuclein inhibited the earlier stage of vesicle fission, providing the first evidence that different molecular species of α-synuclein produce distinct effects on SV trafficking. Here, we focused on the effects of physiological α-synuclein isolated by size-exclusion chromatography (SEC) from healthy human brain, comprising a mixed population of α-synuclein that includes physiological tetramers as well as monomers. Although introduced intra-axonally at low nanomolar concentrations, synapses treated with SEC fractions rich in physiological α-synuclein exhibited a partial depletion of the SV pool, which was compensated by larger diameter SVs and increased number and size of large (>100nm) intracellular vesicles ("cisternae"), suggesting moderate effects on intracellular SV trafficking. However, unlike monomeric and dimeric recombinant α-synuclein, normal brain-derived α-synuclein produced no significant effects on clathrin-mediated synaptic vesicle endocytosis from the plasma membrane. These data provide additional evidence that different molecular species of α-synuclein can produce distinct effects on SV trafficking and suggest that physiological α-synuclein multimers may be partially protective against the deleterious effects of monomers. Ongoing experiments are aimed at identifying the underlying mechanisms and testing the effects of α-synuclein isolated from brains of patients with PD or DLB. Together, these studies should lend insights into the normal synaptic functions of α-synuclein and how these are altered in disease.

Title: Synapsin and alpha-synuclein co-regulate synaptic transmission in cultured hippocampal neurons

Authors: *D. GITLER[1], M. ATIAS[1], Y. TEVET[1], A. STAVSKY[1], S. TAL[1], J. KAHN[1], S. ROY[2]
[1]Dept. of Physiol. and Cell Biol., Ben-Gurion Univ. of the Negev, Beer Sheva, Israel; [2]Dept. of Neurosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Synaptic transmission is regulated by synapsin and alpha-synuclein (αsyn), the latter being prominently associated with neurological disease. These proteins inversely affect the density of vesicles in the presynaptic terminal and the overall capability of terminals to secrete neurotransmitter. We therefore hypothesized that synapsin and αsyn interact functionally to co-regulate synaptic properties. To test our hypothesis, we directly probed the proximity between synapsin Ia and αsyn and investigated their co-dependence in affecting vesicle recycling. Fluorescence resonance energy transfer (FRET) measurements illustrated that synapsin and αsyn are within molecular-interaction range of each other at rest, but that synaptic activity dissociates them. Moreover, we uncovered that deletion of the synapsins abolishes the inhibitory effect of αsyn on synaptic vesicle recycling, measured using synaptophysin-2XpHluorin and FM1-43. We found that the reduction in the relative size of the recycling pool of vesicles by αsyn was dependent on the presence of synapsins, as was the ability of αsyn to restrict synaptic vesicle mobility between synapses. Finally, the inhibitory effect of αsyn on neurotransmission was reinstated by the reintroduction of exogenous synapsin Ia in synapsin triple-knockout neurons. Our results thus show that key synaptic effects of αsyn are synapsin-dependent, they provide novel insight on the physiological role and interactome of αsyn, and suggest novel opportunities for therapeutic intervention.

Title: Hsc70 is an *in vivo* target of excess α-synuclein at synapses

Authors: *M. MCQUILLAN[1], A. T. MEDEIROS[1], S. M. L. BANKS[2], I. TESSARI[3], L. BUBACCO[3], R. SOUSA[4], E. M. LAFER[4], J. R. MORGAN[1]

Abstract: Parkinson's disease (PD) is characterized by atypical aggregation of α-synuclein in neurons, including at synapses. α-Synuclein is a presynaptically-localized protein that exists physiologically as monomers and multimers. Altering the balance of these normal molecular species leads to aggregation and toxicity in neurons. However, very little is known about how disease-related events, such as overexpression, multimerization or aggregation, affect presynaptic processes. We and others have shown that acute and chronic increases in α-synuclein levels inhibit synaptic vesicle (SV) recycling and/or re-clustering. The underlying mechanisms are presently unknown, prompting the current studies. Using lamprey giant reticulospinal synapses, we show that acute introduction of excess monomeric α-synuclein impairs the uncoating of clathrin-coated vesicles (CCVs) during clathrin-mediated SV recycling. Furthermore, α-synuclein interacts directly *in vitro* with Hsc70, the chaperone protein that serves as the clathrin uncoating ATPase at synapses. Immunofluorescence assays further revealed that increasing the levels of monomeric α-synuclein inhibited stimulation-dependent recruitment of Hsc70 to synapses, indicating that α-synuclein sequesters Hsc70 *in vivo*. Co-injection of exogenous bovine Hsc70 along with α-synuclein rescued the clathrin uncoating and endocytic defects, implicating Hsc70 as a possible ameliorator of α-synuclein induced synaptic defects. Recently, we have begun to examine the effects of α-synuclein multimers at synapses and their potential interactions with Hsc70. When acutely introduced to lamprey synapses, dimeric α-synuclein also inhibited clathrin-mediated SV recycling. However, unlike monomers, dimeric α-synuclein impaired an earlier stage of vesicle fission, while the CCVs were unaffected, indicating that different molecular species of α-synuclein produce distinct effects at synapses.

Further supporting this idea, preliminary data suggest that α-synuclein dimers increase the amount of Hsc70 at unstimulated and stimulated synapses, relative to monomeric α-synuclein. This observation provides additional evidence that α-synuclein targets synaptic Hsc70 *in vivo* and may also explain why CCV uncoating is unaffected under these conditions. Ongoing experiments will determine whether α-synuclein dimers and other multimers functionally interact with Hsc70. Taken together, these data implicate synaptic Hsc70 as a target of excess α-synuclein at synapses and provide mechanistic insight into the α-synuclein induced synaptic defects associated with PD and other synucleinopathies.

Title: Endocytosis is the primary target for short-term overexpression of alpha-synuclein

Authors: X. WU[1], T.-W. LIN[1], W. JANG[2], H.-Y. YUE[1], *J. XU[3]
[1]Dept Neurosci. and Regenerative Med., Augusta Univ., Augusta, GA; [2]Neurosci. and Regenerative Med., Med. Col. of Georgia At Augusta Univ., Lawrenceville, GA; [3]Dept. of Neurosci. and Regenerative Med., Med. Col. of Georgia, Augusta Univ., Augusta, GA

Abstract: Multiplication and mutations of alpha-synuclein, a protein primarily located at nerve terminals, are one of the major risk factors in familial and sporadic Parkinson's disease as well as dementia with Lewy bodies. At the cellular level, short-term overexpression or acute oversupply of alpha-synuclein in neurons has been reported to change the cellular excitability by forming non-selective ion pores, affect Ca channel partition by reducing membrane cholesterol, impair neurotransmission by disrupting vesicle clusters, and reduce vesicle supply by inhibiting endocytosis. These findings raise an interesting question as to which process is the initial and more vulnerable target for increased levels of alpha-synuclein. To address this question, we first performed whole-cell patch-clamp recordings at the calyx of Held terminals from postnatal 8-10 days old (P8-10) control mice and transgenic mice that selectively overexpress human A53T alpha-synuclein. Compared to control, calyx terminals from the transgenic mice did not show any change in the resting membrane potential, action potential firing, the amplitude voltage-gated Ca^{2+} channel current, or the voltage-dependence of Ca^{2+} channels. Endocytosis, instead, was significantly reduced in mutant terminals. These results suggest that excess A53T alpha-

synuclein preferentially disturbs endocytosis. To test whether similar effects occur in conventional synapses, we transfected the primary cultures of mouse hippocampal neurons with plasmids to overexpress human wild-type or mutants of alpha-synuclein. By pHluorin imaging, we found that overexpression of wild-type alpha-synuclein or A53T synuclein inhibited endocytosis of vesicular membrane proteins, synaptobrevin and synaptophysin, following exocytosis. Overexpression of A30P alpha-synuclein did not cause significant change to endocytosis. Taken together, we conclude that membrane endocytosis is the initial target regulated by increased levels of alpha-synuclein both in large nerve terminals and small conventional boutons. The mechanisms of such regulation are under investigation.

Abstract: L1CAMs are cell adhesion molecules involved in the development of the nervous system. As transmembrane proteins, L1CAMs transduce extracellular signals into cellular responses that require cross-talk with the cytoskeletal and intracellular signaling networks. Mutations in L1CAMs are directly linked to the neurological L1 syndrome and are implicated in neuropsychiatric disorders such as schizophrenia, the autistic spectrum disorder, and addiction. L1CAMs are conserved in vertebrates as well as invertebrates such as *Caenorhabditis elegans* and *Drosophila melanogaster*. Previous studies in *C. elegans, Drosophila* and mice revealed developmental roles for L1CAM including the axon guidance and dendrite morphogenesis, as well as maintenance of neural integrity. We recently uncovered a non-developmental role for *C. elegans* L1CAM, which is encoded by the *sax-7* gene, in promoting coordinated locomotion. *sax-7* genetically interacts with *rab-3*, *unc-13*, and *snb-1*, genes that function in the synaptic vesicle cycle, resulting in synthetic uncoordinated (Unc) locomotion. To determine the basis of the synthetic Unc phenotype, we performed a genetic suppressor screen and identified loss-of-function mutations in *ksr-1*, which encodes a scaffolding protein that facilitates MPK-1/Erk

activation. In addition to these genetic and behavioral findings, we have conducted electrophysiological and electron microscopy (EM) analyses to examine how SAX-7 and MPK-1/Erk signaling promote locomotion. The preliminary electrophysiology results show changes in evoked synaptic release consistent with the involvement of these genes in the synaptic transmission. These findings are further supported by high pressure freeze EM (HPF-EM) analysis. Together these functional data provide new insights into the interpretation of the behavioral phenotypes and the underlying circuitry involved.

Title: Acute photoinactivation of a cGMP-dependent protein kinase reveals multiple synaptic functions at the *Drosophila* larval neuromuscular junction

Authors: *J. S. DASON[1], A. M. ALLEN[2,3], O. E. VASQUEZ[3], M. B. SOKOLOWSKI[3]
[1]Univ. of Windsor, Windsor, ON, Canada; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Kinases are pleiotropic and regulate a wide range of processes in neurons. However, it remains challenging to test the functions of kinases in processes that are tightly coupled owing to the inability to inactivate them with a high spatiotemporal resolution. For example, cGMP-dependent protein kinase (PKG) has been implicated in both synaptic vesicle (SV) exo- and endocytosis. These processes are tightly coupled, thus pharmacological and genetic approaches are unable to distinguish whether PKG affects both processes separately or only one with concomitant effects on the other. Here, we tagged the *Drosophila foraging* (*for*) gene, which encodes a PKG, for fluorescein-assisted light inactivation (FALI). We uncoupled SV exo- and endocytosis using a *shibire* temperature-sensitive dynamin mutant and then inactivated FOR with FALI. We discovered a dual role for presynaptic FOR, where FOR inhibits exocytosis during low frequency stimulation and facilitates endocytosis during high frequency stimulation. Additionally, glial FOR negatively regulates nerve terminal growth and this developmental effect

was independent from FOR's effects on neurotransmission. Our findings demonstrate the multifaceted nature of kinases and the need to inactivate them with high spatiotemporal resolution.

Title: The effect of acute ATP depletion on synaptic vesicle endocytosis visualized at the ultrastructural level

Authors: *Q. GAN[1], S. WATANABE[2]
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept. of Cell Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: Following synaptic vesicle fusion at the presynaptic terminal, vesicular membrane and proteins must be retrieved via endocytosis to replenish the vesicle pool. A recent study revealed using the pHluorin assay that local depletion of ATP at presynaptic terminals impairs the rate of vesicle cycling during sustained synaptic activity, possibly by blocking endocytosis. However, due to limitations inherent to the pHluorin approach, it is unknown which exact step in the vesicle cycling process is most sensitive to the availability of ATP. In the present study, we used time-resolved electron microscopy to capture rapid ultrastructural changes in the presynaptic membrane of cultured hippocampal neurons at various time points following stimulation. We combined this method with drug treatments that acutely block ATP synthesis, and found that acute ATP depletion leads to the arrest of spontaneous as well as activity-induced synaptic vesicle endocytosis at early stages. In addition, blocking oxidative phosphorylation alone has a weaker effect than blocking both oxidative phosphorylation and glycolysis. This suggests that anaerobic glycolysis alone might be able to partially meet the energy demand of vesicle cycling. Our results shed new light on the energetics of synaptic vesicle endocytosis, and may have important implications for the pathophysiology of brain ischemia.

Title: Differential effects of the neurotoxin taipoxin on distinct forms of endocytosis at central nerve terminals

Authors: *W. JANG, T.-W. LIN, H.-Y. YUE, S. LI, J. XU
Neurosci. and Regenerative Med., Med. Col. of Georgia, Augusta Univ., Augusta, GA

Abstract: Nerve terminals require endocytosis to maintain neurotransmission and synapse integrity. Depending on the intensity of neuronal activity, endocytosis involves different molecular machineries and demonstrates different forms, for example, slow endocytosis, rapid endocytosis, and endocytosis overshoot. To understand the different mechanisms underlying each form of endocytosis, it is important to have genetic and pharmacological tools that selectively inhibit or preserve that form. A snake neurotoxin, taipoxin, has long been known to block neurotransmission by impairing vesicle recycling. However, it remains a question as to whether taipoxin selectively affects any form(s) of endocytosis. Here, using whole-cell membrane capacitance measurements, we studied the effects of acute dialysis of taipoxin at the calyx of Held, a large auditory central synapse accesible to patch clamp technique. In control at 21-24 °C, stimulation with a train of ten 20 ms depolarization pulses at 10 Hz induced vesicle exocytosis followed by rapid endocytosis and slow endocytosis. Dialysis of taipoxin led to severe block of both forms of endocytosis. Taipoxin increased the amount of exocytosis induced by the first stimulation, but reduced it for the subsequent stimulation likely because releasable vesicles were depleted. In control at 33-35°C, stimulation with 500 action potential-like pulses induced excess endocytosis, in which the retrieved membrane exceeds the fused membrane in quantity. Dialysis with taipoxin caused partial inhibition of excess endocytosis. Combination of taipoxin and the nonhydrolyzable ATP analog ATPγS did not produce additional inhibition of excess endocytosis. As we recently found, ATP hydrolysis is required for slow endocytosis and rapid endocytosis, but not for the retrieval of pre-existing membrane that contributes to excess endocytosis. Collectively, our results suggest that taipoxin can be used to isolate endocytosis of pre-existing membrane and dissect mechanisms of endocytosis in future studies.

Title: Selective cleavage of synaptobrevin by botulinum toxins reveals the prefusion state of the SNARE complex

Authors: *J. BRADY, A. VASIN, M. BYKHOVSKAIA
Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: Neurons release neurotransmitters via the fusion of synaptic vesicles with the neuronal plasma membrane. Vesicle are attached to the membrane via the SNARE complex, a coil-coiled four-helical bundle which includes the vesicle attached protein Synaptobrevin (Syb) zippered onto the membrane associated t-SNARE bundle. It is thought that Syb is partially unraveled in the prefusion SNARE state, however, the specific structure of the partialy zippered prefusion SNARE complex is still debated. The cytosolic protein Complexin (Cpx) interacts with the SNARE complex and inhibits spontaneous vesicle fusion, possibly by preventing the full SNARE zippering. To investigate the pre-fusion state of the SNARE complex, we took advantage of botulinum neurotoxins (BoNT) that cleave unstructured Syb at distinct sites: serotype G, which cleaves Syb at the membrane proximal site (Layer 7), serotype B, which cleaves Syb at a more distal site (Layer 6), and serotype D, which cleaves Syb in the middle of the SNARE bundle in the vicinity of the ionic layer. BoNT mixed with a water soluble fluorescent dye was loaded through a suction pipette into a cut axon at the Drosophila larval neuromuscular junction (NMJ). The spontaneous activity was recorded continuously for thirty minutes from individual boutons at abdominal muscles 6 or 7 with focal macropatch electrodes. To minimize the loading time, we selected the boutons closest to the axon. In the end of each recording, we ascertained that the fluorescent dye reached the bouton. We found that serotype G, in contrast to other serotypes, produced a rapid depression of the spontaneous transmission, suggesting that in the prefusion SNARE state Syb is unraveled up to the Layer 6. To understand the role of Cpx in regulating the prefusion state of the SNARE complex, we repeated these experiments at the cpx-/- Drosophila line. Our results are consistent with the model wherein Cpx promotes a partially unzippered state of Syb.

Title: Isoflurane inhibits presynaptic vesicle fusion machinery, thereby preferentially blocking high frequency excitatory neurotransmission

Authors: *H.-Y. WANG[1], K. EGUCHI[2], T. TAKAHASHI[3]
[1]Okinawa, Japan; [2]Mol. Neurosci. group, Inst. of Sci. and Technol. Austria, Klosterneuburg, Austria; [3]Cell. and Mol. Synaptic Function Unit, Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: Volatile anesthetics are widely used to lower the level of consciousness for surgery and animal experiments, but their primary cellular target remains unidentified. At mammalian central synapses, the volatile anesthetic isoflurane attenuates transmitter release. At the calyx of Held in rat brainstem slices, quantal analysis indicated that isoflurane reduces both the release probability and the number of functional release sites. In presynaptic recording, isoflurane is shown to directly inhibit Ca^{2+} channels. Presynaptic membrane capacitance measurements revealed that isoflurane inhibits Ca^{2+} influx-independent component of exocytosis evoked by long pulses. In simultaneous recording of presynaptic and postsynaptic action potentials evoked by repetitive stimulations, isoflurane preferentially impaired fidelity of high-frequency transmission, with no effect on low-frequency transmission. We conclude that the primary target of isoflurane anesthesia is vesicle fusion machinery, which supports high-frequency bursts of postsynaptic action potentials required for the maintenance of consciousness.

Title: Neonatal exposure to anesthesia inhibits key protein regulators of synaptic vesicles docking and fusion

Authors: N. ATLURI, B. FERRARESE, H. OSURU, C. KELLER, R. SICA, Z. ZUO, *N. LUNARDI
Anesthesiol., Univ. of Virginia Hlth. Syst., Charlottesville, VA

Abstract: Introduction: The effects of general anesthetics (GA) on synaptic vesicle exocytosis remain largely unexplored. In particular, it is not known how GA affects neurotransmitter release proteins during brain development. We previously demonstrated long-lasting decrease in the number of readily releasable vesicles docked at the active zone of CA1-subicular pre-synaptic boutons several days after neonatal GA. Here we test the hypothesis that the observed decrease is due to GA-induced impairment of transmitter release proteins involved in docking and fusion of vesicles to the pre-synaptic plasma membrane.
Methods: On postnatal day 7 (P7, peak of synaptogenesis) rats of both sexes were randomly allocated to receive a) sevoflurane 2.5% and oxygen (O2) 40% for 5 h or b) midazolam 9 mg/kg intraperitoneally, followed by 6 h of nitrous oxide 70%, isoflurane 0.75% and O2 30%. Sham-control rats were administered O2 40%, or intraperitoneal DMSO and O2 30%, respectively. Brains were harvested and the CA1-subiculum collected under a dissecting microscope. Protein and mRNA expression/activation levels of synapsin 1 (SYN 1), its active phosphorylated form (p-SYN 1, a critical effector of vesicle docking), and synaptotagmin 1 (SYT 1, a key facilitator of vesicle fusion) were measured using western blot and quantitative polymerase chain reaction, at 3 developmental time points: 24 h after GA (P8), 5 days after GA (P12) and at P24 (an age that approximates early adolescence in rats). The presence of developmental learning/memory deficits was assessed using the Barnes Maze at P30. Experimenters were blinded to experimental condition.
Results: We found a significant decrease in the levels of SYN 1 (N=12/group, p=0.009 and p=0.008), p-SYN 1(N=12/group, p=0.001 and p=0.03) and SYT 1 (N=12/group, p<0.0001 and p=0.001) at P12 and P24 in rats exposed to midazolam-nitrous oxide-isoflurane. These animals also exhibited a significant decrease in mRNA levels of SYN 1 (N=7/group, p=0.009) and SYT 1 (N=7/group, p=0.0007) at P8. Rats exposed to sevoflurane displayed a significant decrease in SYN 1 at P8 (N=12/group, p=0.02) and P12 (N=12/group, p=0.008). Female rats exposed to midazolam-nitrous oxide-isoflurane (N=9/group) exhibited impairments in long-term at P41 (p=0.03), but not short-term, memory. Female rats exposed to sevoflurane (N=10/group) showed impaired learning during day 3 of task training (p=0.03), and impaired short-term (p=0.01) at P34 and long-term (p=0.01) spatial memory.
Conclusions: Exposure to GA during brain development may depress synaptic vesicle exocytosis by impairing the expression of key pre-synaptic proteins that regulate vesicle docking and fusion.

Title: Synaptotagmin III regulates exosome export through calcium binding to the C2AB domains

Authors: N.-Y. YU[1], Y.-H. TSAI[1], H.-J. YANG[4], *C.-T. WANG[5,1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan; [5]Taipei, Taiwan

Abstract: The Synaptotagmin (Syt) protein superfamily, serving as calcium sensor during calcium-dependent exocytosis, consists of two calcium-binding C2 domains (C2A and C2B). Upon calcium binding, Syt-C2AB interacts with SNAREs, thus triggering vesicle fusion. Among Syt isoforms, Syt III particularly consists of six calcium-binding sites. We previously found that through calcium binding to the C2AB domains, Syt III can regulate the fusion pore kinetics of dense-core vesicles (DCVs) and modulate the interaction with a t-SNARE, SNAP-25. Because Syt III is localized mainly to plasma membrane but partially to DCVs, we speculated that in addition to vesicle fusion, Syt III may mediate other cellular functions. Previous studies showed that one type of extracellular vesicles (exosomes) can be released in a calcium-dependent manner. Syt VII, an isoform similar to Syt III, can regulate exosome export, leading to a hypothesis that Syt III may also regulate exosome export. However, there is no evidence for this up to date. In this study, we determined the role of Syt III-C2AB in regulating exosome export. After overexpressing Syt III or Syt III-C2AB* (a mutant harboring the weakened calcium-binding ability in the C2AB domains) in PC12 cells, we detected the changes in subcellular localization of exosomes with the marker, CD9 or CD63. The results from immunofluorescence staining demonstrated that in the absence of high-KCl stimulation, Syt III was evenly distributed in the cytoplasm, but localized to plasma membrane upon high-KCl treatment. Moreover, upon high-KCl stimulation, overexpressing Syt III enhanced exosome export. By comparing with Syt III-overexpressing cells, exosome export was disturbed in cells overexpressing Syt III-C2AB* upon KCl depolarization. Furthermore, by harvesting the KCl-treated medium to isolate exosomes for western analysis, we confirmed that Syt III-C2AB* reduced the amount of exosomes secreted to the medium compared to Syt III. In conclusion, our results suggest that Syt III regulates exosome export through calcium binding to the C2AB domains.

Title: Age-related cognitive impairment: Role of reduced synaptobrevin-2 levels in the decline of learning and memory

Authors: *F. DEAK[1,2,3]
[1]ROCA/Geriatric Med., Univ. of Oklahoma, Oklahoma City, OK; [2]Oklahoma Ctr. for Neurosci., Oklahoma City, OK; [3]Geriatric Med., Univ. Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Introduction: Age related cognitive decline is one of the major disabilities that affect the elderly. It is estimated that number of patients suffering from dementia will reach 10 million in the United States by the year 2030 with significant socio-economic impacts. Synaptic plasticity is a central mechanism in learning and memory and synaptic dysfunction is emerging as the major cause of mild cognitive impairment and dementia. The cellular and molecular changes leading to cognitive decline with age remain elusive. Synaptobrevin-2 (syb2), the major vesicular SNAP receptor protein, highly expressed in the cerebral cortex and hippocampus, is essential for synaptic transmission. We have analyzed syb2 protein levels in mice and found a decrease with age. We hypothesized that reduction of syb2 protein levels with age mediates cognitive decline.
Methods: To investigate the functional consequences of lower syb2 expression we have used adult syb2 heterozygous mice ($syb2^{+/-}$) with reduced syb2 levels. This allowed us to mimic the age-related decrease of syb2 in the brain in order to selectively test its effects on learning and memory. We performed behavioral tests for spatial learning and memory using the radial-arm water maze (RAWM) and a complex cohabitate environment called Intellicage. Neuronal plasticity was assessed by long-term potentiation (LTP) assays on hippocampal slices. We used live fluorescence microscopy to measure the synaptic vesicular (SV) release rate in neuronal cultures.
Results: We found that syb2 knock-out mice express syb2 at about the same level at 12 month-of-age as old (24 mo) wild-type animals. This is 50-60% of the protein levels found in young wild-type littermates (n=3, $p<0.01$, Student t-test). $Syb2^{+/-}$ mice maintained basic spatial memory acquisition for simple place finding (RAWM) but was impaired in spatial memory and learning complex tasks in Intellicage at age of 12 mo compared to WT (n=7-14). $Syb2^{+/-}$ hippocampal

neurons had reduced release probability, reduced synaptic plasticity and impaired LTP in the CA1 region. Syb2$^{+/-}$ neurons also have lower vesicular release rates (~35% reduction at 15 seconds, $p<0.01$ compared to WT). We also obtained results from 24 mo syb2$^{+/-}$ animals, which had impaired learning and memory skills as they perform worse at this age in the radial arm water maze assay.
Conclusions: Our study demonstrates that reduced syb2$^{+/-}$ expression with age is sufficient to cause cognitive impairment.

Title: Epac interacts with rim1α and acts on presynaptic long-term potentiation in the cerebellum

Authors: *W. XIN-TAI[1], F.-X. XU[2], Y. SHEN[3]
[1]Keyan B511, Dept. of Neurobio., Zhejiang Univ. Sch. Of Med., Zhejiang, China; [2]Zhejiang Univ. Sch. of Med., Hangzhou, China; [3]Zhejiang Univ. Sch. Med., Hangzhou, China

Abstract: Different forms of plasticity in Purkinje cells (PCs) are important for the cerebellum-related motor learning and brain disorders. cAMP plays a central role in a presynaptic long-term potentiation (LTP) at the parallel fiber-PC synapses. However, the downstream machinery that is involved in this presynaptic LTP is unclear. Here, we investigated the roles of EPAC1 and EPAC2, the cAMP effectors, in 8-Hz stimulation-induced presynaptic LTP at parallel fiber-PC synapses. The deletion of EPAC1 and EPAC2 did not affect the cyto-architecture of the cerebellum. However, both 8-Hz LTP and forskolin-mediated potentiation of parallel fibers neurotransmission were impaired, demonstrating that EPAC contributes to cAMP-dependent potentiation of transmitter release. We also found that synaptic facilitation during short trains was affected by loss of EPAC, which was further corroborated by the reduction of docked vesicle number in EPAC double-knockout mice. We continued to find that EPAC interacted with Rim1α and modulated its activity. Apply EPAC agonist 8-pcpt increased Rab3A-RIM1α-Munc13-1 tripartite complex, and EPAC ablation reduced Rab3A-RIM1α-Munc13-1 tripartite complex in the cerebellar synaptosome fraction. Together, our data demonstrate that EPAC is a novel regulator for
Rim1α and the maintenance of RRP at presynaptic sites, and also associated with presynaptic PC-LTP.

Keywords: EPAC; Rim1α; cAMP; Purkinje cell; cerebellum

Abstract: Synaptic transmission relies on regulated cycles of synaptic vesicle exocytosis and endocytosis in the presynaptic terminal. To guarantee an efficient release, dysfunctional presynaptic proteins and organelles have to be continuously removed through endosomal sorting and autophagy. Alterations in synaptic vesicle recycling and in the endosomal-autophagic pathway have been extensively linked to neurodevelopmental abnormalities and neurodegeneration, as they directly impact on neuronal survival, synaptic transmission and plasticity. Several proteins have a well-known function in the regulation of synaptic vesicle recycling and of endosome-autophagosome trafficking in the presynaptic terminal, but the identification of new molecular players is desirable to draw a complete picture of these processes and to enhance the possibilities of targeted drug design. We used the algorithm GAMMA (Global Microarray Meta-Analysis) to search for uncharacterized genes with a putative function in synaptic vesicle recycling. We identified APache (*Kiaa1107*) as a novel regulator of clathrin-mediated endocytosis of synaptic vesicles and of autophagosome trafficking. APache is highly enriched in the central nervous system, with the highest levels of mRNA and protein in the cerebral cortex, hippocampus and striatum. Its expression is neuron-specific and developmentally regulated in both mouse brain and primary neurons. APache interacts with the

clathrin adaptor protein complex AP-2 and participates to clathrin-mediated endocytosis. In mature neurons, ultrastructural analysis of presynaptic terminals reveals that APache knockdown induces a significant reduction of synaptic vesicle density and of clathrin-coated vesicles. This is accompanied by an accumulation of enlarged endosomes and autophagic vacuoles at presynaptic terminals. Finally, APache silencing decreases excitatory synaptic transmission and affects early neuronal development *in vitro* and *in vivo*. Until now, genetic mutations have not been identified in the human *KIAA1107* gene. However, our data suggest that future studies should address whether altered levels of APache might contribute to neurodevelopmental and/or neurodegenerative diseases.

Title: Dynamin-1 restrains vesicular catecholamine release to a sub-quantal mode in mammalian adrenal chromaffin cells

Authors: *Q. ZHANG, Q. WU, B. LIU, Y. LI, X. WU, F. ZHU, Z. ZHOU
Peking Univ. Inst. of Mol. Med., beijing, China

Abstract: Dynamin 1 (dyn1) is required for clathrin-mediated endocytosis in most secretory cells, including neurons and neuroendocrine cells. In 1996, we first reported two modes of Ca^{2+}-dependent catecholamine release from single large dense-core vesicles: quantal through “full-fusion-like” (FFL) and sub-quantal through "kiss-and-run" (KAR) in adrenal chromaffin cells (ACCs), which have been confirmed by us and others. Quantal size (QS, catecholamine release per exocytotic event) is increased by acute pharmacological manipulation of dyn1, however, the nature of previously-assumed full-quanta and KAR sub-quanta remain hotly debated. Here, using genetic dyn1-knockout (KO) ACCs, we showed that 1) KO increased QS (both average and largest QS) by ≥200% without increasing the vesicle size and vesicular content; 2) the KO-induced increase in QS was rescued by overexpressing WT-dyn1 (but not its deficient mutant or dyn2); 3) the ratio of FFL *versus* KAR events was substantially increased by dyn1-KO; 4)

following a release event, more protein contents were retained in WT *vs* KO vesicles; and 5) the fusion pore size d_p was increased from ≤9 nm to ≥9 nm by dyn1-KO. Thus, most (if not all) Ca^{2+}-induced exocytotic events occur in the sub-quantal/KAR release mode in native ACCs, implying that the dyn1-dependent sub-quantal mode plays an essential role in neurotransmission and hormone signaling.

Title: Characterization of Neuro-2a cells as a model of neuronal catecholamine and ATP co-release

Authors: *B. KIM, D. POBURKO
Biomed. Physiol. & Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Sympathetic perivascular nerves co-release several neurotransmitters, including adenosine-5'-triphosphate (ATP) and norepinephrine (NE). Past studies of the molecular mechanisms of ATP and NE co-storage and co-released and whether these events occur at the level of the single sympathetic nerve endings, or varicosities, have been limited by the molecular and spatial resolution of current methods to detect vesicle release. Using immunofluorescence microscopy we previously showed that vesicles containing ATP and NE appear to be distinct in intact blood vessels and cultured superior cervical ganglia neurons. To assess the differential kinetics of vesicle release and the potential colocalization of release sites for ATP and NE containing vesicle, we developed genetically encoded fusion proteins of the vesicular monoamine transporter VMAT2 (SLC18A2) and the vesicular nucleotide transporter VNUT (SLC17A9) with pH-sensitive fluorescent proteins as optical reporters of release of NE and ATP containing vesicles. The constructs are VMAT2-pHuji (a red pH-sensor) and VNUT-pHluorin. We sought a cell line that natively expresses VMAT2 and VNUT containing vesicles as a model in which to characterize these reporters and fundamental aspects of co-release. We examined the dopaminergic Neuro-2a (N2a) cell line as a potential model of catecholamine and ATP co-release as a surrogate for primary sympathetic neurons. We further created pH-insensitive reporters to characterize vesicle pool localization and trafficking. Exogenously expressed constructs traffic to neurites generated in response to differentiation cues, and VMAT2 and

VNUT appear to be expressed in common varicosities but at variable ratios, indicating that they are not strictly localized to the boutons at a constant stoichiometry. Moreover, the release of VMAT2 and VNUT containing vesicles exhibit differential release and recycling kinetics. Thus this cell line represents promising model in which to further identify fundamental aspects of differential trafficking and release of VMAT2 and VNUT containing vesicles, while VMAT-pHuji and VNUT-pHluorin permit simultaneous detection of catecholaminergic and purinergic vesicle release.

Title: Endocytosis helps to clear release sites and maintain the pool of releasable vesicles in a mature glutamatergic synapse

Authors: *A. A. DAGOSTIN, H. VON GERSDORFF
Vollum Inst., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Vesicle exocytosis is fundamental for diverse biological events, including neurotransmission. After vesicle fusion and transmitter release, the fused vesicle membrane must be retrieved and recycled in order to maintain vesicle pool sizes and presynaptic exocytic machinery. In this process, dynamin is a key protein for endocytosis, responsible for membrane fission and, ultimately, the first step in vesicle pool replenishment. To study whether the disruption of the endocytic function through dynamin blockade impairs the neurotransmission at high frequencies, we cut brainstem slices from mice containing the Medial Nucleus of the Trapezoid Body (MNTB) and recorded evoked EPSCs from MNTB principal cells after hearing onset (postnatal day P20 to P30). All recordings were performed using an external solution with 1.2 mM Ca^{2+} and at 35°C. To block dynamin function, we preincubated brainstem slices with 30 µM Dyngo 4A for at least 20 minutes prior to recordings. Dyngo 4A is an activity-dependent blocker of dynamin and to ensure its effect, we evoked 150 stimuli at 300 Hz, 50 times. This protocol did not trigger any long term potentiation/depression in controls and was enough to see an effect of the drug. After this conditioning, cells were stimulated with 300Hz trains of 100 stimuli, which yielded EPSCs with amplitudes reduced by >50% in Dyngo 4A compared to control. The reduced EPSC amplitude in the presence of Dyngo 4A may be explained by a

reduction in vesicle pool size (smaller RRP) which becomes clear when we apply the Elmqvist & Quastel extrapolation method to retrieve the RRP data from control and Dyngo 4A recordings: 44 nA and 35 nA, respectively. The effect on EPSC amplitude in the presence of Dyngo 4A may also be explained by a lower vesicle recruitment rate (from 18 ± 2 to 11 ± 3 vesicles/ms - quantal size corrected using a control/kynurenic acid steady state EPSC amplitude ratio) and an inefficient clearance of the active zone from fused vesicular membrane. Even though Dyngo 4A did not change the EPSCs kinetics, the recovery time from depression was longer, with an increase in both the fast and slow time constants of recovery (fast: 30 to 90 ms; slow: 1.8 to 2.7s; control and Dyngo 4A, respectively). These results suggest that dynamin reduces the RRP due to a diminished recovery rate from depression. This may lead to a jamming of the vesicle release site, since the recently fused vesicles are not efficiently cleared anymore from the active zone.

Title: Synaptophysin and synaptogyrin regulate fusion pore kinetics during Ca^{2+}-triggered exocytosis in chromaffin cells

Authors: *Y.-T. HSIAO[1], C.-W. CHANG[1,2], M. B. JACKSON[1]
[1]Dept. of Neurosci., Univ. of Wisconsin-Madison, Madison, WI; [2]J. David Gladstone Inst., Univ. of California, San Francisco, CA

Abstract: Synaptophysin (syp) and synaptogyrin (syg) are major secretory vesicle proteins. Syp and syg have similar structures with four transmembrane domains and a cytoplasmic C-terminal tail that can be phosphorylated. Previous studies have shown that both syp and syg regulate exocytosis, vesicle cycling, and synaptic plasticity, but their roles in the membrane fusion steps of Ca^{2+}-triggered exocytosis remain unclear. To investigate this issue, we expressed syp or syg in chromaffin cells from double knockout (DKO) mice that lack both syp and syg, and used amperometry to evaluate changes in dynamic processes during catecholamine release. The frequency of exocytotic events was lower in DKO cells than in wild-type cells. Expressing syp in DKO cells increased the frequency slightly whereas expressing syg increased the frequency about 2-fold. Expression of syg, but not syp, in DKO cells reduced the fraction of kiss-and-run events, suggesting that syg may regulate the mode of exocytosis and favor full-fusion events. Furthermore, the duration of prespike feet in DKO cells was longer than in wild-type cells,

indicating that the absence of syp and syg stabilize the initial fusion pore. Expressing syp or syg in DKO cells greatly decreased the duration, suggesting that syp and syg drive the expansion of the initial fusion pore toward full fusion. Our results demonstrate that both syp and syg influence events in membrane fusion during Ca^{2+}-triggered exocytosis of catecholamine-containing dense-core vesicles, and that syg has stronger effects than syp.

Title: Visualization of membrane pore in live cells reveals a dynamic-pore theory governing fusion and endocytosis

Authors: *W. SHIN, L. GE, G. ARPINO, S. VILLARREAL, E. HAMID, H. LIU, W.-D. ZHAO, P. WEN, H.-C. CHIANG, L.-G. WU
NINDS, NIH, Bethesda, MD

Abstract: Fusion is thought to open a pore to release vesicular cargoes vital for many biological processes, such as exocytosis, intracellular trafficking, fertilization, and viral entry. However, fusion pores have not been observed and thus proved in live cells. Its regulatory mechanisms and functions remain poorly understood. Here we visualized fusion pores in live (neuroendocrine) cells with super-resolution STED microscopy. We discovered extremely dynamic pore behaviors, including opening, expansion, constriction, and closure, where the pore diameter may vary between 0 and 490 nm within 26 ms to seconds (vesicle size: 180-720 nm). These pore dynamics result from competition between pore expansion mediated by F-actin-provided membrane tension and pore constriction/closure mediated by calcium and dynamin. They determine the extent and rate of vesicular cargo release and vesicle retrieval. Our findings provide the missing live-cell evidence proving the fusion-pore hypothesis, and establish a new pore theory accounting for fusion, endocytosis and their regulation.

Title: Influence of a cooling compound, icilin, on penicillin G-induced epileptiform discharges in a rat model: Validation of focal cortical cooling effects by TRPM8 activation

Authors: *H. MORIYAMA[1], S. NOMURA[1], H. KIDA[2], T. INOUE[1], H. IMOTO[1], Y. MARUTA[1], Y. FUJIYAMA[1], D. MITSUSHIMA[2], M. SUZUKI[1]
[1]Neurosurg., [2]Physiol., Grad. Sch. of Medicine, Yamaguchi Univ., Ube, Japan

Abstract: Focal cortical cooling suppresses penicillin G (PG)-induced epileptiform discharges (EDs) in the cortex. Cooling from 25°C to 15°C activates transient receptor potential melastatin 8 (TRPM8), but involvement of thermosensitive TRP channels in focal cortical cooling for PG-induced EDs has not been widely studied. Therefore, we examined whether TRPM8 activation can suppress PG-induced EDs in the sensorimotor cortex. Icilin, a TRPM8 agonist, was injected after PG injection, and an electrocorticogram (ECoG) and cortical temperature were continuously recorded for 4 h. Spike amplitude, duration, firing rate, and power spectrum density in EDs were measured to evaluate the effects of icilin. PG-induced EDs and increased delta, theta, alpha, and beta power spectra occurred in focal ECoG. Without a change of cortical temperature, icilin dose-dependently suppressed EDs. In particular, 3.0 mM icilin significantly suppressed PG-induced spike amplitude, duration, and firing rate, and improved each band power density in EDs to the level of basal activity in ECoG. These results suggest that TRPM8 activation in epileptic brain regions may be a new approach to treatment for patients with refractory epilepsy.

Abstract: The cation chloride cotransporters (NKCC1 and KCC2), which transport chloride within and outside the cell respectively, are responsible for the intracellular chloride concentration. The intracellular chloride concentration determines the strength and polarity of gamma-aminobutyric acid (GABA)-mediated neurotransmission. By the other hand, the ketogenic diet (KD) a high fat and low carbohydrate diet, has been used as a non-pharmacological treatment in refractory epilepsy, although the mechanism of action is unknown. This diet increases β-hydroxybutyrate (a ketone body), which probably modifies NKCC1 activity. The aim of this study was to evaluate the effect of the ketogenic diet on the KCC2 expression in the rat dentate gyrus. Male Sprague-Dawley pups were divided into: control group (n=5) (standard lab-chow diet, ND), and ketogenic diet group (n=5) and fed after weaning and through three months. At the end of the treatment, the body weight and β-hydroxybutyrate blood levels were measured. Rats were sacrificed with pentobarbital over-doses and their tissues fixed via intracardiac perfusion. Brains were removed, post-fixed and cryo-protected, afterwards 50 micron coronal serial sections were obtained and immunostained for KCC2. KCC2 staining images in dentate gyrus of ND and KD fed rats were obtained using Olympus BX51 microscope connected to a digital video camera (MBF Bioscience), and analyzed using NIH ImageJ v1.52a program (USA). The images were obtained in three regions: molecular, granular and polymorphic layer using an objective lens of 20x, the values were expressed as optical density (OD) units. t Student test was performed using SPSS v25 program ($p < 0.05$). The KD group reported higher beta-hydroxybutyrate blood levels than controls. The body weight and KCC2 optical density not showed any significant difference between control and ketogenic groups in any of the regions analyzed. Thus, we conclude that the KD applied over a long period after weaning does not modify the expression of KCC2 in rat dentate gyrus.

Title: Molecular imaging reveals pro- and anti-inflammatory effects of fingolimod in a mouse model of epileptogenesis

Authors: *B. J. WOLF[1,2], P. BASCUÑANA[1], I. LEITER[1], L. B. N. LANGER[1], T. L. ROSS[1], F. M. BENGEL[1], J. P. BANKSTAHL[1], M. BANKSTAHL[2]
[1]Hannover Med. Sch., Hannover, Germany; [2]Univ. of Vet. Med. Hannover, Hannover, Germany

Abstract: Neuroinflammation is a hallmark of epileptogenesis and has been considered as target for anti-epileptogenic treatment. The sphingosine-1-phosphate analog fingolimod (FTY720) is used for anti-inflammatory treatment in multiple sclerosis. Here, we used molecular imaging targeting the translocator protein (TSPO), which is over-expressed in activated microglia, to quantify effects of FTY720 during epileptogenesis.
Status epilepticus (SE) was induced by injecting kainate into the right hippocampus of male NMRI mice. Six hours after SE induction, mice received either 0.3 mg/kg FTY720 (SE n=8; sham n=5) or vehicle injections (SE n=18; sham n=8) once daily for 6d. Static [^{18}F]GE180 TSPO PET scans were performed 1 and 2 weeks after SE. Subsequently, mice were sacrificed for immunohistochemistry.
TSPO signal in post-SE mice was increased over sham by up to 90% in the kainate injection area, up to 49% in the ipsilateral ventral hippocampus, thalamus and cortex and up to 39% on the contralateral side in dorsal and ventral hippocampus, peaking at 2 weeks after SE ($p<0.05$). FTY720 treatment further elevated TSPO PET signal at 7 days post SE by 17% in the ipsilateral hippocampus vs vehicle-treated mice ($p<0.05$). Conversely, TSPO signal was 19% lower in the contralateral cortex and ventral hippocampus ($p<0.05$) after 2 weeks of FT720 treatment. Atlas-based results were confirmed by statistical parametric mapping (SPM). Immunohistochemical analyses at 2 weeks post-SE revealed reduced astrocyte activation in the contralateral hippocampus after treatment, but no neuroprotection.
[^{18}F]GE180 PET identified regional microglia activation during epileptogenesis. FTY720

treatment evoked a localized increase in TSPO expression in the kainate injection area, and a reduction in areas distant to the injection site. Stimulation as well as reduction of local inflammation by FTY720 may underlie reported anti-eplieptogenic properties of the treatment.

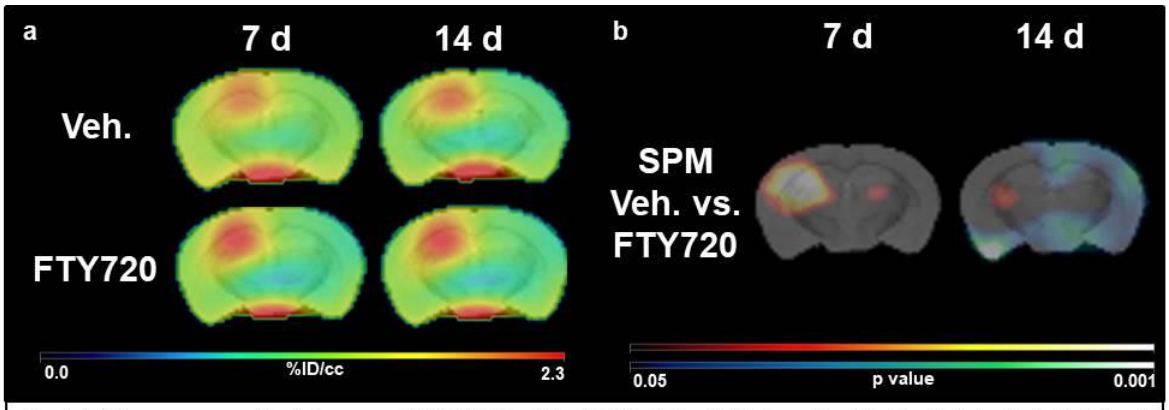

Fig.1: (a) Average coronal brain images of [^{18}F]GE180 uptake (%ID/cc) 7 and 14 days after SE of vehicle treated (Veh.) and FTY720 treated animals (b) Statistical parametric mapping analysis of [^{18}F]GE180 uptake during epileptogenesis using SPM12 software. Coronal t-maps resulting from comparisons of [^{18}F]GE180 uptake between vehicle treated and FTY720 treated animals after 7 and 14 days after SE. (student's t-test, $p<0.05$, minimum cluster size of 50 voxels).

Title: Antioxidative and antiapoptotic effect of dehydroepiandrosterone on iron-induced epilepsy model

Authors: *C. PRAKASH, M. MISHRA, P. KUMAR, D. SHARMA
Jawaharlal Nehru University, New Delhi, New Delhi, India

Abstract: Epilepsy is a complex neurological disorder categorized by recurring seizures. Despite recent advancements in pharmacological interventions, there is no effective treatment available for epilepsy. Although, many antiepileptic drugs are available which suppress seizures but have severe side effects. Oxidative stress is underlying mechanism in the initiation and progression of epilepsy. Enhanced oxidative stress is also implicated in apoptotic cell death. Hence, identification of safe antiepileptic agent with neuroprotective properties is of great importance.

Thus, we assessed exogenous treatment of dehydroepiandrosterone (DHEA) in iron-induced epilepsy. The present study is focused on the antioxidative and antiapoptotic effect of DHEA. Male Wistar rats were made epileptic by injecting intracortical injection of $FeCl_3$ and received i.p. injection of DHEA at 30 mg/kg body wt./day for 7, 14 and 21 days. Epileptogenesis was confirmed by monitoring EEG. Neuronal degeneration and apoptosis were assessed by cresyl violet staining and TUNEL assay. Oxidative stress was assessed in tissue homogenate by biochemical analysis of lipid peroxidation. The activities of antioxidant enzymes (superoxide dismutase, glutathione-s-transferase, glutathione peroxidase and glutathione reductase) were also measured. Additionally, the expression of antioxidant enzymes and cleaved caspase-3 was analysed by RT-PCR and western blots respectively. In results, DHEA suppresses seizure, neuronal degeneration, oxidative stress and enhances antioxidant defense in epileptic rats. Moreover, DHEA upregulates the mRNA expression of antioxidant enzymes while downregulates protein expression of caspase-3. In conclusion, the present study indicates that DHEA exerts as a potent neuroprotective anent against iron-induced epilepsy via upregulation of antioxidant enzymes and reversal of caspase-dependent apoptosis.

Title: Exploring the role of mycophenolate mofetil on neurohistopathological changes and gene expression in rat model of lithium pilocarpine induced spontaneous recurrent seizures

Authors: *A. G. MAZUMDER, V. PATIAL, D. SINGH
CSIR-Institute of Himalayan Bioresource Technol., Palampur, India

Abstract: Neuroinflammatory processes remain a key factor for the progression of epileptogenesis particularly in case of temporal lobe epilepsy (TLE). Earlier reports have shown that cytokines released during inflammation binds to its receptor site and activate several pathogenic pathways that play a crucial role in neuroanatomical, molecular and biochemical changes resulting in epilepsy. Mycophenolate mofetil, commonly used as an immunosuppressant, has shown neuroprotective effects in several preclinical and clinical studies. In our preliminary studies, mycophenolate mofetil showed a reduction in seizure severity and aggression-like behavior.[1] The present work was designed to study the effect of mycophenolate

mofetil on neurohistopathological changes and hippocampal mRNA expression in a rat model of lithium-pilocarpine-induced epileptic spontaneous recurrent seizures. Male wistar rats randomly divided into different groups were subjected to lithium pilocarpine induced chronic seizure method, followed by 28 days post treatment with mycophenolate mofetil at different doses. Following seizure and behavioral recordings, rats were decapitate, histopathological parameters were assessed using various staining procedures such as Nissl stain, Timm stain and hippocampal mRNA expression studies were studied using quantatitative real time-PCR. The results showed that treatment with the mycophenolate mofetil distinctively reduced neuronal death and mossy fiber sprouting along the hippocampus, considered as a characteristic neurohistopathological feature of TLE. It also caused attenuation of amplified gene expression. Our findings concluded that mycophenolate mofetil, apart from being antiepileptic, also reduced neurohistopathological changes and aberrant gene expression in the hippocampus of epileptic rats.

Title: The ketogenic diet increases serotonin levels in the mouse brain

Authors: *F. A. TERAN, Y. KIM, G. B. RICHERSON
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Sudden unexpected death in epilepsy (SUDEP) is a major cause of mortality in people with drug-resistant epilepsy. We recently demonstrated that SUDEP in a mouse model of Dravet Syndrome (DS) is due to seizure-induced respiratory arrest. Our preliminary studies show that SUDEP in DS mice is greatly reduced with a ketogenic diet (KD), an effect that is independent of ketosis but is correlated with higher brain levels of serotonin (5-HT). Defects in the 5-HT system have been linked to both respiratory dysfunction and SUDEP. We hypothesize the rescue effect of the KD is not due to ketosis, but rather to a specific dietary component that alters 5-HT metabolism. To assess the effect of a KD on 5-HT metabolism in the mouse brain, C57BL/6J

(WT) mouse littermates were placed either on a KD or a conventional diet for five days starting soon after weaning (P20). Brain levels of 5-HT, 5-hydroxyindole acetic acid (5-HIAA), L-tryptophan (Trp), dopamine (DA), homovanillic acid (HVA), 3,4-dihydroxyphenylacetic acid (DOPAC) and norepinephrine (NE) were measured from whole brain tissue using HPLC-ECD. In addition, extracellular 5-HT and DA were measured *in vivo* using microdialysis. Guide cannulae were implanted stereotaxically under anesthesia in the amygdala, a region implicated in seizure propagation and postictal apnea, of WT mice. Implanted animals were placed in a freely moving collection system and allowed to recover for at least 20 hours. Basal monoamine dialysate samples were collected for three hours, after which mice were administered decanoic acid (C10), a medium chain fatty acid found in KDs and known to be anticonvulsant, or vehicle via oral gavage, and samples were collected for three more hours. To measure the releasable pool of 5-HT and DA, 3,4-methylenedioxymethamphetamine (MDMA) was injected i.p. to cause heteroexchange release of 5-HT and DA and additional samples were collected. Total brain 5-HT, 5-HIAA, Trp and NE were 1.3 to 1.5-fold higher in KD-fed mice compared to littermates fed a control diet ($p<0.05$ with Mann-Whitney U-tests; n=8 per group). Preliminary data show that intragastric administration of C10 (n=3) or vehicle (n=2) had no effect on baseline extracellular 5-HT or DA levels over 3 hours. However, treatment with C10 led to a 300-fold increase in MDMA-induced release of 5-HT, but not DA, from the amygdala compared to control diet. Our preliminary results indicate that a KD and C10 both alter 5-HT metabolism. C10, and possibly other components of KDs, may be protective in part by increasing brain 5-HT. Future experiments include testing effects of 5-HT depletion on mortality in KD-treated DS mice.

Abstract: In an effort to discover novel anticonvulsants, we prepared and characterized several phenylamides and studied their anticonvulsant activity against seizures induced by

pentylenetetrazol in CD-1 mice. Compounds 2-hydroxy-2-(3',5'-bis(trifluoromethylphenyl)) propionamide (**1**), 2-hydroxy-2-(3'-trifluoromethylphenyl) propionamide (**2**), 2-hydroxy-2-(3',5'-bis(trifluoromethylphenyl)) butyramide (**3**) and 3-hydroxy-3-(3',5'-bis(trifluoromethylphenyl)) butyramide (**4**) were prepared using condensation reactions and characterized through infrared spectrophotometry and nuclear magnetic resonance spectroscopy. Each of the four compounds exhibited an anticonvulsant activity in mice greater than that of sodium valproate, a widely-used antiepileptic, against seizures induced by pentylenetetrazol. Compounds **1**, **3** and **4** were equipotent with phenobarbital. Isobologram plots showed that phenylamides and phenobarbital exhibit an additive anticonvulsant effect against seizures induced by pentylenetetrazol. This study shows that phenylamides represent a new class of anticonvulsant compounds worthy of further development for potential antiepileptic therapy.

Title: Sulfasalazine as a treatment for acquired epilepsy

Authors: O. ALCOREZA[1], *S. L. CAMPBELL[2], H. SONTHEIMER[3]
[1]Virginia Tech. Carilion Res. Inst., Blacksburg, VA; [2]Animal and Poultry Sciences/ Sch. of Neurosci., Virginia Polytechnic Inst. and State Universit, Blacksburg, VA; [3]Sch. of Med. and Res. Inst., Virginia Tech. Sch. of Neurosci., Roanoke, VA

Abstract: Epilepsy affects approximately 2.2 million Americans, with 150,000 new cases being diagnosed each year. Despite some success managing epilepsy, current therapeutics offer no benefit to 1-in-3 patients. Previous studies from our lab revealed that primary brain tumors release glutamate and induce electroencephalographic (EEG)-confirmed behavior seizures in adult mice implanted with human-derived glioma cells. These studies identified increased expression of system xc (SXC), a cysteine/glutamate exchanger, on glioma cells as a major contributor to elevated glutamate levels in tumor-implanted mice. Inhibition of SXC via sulfasalazine (SAS), a FDA-approved anti-inflammatory drug, decreased glutamate release and EEG-confirmed behavior seizures.
SXC is normally expressed on glial cells and gliosis is a prominent feature of many forms of epilepsy. Additionally, recent studies revealed that astroglial dysfunction, leading to pathological

changes in the extracellular environment and neuronal metabolism, may play a critical role in the initiation of seizures and development of epilepsy. We therefore hypothesize that gliosis may cause an increase in SXC expression leading to enhanced glutamate release in acquired epilepsies and that treatment with SAS can decrease seizure occurrence in mouse models of epilepsy. To test this, we used the kainic acid (KA)-induced model of acquired epilepsy, which present with gliosis, to characterize changes in the expression of SXC. Our preliminary data reveal that animals treated with KA showed increase protein expression of SXC in the hippocampus and that treatment with SAS decreases the expression of SXC. Using the beta-1 integrin knockout (β1KO) mouse model, which is characterized by widespread chronic astrogliosis and spontaneous seizures, our preliminary data demonstrate elevated SXC protein expression in the cortex of β1KOs and a decrease in seizure activity after SAS treatment. These results suggest that SXC may play a role in the pathogenesis of acquired epilepsies and that further studies on SXC and the effects of SAS is warranted as a potential novel therapeutic modality. As most treatments for epilepsy involves modifying neuronal excitatory or inhibitory mechanisms, SXC provides an unexplored glial target for decreasing glutamate release in acquired epilepsies.

Title: Dusp4: An endogenous anti-epileptogenic inhibitor of map kinase signaling

Authors: *A. KIRCHNER, S. BAGLA[1], F. DACHET[2], J. A. LOEB[2]
[1]Wayne State Univ., Detroit, MI; [2]Med., Univ. of Illinois at Chicago Col. of Med., Chicago, IL

Abstract: BACKGROUND: One third of epileptic patients are resistant to current drugs, many of which produce significant side effects. To develop improved therapeutics, the pathways that underlie epileptic areas of the neocortex need to be better understood. Using high-throughput genomic studies of human epileptic neocortical tissue, we identified the mitogen activated protein kinase (MAPK) pathway as highly upregulated in epileptic regions and have further shown that inhibition of MAPK reduces epileptic spiking in an animal model. Here, we evaluated these genes within the MAPK family for those that could be novel therapeutic targets. **OBJECTIVES**: To characterize genes involved in MAPK signaling in human neocortical epilepsy as a means to develop novel anti-epileptogenic therapeutics.

METHODS: We identified genes within the MAPK signaling pathway that were differentially expressed in high versus low spiking human cortex studied with long-term intracranial recordings. From 20 pairs of high and low spiking we used ontological methods to identify those genes within the MAPK pathway and then performed a clustering analysis to identify subgroups. In situ hybridizations were then used to localize specific genes and examine their spatial patterns of expression within human epileptic neocortex. Mechanistic studies in SY5Y and human tissues were performed to define roles of candidate genes.
RESULTS: About one third of the differentially expressed genes in high spiking regions were in the MAPK pathway. Clustering of the MAPK genes revealed a larger group contained known MAPK genes previously linked to epileptic regions. Another cluster contained an ERK1/2 inhibitor, DUSP4. In situ hybridization studies revealed that DUSP4 was activated in focal cortical areas where most MAPK genes were shut down, suggesting that DUSP4 turns off MAPK signaling. Repeated depolarization of human neuronal-like cells showed that while DUSP4 mRNA is not induced with activity, DUSP4 protein is dramatically induced and blocks MAPK signaling genes. Human tissue studies confirmed that regions with high levels of DUSP4 protein had lower levels of MAPK signaling genes.
CONCLUSION: DUSP4 is an endogenous inhibitor of MAPK signaling that is activity-dependent and spatially restricted in human epileptic brain regions in a way that could create local boundaries of reduced epileptogenicity. Since MAPK activation may be an important driver of epileptogenesis, treatments that augment DUSP4 expression could be novel inhibitors of the epileptogenic process.

Title: Assessment of antiseizure and neuroprotective effects of novel compounds in a delayed-treatment rat model of organophosphate (OP) exposure

Authors: *J. SPAMPANATO, M. SMOLIK, F. DUDEK
Univ. of Utah, Salt Lake City, UT

Abstract: Exposure to organophosphates (OP), or organophosphate nerve agents, results in status epilepticus (SE) and neuronal damage in the central nervous system. SE is can be lethal; however, early control of seizure activity minimizes mortality, as well as neuronal damage.

Unfortunately, in the event of a mass release in a civilian setting or on the battlefield, treatment of casualties is likely to be delayed to periods longer than typically acceptable for current medications that can be administered without hospital support. Therefore, there is a pressing need for anti-seizure treatments that can be administered with a significant delay and in a pre-hospital setting. Now in our second year, the CounterACT Neurotherapeutic Screening (CNS) Program has screened 9 externally submitted and 8 internally submitted test compounds. For screening, male, Sprague Dawley rats (150-200 g) were implanted with electrodes for recording of the electroencephalogram (EEG). On treatment day, SE was induced by administration of diisopropyl fluorophosphate (DFP). One hour after the start of SE, rats were co-administered midazolam (MDZ) and test compound. EEG was recorded for 24 hours at which time the rats were perfused, brains were sectioned and labeled with Fluoro-Jade B. Neuropathology was assessed as the number of Fluoro-Jade B positive neurons in 10 regions: dorsal CA1, dorsal CA3, hilus, ventral CA1, ventral CA3, amygdala, thalamus, and the parietal, entorhinal and piriform cortices. Here we present a summary of the program to date. Of the coded, externally submitted compounds, we have seen significant anti-seizure effects in the presence and absence of MDZ for two compounds. These compounds reduced both seizure power and seizure duration. Each of these compounds also reduced cell death in one or more brain areas in the presence of MDZ. Tested in the absence of MDZ, both compounds were less effective in reducing seizures and cell death. These data can be compared to ganaxolone which had a minimal effect on seizures and bumetanide which had no effect on seizures. These data demonstrate that OP-induced SE can be reversed even when treated at a long-delay and this delayed treatment can significantly reduce cell death.

Title: Transcranial focal stimulation augments the effects of anticonvulsant drugs in rats

Authors: D. PEREZ-PEREZ[1,2], *L. L. ROCHA[3], W. BESIO[4], J. SOTELO[5]
[1]Natl. Autonomous Univ. of Mexico, Mexico, Mexico; [2]Plan of Combined Studies in Med.,

Mexico, Mexico; [3]CINVESTAV, Mexico, Mexico; [4]Univ. of Rhode Island, Kingston, RI; [5]Natl. Inst. of Neurol. and Neurosurg. of Mexico, Mexico, Mexico

Abstract: Combined therapy in patients with epilepsy is mainstream in the treatment of this condition. It is necessary to find alternative strategies with less adverse effects. On the other hand, transcranial focal stimulation (TFS) has shown anticonvulsant effects that are increased when combined with diazepam. Nevertheless, it is not known if this capability can be translated to other antiepileptic drugs. The aim of the present study was to evaluate the effects of TFS alone and combined with phenytoin (PHT, a sodium channel blocker) or phenobarbital (PB, a GABA receptor agonist), in a model of generalized seizures induced by 3-mercaptopropionic acid (3MP). Male Wistar rats of 250-300 g initial weight, were habituated for 7 days by daily administration of saline solution (SS, 0.9%, 1ml/kg, ip) and 2 minutes of kindly handle. The head of the animals was shaved at the end of the last manipulation. One day after the end of habituation, the rats were administered with PHT (75 mg/kg, ip), PB (15 mg/kg, ip), or SS (1 ml/kg, ip). Fifty-three minutes later, they received TFS (charge-balanced biphasic squared pulses at 200 us of duration, 300 Hz, and 100 mV) or manipulation without stimulation, for 2 minutes. Five minutes after TFS, the rats received 3MP (37.5 mg/kg, ip) and the behavioral changes were evaluated for 30 minutes. Each experimental condition was evaluated in 8 animals. All rats from the Sham group (100%) presented the following behavioral changes: myoclonic jerks, clonus, wild jump, tonic component followed by clonic seizures, with a latency of 284 ± 6.7, 303 ± 6.35, 512 ± 34.6, 684 ± 62.4, and 705 ± 61.5 s, respectively. Animals treated with PHT showed similar incidence of behavioral changes when compared with the Sham group, except for a reduction in wild jump (20%, p=0.05), and tonic component (0%, p=0.007). For PB, the changes were not different from the Sham group except for a lower incidence of the tonic component (28%, p=0.03). TFS did not induce significant changes in the behavioral seizures compared with the Sham group, except for a reduction in the incidence of continuous seizures (40%, p=0.04). However, animals receiving TFS combined with PHT or PB presented a reduction in the incidence of clonic seizures (60% for PHT and 50% for PB), in contrast to the groups receiving the antiepileptic drugs alone. None of the therapeutic strategies modified the seizure latency for the different behavioral changes evaluated. In conclusion, TFS augmented the anticonvulsant effects of PHT and PB in motor generalized seizures.

Title: Cannabidiol decreases the excitability of pyramidal neurons and increases inhibitory drive in hippocampal area CA1

Authors: *S. CHAMBERLAND[1], E. C. ROSENBERG[1], O. DEVINSKY[2], R. W. TSIEN[1]
[1]Neurosci. Inst., [2]Dept. of Neurol., NYU, New York, NY

Abstract: Cannabis has been used for several centuries in the treatment of several diseases. The therapeutic potential of cannabinoids has recently resurfaced. Cannabidiol (CBD), a non-psychoactive cannabinoid, has recently been shown to decrease epileptic seizures in a double-blind placebo-controlled clinical study (Devinsky et al., 2017, 2018). However, the effects of cannabidiol on neuronal activity and neuronal network remain obscure. We used whole-cell and cell-attached recordings in acute hippocampal slices to understand how CBD (10 - 20 μM) modulates neuronal activity.

Our results indicate that CBD reduces neuronal activity through three mechanisms in the CA1 hippocampus. First, CBD increased synaptic inhibition in CA1 pyramidal neurons. Second, CBD decreased the firing rate of CA1 pyramidal neurons at depolarized membrane potentials and capped their maximal firing rate. In contrast, CBD had no effect on CA1 pyramidal cell resting membrane potential or spontaneous firing. In addition, CBD did not affect the action potential waveform. Third, in contrast to pyramidal neurons, GABAergic interneurons recorded in the stratum oriens and in the alveus demonstrated a cell-type specific effect. While fast-spiking interneurons increased their firing rate in response to CBD, the firing rate of regular-spiking interneurons was decreased.

Overall, our results show that CBD acts via multiple functional mechanisms to tone down principal neuronal activity. These mechanisms may contribute to the anti-epileptic properties of CBD. We are currently investigating CBD's cell type-specific mechanism of action and how these effect are summed at the network level to regulate the propagation of activity in the hippocampus.

Title: An investigation of the discriminative stimulus and reinforcing effects of cannabidiol in rats

Authors: *D. J. HEAL[1], S. HOLLAND[1], J. GOSDEN[1], R. A. GRAY[2], S. SMITH[1]
[1]RenaSci Ltd, Nottingham, United Kingdom; [2]Preclincal Pharmacol., GW Pharmaceuticals, Cambridge, United Kingdom

Abstract: Cannabidiol (CBD) is being developed for treating severe, orphan, early-onset, treatment-resistant epilepsy syndromes. We have investigated CBD's discriminative stimulus in rats trained to discriminate between midazolam and saline, and CBD's reinforcing effect by intravenous self-administration (IVSA) in heroin-trained rats. Freely fed female, Lister hooded rats were trained to discriminate midazolam (0.5mg/kg ip) from saline in a 2-choice operant test. Lever-pressing was reinforced by sweetened milk rewards obtained on a FR5 schedule for responses on either lever. Once the rats were competent in the task (>75% correct responding for midazolam and saline), rats were tested with CBD (20, 75, 150 mg/kg po), midazolam (0.5, 1.0, 1.5mg/kg po), alprazolam (0.125, 0.25, 0.5, 1.0mg/kg po). Mildly food-restricted, male, Sprague-Dawley rats were initially trained to lever-press for food rewards before being surgically implanted with in-dwelling jugular catheters. Rats were allowed to self-administer heroin (15µg/kg/inj) on a fixed ratio (FR3) schedule of reinforcement in 2hr training sessions. After establishment of consistent heroin self-administration, the rats were subjected to saline extinction. The reinforcing effects of CBD (20, 100, 500µg/kg/inj), diazepam (1, 3, 4.5 or 10µg/kg/inj) and midazolam (0.3, 1, 1.5, 2.25 or 3µg/kg/inj) were then evaluated on a FR3 schedule in 2hr sessions. Results are mean ± SEM. In drug-discrimination, all CBD doses generalised to saline (maximum generalisation to the ip midazolam cue: 11±5% @ 20mg/kg). Midazolam and diazepam both dose-dependently generalised to midazolam (91±5%, 89±7%, respectively). Heroin maintained self-administration in rats (17.6±0.5 inj/session, n=39) at levels significantly greater ($p<0.001$) than saline (3.7±0.2 inj/session, n=39). CBD (100µg/kg/inj) [6.9±1.8 inj/session, n=8] maintained self-administration at levels significantly greater than saline ($p<0.05$). Diazepam (3µg/kg/inj) [7.0±2.1 inj/session, n=8] and midazolam (1.5µg/kg/inj) [7.3±1.3 inj/session, n=16] also served as positive reinforcers ($p<0.05$). This study is the first to systematically investigate the discriminative and reinforcing potential of CBD. The results reveal that CBD did not produce benzodiazepine-like psychoactive effects in rats. CBD served as a

weak reinforcer at a single dose in heroin-trained rats. Diazepam and midazolam also served as weak reinforcers at a single dose.

Title: Screening for anti-epileptic compounds with an *in vitro* epilepsy model based on the human ipsc-derived microbrain® 3D platform

Authors: *O. GUICHERIT[1], C. CARROMEU[1], S. DEA[1], N. SODHI[1], F. ZANELLA[1], C. ANDERSEN[1], B. C. GAY[2], J. M. ANDRESEN[2], G. R. STEWART[2]
[1]Stemonix, San Diego, CA; [2]Pairnomix LLC, Plymouth, MN

Abstract: Epilepsy is one of the most prevalent neurological disorders, with over 50 million sufferers worldwide. Current anti-epileptic dugs (AEDs) only treat symptoms and carry significant risk for drug interactions and adverse effects. Moreover, up to one-third of all epileptic patients are refractory to AEDs. This significant unmet medical need creates an urgent demand for safer and more effective AEDs. Towards that end, we set out to develop an *in vitro* model based on the StemoniX human induced pluripotent stem cell (iPSC)-derived microBrain® 3D Platform to identify drugs with potential anti-epileptic activity. The microBrain® 3D 384-well screening plates contain neural spheroids comprised of a physiologically relevant mixture of fully differentiated cortical-like neurons and astrocytes from a single human donor source of iPSCs. The homogeneous spheroids show large, consistent, spontaneous and synchronous calcium oscillations, and are responsive to a variety of pharmacological neuromodulators. For drug screening, the microBrain® 3D spheroids were first characterized with known neuromodulators and AEDs alone. Next, a collection of 120 targeted Pairnomix proprietary compounds was evaluated. These compounds were selected based on their demonstrated ability to modulate the *in vitro* activity of ion channels implicated in epilepsy. The library comprises compounds with different mechanisms of action: sodium channel inhibitors, potassium channel activators, $GABA_A$ receptor channel activators, and glutamate receptor channel inhibitors. This 120-drug panel was screened against the microBrain® 3D platform at 3 different concentrations (0.1, 1, 10 µM) across two replicates. Hit compounds with substantial inhibitory activity in the assay were then re-tested in serial dilution to confirm activity and derive an IC_{50} and maximal

effectiveness from concentration-response curves. Testing was done in the presence and absence of a seizure-inducing compound (4-Aminopyridine). More than half the compounds showed robust inhibition of the spontaneous calcium oscillations consistent with their known ion channel activity and potential as novel AEDs. The assay also showed a large dynamic range, with many compounds reaching over 99% inhibition in a concentration-dependent fashion. Finally, none of the test compounds demonstrated overt toxicity. Overall, the microBrain® 3D platform generated remarkably consistent and reproducible results, establishing the microBrain® 3D platform as a useful and robust cell-based platform for high-throughput drug screening.

Abstract: There is an increasing interest in using more complex, biologically relevant, and predictive cell-based assays for assay development and compound screening. StemoniX microBrain® 3D Assay Ready Platform is a high throughput 3D culture platform that more closely resembles the tissue development and constitution of native human brain tissue. In this platform, human iPSC-derived neuronal spheroids are composed of a physiologically relevant co-culture of functionally active cortical glutamatergic and GABAergic neurons and astrocytes. This balanced cellular mix allows the development of a neural network enriched in synapses, creating a highly functional neuronal circuitry. The neuronal cells in the microBrain 3D spheroids are physiologically active, with spontaneous synchronized, readily detectable calcium

oscillations.
We used fast kinetic fluorescence imaging on the FLIPR® Tetra System to measure the patterns and frequencies of the Ca2+oscillations of neuro-spheroids as monitored by changes in intracellular Ca2+ levels with calcium-sensitive dyes. A set of known neuromodulators was tested, including agonists and antagonists of NMDA, GABA and AMPA receptors; kainic acid, analgesic, and anti-epileptic drugs. Changes were observed as inhibitions or activations of the oscillation patterns, matching the expected effect of the correspondent neuromodulator. In addition, we tested a set of known neurotoxic compounds including selected pesticides and flame retardants and demonstrated sensitivity of the assay to the effects of compounds. Assay was optimized for HTS in 384-well plates and allows for the characterization of oscillation profiles in neural spheroid by using multi-parametric analysis with ScreenWorks Peak Pro Software. The automatically measured read-outs include the oscillation rate, peak frequency, peak width, amplitude, and waveform irregularities. In addition, the potential impact of treatment on cell viability and mitochondrial integrity was evaluated by high content imaging using ImageXpress® Micro Confocal High-Content Imaging System. We determined EC50s for the impact of different compounds on the Ca2+ oscillation rates or cell viabilities. In conclusion, we demonstrated that functional and morphological assays using 3D neuronal spheroids formed with human iPSC-derived cells can be used for evaluation of drug candidates and neurotoxicity assessment.

Title: ATF4 is downregulated during synaptic plasticity potentially to maintain depression or reset potentiation

Authors: *F. AMAR[1], C. CORONA[2], J. LIU[3], E. GRAEFF[4], L. GREENE[3], M. L. SHELANSKI[1]

Abstract: Activating transcription factor 4 (ATF4/CREB2), in addition to its well-studied role in stress responses, has also been proposed to play other important physiologic functions in the nervous system including regulation of learning and memory. ATF4 has been proposed to both impair and enhance neuronal plasticity and memory, though the studies that have directly regulated ATF4 rather than regulating it through upstream activators or dominant negative inhibitors all indicate that ATF4 is required for normal learning and memory. Our hypothesis is that ATF4 is a homeostatic regulator of synaptic function and that either paucity or excess could affect learning and memory. To further shed light on the possible role of ATF4 in these functions, we examined how ATF4 is modulated during synaptic plasticity. Long-term potentiation (LTP) and long-term depression (LTD) are the underlying molecular mechanism for learning and memory. Thus, we investigated whether either chemically induced LTP or LTD (cLTD, cLTD) modulates ATF4 levels in neurons. Using cultured hippocampal and cortical neurons we found that glutamate-induced LTP reduced ATF4 protein for up to 4 hours and NMDA-induced LTD rapidly induced downregulation over 24 hours. LTP-induced ATF4 depletion required NMDA receptor activation and the initiation of the MEK, pERK pathway upstream of eiF2α phosphorylation. The NMDAR antagonists AP5 and MK801, but not the other ionotropic or metabotropic glutamate receptor antagonists, blocked cLTP and cLTD-induced ATF4 down-regulation as did MEK inhibitor U0126. This cLTP and cLTD-induced ATF4 down-regulation was followed by a decrease in the actin stabilizing protein Cdc42, a protein known to be regulated by ATF4 via RhoGDIα. Interestingly, ATF4 overexpression did not affect initiation of cLTP but appeared to prevent the return of mEPSPs to baseline levels at 24 hours post induction which is normally observed in cells with endogenous levels of ATF4. Together our findings indicate that NMDA receptor dependent cLTP is accompanied by a rapid depletion of ATF4 protein levels that may be necessary to reset the system and allow subsequent rounds of learning and memory.

Title: Generation of a ATF4 conditional KO mouse line for elucidating the role of ATF4 in learning and memory

Authors: *C. CORONA[1], F. AMAR[3], C.-S. LIN[2], L. GREENE[4], M. L. SHELANSKI[3]
[1]Dept. of Pathology and Cell Biol., [2]Columbia Univ., New York, NY; [3]Pathology and Cell Biol., Columbia Univ. Med. Ctr., New York, NY; [4]Pathology and Cell Biol., Columbia Univ. Press, New York, NY

Abstract: Activating Transcription Factor 4 (ATF4) is a member of the ATF/cAMP responsive element binding protein (CREB) family which is involved in learning and memory. In this regard, we previously reported that specific long-term hippocampal ATF4 down-regulation induces deficits in synaptic plasticity and memory accompanied by a reduction in glutamatergic functionality. In addition, under the same conditions, our electrophysiological data show that ATF4 down-regulation significantly increases the frequency of spontaneous action potentials, an effect mediated by the reduction of the Rho GTPase Cell Division Cycle 42 (Cdc42) and, consequently, membrane $GABA_B$ receptor levels. Because of the conditions of long-term down-regulation of ATF4 employed in our previous studies (4-6 weeks *in vivo*, 14 days *in vitro*), the precise short-term role of ATF4 in the cascade of events involved in learning and memory are still unclear. For instance, it remains to be seen whether short-term modulation of ATF4 that does not impact synaptic structure will improve or impair synaptic plasticity, as well as whether behavioral protocols that stimulate learning and memory formation require ATF4 in order to be effective. Given the challenges in using ATF4 KO mice (adult animals are blind and show severe skeletal abnormalities) to answer these questions, we created a region-specific inducible model of ATF4 down-regulation by generating an ATF4 floxed mouse line and crossing it with a line with CRE expressed under the CAMKII promoter. Our preliminary data with the offspring show that five consecutive days of Tamoxifen injections (75mg/kg body weight) followed by a five days waiting period is sufficient to induce an 80% down-regulation of ATF4 protein in the forebrain but not in the cerebellum. This selectively induced down regulation of ATF4 in the adult mouse does not appear to cause any visual or skeletal deficits. These mice are a novel system for investigating the role of ATF4 in learning and memory processes in a time controlled manner. This mouse will also be useful for studying the role of ATF4 in neurodegenerative diseases such as Alzheimer's disease as one can modulate ATF4 before or after AD related pathologies are apparent.

Title: Intracellular regulation of calcium-calmodulin dependent protein kinase type II function by NMDA receptor subunit GluN2B

Authors: *L. K[1], M. M[1], A. R C[1], R. RAJU[2], A. ANIRUDHAN[2], O. R V[1]

Abstract: Ca^{2+}/calmodulin dependent protein kinase type II (CaMKII) is enriched in the post synaptic density (PSD) of excitatory synapses. It participates in cellular events such as long-term potentiation (LTP), neurogenesis and excitotoxicity. CaMKII is activated by calcium entry through N-methyl-D-aspartate receptor (NMDAR). Upon binding of Ca^{2+}-calmodulin complex, CaMKII undergoes autophosphorylation at Thr^{286} making it autonomously active. Active CaMKII can translocate to PSD and bind with NMDAR subunit GluN2B. This interaction is implicated in the induction of LTP and also in pathological signaling. CaMKII can engage in two types of binding to GluN2B depending upon the extent of calcium stimulation. Brief stimulation causes reversible binding (S-site binding) and longer stimulation results in persistent binding (T-site binding) intracellularly (Bayer *et al*, 2006, *J. Neursci*., 4, 1164-1174). GluN2B binding to the T-site significantly modulates CaMKII catalysis, leading to a reduced but stable activity (Cheriyan *et al*, 2011, *PLoS One.* 6: e16495). In addition, dephosphorylation of phospho-Thr^{286} of α-CaMKII was also inhibited by binding to GluN2B *in vitro* which is mediated by His^{282} and Glu^{96} of α-CaMKII (Mayadevi *et al*, 2016, *PLos One*, 11(9): e0162011). The modulation of activity and protection of dephosphorylation of CaMKII by GluN2B might play important roles in memory formation or in excitotoxicity. To investigate the existence of the regulation of α-CaMKII by GluN2B under intracellular conditions, experiments were conducted by giving brief and extended stimulation using calcium and the ionophore, ionomycin, to HEK-293 cells in which GFP-α-CaMKII and GluN2B sequence were ectopically expressed. Subsequently, the phosphorylation status of α-CaMKII-Thr^{286} was analyzed as an indicator of CaMKII activity. We found that α-CaMKII-Thr^{286} was phosphorylated upon short stimulation which was reversed by subsequent incubation in the absence of calcium. The reversal was mediated by phosphatases as it was prevented by okadaic acid. However Thr^{286}-phosphorylation persisted under conditions in which CaMKII-GluN2B association also persisted such as upon extended stimulation. This appears to be due to the regulated dephosphorylation of α-CaMKII when it is bound to GluN2B. Mutants such as H282A-α-CaMKII that are defective in the GluN2B-mediated regulation are being studied using this system. Our data demonstrates the regulation of CaMKII dephosphorylation by GluN2B under intracellular conditions.

Title: Dissecting the contribution of beta-adrenergic signaling to hippocampal synaptic plasticity using biased ligands

Authors: *M. S. SHETTY[1,2], K. T. BLACKWELL[3], T. ABEL[1,2]
[1]Dept. of Mol. Physiol. and Biophysics, [2]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA; [3]Dept. of Bioengineering, Volgenau Sch. of Engin., George Mason Univ., Fairfax, VA

Abstract: Different forms of activity-dependent synaptic plasticity, involving diverse signaling mechanisms, underlie learning and memory. These synaptic plasticity processes are subject to modulation by a variety of neurotransmitters. The noradrenergic system, activated by emotional arousal, stress and novelty, is one of the critical modulators of synaptic plasticity and memory in the hippocampus. In particular, the β-adrenergic receptor (β-AR)-mediated signaling has been highly implicated. Recent evidence suggests that the activation of β-ARs can recruit multiple independent arms of downstream signaling cascades such as Gsα-mediated, Giα-mediated or β-arrestin-mediated pathways, all of which converge on the activation of MAPK (ERK1/2). This diversity leads to the question of which downstream signaling pathways mediate β-adrenergic facilitation of specific forms of synaptic plasticity. We have begun addressing this question by using a computational model of these signaling pathways to predict the outcome of a variety of stimulation paradigms, both with and without β-adrenergic activation in the model. The predictions from the simulations are then tested using acute hippocampal slice electrophysiology experiments combined with pharmacological manipulations using biased ligands. The results

show that carvedilol, a biased β-AR ligand that recruits β-arrestin and MAPK activation but does not increase cAMP levels, fails to induce persistent long-term potentiation (LTP) when combined with a low-frequency stimulation protocol (LFS; 5Hz, 3 min). The same LFS leads to persistent LTP when combined with the application of isoproterenol, a full agonist of β-AR. These results confirm predictions from the computational model. We are now testing the effect of carvedilol co-application on the short-lasting LTP induced by a single 100 Hz stimulation, which as predicted by the model, should not lead to LTP enhancement. We also will be testing the effects of other ligands, such as carazolol that leads to MAPK activation independent of cAMP- or β-arrestin-mediated pathways and ICI-118551, a complete antagonist of the β-AR. These findings will help dissect the β-AR signaling mechanisms underlying specific forms of synaptic plasticity.

Abstract: PKMζ is a brain-specific, atypical PKC isoform that has been proposed to maintain LTP and long-term memory through its persistent kinase activity. During long-term potentiation (LTP) and long-term memory induction, new PKMζ is synthesized from a dedicated PKMζ mRNA, generated from an alternate internal promoter within the PKCζ/PKMζ gene *(Prkcz).* Using a pharmacogenetic approach, a recent study (Tsokas et al., 2016) demonstrated that another atypical PKC, PKCι/λ, the gene product most closely related to PKMζ,

compensates for the absence of PKMζ in constitutive PKCζ/PKMζ knockout (KO) mice, thus explaining the findings that LTP and long-term memory can be maintained in the absence of PKMζ in these mice (Volk et al., 2013). To further examine potential mechanisms for compensation of PKMζ during LTP and long-term memory, we generated tamoxifen-inducible conditional knockout (cKO) mice of PKCζ/PKMζ by crossing PKCζ/PKMζ$^{fl/fl}$ mice with CaMKII-CreERT2 mice (PKCζ/PKMζ$^{fl/fl}$;CreER). The PKMζ-cKO mice received daily intraperitoneal injections of tamoxifen for 5 days; control mice were either wild-type mice injected with tamoxifen or PKCζ/PKMζ$^{fl/fl}$;CreER mice injected with vehicle. Three days after the final injection, the mice were sacrificed and their dorsal hippocampi were excised and CA1 region assayed for PKMζ mRNA, total PKMζ- and PKCι/λ-specific antisera, as well as two markers of PKMζ activity, phospho-Thr555/Thr563 PKCζ/λ antisera recognizing the atypical PKC site phosphorylated by mTORC2 and/or autophosphorylation, and phospho-atypical PKC activation loop antisera (phospho-PKCζ/λ Thr410/403). The results reveal that after knockdown of PKMζ, cKO mice compensate by increasing the activity of the remaining PKMζ, as indicated by large increases in both the phospho-Thr555/Thr563 and phospho-Thr410/403 immunostaining of the residual PKMζ. In addition, PKMζ cKO mice show increased expression of total PKCι/λ, similar to the compensatory mechanism of constitutive PKMζ KO mice. Thus, both enhanced activation of residual PKMζ and increased PKCι/λ compensate for the partial loss of PKMζ in cKO mice. Future experiments will examine whether these compensatory mechanisms contribute to the maintenance of LTP and long-term memory in PKMζ cKO mice.

Title: P18 is critical for lysosomal Ragulator-Rag complex assembling and synaptic plasticity in hippocampal neurons

Authors: *J. SUN[1], Y. LIU[2], X. HAO[1], W. LIN[1], B. DIEP[2], E. CHIANG[2], M. BAUDRY[2], X. BI[1]
[2]GCBS, [1]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Accumulating evidence indicates that the lysosomal Ragulator complex is essential for full activation of the mechanistic target of rapamycin complex 1 (mTORC1). A recent crystal structure study revealed that p18 (aka LAMTOR1) forms a “ribbon” around the other 4 members of the Ragulator to stabilize the complex and provide contact points for Rag GTPases, which recruit and activate mTORC1 on lysosomes. Yet, the precise function of p18 in CNS has rarely been studied. We report here that in hippocampal neurons, p18 is essential for lysosomal localization of other Ragulator members and Rag GTPases, as p18 knockdown (KD) markedly reduced the lysosomal localization of LAMTOR4 and RagA. We further showed that lysosomal localization of the Ragulator-Rag complex is essential for mTORC1 activation in hippocampal neurons. We previously reported that Ube3a, an E3 ligase that plays important roles in brain development and function, ubiquinates p18, resulting in its proteasomal degradation, and Ube3a deficiency in hippocampus of Angelman syndrome (AS) mice produces increased lysosomal localization of p18. We found that increased p18 levels in AS mice are associated with increased lysosomal localization of the Ragulator-Rag complex and mTORC1, but not mTORC2. Our results also support the idea that the Ragulator functions not only as a platform but also as a Rag GTPase GEF to facilitate mTORC1 activation. Furthermore, our in vivo experiments showed that p18 KD in AS mice, in addition to “normalizing” mTORC1/mTORC2 activation, restored TBS-induced LTP, increased the number of mature dendritic spines in hippocampus and restored hippocampus-dependent learning. Intriguingly, p18 KD in WT mice impaired LTP, reduced the number of mature spines, and reduced context-dependent learning performance. Immunostaining results of Arc in CA1 dendritic field showed that levels of Arc were significantly higher in control siRNA-injected AS mice, as compared to control siRNA-injected WT mice; p18 KD significantly reduced Arc expression in both WT and AS hippocampal slices. In addition, p18 KD induced a larger reduction in Arc expression in WT than in AS mice, which may contribute to reduced LTP in p18 siRNA WT group. Collectively, our results indicate that an optimal level of lysosome-anchored Ragulator-Rag complex is required for normal activation of mTORC1, which is critical for functional and structural synaptic plasticity as well as learning and memory.

Abstract: We previously reported that Rabphilin3A (Rph3A) plays a key role in the stabilization of GluN2A-containing NMDA receptors at synapses through the formation of a ternary complex with GluN2A and PSD-95. In particular, perturbing GluN2A/Rph3A interaction induces a decrease of NMDAR-mediated currents and dendritic spine density (*Stanic et al., Nat. Comm., 2015*). Based on these previous observations, the two main goals of the present study are: i. investigating the role of Rph3A in functional and structural synaptic plasticity at hippocampal synapses and ii. elucidating the molecular mechanisms regulating Rph3A binding to NMDA receptors and its consequent recruitment at the postsynaptic density (PSD). Different experimental protocols were used to induce synaptic plasticity *in vitro and in vivo* in presence or absence of agents modulating Rph3A function. Following treatments, Rph3A interaction with NMDA receptor complex, its localization at the excitatory synapse, synaptic plasticity and dendritic spine morphology were evaluated by using a vast array of biochemical, imaging and electrophysiological analyses. Electronic microscopy experiments revealed that about 50% of spines display Rph3A in resting conditions in hippocampal neurons. Interestingly, Rph3A-positive spines show increased PSD length and thickness and an increase of spine volume. Knock-down of Rph3A by shRNA greatly impedes the insertion of GluA1-containing AMPA receptors at the synapse following induction of chemical long-term potentiation (cLTP). Accordingly, inhibition of Rph3A activity leads to failure in LTP induction by high-frequency stimulation and prevents LTP-dependent structural modifications of spines. Overall, our study demonstrate that Rph3A is necessary to trigger functional and structural synaptic plasticity at the excitatory glutamatergic synapse.

Title: Drebrin binds to CaMKIIβ and forms activity-dependent tripartite interaction between drebrin, CaMKII and F-actin in dendritic spines

Authors: *T. SHIRAO[1], H. YAMAZAKI[1], Y. SEKINO[2]
[1]Gunma Univ. Grad Sch. Med., Maebashi-Shi, Japan; [2]Univ. of Tokyo, Grad Sch. Pharma Sci., Tokyo, Japan

Abstract: Drebrin increases F-actin stability by elongating the helical crossover of F-actin. Drebrin is highly concentrated in dendritic spines and exit from it in an activity-dependent manner. In this study, we identified Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) β isoform as a novel drebrin-binding protein using a yeast two-hybrid system. We analyzed the drebrin-binding region of CaMKIIβ by immunoprecipitation from HEK293 cells transfected with Drebrin-FLAG and HA-CaMKIIβ 1-280 or 281-542. Anti-FLAG immunoprecipitations showed that drebrin interacts with CaMKIIβ 1-280, but not CaMKIIβ 281-542. A non-F-actin binding CaMKIIβ isoform CaMKIIβe could bind to drebrin, suggesting that CaMKIIβ directly binds to drebrin but not through their actin-binding activity. Then, we investigated the drebrin–CaMKIIβ relationship in dendritic spines using rat hippocampal neurons. CaMKIIβ was localized at dendritc spines in the control neurons but not in the drebrin knockdown (KD) neurons. Although CaMKIIα did not bind to drebrin, the spine-localization of CaMKIIα was also weakened in the drebrin-KD neurons, suggesting that drebrin stabilizes CaMKIIα&β hetero-oligomer in dendritic spines by interacting with CaMKIIβ. Fluorescence recovery after photobleaching analysis showed that drebrin KD increased the stable fraction of CaMKIIβ, indicating the presence of drebrin-independent, more stable CaMKIIβ. Super-resolution microscopy (N-STORM) elucidated that CaMKIIβ is widespread in a dendritic spine and partially co-localizes with drebrin in the inner region of dendritic spines during the resting state. NMDA receptor activation decreased CaMKIIβ colocalization with drebrin while it increased CaMKIIβ colocalization with PSD. In parallel with this change, NMDA-receptor activation induced drebrin exodus from dendritic spines. Previous study shows that CaMKIIβ detaches from F-actin by autophosphorylation. Together, we conclude that drebrin stabilizes CaMKIIβ in the inner region of dendritic spines as drebrin/CaMKII/F-actin tripartite complex, and this interaction is regulated by neuronal activity.

Title: Increased sucrose experience prevents sucrose-induced increases in glutamate AMPA receptor phosphorylation in dorsal hippocampal neurons

Authors: N. BARNETT[1], A. P. ROSS[1], A. D. FAULKNER[2], R. C. HANNAPEL[1], *M. B. PARENT[1]

Abstract: Evidence in humans suggests that meal-related memory influences later eating behavior. Memory can serve as a vital mechanism for controlling eating behavior because it provides a record of recent intake that likely outlasts most physiological signals generated by ingestion. We have proposed that dorsal (dHC) and ventral hippocampal (vHC) neurons, which are critical for memory, limit energy intake during the postprandial period. In support, our lab found that temporarily inactivating dHC or vHC neurons after the consumption of a sucrose meal decreased the latency to eat the next sucrose meal and increased the size of that meal. If dHC or vHC neurons control intake through a process that requires memory, then ingestion should increase events necessary for synaptic plasticity in dHC and vHC during the postprandial period. To test this, we determined whether ingesting a sucrose solution induces phosphorylation of AMPAR GluA1 subunits at serine 831 ($pSer^{831}$) and serine 845 ($pSer^{845}$) residues. We also determined whether increasing the amount of previous experience with the sucrose solution, which would be expected to decrease the mnemonic demands associated with that meal, would also attenuate sucrose-induced phosphorylation. Specifically, we exposed male Sprague-Dawley rats to a sucrose solution for 10 min/day for 3, 5 or 10 days and their brains were harvested 90 min after their last sucrose bout. Quantitative immunoblotting of dHC and vHC membrane fractions demonstrated that sucrose ingestion increased postprandial dHC $pSer^{831}$ and that increased sucrose experience prevented this effect and decreased vHC $pSer^{831}$. Sucrose ingestion did not affect $pSer^{845}$ in either dHC or vHC. The sucrose-induced increase in dHC GluA1 $pSer^{831}$ is noteworthy because previous research has shown that learning produces a comparable elevation of dHC GluA1 $pSer^{831}$, which results in increased glutamate AMPA receptor conductance and augmented synaptic strength. These findings indicate that ingestion activates

proteins necessary for synaptic plasticity and memory in dHC, which is consistent with the hypothesis that dHC neurons form a memory of a meal.

Title: LTP-induced translocation of MAP2 into dendritic spines

Authors: *Y. KIM[1], Y.-N. JANG[1], N. KIM[1], S. NOH[1], J.-Y. KIM[1], R. BELLMORE[2], H. PARK[1], J. MUN[1], J. RAH[1], D. T. PAK[2], K. LEE[1]

Abstract: Long-term potentiation (LTP) is a cellular model for information storage which involves synaptic reorganization of signaling and regulatory proteins leading to structural and functional plasticity. Microtubule-associated protein 2 (MAP2) is a microtubule binding protein required for the regulation of microtubule dynamics and stability. Using biochemical, cell biological, and imaging approaches, we found that a subpopulation of MAP2 in dendritic shaft rapidly translocated to dendritic spines in response to chemical LTP (cLTP) stimulation. Spine translocation of MAP2 was dependent on NMDA receptor activation and intracellular calcium concentration, while either chemical long-term depression or KCl-mediated depolarization failed to induce MAP2 spine translocation. Bath application of independent Ras-MAPK inhibitors significantly reduced the number of neurons with MAP2-positive spines, whereas other pharmacological inhibitors against a variety of key synaptic protein kinases including CaMKII, PKC, and PKA did not affect the cLTP-induced MAP2 spine translocation in cultured rat hippocampal neurons. Live cell confocal imaging showed that the spine translocation of MAP2 coupled with cLTP-induced spine enlargement. Coherently, surface AMPA receptor levels were increased in neurons with MAP2-positive spines compared to those with MAP2-negative spines following cLTP stimulation. Furthermore, immuno-electron microscopy combined with electrical LTP stimulation revealed synaptic localization of MAP2 in dendritic spines of CA1

hippocampal neurons in acute brain slices. Together, these results suggest a novel role of MAP2 in synaptic plasticity in addition to its well-established function of microtubule regulation in dendritic compartment.

Title: The impact of PKA-dependent phosphorylation of GluN2B at Ser1166 on hippocampal plasticity and cognition

Authors: *M. W. PORCH[1], J.-Y. HWANG[1], A. E. CHAVEZ[2], R. S. ZUKIN[1]
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Neurosci., Univ. De Valparaiso, Valparaiso, Chile

Abstract: NMDA receptors (NMDARs) are glutamate-gated ion channels that are enriched at excitatory synapses, where they are strategically positioned to play a crucial role in regulation of synaptic function. A unique feature of NMDARs is their high permeability to Ca^{2+}. Ca^{2+} influx through NMDARs is essential for synaptogenesis, plasticity of neural circuitry, and higher cognitive functions, such as learning and memory. Emerging evidence reveals that PKA signaling represents a fundamental mechanism by which NMDAR-mediated Ca^{2+} influx is modulated in neurons. We recently identified serine 1166 (Ser1166) in GluN2B to be the molecular target of PKA phosphorylation relevant to PKA-dependent NMDAR Ca^{2+} permeability. Whereas the impact of Ser1166 on NMDAR Ca^{2+} permeability is well-established, its role in NMDAR-dependent synaptic plasticity and cognition is, as yet, unclear. To address this issue, we generated a mouse in which we knocked in GluN2B containing a single point mutation, S1166A, by means of CRISPR/cas technology. Whereas basal synaptic transmission and synaptic plasticity in the form of high frequency stimulation induced LTP (HFS-LTP) was normal in the knockin mice, theta-burst stimulation-induced LTP (TBS LTP) at CA1 synapses was greatly diminished in slices from knock-in vs. wild-type mice. A distinguishing feature of spaced TBS- *vs*. condensed HFS-LTP at CA1 synapses is a requirement for the transient synaptic incorporation of GluA2-lacking AMPARs during the induction phase of LTP, which are subsequently replaced by GluA2-containing AMPA receptors. A hypothesis under consideration is that Ser1166 is critical for synaptic incorporation of Ca^{2+} permeable (but not Ca^{2+}-

impermeable) AMPARs. We found that, upon induction of TBS-LTP, AMPARs EPSPs are inwardly rectifying and that the LTP is blocked by inhibition of Ca^{2+} permeable AMPARs with IEM-1460 and philanthotoxin 74. TBS LTP in KI mice was rescued by rolipram, which acts as a PKA activator and leads to the insertion of Ca^{2+}-permeable AMPARs to rescue LTP, and by a transient increase in extracellular Ca^{2+}. We further showed that visual cognition, assessed by means of the novel object recognition task, was markedly impaired in knockin *vs*. wild-type mice. Thus, loss of a single site within the GluN2B subunit not only eliminates PKA-induced Ca^{2+} signaling in spines, but greatly diminishes Ca^{2+}-permeable AMPAR-dependent synaptic plasticity in the form of TBS-LTP and hippocampal-based memory in the form of visual recognition.

Title: Characterization of PP1 isoforms in CA1 post-synaptic plasticity

Authors: *K. F. FOLEY[1,2], J. ZHANG[2], H. HOU[2], A. C. NAIRN[3], H. XIA[1,2]

Abstract: Protein phosphatase 1 (PP1) is one of the primary regulators of post-synaptic plasticity, attenuating long-term potentiation (LTP) and required for NMDA receptor-induced long-term depression (LTD). In addition to the electrophysiological characterization of PP1 activity, behavioral studies have demonstrated that PP1 activity can constrain learning and memory. Likewise, its inhibition can prolong memory and facilitate LTP. However, there are three separate PP1 genes in mammals, all of which are expressed in neural tissue. Previous studies have made little distinction between these isoforms, using indiscriminate pharmacological inhibition. Although they share a common, conserved catalytic domain, there is little homology in their N- and C-termini, leading to differences in localization and protein binding. For example, PP1α and PP1γ1 are enriched in dendritic spines whereas PP1β is enriched in dendrites. To elaborate the differences between PP1 isoforms, we selectively knockout each isoform in mice and perform acute slice recordings in CA1 of the hippocampus. While PP1β KO during early development is lethal, PP1α and PP1γ KO mice are viable. Surprisingly, PP1α and PP1γ KO mice show no significant change in CA1 LTP following high frequency stimulation. In

line with differences in localization, these findings suggest a possible compensation between PP1α and PP1γ while PP1β is necessary for development. Further work is needed to delineate the possible differential roles of PP1α, β, and γ in synaptic functions.

Abstract: Dendritic spines are small subcompartments along dendrites that act as epicenters of synaptic communication and signaling activity. These spines have several characteristic shapes, and while it is known that this shape is associated with their function, this relationship is not well understood. In this work, we investigate the relationship between the shape and size of both the spine head and spine apparatus in governing calcium dynamics. Calcium is a vital secondary messenger in the spine that triggers various signaling cascades leading to long term potentiation or depression, and spine volume changes. To elucidate this relationship, we developed a spatial continuum model of calcium dynamics through various flux sources including N-methyl-D-aspartate receptors (NMDAR), voltage sensitive calcium channels (VSCC), and various ion pumps. With this model, we show that i) size and shape of the spine regulate calcium dynamics. ii) Membrane fluxes nonlinearly impact calcium dynamics both temporally and spatially. iii) The spine apparatus rescales calcium by acting as a sink. iv) Buffering proteins are required for physiological temporal dynamics that match experimental and computational calcium models.

Title: Mechanisms of hippocampal long-term potentiation (LTP) are sexually dimorphic in rodents

Authors: A. A. LE[1], W. WANG[2], C. D. COX[1], J. C. LAUTERBORN[1], E. R. LEVIN[3], G. LYNCH[1], *C. M. GALL[1]
[1]Anat. and Neurobio., [3]Dept. of Med., [2]Univ. of California, Irvine, CA

Abstract: Men are generally better than women in learning spatial relationships whereas the reverse holds for semantic information, but the neurobiological bases for these differences are not understood. We will describe a striking sexual dimorphism in synaptic mechanisms of memory encoding in hippocampal field CA1, a region critical for spatial learning. Studies of acute hippocampal slices from adult rats and mice showed that theta-burst stimulation (TBS)-induced long-term potentiation (LTP) in the Schaffer-Commissural (S-C) projections to CA1 depends upon endogenous estrogen and estrogen receptor α (ERα) in gonadally intact, adult females but not in males. Antagonists for ERß or GPER1 receptors did not disrupt S-C LTP in either sex. Experiments with mutant mice that express only nuclear or membrane forms of ERα (NOER or MOER mice, respectively) confirmed that LTP depends on membrane ERα in females. Quantitative immunofluorescence revealed that the sex differences extend to activity-induced kinase signaling at S-C synapses: TBS driven phosphorylation of ERK1/2 and Src requires ERα in females only. Downstream actin signaling initiated by RhoA, TrkB, and ß1-integrin was comparable between the sexes, except for the expected dependency on ERα in females. Finally, spatial learning activated synaptic ERK1/2 and Src in both sexes but in females this response and long-term memory required ERα. In all, induction of memory-related synaptic modifications by naturalistic patterns of afferent activity involves an ERα-kinase link in females that is not utilized by males. We propose that the addition of this step alters LTP parameters and thereby elevates the threshold for encoding of certain forms of memory. Potential advantages associated with a higher threshold will be discussed.

Title: AKAP150 palmitoylation regulates synaptic incorporation of Ca^{2+}-permeable AMPARs basally and during LTP

Authors: *A. M. PURKEY[1], K. M. WOOLFREY[1], K. C. CROSBY[1], D. G. STICH[2], W. S. CHICK[3], J. AOTO[1], M. L. DELL'ACQUA[1]

Abstract: Synaptic incorporation of Ca^{2+}-permeable AMPA-type glutamate receptors (CP-AMPARs) containing GluA1, but lacking GluA2, subunits contributes to multiple forms of synaptic plasticity, including long-term potentiation (LTP). A-kinase anchoring protein (AKAP) 150 scaffolds kinases and phosphatases to AMPARs to regulate GluA1 phosphorylation and trafficking. AKAP150 targeting to cellular membranes is modulated through its palmitoylation on two Cys residues. Here, we developed a palmitoylation-deficient knock-in mouse to show that AKAP150 palmitoylation regulates CP-AMPAR incorporation at hippocampal CA1 synapses. Using a combination of biochemical, super-resolution fluorescence imaging, and electrophysiological approaches, we found that palmitoylation promotes AKAP150 association with the postsynaptic density (PSD) and limits basal CP-AMPAR synaptic incorporation. In addition, we found that AKAP150 palmitoylation is required for LTP induced with weaker stimuli that recruit CP-AMPARs but not stronger stimuli that recruit predominantly GluA2-containing AMPARs. Thus, AKAP150 palmitoylation controls its postsynaptic localization to maintain proper basal and activity-dependent regulation of synaptic AMPAR subunit composition.

Title: Competitive tuning of Ca2+/calmodulin activated proteins provides a homeostatic effect in synaptic plasticity

Authors: *M. C. PHARRIS, N. M. PATEL, D. R. ROMANO, T. L. KINZER-URSEM
Weldon Sch. of Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Synaptic plasticity depends on NMDA receptor-mediated calcium ion (Ca^{2+}) flux. Intracellular Ca^{2+} binds to the Ca^{2+}-sensor calmodulin (CaM), which modulates downstream effector proteins including kinases, phosphatases, and ion channels, whose differential activation leads to either potentiation or depression of synaptic strength. The activation of individual downstream CaM binding proteins (CBPs) is in-part a function of the frequency of Ca^{2+} flux, such that each CBP is preferentially "tuned" to different Ca^{2+} input signals. Tuning of CBP activation may depend on a variety of mechanisms such as feedback loops and spatial effects. Here, we will explore an additional mechanism called "competitive tuning" in which competition among CBPs for binding to Ca^{2+}/CaM is sufficient to recreate *in silico* the observed *in vivo* Ca^{2+} frequency-dependence of several CBPs. For example, the CBP calcineurin preferentially binds CaM at low frequencies (<10Hz) in a competitive model of many explicitly-defined CBPs, in agreement with experimental results.
One prediction of competitive tuning is that CaM-binding of Ca^{2+}/CaM-dependent kinase II (CaMKII) decreases with decreasing concentration of the CaM buffer neurogranin. This counter-intuitive result highlights how the dynamics of CBP activation may strongly depend on the identity and concentration of the proteins that constitute the competitive pool.
We hypothesize that although perturbations may decrease activation of one CBP such as CaMKII, a separate but functionally similar competitor could compensate, providing a chemostatic effect. We explore this mechanism by first quantifying the effect of parameter perturbations on competitive tuning. We also extend our model to include phosphatase activity and AMPA receptor phosphorylation (AMPARp); a hallmark of synaptic plasticity. With this extended model we proceed to examine the effect of perturbations in the concentration of the CaM buffer neurogranin. Neurogranin knockout simulations show a realignment in competition for CaM that decreases Ca^{2+}/CaM-dependent kinase II activation, but interestingly, overall AMPARp levels are maintained by a concomitant increase in adenylate cyclase 8 (AC8)

activation. Our results provide further evidence that competitive tuning is an important mechanism in the regulation of synaptic plasticity.

Title: Integration of spatiotemporally distinct signals by PKCα during synaptic plasticity

Authors: *L. A. COLGAN[1], M. HU[1], J. A. MISLER[1], P. PARRA-BUENO[1], C. M. MORAN[1], M. LEITGES[2], R. YASUDA[1]

Abstract: The Protein kinase C (PKC) family of enzymes has long been established as critical for synaptic plasticity. However, it is unknown whether Ca^{2+}-dependent PKC isozymes are activated in dendritic spines during plasticity, and if so, how this synaptic activity is encoded by PKC. Here, using newly-developed, isozyme-specific sensors, we demonstrate that classic isozymes are activated to varying degrees and with unique kinetics. PKCα is activated robustly and rapidly in stimulated spines and is the only isozyme required for structural plasticity. This specificity, depends on a PDZ-binding domain present only in PKCα. The activation of PKCα during plasticity requires both NMDAR Ca^{2+}-flux and autocrine BDNF-TrkB signaling, two pathways that differ by orders of magnitude in their spatiotemporal scales of signaling. Our results suggest that by integrating these two signals, PKCα combines a measure of recent, nearby synaptic activity with local synaptic input, enabling complex cellular computations such as heterosynaptic facilitation of plasticity necessary for efficient hippocampal-dependent learning.

Title: Unified biochemical model for long-term synaptic plasticity in the cortex - What are the essential pathways?

Authors: *T. MÄKI-MARTTUNEN[1], K. T. BLACKWELL[2], A. G. EDWARDS[3]
[1]Simula Res. Lab., Lysaker, Norway; [2]Mol. Neurosci., George Mason Univ., Fairfax, VA; [3]Scientific Computing, Simula Res. Lab. AS, Lysaker, Norway

Abstract: Despite the advances made in mechanistic modelling of long-term potentiation (LTP) and depression (LTD) in hippocampus (Ajay & Bhalla 2004, Eur J Neurosci 20(10):2671-80), cerebellum (Antunes & de Schutter 2012, J Neurosci 32(27):9288-9300), and basal ganglia (Lindskog et al. 2006, PLoS Comput Biol 2(9): e119), the signaling pathways underlying long-term plasticity in the neocortex remain less understood. Nevertheless, plasticity in neocortical synapses is crucial to many tasks performed by prefrontal and sensory cortices (Carcea & Froemke 2013, Prog Brain Res 207:65-90), and accordingly, a number of brain disorders have been associated with deficits in neocortical plasticity (Battaglia et al. 2007, Biol Psychiatry 62(12):1405-1412; Çavuş et al. 2012, Biol Psychiatry 71(6):512-520). Remarkably, computational models of Hebbian learning have been widely adopted in *in silico* studies of neocortical circuits. These models, however, typically fail to describe the subcellular mechanisms underlying the plasticity and thus prevent from drawing conclusions on the genetic and metabolic deficits underlying the brain disorders. In this work, we review the molecular mechanisms proposed for long-term plasticity in the neocortex. In particular, we identify the proteins and signaling molecules that act at the post-synaptic domain of pyramidal cells to induce and maintain LTP or LTD. The dependence of these pathways on protein synthesis is not explored. Figure 1 shows the composition of known major pathways and their mutual dependencies. These pathways are similar to the pathways that are important for hippocampal plasticity, although the dopaminergic signaling cascades may play a more central role in cortical LTP/LTD than in hippocampal LTP/LTD.

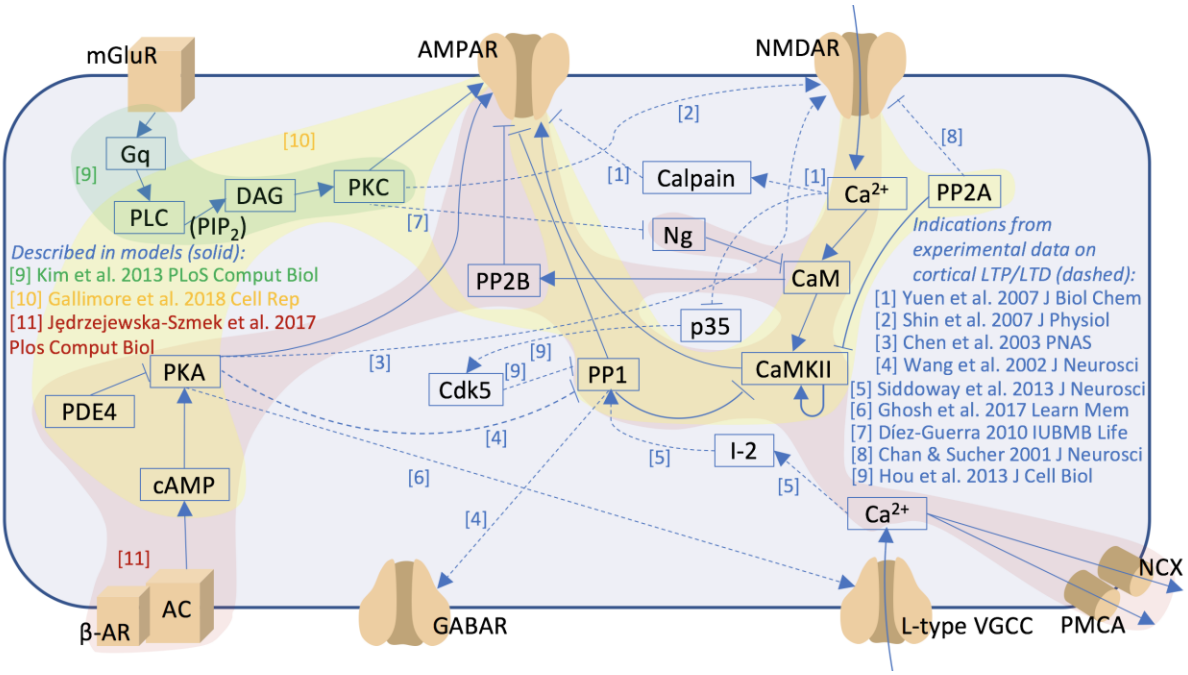

Figure 1. Signaling pathways leading to LTP/LTD in neocortical synapses (at the post-synaptic domain). Solid connections represent actions that have been previously described in computational models of other brain regions (see colored background), whereas dashed lines represent actions not yet described in models.

Title: Adult-selective deletion of KIBRA reduces long-term potentiation and increases sharp wave ripples

Authors: *M. L. MENDOZA, L. D. QUIGLEY, R. PENDRY, B. E. PFEIFFER, L. J. VOLK
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Our capacity to learn and remember changes dynamically throughout our lifespan, however the molecular, synaptic, and circuit basis for age-related changes in cognition remain poorly understood. Synaptic plasticity is widely accepted as a key cellular mechanism underlying cognitive functions such as learning and memory. At the molecular level, dynamic AMPA receptor (AMPAR) trafficking is critical for many forms of synaptic plasticity. AMPAR trafficking is regulated by multiple proteins including the synaptically-localized scaffold protein known as KIBRA. Human genetic evidence suggest that common KIBRA polymorphisms are associated with natural variation in human memory performance. Interestingly, though KIBRA is expressed throughout development and adulthood, deficits in synaptic plasticity do not emerge until early adulthood in constitutive KIBRA knockout mice. Whether the loss of KIBRA facilitates synaptic maturation during juvenile development, or adult synapses are selectively vulnerability to a loss of KIBRA remains to be addressed. Thus, to determine if adult neurons are selectively vulnerable to a loss of KIBRA, we generated an inducible knockout mouse by breeding *Kibra* $^{floxed/floxed}$ mice with CaMKII Cre^{ERT2} mice. Here, we demonstrate that reducing KIBRA expression selectively in adult mice reduces long-term potentiation (LTP), but surprisingly has no affect on long-term depression (LTD). Furthermore, we observed no difference in basal synaptic transmission. Next, we sought to examine how the aforementioned deficits in LTP influence hippocampal circuit function. By utilizing *in vivo* electrophysiology in freely behaving mice, our preliminary data indicate that reducing KIBRA expression selectively in adult mice increases the frequency of hippocampal sharp wave ripples. In ongoing studies we are investigating circuit function during adolescent development in KIBRA KO mice as well as molecular mechanisms by which KIBRA influences LTP.

Title: Evidence for a sex difference in the requirement of PKA to induce long-term potentiation in the hippocampus

Authors: *A. JAIN, C. S. WOOLLEY
Northwestern Univ., Evanston, IL

Abstract: The involvement of cAMP-activated protein kinase A (PKA) in long-term potentiation (LTP) of CA3-CA1 synapses in the hippocampus has been studied extensively. While most studies indicate little role for PKA in early LTP, some studies have shown that early LTP can be PKA sensitive. For example, LTP induced by pairing postsynaptic depolarization with presynaptic stimulation was reduced by ~30% in the presence of a PKA inhibitor (Otmakhova et al., J Neurosci 2000; 20:4446-51). Separately, our lab has identified a sex difference in the requirement for PKA in synaptic potentiation induced by acute estradiol (E2) application to hippocampal slices; E2-induced potentiation was abolished by PKA inhibition in females, but was unaffected in males. In the current study, we asked whether the sex difference in PKA involvement in synaptic potentiation generalizes to LTP.
We recorded excitatory postsynaptic currents (EPSCs) in acute hippocampal slices from adult male and female rats with or without the cell-permeant PKA inhibitor mPKI (0.5 μM) in the bath. After recording 10-15 min of baseline EPSCs, we induced LTP by pairing postsynaptic depolarization to 0 mV with 200 presynaptic stimulations delivered at 1.4 Hz and continued recording for 30-70 min. We calculated the magnitude of potentiation within each cell by averaging the amplitude of all EPSCs recorded following LTP induction compared to all EPSCs recorded during the baseline period. In the absence of the PKA inhibitor, the magnitude of LTP was similar in males and females. Overall, EPSC amplitude increased by 145 ± 30% above baseline in males and by 121 ± 15% above baseline in females (unpaired t-test, $t = 1.14$, $df = 14$, $p = 0.27$). In contrast, LTP induced in the presence of the PKA inhibitor was starkly different between the sexes. In males, PKA inhibition attenuated LTP to 82 ± 36% above baseline, whereas in females, PKA inhibition essentially abolished LTP, to only 14 ± 16% above baseline (two-way ANOVA, sex x mPKI interaction, $F(1,21) = 5.6$, $p = 0.03$). Although still preliminary, these results suggest a sex difference in the involvement of PKA in the mechanisms that underlie LTP: Whereas PKA contributes to pairing-induced LTP in males, as has been reported previously, PKA appears to be required for pairing-induced LTP in females. Further experiments will be done to confirm these results and to extend male-female comparisons of PKA sensitivity to other forms of LTP. If confirmed, a sex difference in the PKA requirement for LTP will add to a growing literature demonstrating latent sex differences in mechanisms of synaptic modulation in which males and females achieve similar functional endpoints through distinct underlying mechanisms.

Title: Modification of ion channel gene expression regulates the expression of multiple ionic currents

Authors: *J. P. GOLOWASCH[1], D. H. DAUDELIN[1], H. G. ROTSTEIN[2], D. J. SCHULZ[3]
[1]Dept Biol. Sci., [2]Biol. Sci., NJIT, Newark, NJ; [3]Div. of Biol. Sci., Univ. of Missouri-Columbia, Columbia, MO

Abstract: The nervous system must maintain relatively stable properties while adapting to changes in the environment. The wide variety of inputs and perturbations that neurons receive during their lifetime is thought to make neurons of the same type express the same genes to different levels (Marder & Taylor, 2011), while maintaining an identical phenotype. Ionic current variability in identical cells is widespread (Marder, 2011, Schulz 2006) and is thought to be constrained by the co-regulated expression of subsets of ion channels (Golowasch, 2014). The result is that ionic currents and maximal conductances appear correlated in populations of identical cells, which has been observed in multiple cell types of various animal species (Temporal et al. 2011, Tobin et al, 2009, Trinh et al, 2017). Thus far, only theoretical work has shown potential mechanisms that generate such correlated currents (O'Leary et al 2014). However, direct manipulation of the genes involved to test the hypothesis that co-regulation of ion channels is the underlying mechanism has been limited (MacLean et al, 2003). Consistent with this hypothesis, we predict that up- or down-regulation of one ion channel should result in up- or down-regulation of other channels whose mRNA or ionic currents have been shown to correlate with it (Temporal et al. 2011, Khorkova and Golowasch 2007, Schulz et al. 2006). We probe these mechanisms by tampering with the expression levels of individual ion channels in neurons of the crab *Cancer borealis* stomatogastric ganglion and studying how the unperturbed ion channels of the cells react. For this, we inject mRNA that codes for specific channels directly into neurons to boost their expression or alternatively inject double stranded RNA (dsRNA) to depress expression. We co-inject mRNA or dsRNA with Green Fluorescent Protein (GFP) mRNA to track expression. We have confirmed that expression of GFP alone does not significantly affect ionic current levels after 2 days (n=9). Preliminary results (n = 11) show that 2 days after *Shal* dsRNA is injected expression, both the transient K^+ current, I_A (coded by *Shal*, P=0.011), and the high-threshold, voltage-gated outward potassium currents, I_{HTK} (P=0.024), decrease significantly (paired t-tests) relative to control measurements taken at the time of dsRNA injection. This leads to the conclusion that a regulatory mechanism is in place in these neurons that tracks the levels of certain ion channels, and that at least one other current known to be correlated with the target channel in unperturbed cells is similarly affected. We predict that overexpression will have the reciprocal effects, and also that multiple channels are affected.

Title: Frequency-dependent coupling between neuronal activity and mitochondrial Ca^{2+} dynamics *in situ*

Authors: *C. J. GROTEN[1], A. NELSON[1], B. A. MACVICAR[2]
[2]Ctr. for Brain Health/Psychiatry, [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Alterations in mitochondrial energy production in neurons have dramatic consequences for brain health. Despite this, the mechanisms by which mitochondria influence/respond to neuronal function have not been fully examined in native brain tissue. As a first step towards understanding potentially unique aspects of this relationship, we examined a role for mitochondrial Ca^{2+} dynamics in the CNS. While this property has long been associated with pathological changes in ATP/ROS production and apoptotic signalling, its significance for brain function is unclear. To address this, I utilized two-photon microscopy and examined the relationship between action potential frequency and cytosolic Ca^{2+}/mitochondrial Ca^{2+} in neurons from cortical brain slices. Current-clamp recordings from pyramidal neurons expressing the mitochondrial Ca^{2+} reporter mitoRGECO1.0 revealed a firing frequency threshold (5 Hz) above which a long-lasting change in the Ca^{2+} content of somato-dendritic mitochondria was observed. These responses were reduced by blocking voltage-gated Ca^{2+} channels or the mitochondrial Ca^{2+} uniporter (using Ru360). Consistent with these findings, Ru360 substantially enhanced the magnitude/duration of cytosolic Ca^{2+} signals only at firing frequencies above 5 Hz. Collectively, our results reveal that dramatic changes in mitochondrial [Ca^{2+}] occur *in situ* in a non-pathological setting. Our findings suggest that the link between spike frequency and mitochondrial [Ca^{2+}] changes could regulate both cellular energetics and cytosolic [Ca^{2+}] signalling during heightened neuronal excitability.

Title: Differential current accumulation from antidromic action potentials modulates stimulus encoding

Authors: *M. DEMAEGD, W. STEIN
Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Information propagation in neurons is often presumed unidirectional from encoding sites in the dendrites through the axon to the synaptic terminals. However, antidromic action potentials originating from 'ectopic' initiation sites are common in many nervous systems. These action potentials can invade dendritic encoding regions or the axon initial segment and alter the neuron's sensitivity to incoming stimuli. While this effect is well described, little is known about the underlying mechanisms.

We are studying the effects of antidromic action potentials on stimulus encoding using the single cell muscle tendon organ AGR (anterior gastric receptor) in the crab stomatogastric nervous system. AGR initiates ectopic action potentials in its axon, the frequency of which is under direct neuromodulatory control by higher order chemosensory neurons. As ectopic action potentials invade AGR's peripheral dendrites antidromically, there is a frequency-dependent decrease in AGR's sensitivity to changes in muscle tension. We hypothesize that these effects on stimulus encoding are due to slow ionic currents that accumulate differentially with changes in ectopic frequency.

To predict which intrinsic ionic currents may mediate changes in stimulus encoding, we designed a computational model with axon and dendritic compartments using Hodgkin and Huxley equations. The model suggests that fast Sodium and Potassium channels are insufficient to cause frequency-dependent changes in stimulus encoding from invading action potentials. In contrast, slower currents could accumulate differentially with antidromic frequency and introduce frequency-dependent membrane excitability changes via modulation of membrane potential and total conductance. Strength and sign of excitability changes depended on current direction and time constant of activation. Hyperpolarizing currents and slower time constants resulted in the greatest reduction in membrane excitability. These effects were facilitated when time constants became progressively slower with hyperpolarization.

Our model thus predicts that invading action potentials modulate stimulus encoding via current

accumulation at the stimulus encoding site. We are now testing this prediction using electrophysiological and molecular techniques using AGR's sensory response as a measure.

Title: The electrical impact of axon initial segment plasticity

Authors: *S. GOETHALS, R. BRETTE
Sorbonne Univ., INSERM, CNRS, Inst. De La Vision, Paris, France

Abstract: In most vertebrate neurons, action potentials are triggered at the distal end of the axon initial segment (AIS). They are then transmitted to the soma where they are regenerated and further propagated in the dendritic tree. The exact AIS start position and length is highly variable across and within neuron types. Moreover, recent studies have reported that the AIS undergoes structural plasticity. Changes in electrical activity can trigger a relocation or elongation/shortening of the AIS. In view of the crucial role of the AIS in spike initiation, these observations raise the question of the function of AIS geometry. What is the specific effect of AIS plasticity on electrical function? Experimentally, that effect is not straightforward to understand because AIS plasticity goes along with other intrinsic changes such as channel expression and phosphorylation. Simulations have also shown a variety of effects, with no clear understanding of the conditions for each of them. So we analyzed theoretically the effect of changes in position, length and sodium channel density on electrical function. We start by studying analytically the impact of AIS geometry on excitability in a simple axon model. First, we look at the impact of changes in AIS geometry on the somatic voltage threshold. Considering only Na channels in the AIS, our theoretical results suggest that the threshold depends mainly on the middle position of the AIS and on the total number of Na channels. In particular, shifting the AIS away from the soma decreases the threshold and in consequence increases excitability. Second, we show that if we add a hyperpolarizing current at the AIS (e.g. Kv channels), the effect of shifting the AIS is reversed. Third, we examine the impact of AIS geometry on the current that backpropagates to the soma. We find that this impact is determined by different parameters. The backpropagating spike is mainly determined by the AIS start position, and by the Na channel density in the AIS. These theoretical results agree with simulations of an action

potential model. Although previous studies have focused on changes in intrinsic excitability, we point out that the electrical effect of AIS plasticity is multidimensional. In particular, different geometrical factors affect the spike threshold and the backpropagation to the soma.

Title: Burst firing of hippocampal mossy fibers by local blockade of axonal potassium channels

Authors: *H. KAMIYA
Dept. of Neurobio., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan

Abstract: A potassium channel blocker 4-aminopyridine (4-AP) has been shown to exert pronounced convulsive action and generates burst discharges when applied to hippocampal slices. However, it remains unclear how a blockade of potassium channels leads to generation of burst discharges. An intriguing possibility is ectopic spiking from the sites different from those for physiological spike initiation at the axon initial segment, as suggested for other experimental models of epileptogenesis in the hippocampus. To test for possible ectopic spike generation at distal axon by 4-AP application, direct recordings from exceptionally large mossy fiber terminals in mouse hippocampal slices were made with loose-patch clamp technique. To localize the action of 4-AP on distal axon, focal perfusion around the recording site were used in combination with recordings from mossy fiber terminals. Focal application of 4-AP on distal portion of mossy fibers reliably induced burst discharges of the mossy fiber terminals. Numerical simulation based on a realistic mossy fiber model suggested that local blockade of axonal potassium channels prolonged duration of action potentials and thereby caused reverberating spiking activities at distal axons and subsequent antidromic propagation towards the soma. Taken together, it was suggested that local blockade of voltage dependent potassium channels in distal axons by application of 4-AP is sufficient to cause a hyperexcitable state of hippocampal mossy fiber axons and initiate bursting activities of the CA3 neuronal network.

Title: Pedunculopontine intrinsic gamma oscillations are blocked by histone deacetylase inhibitors

Authors: *E. E. GARCIA-RILL[1], V. BISAGNO[2], F. J. URBANO[3]
[1]Slot 847, Ctr. for Translational Neurosci, Little Rock, AR; [2]ININFA-CONICET, Buenos Aires, CABA, Argentina; [3]IFIBYNE-CONICET, Buenos Aires, Argentina

Abstract: Epigenetic mechanisms (i.e., histone post-translational modification and DNA methylation) play a role in regulation of gene expression in response to a wide range of environmental stimuli. Histone deacetylases (HDACs) are epigenetic regulators that regulate the histone tail, chromatin states, protein-DNA interaction, and transcription.HDACs and their inhibitors are promising candidates for treating cancer and several neurodegenerative disorders. However, the mechanisms of action of HDAC inhibitors need to be elucidated. Indeed, there are potential neurological side effects by modulating HDAC functions. More research is needed to design new and more specific HDAC inhibitors with the lowest range of neurological side effects. The pedunculopontine nucleus (PPN) is an element of the reticular activating system that regulates arousal. We previously described intrinsic gamma oscillations in PPN neurons that are subserved by voltage-dependent, high threshold N- and P/Q-type Ca2+ channels. In the present study, we investigated whether PPN intrinsic gamma oscillations are affected by inhibition of histone deacetylation *in vitro*. Our results on 150 PPN neurons showed that, a) acute in vitro exposure to the HDAC Class I and II inhibitor trichostatin A (TSA, 1uM) eliminated high threshold, voltage-dependent Ca2+ channel-mediated oscillations in the gamma band range, but not lower frequencies ($p<0.05$), b) pre-incubation with TSA (1uM, 90-120 min) led to a similar decrease specifically in gamma band oscillations (One-way ANOVA, $p<0.05$), c) a significant reduction in Ca2+ currents (I_{Ca}) was elicited by TSA, d) a HDAC Class I inhibitor MS275 (500 nM), and a HDAC Class IIb inhibitor tubastatin A (150-500 nM), both failed to affect intrinsic gamma oscillations in PPN neurons ($p>0.05$). These results suggest that there is a specific effect on gamma band oscillations when histone deacetylation is blocked and that these phenomena might underlie the negative side effects of HDAC inhibitors on arousal.

Title: a7 nAChR in hippocampal theta generation

Authors: *Z. GU, J. L. YAKEL
Neurobio. Lab., NIEHS/NIH, Rtp, NC

Abstract: We have recently found that hippocampal muscarinic acetylcholine receptors (mAChRs) are important for theta generation in the entorhinal hippocampal network in freely moving mice. Here we show that the alpha 7 nicotinic AChRs (α7 nAChR) also play an important role in theta generation. Local hippocampal infusion of selective antagonists of the α7 nAChR partially reduced hippocampal theta power in freely moving mice, similar to the effect of mAChR antagonists. There was no significant additive effect when the two antagonists were combined. Our *in vitro* studies in cultured slices suggest that mAChR activation promotes transient theta generation, while α7 nAChR activation may prime the network to future theta generation by the same inputs. With receptor knockout in neuronal subpopulations, we found that α7 nAChRs expressed in interneurons play an important role in theta generation, while we previously found that m1 mAChRs expressed in pyramidal neurons played the major role in theta generation. These results suggest that neuronal subpopulations recruit different cholinergic receptors to support theta generation. Currently we are trying to identify the interneuron subpopulations that are involved in α7 nAChR-dependent theta generation.

Abstract: There are more than 20 subtypes of interneurons in the hippocampus, targeting different subcellular domains of the principal cells, and providing diverse modulation of synaptic integration and neuronal firing patterns. It was shown experimentally that repeated inhibition of hippocampal CA1 somatostatin-positive interneurons can induce lasting potentiation of Schaffer collateral to CA1 EPSCs, suggesting that in addition to acutely gating the generation of action potentials, repeated dendritic disinhibition also plays a role in the induction of synaptic plasticity. We used a biophysically realistic computational model to examine mechanistically how inhibitory inputs to hippocampal pyramidal neurons can modulate the plasticity of excitatory synapses.
We found that reduced GABA release (disinhibition) could lead to increased NMDAR activation and intracellular calcium concentration, which could in turn upregulate AMPAR permeability. Repeated disinhibition of the excitatory synapses could lead to larger and longer lasting increase of the AMPAR permeability, i.e. synaptic plasticity.
We also found experimentally that repeated cholinergic activation can also induce synaptic plasticity through a7 nAChRs expressed in interneurons. Currently we are exploring the interneuron subtypes that may be involved in a7 nAChR-dependent synaptic plasticity, and how can they modulate disinhibition of excitatory synapses.

Title: Intrinsic mechanisms of frequency selectivity in the proximal dendrites of CA1 pyramidal neurons

Authors: *C. L. COMBE[1], C. C. CANAVIER[2], S. GASPARINI[1]
[1]Neurosci. Ctr., [2]Neurosci. Ctr. and Dept. of Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Gamma oscillations, one of multiple bands of synchronous activity, are thought to play a role in learning and memory. Multisite recordings within the rat hippocampal formation indicate that different behavioral tasks are associated with synchronized activity between areas CA3 and CA1 at either slow (25-50 Hz) or fast (65-100 Hz) gamma. Slow gamma is phase-locked to activity in area CA3 and presumably driven by the Schaffer collaterals.
We used a combination of computational modeling and *in vitro* slice electrophysiology to test the hypothesis that the intrinsic properties of CA1 pyramidal neurons prime them to "listen" to different bands of gamma frequency input from CA3, depending on physiological conditions, and to identify the mechanisms involved. Both approaches demonstrated that, under control conditions, in response to temporally precise input at Schaffer collaterals, CA1 pyramidal neurons fire preferentially in the slow gamma range regardless of whether the input is at fast or slow gamma frequencies, suggesting frequency selectivity in CA1 output with respect to CA3 input. In response to 10 pulse-trains, cells fired an average of 8.8 ± 0.1 spikes in response to 40 Hz stimulation and 5.3 ± 0.1 spikes at 100 Hz stimulation ($p < 0.0005$, $n = 16$). In addition, phase-locking was more precise for slow gamma than fast gamma input: the vector strengths, *r*, from the cumulative data across all neurons were 0.899 (0.888-0.910) at 40 Hz and 0.577 (0.537-0.616) at 100 Hz; 95% confidence intervals in parentheses. Synaptic depression did not play a role in frequency selectivity at Schaffer collateral inputs, as subthreshold EPSPs showed only patterns of summation at both slow and fast gamma frequencies. The frequency selectivity was absent when stimulation was achieved through trains of 2 ms-current injections in the soma (9.9 ± 0.1 spikes at 40 Hz and 9.2 ± 0.3 at 100 Hz, $p = 0.221$, $n = 10$). The frequency selectivity was also greatly attenuated when the Ca^{2+}-activated K^+ (SK) current was removed from the model or blocked *in vitro* with apamin (the number of action potentials generated by 100 Hz input significantly increased from 5.5 ± 0.2 in control to 6.7 ± 0.3 in apamin, exact $p = 0.002$, $n = 10$), or by the broad-spectrum cholinergic agonist carbachol (control, 5.3 ± 0.1; carbachol 6.4 ± 0.2; exact $p = 0.016$, $n = 7$). Perfusion of slices with $BaCl_2$ (100 µM) to block A-type K^+ channels tightened this frequency selectivity (at 100 Hz, control, 5.3 ± 0.1; $BaCl_2$ 4.5 ± 0.1, exact $p = 0.008$, $n = 8$). We propose that these intrinsic mechanisms provide a means by which CA1 phase locks to CA3 at different gamma frequencies preferentially *in vivo*, as physiological conditions change with behavioral demands.

Title: Data-driven biophysical models of hippocampal CA3 pyramidal cell-types to investigate cellular mechanisms of sharp-wave generation

Authors: *D. L. HUNT[1], N. P. SPRUSTON[2], D. LINARO[3]
[1]Janelia Res. Campus, Ashburn, VA; [2]HHMI Janelia Res. Campus, Ashburn, VA; [3]Univ. of Antwerp, Wilrijk, Belgium

Abstract: Hippocampal sharp-waves are network synchronization events originating in the CA3 region. They are vital to memory function, yet little is known about how they are generated. Our previous work has revealed that the hippocampal CA3 region consists of two principal cell-types, including classically described regular-spiking pyramidal cells adorned with postsynaptic spiny structures known as thorny excrescences, and intrinsically bursting pyramids that lack these specialized spines (i.e., athorny). We investigated the functional roles of these two cell types by recording their activity patterns during sharp-waves *in vivo*. The data suggest a novel cellular mechanism for sharp-wave initiation by cell-type-specific bursting of athorny pyramids, which promotes the synchronized generation of single spikes in a population of thorny pyramids underlying the sharp-wave local field potential. Understanding how thorny and athorny cells integrate their synaptic inputs to produce regular-spiking and burst-firing output *in vivo* would contribute to a more detailed mechanistic understanding of sharp-wave generation. Here we adopted a modeling approach to gain insight into the biophysical mechanisms of cell-type-specific synaptic integration. To this end, we have developed biophysically detailed multi-compartmental models based on high-resolution morphological reconstructions and *in vitro* patch-clamp electrophysiology (subthreshold and suprathreshold waveform features extracted from the membrane potential of the cells in response to somatic current injection) from both CA3 cell-types. To recapitulate the cell-type-specific intrinsic properties, we implemented a multi-objective optimization framework in conjunction with a genetic algorithm to tune the parameters of the cell-type-specific models. The genetic algorithm evolves a population of models exhibiting values of the features that closely match the experimental data from *in vitro* experiments. Subsequently, we inferred the structure of synaptic input during sharp-waves by finding activation patterns that mimic the distribution of inter-spike-intervals observed in CA3 principal cells recorded *in vivo*. These models can be used to make testable predictions concerning the relationship between the biophysical properties of principal neurons, their synaptic connectivity in the circuit, and their firing patterns during sharp waves *in vivo*.

Abstract: To elucidate the microcircuits that take part in neuronal oscillations, it is crucial to understand how the intrinsic properties of the participating neurons (e.g., ionic currents, morphology) interact with the network properties (excitation/inhibition balance) to produce the rhythms. Several neuron types exhibit membrane potential resonance (MPR) generated by a combination of restorative and regenerative ionic currents. Because these currents may be heterogeneously distributed in space and active at different voltage ranges, neurons may exhibit more than one type of MPR. The consequences of this multiplicity of MPRs for spiking activity are not well understood. It is also not well understood how biophysical (e.g. channel-mediated), morphological (e.g. compartmental/spatial) and network filtering properties interact. We address these issues theoretically in the context of the hippocampal area CA1 microcircuit using mathematical modeling and numerical simulations. Pyramidal neurons (PYR) have been shown to exhibit MPR in the theta (4-10 Hz) range by two different mechanisms (Hu et al., 2002), one primarily somatic (I_M and I_{Nap}) and the other primarily dendritic (I_h). PV^+ interneurons (INT) have been reported to be low-pass filters (Zemankovics et al., 2010) or to exhibit MPR at gamma frequencies (~40 Hz) by unknown mechanisms (Pike et al., 2000). The minimal model we use includes these two cell types with AMPA excitation (PYR to INT), $GABA_A$ inhibition (INT to PYR) and periodic inputs. INT gamma resonance was generated by I_{Ks} (slow-potassium) and amplified by either I_{Nap} or I_{Kir}. In PYR, the spatial separation of the two resonances in multi-compartment models allows the I_h-based rebound spiking to be more robust, as compared to single-compartment models. The PYR MPR fails to be communicated to the spiking regime upon direct PYR activation, independently of the INT model employed, consistent with previous observations in vivo (Stark et al., 2013). When INT are modeled as low-pass filters, direct INT activation creates a PYR spiking low-pass filter by post-inhibitory rebound mechanisms. In

contrast, when INT are modeled as gamma band-pass filters, direct INT activation generates a theta-band spiking resonance in the PYR as a result of the interplay of the PYR low-pass and the INT high-pass filtering properties in the theta frequency range. The results of this work have direct implications for the generation of network resonance in periodically forced PYR-INT networks involving the interplay of filtering properties at different levels of organization, and suggest a novel network-based mechanism for spiking-regime theta-band resonance.

Title: Monitoring dendritic excitability during behavior using neuropixels silicon probes

Authors: *A. ROTH, N. A. STEINMETZ, V. CHEREPANOVA, M. CARANDINI, K. D. HARRIS, M. HAUSSER
Univ. Col. London, London, United Kingdom

Abstract: Action potentials backpropagate into the dendrites of many types of neurons, providing a report of neuronal output to dendritic synapses and shaping local plasticity rules for updating their weights. The spatial extent of backpropagation both shows systematic variation across neuronal types, and can change rapidly in individual neurons due to changes in synaptic input, brain state and/or neuromodulation. While action potential backpropagation has been characterized in many experiments in vitro and in vivo, its modulation during behavior has not been well studied. Backpropagating action potentials can also be associated with local dendritic electrogenesis, for example during triggering of calcium spikes in layer 5 neocortical pyramidal neurons, with its own conditions and consequences for synaptic and intrinsic plasticity, and thus for the learning rules implemented in single neurons and neuronal networks.
We are addressing these problems using Neuropixels silicon probes sampling the extracellular potential simultaneously from 384 densely-spaced recording sites along a linear shank running parallel to the apical dendrite of layer 5 pyramidal neurons. This configuration allows the extracellular signature of action potential backpropagation to be recorded at high spatial and temporal resolution during behavior. Recordings were performed in visual cortex of awake,

head-fixed mice exposed to sparse noise visual stimuli or darkness, while their forepaws rested on a wheel whose movements were recorded. After spike sorting based on classical signals of putatively somatic origin, the dendritic signatures of well-isolated units were examined in a spatiotemporal spike-triggered average of the extracellular potential. Units with a soma in neocortical layer 5 whose average extracellular signature in this plot could be followed over the largest spatial extent towards the surface of the cortex were selected for further analysis.
In these units, the average velocity of the signal propagating from the soma towards the pia was in the range of 0.4 to 1.2 m/s, consistent with the propagation velocity of action potentials in neocortical pyramidal neurons at physiological temperature. The space constant of decay of these signals, when fitted with a single exponential, was on the order of 100 µm, but often exhibited a smaller-amplitude long-range component. We are currently using this approach to monitor active dendritic events during behavior, as well as track the changes in dendritic excitability that may accompany learning.

Title: Fear learning modulates neural and dendritic activity in the auditory cortex

Authors: *L. GODENZINI, L. M. PALMER
Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia

Abstract: Neural activity underlying sensory perception in the neocortex is constantly modified by learning. For example, learning induces a shift in network activity, enhancing feedback signalling. Despite its importance, how single neurons integrate such changes in feedback input during learning is currently unknown. Here, this is addressed by investigating somatic and dendritic activity in the auditory cortex following fear learning. In differential fear conditioning, mice robustly learn to discriminate between two auditory stimuli, previously presented with (CS+) or without (CS-) a mild foot shock. Using patch clamp electrophysiology in vivo, we identified changes in neuronal excitability of layer 2/3 pyramidal neurons in the auditory cortex, following fear learning. Despite no difference in subthreshold auditory evoked activity, action potential generation in response to the CS+ was significantly greater compared to the CS-. To investigate whether dendrites in the auditory cortex also alter their activity following fear learning, dendritic activity was assessed using two-photon Ca^{2+} imaging in layer 2/3 pyramidal

neurons sparsely expressing the genetic Ca^{2+} indicator, GCaMP6f. Here, tuft dendrites differentially responded to the auditory stimuli presented during fear conditioning. A subset of dendrites were active only during the presentation of either CS+ or CS-, whereas, other dendrites were active during both conditions. Taken together, these results suggest that dendrites in the upper cortical layers of the auditory cortex are differentially involved in driving neural signalling during auditory fear learning.

Title: Voltage and calcium signals in dendrites of medium spiny neurons

Authors: *J. JANG[1], S. D. ANTIC[2]
[1]Univ. of Connecticut Hlth., Farmington, CT; [2]Neurosci, UConn Hlth., Farmington, CT

Abstract: The medium spiny neuron (MSN) is a key neuron in the basal ganglia circuit, involved in several major neurological disorders including Parkinson's disease, Huntington's disease and attention deficit hyperactivity disorder (ADHD). MSNs exhibit two neural states. The "Down state" (hyperpolarized membrane potential) alternates with the "UP state" (depolarized membrane potential) in accordance to the temporal availability of glutamatergic synaptic inputs impinging onto their spiny dendrites. To understand the functional roles of MSNs, it is necessary to study dendritic physiological properties. Intrinsic membrane properties of MSN dendrites are poorly understood because glass electrode recordings are not tolerated well by thin dendritic branches. Here, we performed simultaneous somatic whole-cell recording with dendritic imaging to focus on dendritic properties. We injected voltage sensitive dyes (JPW-3028 and JPW-4008) or Ca^{2+} indicators (OGB1 and Fluo-5N) into MSNs. Dendritic membrane potential changes were induced by backpropagating action potentials (bAPs) or by local application of glutamate on dendrite. Our results reveal an increasing dendritic AP peak latency depending on the distance from the soma. The amplitudes of action potential-induced dendritic Ca^{2+} influxes decrease with distance from the soma suggesting a distance dependent attenuation of bAPs in dendrites of MSNs. Next, we characterized the voltage waveforms of glutamate evoked plateau potentials in dendrite and cell body simultaneously. Invariably, the dendritic plateaus preceded somatic plateau potentials and the initiation phase of the dendritic UP state

(plateau) was steeper than that in the soma, consistent with a local initiation of the dendritic plateau. Detailed characterization of voltage and Ca^{2+} signals is expected to reveal the intrinsic dendritic properties and bring us closer to the functional roles of MSNs in the basal ganglia circuits. Title: Estrous cycle-dependent sex differences in rat dorsal striatal medium spiny neuron excitability

Authors: *J. WILLETT, A. JOHNSON, O. PATEL, D. DORRIS, J. MEITZEN
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: The neuroendocrine environment in which the brain operates is both dynamic and differs by sex. How this unstable neuroendocrine state affects neuron properties has been significantly neglected in neuroscience research. Behavioral data across humans and rodents indicate that natural changes in steroid sex hormone exposure affect sensorimotor and cognitive function in both normal and pathological contexts. These behaviors are critically mediated by the dorsal striatum: a well-conserved constituent of the basal ganglia that is instrumental for forebrain function, various forms of learning, and sensorimotor performance. In the dorsal striatum, medium spiny neurons (MSNs) are the predominant and primary output neurons. As such, MSNs are fundamental components of the circuits which underlie striatal-mediated behaviors. Importantly, MSNs express membrane-associated estrogen receptors and demonstrate estrogen sensitivity. However, the effects of cyclical hormone changes across the estrous cycle on the basic electrophysiological properties of MSNs have not been investigated. Here, I test the hypothesis that dorsal striatal MSN intrinsic excitability is a dynamic property that is modulated in adult females across the estrous cycle via the associated changes in steroid sex hormone levels. I performed whole-cell patch clamp recordings on male, diestrus female, proestrus female, and estrus female MSNs in acute brain slices obtained from adult rat dorsal striatum. Assessment and analysis of the electrophysiological properties indicate that the properties that govern cellular excitability differ over the course of the estrous cycle for female MSNs. Overall, given the estrous-dependent sex differences in the normal and pathological behavioral output of

circuits involving the dorsal striatum, understanding the nature of neuroendocrine modulation of MSN function is an important research goal.

Title: Estrous cycle-induced sex differences in medium spiny neuron excitatory synaptic transmission and intrinsic excitability in adult rat nucleus accumbens core

Authors: *S. PROANO, H. MORRIS, L. KUNZ, J. MEITZEN
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Naturally occurring hormone cycles in adult female humans and rodents create a dynamic neuroendocrine environment. These cycles include the menstrual cycle in humans, and its counterpart in rodents, the estrous cycle. These hormone fluctuations induce sex differences in the phenotypes of many behaviors, including those related to motivation, and associated disorders such as depression and addiction. This suggests that the neural substrate instrumental for these behaviors, including the nucleus accumbens core (AcbC), likewise differs between estrous cycle phases. It is unknown if the electrophysiological properties of AcbC output neurons, medium spiny neurons (MSNs), change between estrous cycle phases. This is a critical knowledge gap given that MSN electrophysiological properties are instrumental for determining AcbC output to efferent targets. Here we test whether the intrinsic electrophysiological properties of adult rat AcbC MSNs differs across female estrous cycle phases and to males. We recorded MSNs using whole cell patch-clamp technique in two experiments: the first using gonad-intact adult males and females in differing phases of the estrous cycle, and the second using gonadectomized males and females wherein estrous cycle was eliminated. MSN intrinsic electrophysiological and excitatory synaptic input properties robustly changed between female estrous cycle phases and males. Sex differences in MSN electrophysiology disappeared when the estrous cycle was eliminated. These novel findings indicate that AcbC MSN electrophysiological properties change across the estrous cycle, providing a new framework for understanding how biological sex and hormone cyclicity regulate motivated behaviors and other AcbC functions and disorders.

Title: Effect of neonatal hormone exposure on electrophysiological properties of striatal medium spiny neurons in prepubertal rats

Authors: *J. CAO, J. MEITZEN
North Carolina State Univ., Raleigh, NC

Abstract: Steroid sex hormones and genetic sex regulate the phenotypes of motivated behaviors and relevant disorders. Growing evidence indicates that sex differences can exist in many brain areas other than those directly involved in reproduction, which includes the dorsal striatum (caudate/putamen) and nucleus accumbens. This striatal regions show robust sex differences in gene expression, neuromodulator action (including dopamine and 17β-estradiol), and relevant sensorimotor behaviors and pathologies such as the responsiveness to drugs of abuse.
Our laboratory has demonstrated that the electrophysiological properties of rat striatal medium spiny neurons (MSNs) vary by sex, including female MSNs exhibiting increased intrinsic excitability compared with male MSNs in prepubertal rat dorsal striatum. These data suggest that neonatal masculinization via sex hormone action may regulate MSN electrophysiological properties in dorsal striatum, similar to previously published findings that neonatal estradiol exposure masculinizes rat nucleus accumbens core MSNs. Here we test the hypothesis that neonatal estradiol exposure also regulates the electrophysiological properties of dorsal striatal MSNs. To accomplish this, we exposed female and/or male rats to either estradiol, agonists of estrogen receptors α, β, or GPER-1, or vehicle control, on the first two days after birth. We then recorded the electrophysiological properties of MSNs on PND 16-23. MSN electrophysiological properties were found to be largely mature at that developmental stage. Further data analysis is ongoing, and encompasses action potential, intrinsic excitability, passive membrane properties and mEPSC properties. The results from this experiment will demonstrate whether neonatal hormone exposure will eliminate the sex difference of increased intrinsic excitability in female, and the underlying hormone. These data will help elucidate the underlying mechanisms by which sex differences in striatal neuron properties are generated.

Title: Response propagation through photoreceptors that mediate high-acuity vision

Authors: G. S. BRYMAN[1], A. LIU[2], *M. H. DO[2]
[1]Program in Neurosci., Harvard Med. Sch., Boston, MA; [2]F.M. Kirby Neurobio. Ctr., Boston Children's Hosp., Harvard Med. Sch., Boston, MA

Abstract: Humans and many other primates have the highest visual acuities observed in mammals (Veilleux and Kirk, 2014). This performance originates in the fovea, where the image is resolved at a fine grain by cone photoreceptors that are uniquely slender and tightly packed. Light has direct access to this photoreceptor array due to the lateral displacement of downstream cells. Foveal cones drive these cells by extending axons, called Henle fibers, that can reach half a millimeter in length (Drasdo et al., 2007; Perry and Cowey, 1988). High visual acuity depends on the effective propagation of graded electrical responses through the elongated foveal cones. However, computational modeling suggests that frequencies important to vision are attenuated several-fold by propagation (Hsu et al., 1998). We have now addressed this topic experimentally using macaque cones. Our principal approach was to make simultaneous patch-clamp recordings from the inner segment (IS) and presynaptic terminal of single cones that were dissociated from the retina, injecting currents of various waveforms into the IS and recording the membrane voltage at both sites. We found that peripheral cones had IS and terminal responses that were nearly indistinguishable, consistent with their stout shapes and short (~40 micron) axons. With regard to foveal cones, even the longest displayed effective propagation—for a stimulus at 60 Hz, IS and terminal responses differed by <20% in amplitude and phase lag. Although voltage-gated ion channels produced dynamic nonlinearities such as resonance and adaptation, blocking them did not diminish propagation. Indeed, passive compartmental models built according to the responses and morphologies of recorded cones showed propagation with little attenuation. These models indicated that one key property is a cytoplasmic resistivity that is >1 order of magnitude lower than values reported for cones of other species (Lasater et al., 1989). The characteristics of

dissociated cones were similar to those of cones that we examined in the intact retina using single-site (IS) recordings. We conclude that electrotonic conduction is sufficient for high-fidelity, graded signaling that is robust to the extreme morphological variation of primate cones and is suitable for the sharp acuity of foveal vision.

Abstract: Understanding the neural correlates of consciousness remains a fundamental task in neuroscience for both clinical and scientific reasons. In particular, changes in the membrane potential of cortical neurons have been associated with different states of consciousness, such as wakefulness, sleep, and general anesthesia. We used automated, *in vivo* whole-cell recordings to observe the membrane potential of neurons in the mice barrel cortex before and after drug-induced loss of consciousness. We tested the effects of two clinically relevant anesthetic drugs: dexmedetomidine and ketamine. Dexmedetomidine is an alpha-2 noradrenergic antagonist, and ketamine is an NMDAR blocker. Both drugs were infused systemically via an indwelling

intraperitoneal cannula after baseline recordings of active and quiet wakefulness. The point of loss consciousness was estimated through a probabilistic function of the motion flow obtained from video recordings of the mice spontaneous behavior. Before drug dosing, the membrane potential was characterized by slow fluctuations in the membrane potential, about one per second, interspersed with persistent depolarizations typically accompanied by spiking and coincident with periods of active wakefulness. After dosing, both drugs abolished the persistent depolarizations, but the slow fluctuations remained and became more periodical as compared to those observed during quiet wakefulness. Simultaneous recordings of pairs of neurons revealed that these fluctuations were synchronous within hundredths of micrometers. Previous studies using gaseous anesthetics have shown that the quiescence periods during loss of consciousness can be as long as one second. This is not the case during ketamine and dexmedetomidine-induce loss of consciousness. However, our results are consistent with previous observations of locally synchronous slow oscillations in human cortex during propofol-induced loss of consciousness. Therefore, both prolonged quiescence of the membrane potential and oscillatory entrainment of the local cortical network seem to be incompatible with a normal state of alert consciousness, and the actions of drugs with different pharmacological targets can result in loss of consciousness through either of these two mechanisms.

Abstract: Anesthetic-induced altered states of consciousness are thought to be associated with highly structured oscillations in the brain. Although many general anesthetics act as $GABA_A$ allosteric modulators, ketamine is a NMDA antagonist and has unique EEG profiles. Here we have investigated the neuronal dynamics of the ketamine-induced loss of consciousness (LOC) and return of consciousness (ROC) in primates. We recorded local field potentials (LFPs) and single neuron activity in a somatosensory (S1) and ventral premotor (PMv) network in two macaque monkeys using microelectrode arrays. The animals' behavioral response was analyzed using a state space model (Fig. 1A). Ketamine was infused at 100 µg/kg/min for 60 min through a vascular port. During wakefulness, the spectrograms showed prominent beta oscillations in both S1 and PMv (Fig. 1B, C). Following the start of ketamine infusion, the beta oscillations appeared to be disrupted before LOC . LOC was then identified during a gradual increase in the high beta-gamma oscillations and the appearance of alpha oscillations. The slow-delta oscillations did not increase following LOC, contrary to the effects of propofol and dexmedetomidine. ROC was observed during a gradual decrease in the gamma power and an increase in the beta power. Neither LOC nor ROC appeared to correspond with a distinctive neural change . ROPAP was also identified in the half of ketamine sessions . Ketamine significantly increased the average spike firing rate in both S1 and PMv (Fig.1D). Our results demonstrate that ketamine-induced LOC is identified during a gradual increase of gamma oscillations. The slow-delta and alpha-theta oscillations only increase as ketamine infusion continues, suggesting an association with deeper anesthetic level or unarousability. Contrary to the distinctive dynamics during propofol-induced LOC and ROC, ketamine-induced LOC and ROC are both identified during a gradual change of the oscillatory profile, suggesting that general anesthetics of distinct molecular mechanisms may induce unconsciousness through unique mechanisms.

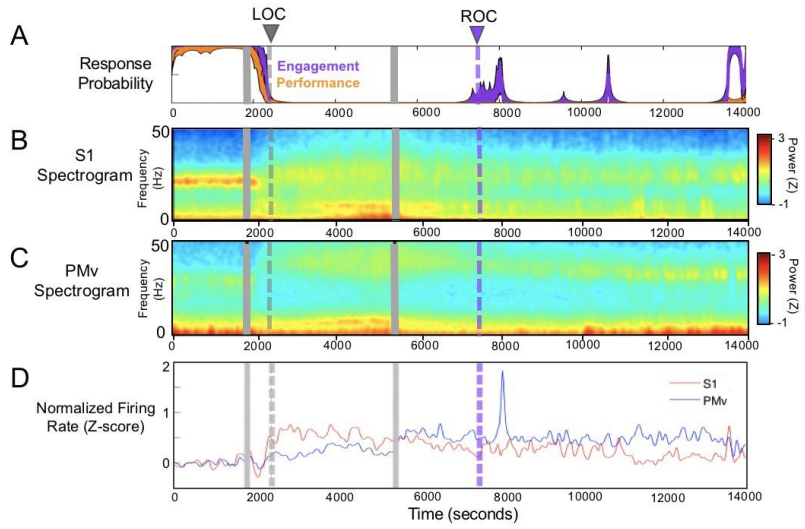

Figure 1. Neuronal dynamics changes in S1 and PMv during ketamine induction and recovery. **A**. Task response probability. *LOC* was defined as the time at which the probability of any response was less than 0.3 (gray arrow and dotted lines), *ROC* as the first time, since being unconscious, at which the probability of any response was greater than 0.3 (purple arrow and dotted lines), and *ROPAP* as the first time at which the probability of a correct response was greater than 0.9 during recovery. ROPAP was not observed during this recording session. **B**. Spectrograms in S1. **C.** Spectrograms in PMv. **D**. Average firing rate in S1 (red) and PMv (blue). Ketamine was infused at 100 µg/kg/min from 1800 sec to 5400 sec (gray lines).

Title: Similitudes and differences in the functional properties of membrane proteins between species

Authors: *D. C. BERTRAND, S. BERTRAND, K. KAMBARA
Hiqscreen, Vesenaz - GE, Switzerland

Abstract: While it is immediately recognized that species display significant differences in their morphology and at deeper structural levels for example in the brain organization, it is often thought that functional properties of membrane proteins such as ligand gated or voltage gated ion channels are essentially closely related. This mode of thinking is easily understood when considering fundamental properties of, for example, voltage gated ion channels which are at the origin of the action potential and the strong homologies observed between the squid axon and the human nerve. This reasoning bias can have, however, a significant impact in the drug discovery. Since any compound aimed at clinical trials requires safety experiments conducted in several species (i.e. rodents, rabbits or dogs), the question of similitude and/or differences should be considered.

Whereas it is often not possible to examine with appropriate details the function of membrane proteins expressed in specific neurons or cells, the rapidly increasing knowledge of genomes offers new alternatives to challenge the question of species differences. Moreover, with the combination of efficient data base analysis with plasmid synthesis and expression in a recombinant system, such as the *Xenopus* oocytes, it is now possible to examine the functional properties of a specific protein across many different animal species.

Although it was already documented that functional properties of a given protein can be altered by the modification of a single base in the genomic sequence, such as observed in genetically transmissible diseases, comparison of functional properties of specific receptors including NMDA, $5HT_3$, nAChRs, $GABA_A$ are further underlining the relevance of appropriate testing and how this could save important time and cost in the drug development pathway.

Title: Astrocyte thrombospondin-1 expression is altered in Fragile X syndrome following treatment with exogenous UTP

Authors: *K. E. REYNOLDS, A. L. SCOTT, L. C. DOERING
McMaster Univ., Hamilton, ON, Canada

Abstract: The neurological symptoms of Fragile X syndrome (FXS) arise due to aberrant glial-neural communication, driven in part by dysregulation of astrocyte-secreted synaptic proteins. In FXS, expression of the astrocyte-secreted protein thrombospondin-1 (TSP-1) is decreased, thereby impairing the structure and density of immature excitatory synapses. TSP-1 expression is thought to be regulated through UTP-induced activation of purinergic/pyrimidinergic P2Y receptors; however, the impact of pyrimidinergic signaling on TSP-1 expression in FXS remains unstudied. We therefore cultured cortical astrocytes from postnatal transgenic *Fmr1* knockout ($Fmr1^{-/-}$) and wildtype ($Fmr1^{+/+}$) mice, and investigated their response to treatment with 0.1uM-100uM exogenous UTP. Western blotting and immunocytochemistry revealed significant increases in intracellular TSP-1 expression in both wildtype and *Fmr1* knockout astrocytes following UTP treatment. Wildtype astrocytes displayed a linear dose-response relationship between TSP-1 expression and UTP concentration, while knockout astrocytes exhibited maximal TSP-1 expression following each UTP dose, suggesting differential P2Y receptor activation between genotypes. This upregulation of TSP-1 was not simply a consequence of UTP-driven hypertrophy, as astrocyte size remained consistent between naïve and UTP-treated astrocytes of both genotypes. Furthermore, UTP treatment produced contrasting patterns of TSP-1 release; *Fmr1* knockout astrocytes secreted greater quantities of TSP-1 than their wildtype counterparts. These results suggest that pyrimidinergic signaling may be differentially regulated in FXS astrocytes, resulting in elevated production and release of TSP-1 following stimulation with UTP. Future directions include co-treatment with exogenous UTP plus P2Y receptor antagonists, as well as quantification of baseline physiological UTP levels in FXS astrocytes using mass spectrometry. By further exploring the relationship between pyrimidinergic signaling and TSP-1 expression, we can begin to elucidate the therapeutic relevance of this pathway to FXS.

Title: Aberrant calcium channel expression is associated with reactive astrocytosis in optic nerve head astrocytes

Authors: *A. K. GHOSH[1,2], V. R. RAO[2], Y. NAUMCHUK[3,4], V. B. MAKSYMENKO[4], E. B. STUBBS, Jr.[2,5], S. KAJA[2,3,5]

Abstract: Glaucoma is a progressive optic neuropathy that manifests with a triad of characteristic pathological changes, including optic nerve head remodeling, damage to the optic nerve, and retinal ganglion cell loss. Optic nerve head astrocytes (ONHAs) are the primary cell type in the optic nerve head; in response to noxious stimuli, ONHAs undergo reactive astrocytosis (RA), a physiological response characterized by increased expression of glial fibrillary acidic protein (GFAP), as well as increased proliferative and migratory potential. RA of ONHAs underlies optic nerve head remodeling in glaucoma.The molecular mechanisms underlying RA remain largely unknown; however, aberrant expression of plasma-membrane calcium channels has previously been reported to contribute to RA in the CNS (Burgos *et al*. Glia 2007, 55:1437-48). Therefore, the goal of the present study was to determine the expression of multiple types of plasma membrane calcium channels in ONHAs during RA to further elucidate their potential roles in glaucoma.RA was induced by two methods, by exposure either to hyperbaric pressure (25 - 30 mmHg above ambient pressure for 16 - 20 hours) using a custom-built pressure chamber or mechanical strain (10% equibiaxial stretch for 16 hours) using a Flexcell® FX-5000 Tension System (Flexcell International). Induction of RA was confirmed by increased GFAP immunoreactivity. Expression of the pore-forming subunits of voltage gated ion channels (pan-$Ca_V\alpha$) was increased 2.2-fold during RA ($P < 0.05$). We determined that this increase was largely mediated by the aberrant expression of $Ca_V2.1$ (P/Q-type) calcium channels. We detected strong immunoreactivity for mechanosensitive Piezo1 channels. Piezo1-specific

immunoreactivity was present exclusively near the plasma membrane, and increased 2.1-fold ($P < 0.001$) during RA. A similar increase in Piezo1 mRNA were observed ($P < 0.01$). A detailed electrophysiological analysis of aberrant calcium channel currents in ONHAs is currently underway. Our data are in accordance with earlier reports that have reported upregulation of voltage-gated calcium channels in hippocampal astrocytes during astrocytosis (Burgos *et al*.), and a study finding increased Piezo1 mRNA levels in the optic nerve head of glaucomatous dba/2J mice (Choi *et al*. Mol Vision 2015, 21:749-66). Our data tentatively suggest a conserved mechanism underlying RA and implicate mechanosensitive and voltage-gated plasma membrane calcium channels in the pathophysiology of glaucoma.

Title: Scutellarin promotes microglia mediated astrogliosis in ischemia injury in rats and astrocytic reaction *in vitro*

Authors: *Y. YUAN[1], M. FANG[2], J. LU[3], H.-E. LI[1], M. ZHAO[1], C.-Y. WU[1], E.-A. LING[4]
[1]Dept. of Anat. and Histology/Embryology, Kunming Med. Univ., Yunnan, China; [2]Guangdong Gen. Hosp., Guangdong, China; [3]Defence Med. and Envrn. Res. Inst., Singapore, Singapore; [4]Dept. of Anatomy,, Yong Loo Lin Sch. of Med., Singapore, Singapore

Abstract: Scutellarin, an anti-inflammatory agent, has been reported to effectively suppress microglia activation in rats with middle cerebral artery occlusion (MCAO) and in BV-2 microglia. We have shown that scutellarin decreased the production of proinflammatory cytokines and reactive oxygen species in activated microglia. Robust microglia activation was followed by astrogliosis. We reported recently that scutellarin also promoted astrocytic reaction but through activated microglia. However, the effects of scutellarin on reactive astrocytes have not been fully explored. This study was aimed to determine more specifically the outcomes of scutellarin treatment in reactive astrocytes that play an important role in tissue repair. Expression

of brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3) and insulin-like growth factor-1 (IGF-1), and cell cycle markers cyclin-D1/B1 was assessed by immunofluorescence staining and western blot in reactive astrocytes in scutellarin injected MCAO rats. The above-mentioned proteins were also investigated in TNC1 and primary astrocytes, treated respectively with conditioned medium from BV-2 microglia with or without pretreatment of scutellarin and lipopolysaccharide (LPS) in vitro. The migration and morphological change of astrocytes induced by microglial conditioned medium was detected by the transwell chamber assay and electron microscopy respectively. Robust astrocyte reaction was observed in the penumbral region in ischemic cerebral cortex after MCAO with treatment of scutellarin. Reactive astrocytes significantly increased in number and exhibited hypertrophy bearing long extending processes. Expression of BDNF, NT-3, IGF-1, and cyclin-D1/B1 was markedly augmented following the treatment of scutellarin in MCAO rats. In addition, TNC1/primary astrocytes responded vigorously to micrglial conditioned medium treated with scutellarin + LPS as shown by enhanced expression of all the above markers by Western and immunofluorescence analysis. Migration of TNC1 in conditioned medium was significantly decreased. Furthermore, hypertrophic TNC1 astrocytes in conditioned medium showed abundant microfilaments admixed with microtubules by electron microscopy. The results suggest scutellarin is neuroprotective which can amplify astrogliosis but through activated microglia, and concurrently induces morphological and functional changes in reactive astrocytes.

Abstract: Viral infection in perinatal period may affect early brain development, which increases the risk for psychiatric disorders such as schizophrenia. Our previous findings showed that polyriboioinic-polyribocytidylic acid (polyI:C) treatment in neonatal mice, which mimics virus infection by inducing innate immune system, leads to behavioral abnormality in adulthood. Furthermore, polyI:C treatment induces the expression of interferon-induced transmembrane protein 3 (Ifitm3) in astrocytes but not neurons. Ifitm3 may mediate polyI:C-induced neuronal impairment through the induction of humoral factors secreted from astrocytes. However, it remains unknown which molecular entity leads to the neuronal impairment. To answer this question, we screened humoral factors secreted from astrocytes by proteomic approach. As a result, we identified Follistatin like-1 (Fstl1) as a candidate astroglial factor. Astrocyte condition medium (ACM) from secondary cultured astrocytes treated with polyI:C contained a significantly higher amount of Fstl1 protein than the level in control ACM. Increase in Fstl1 level by polyI:C treatment was not observed in astrocytes from Ifitm3 KO mice. Treatment of recombinant Fstl1 on primary cultured neurons induced an impairment of neurite elongation, whereas, knockdown of Fstl1 in astrocytes diminished the neuronal impairment caused by treatment with ACM. These results suggest that astrocyte-derived Fstl1 plays a crucial role in polyI:C-induced neuronal impairment.

Abstract: Multiple sclerosis (MS) is an autoimmune disease characterized by neuroinflammation, demyelination and neurodegeneration in the central nervous system (CNS). Peripheral immune cells, including T lymphocytes, play pivotal roles in MS pathogenesis.

However, not all cell types involved in neuroinflammation are known. Here, we identify a subtype of astrocytes, which we named ***ieAstrocytes*** ("immediate early astrocytes"), as being early responders during experimental autoimmune encephalomyelitis (EAE). An unbiased screen for cellular activation during EAE was developed using TetTag c-Fos reporter mice, that labeled c-Fos-activation-experienced cellular nuclei with a stable GFP, fused with histone H2B. A four-dimensional (temporal and spatial) cellular c-Fos activation map in the spinal cord revealed an expansion of GFP signals during EAE. Immunohistochemistry revealed that over 95% of GFP^+ cells were astrocytes whose fraction linearly increased with EAE severity. Moreover, disease-dependent *ieAstrocyte* formation was suppressed by astrocyte-specific genetic removal of the sphingosine 1-phosphate (S1P) receptor $S1P_1$, as well as by pharmacological inhibition using fingolimod (FTY720), an FDA-approved MS disease-modifying $S1P_1$ functional antagonist. Our results identify 1) astrocyte c-Fos activation as a key step in EAE development, 2) the requirement for S1P signaling in *ieAstrocyte* formation and 3) the inhibition of *ieAstrocyte* formation as a novel mechanism of action of fingolimod. Disease-modifying therapy reducing *ieAstrocyte* formation may be a new strategy to treat relapsing and possibly progressive forms of MS with reduced risk of immunosuppression.

Title: Vitamin B_{12}ameliorates disease in animal model of multiple sclerosis through astrocytic sphingosine 1-phosphate signaling

Authors: *D. JONNALAGADDA[1], A. GROVES[2], Y. KIHARA[1], R. RIVERA[1], G. KENNEDY[1], E. QUADROS[3], M. MAYFORD, 92093[4], J. CHUN, 92093[5]
[1]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [2]UCLA, Los Angeles, CA; [3]SUNY-Downstate Med. Ctr., New York, NY; [4]UCSD, La Jolla, CA; [5]Sanford Burnham Med. Discovery Inst., La Jolla, CA

Abstract: Sphingosine 1-phosphate (S1P) is a bioactive lipid with diverse functions acting through its receptors ($S1P_{1-5}$) expressed on various cell types. Fingolimod (FTY720; Gilenya), upon phosphorylation (FTY720-P), is an analogue of S1P, binding to $S1P_{1,3-5}$, and is the first oral, disease-modifying therapy for multiple sclerosis (MS). The widely known mechanism of action of FTY720-P in MS is through sequestration of pathogenic lymphocytes via $S1P_1$ in the secondary lymphoid organs. Additionally, FTY720 can enter the CNS to access $S1P_{1,3,5}$ in several neural cell types as FTY720-P. It is known that FTY720-P causes internalization and functional $S1P_1$ receptor loss on astrocytes, which is largely responsible for its efficacy in experimental autoimmune encephalomyelitis (EAE), an animal model of MS. This work elucidates how $S1P_1$ on astrocytes can mediate the action of FTY720 in EAE.
Astrocytes are the early-responding cell type in the central nervous system (CNS) of EAE mice and these astrocytes were designated as "immediate early astrocytes" (*ieAstrocytes*) in our previous study. Nuclear RNA sequencing of *ieAstrocytes* was instrumental in our pursuit of exploring how FTY720 mitigates the disease through $S1P_1$ on EAE-activated astrocytes. CD320, a vitamin B_{12} transcobalamin receptor and the only B_{12} uptake receptor in the CNS, was upregulated upon $S1P_1$ loss, therefore it is regarded as a neuroprotective factor. Both CD320-null and B_{12}-deficient mice exhibited severe EAE when compared to their controls. Furthermore, FTY720 lost its efficacy in EAE in the absence of CD320 and B_{12}. This work points towards a combination of FTY720 and B_{12} as a promising therapy for MS.

Title: Gene expression in the frontopolar cortex in schizophrenia

Authors: *A. MEDINA, MD[1], M. WASELUS DAVENPORT[1], D. M. KROLEWSKI[2], J. D. BARCHAS[3], A. SCHATZBERG[4], R. MYERS[5], H. AKIL[2], S. J. WATSON, Jr.[2]
[1]MBNI, Univ. Michigan, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI; [3]Dept Psychiat, Weill Cornell Med. Col., New York, NY; [4]Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA; [5]HudsonAlpha Inst. for Biotech., Huntsville, AL

Abstract: The Frontopolar cortex is one of the least studied areas of the human brain. Cytoarchitectonical studies catalogue it as Brodmann area 10, and functional imaging research suggest a role for this area in attentional control. In addition, it might also be involved in dynamically adjusting the contribution of internal and external information to moment–to-moment cognition.
Disturbances in the ability to discern between the information coming from external vs internal sources might be important in the context of disorders involving deficits in reality monitoring, as is the case in schizophrenia. Functional imaging studies have reported that schizophrenic patients show deficits in rostral prefrontal cortex activation, and it has been suggested that this might be related to patients' deficits in reality monitoring. However, the underlining cellular dysfunctions that may be associated with these disturbances have not yet been studied.
In this study, we aim to analyze the differences in gene expression within the frontopolar cortex between postmortem brain tissue obtained from normal controls and schizophrenic subjects.
Materials and methods: Human brain blocks from the frontopolar cortex of 24 Schizophrenic subjects and 27 controls were obtained from the Brain Donor Program at the University of California, Irvine by agreement with the Pritzker Neuropsychiatric Consortium. The subjects included in the schizophrenic group met diagnostic criteria from the Diagnostics and Statistical Manual of Mental Disorders (DSM-V). In the control group there was no evidence of psychiatric or neurological disorders. Variables accounted for include gender, age and postmortem interval. All subjects used in the study had tissue pH above 6.5 and agonal factor scores (AFS) of zero. Fresh frozen blocks of tissue averaging 500 mg were dissected from the frontopolar region of each subject and processed for RNA extraction to be used for gene expression studies.
Results: Initial test RNA extractions from the fresh frozen tissue rendered adequate RIN values (average 8.1) and RNA content (average 590 ng/uL). Based on our previous results we will focus on reporting the effect of schizophrenia on the astrocytic network of the Frontopolar cortex and will describe gene expression patterns associated with glial activity in schizophrenic subjects compared to normal controls.

Title: The microRNA and mRNA profile of Müller glia after light damage

Authors: *S. G. WOHL[1,2], E. BERCAW[1], A. BAEK[1], I. MOUNT[1], T. A. REH[1]
[1]Dep. of Biol. Structure, Univ. of Washington, Seattle, WA; [2]State Univ. of New York, Col. of Optometry, New York, NY

Abstract: Retinal injury leads to neurodegeneration accompanied by activation of Müller glia (MG), the principal glia of the neural retina. microRNAs (miRNAs) are negative regulators of gene expression and known to change in injured or diseased tissue. For now, there is not much known about the role of miRNAs in the response of MG to neuronal loss, therefore we characterized microRNAs along with mRNAs following light damage.
A MG specific reporter mouse (Rlbp-CreER: $Stop^{fl/fl}$ tdTomato) was crossed onto an albino mouse with a RPE-65 mutation. For the conditional knock out (CKO) of Dicer1 (Dicer-CKO_{MG}), the tdTomato reporter mouse (with and without the RPE-65 mutation) was crossed to a $Dicer^{fl/fl}$ mouse. We light-damaged the mice for 8h. Tamoxifen was administered intraperitoneally for CreER activation. Retinal cross sections at 1, 6, 12, and 18 weeks after light damage and 1, 3, 6, and 12 months after Dicer deletion were analyzed. For miRNA analysis, MG from wild type, light damaged, and Dicer-CKO_{MG} mice were purified by FACS and analyzed using the NanoStrings nCounter® System. Microarrays were used to identify the genes changing after light damage and compared that to RNA-Seq data performed after Dicer-CKO.
One week after light damage, we found a clear thinning in the ONL due to photoreceptor degeneration, concomitant with MG activation, i.e., migration and upregulation of GFAP, one of the hallmarks for gliosis. This phenotype was similar to the phenotype we observed in the Dicer-CKO_{MG} mouse after 6 months, although migrating MG in the Dicer-CKO did not upregulate

GFAP.
By analyzing the microRNA profile, already one week after light damage, there was a drastic decline of the miRNAs highly expressed in the MG by an average of 60%. This was similar to what we found in the Dicer-CKO_{MG} one month after Dicer deletion: a reduction in levels of the same miRNA by an average of 70%. By comparing genes affected in both, light-damaged and Dicer-deleted MG, we found 1502 genes similarly upregulated such as the transcription factors Maff. Gene ontology revealed that most
upregulated genes are involved in apoptosis and the regulation of the immune response. However, in contrast to the Dicer-CKO_{MG}, microglia cell number did not significantly change after light damage.
Our results show neurodegeneration due to light damage leads to a rapid decline of the MG specific miRNAs and to upregulation of injury/disease-associated genes, similar to what occurs after MG specific Dicer-deletion. Therefore, glial miRNAs might be important for the maintenance of the physiological function and might also play a role in degenerative diseases.

Title: Peripheral inflammation alters the morphological and functional properties of medullary dorsal horn astrocytes

Authors: *S. MOUNTADEM, M. ANTRI, R. DALLEL
Inserm/Neurodol U1107, Clermont Ferrand, France

Abstract: Background: Recent evidence suggests that astrocytes play an important role in central sensitization, characterized by the development of allodynia and hyperalgesia. In many disease of CNS, astrocytes acquire reactive phenotypes, reflected by an increase of glial fibrillary acidic protein expression and hypertrophy of processes. However, whether the electrophysiological properties of astrocytes, too, change following peripheral inflammation is still unknown.
Objective: The aim of this study was: i) to characterize the morphological and electrophysiological properties of medullary dorsal horn (MDH) astrocytes in naïve rats and ii) to investigate whether theses parameters vary in persistent inflammatory conditions.
Materials/**Methods**: All experiments, analysis and reporting were ARRIVE-compliant. Experiments were performed according to European Directive 2010/63/EU on the protection of

animals used for scientific purpose. The protocols were authorized by the French Ministry of Higher Education and Research (No 04521.02). Adult male Sprague-Dawley rats (3-5 weeks) received a facial injection of either saline or complete Freund's adjuvant (CFA). Four days after injection, MDH astrocytes were identified using sulforhodamine 101 and recorded using whole-cell patch clamp technics within the *substantia gelatinosa* of *ex vivo* MDH slices. At the end of each recording, epifluorescence was used to assess whether the recorded astrocyte was actually filled with Alexa Fluor 488. Stained astrocytes were then observed with a Zeiss LSM 800 confocal laser scanning microscope. Z-series were scanned at x63 magnification. Reconstruction and morphologic analysis of the soma and arbor projections of Alexa Fluor 488-labeled astrocyte were performed from confocal image stacks with Fiji software.
Results: Four days after injection, compared with astrocytes from saline-injected rats, those from CFA-injected rats displayed i) depolarized resting membrane potentials, ii) larger membrane capacitances without changes in the input resistance, iii) enhanced density of hyperpolarization activated cationic I_H, but, conversely iv) decreased inwardly rectifying potassium K_{IR} and outward K_D currents. Inflammation also induced morphological changes in astrocytes: the arborization area, soma volume as well as total number of branches increased significantly.
Conclusion: These results reveal for the first time that peripheral inflammation alters MDH astrocyte functions and suggest that the reduction in astrocyte K_D and K_{ir} channels might contribute to inflammatory pain.

Abstract: The ventromedial hypothalamus (VMH) is important in regulating metabolism and mental disorders, suchas anxiety and depression. Recent evidence has demonstrated that astrocytes in hippocampus andamygdala play key roles in mediating anxiety behavior through secretingGamma-Aminobutyric Acid(GABA), brain-derived neurotrophic factor (BDNF), fibroblast growth factor 2(FGF2)and other factors.However, the exact role of astrocytes in VMH in regulating anxiety and underlying mechanism is unclear.We have found that, in chronic stressed mice, GABAconcentration in VMH nucleus was significantly elevated, and optogenetic activating GABAergicneural projections in VMH induced significant anxietylikebehavior. In presentstudy,combining optogenetics, pharmacogenetics, brain slice electrophysiology and behavioranalysis, we furtherdemonstrated in S100β-Cremice that selectivemanipulationof VMH astrocytes can bi-directionally regulate anxiety, which shows a gender based difference that male mice showed more perturbable than female after CNO administration. Furthermore, specific optogenetic activation of VMH astrocyte could induce excitatory response in SF-1 neurons, which might imply that astrocytes can mediate anxiety behavior through regulate SF-1 neurons in VMH. Takentogether, our study emphasized VMH astrocytes' role in regulating anxiety-likebehavior in mice.Considering the pivotal role of astrocytes in reuptake and metabolism of neurotransmitters, more study isneeded to dissect the molecular mechanism of VMH astrocytes-mediatedanxiolysis.

Title: Production and characterization of human iPSC-derived reactive astrocyte phenotype

Authors: *S. HAGMAN, T. HYVÄRINEN, S. NARKILAHTI, A. PELKONEN
The Fac. of Med. and Life Sci., Univ. of Tampere, Tampere, Finland

Abstract: Astrocytes have a central role in supporting nervous system physiology. However, in neurodegenerative diseases, such as multiple sclerosis and stroke, astrocytes undergo activation into reactive inflammatory phenotype. The role of reactive astrocytes in neurodegenerative

diseases is controversial, but they may affect disease progression by inducing axonal damage and limiting neuronal repair and remyelination. The aim of this study was to induce reactive astrocyte phenotype and characterize their inflammatory nature. To establish reactive phenotype, we treated human induced pluripotent stem cell (hiPSC)-derived astrocytes with inflammatory cytokines tumor necrosis factor (TNF)-α and interleukin (IL)-1β. Treated astrocytes exhibited morphological change from highly filamentous shape to flattened polygonal appearance. Reactive phenotype was characterized by quantifying GFAP staining intensity, glutamate uptake activity and expression of inflammatory molecules in the mRNA and protein levels. Increased gene expression of known inflammatory factors were detected in reactive astrocytes as compared to controls. Moreover, astrocyte activation induced widespread protein secretion profiles of inflammatory mediators. In reactive phenotype, glutamate uptake activity was impaired when compared to controls. Protocol for inducing reactive astrocytes was promising and astrocytes transformed to inflammatory phenotype. These produced reactive astrocytes can be used in co-culture models together with neurons to study their inflammatory mechanism of axonal damage as well as possible strategies for promoting regeneration.

Title: SRF regulates the generation of neuroprotective reactive astrocytes in the mouse brain

Authors: *M. JAIN[1], P. Y. LU[2], S. C. R. THUMU[1], S. SOMAN[1], V. VERMA[3], D. GUTMANN[4], J. C. CHELLIAH[3], T. V. ARUMUGAM[5], N. RAMANAN[1]

Sch. of Med., St. Louis, MO; [5]Dept. of Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: In response to CNS injury infection and in neurodegenerative disorders, astrocytes become reactive in a process called astrogliosis. To understand the underlying mechanisms,

whole brain transcriptome analysis was done following ischemic stroke in mice. This showed significant downregulation of the stimulus-dependent transcription factor, serum response factor (SRF). To study the role of SRF in astrogliosis, SRF was deleted in astrocytes using a GFAP-Cre transgenic mouse line. In the resultant SRF-GFAP-cKO conditional mutant mice, astrogliosis was observed at 3 weeks of age and persisted throughout adulthood. This was also accompanied by persistent microgliosis. Depletion of microglia following PLX5562 treatment, did not affect astrogliosis suggesting that SRF-deficient reactive astrocytes are not dependent on microglia. To confirm that the gliosis observed in SRF-GFAP-cKO mice is not due to developmental effects of embryonic deletion of SRF, we generated a tamoxifen-inducible conditional mutant mouse, SRF-GFAP-ERT-cKO. Tamoxifen (Tam) administration at 6-8 wk old SRF-GFAP-ERT-cKO mice resulted in astrogliosis at 2 months post-injection that also persisted throughout adulthood. Unlike neurotoxic A1 astrocytes, which have been shown to kill neurons and oligodendrocytes *in vitro*, we observed no evidence of cell death in these SRF mutant mice. Furthermore, we observed no deficits in basal synaptic transmission and LTP was seen in GFAP-ERT-cKO mice. Gene expression analysis by qRT-PCR of whole brain RNA of neocortex of SRF mutant mice showed a predominant expression of neuroprotective A2 reactive astrocyte markers as compared to A1 reactive astrocyte markers. These results together indicated that SRF-deficient astrocytes are unlikely to be neurotoxic. We next asked whether SRF-deficient reactive astrocytes can provide neuroprotection in three models of neural injury: ischemic stroke, stab-wound and kainic acid toxicity. SRF-deficient mice showed significantly decreased cell death after stroke and kainate-induced toxicity, and faster wound-healing following stab-wound. Together, our findings suggest that SRF regulates the generation of neuroprotective astrocytes in the mouse brain and SRF-target genes may provide novel therapeutic targets for treatment following stroke, traumatic brain injury and epilepsy.

Title: Identification of astrocytic dopamine D2 receptor signaling pathways that modulate neuroinflammation in a mouse model of multiple sclerosis

Authors: *Y. WU, S. YIN, S. LU, Y. GUO, Y. YIN, Y. LI, J. HOU, J. ZHOU
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China

Abstract: A growing body of evidence suggests that astrocytes play critical roles in the regulation of brain function under normal conditions as well as in the pathogenesis of various brain diseases. It is, therefore, important and necessary to determine the regulatory network that controls astrocyte functions. Dopamine is well known as a neurotransmitter, playing important roles in multiple brain functions. Previously, we demonstrated that astrocytic dopamine receptor D2 (DRD2) is an important player in the modulation of brain innate immunity (Shao, et al. *Nature*, 2013). However, the molecular mechanism underlying the function of astrocytic DRD2 are largely unknown. Here we show that the signaling pathway of astrocytic DRD2 is distinct from that of neuronal DRD2. Treatment of primary cultured astrocytes isolated from the spinal cord of mouse pups with DRD2 agonist quinpirole markedly increased phosphorylation levels of AKT. In contrast, the same treatment induced profound down-regulation in phosphorylation levels of AKT in the astrocyte cultures. This up-regulation of phosphor-AKT was also seen in DRD2-over-expressing astrocytes. Interestingly, this astrocytic DRD2-AKT signaling pathway is specific to the spinal cord, given that this signaling pathway showed opposite changes in astrocytes from the cerebrocortex and striatum, indicating regional heterogeneity in astrocyte response following DRD2 stimulation. Moreover, we investigated the impact of astrocytic DRD2 in progression in a mouse model of experimental autoimmune encephalomyelitis (EAE), a commonly used animal model for multiple sclerosis. The clinical severity of EAE was significantly ameliorated after glial DRD2 inhibition, which was not observed in global DRD2 knockout mice. Together, our study suggests that astrocytic DRD2-AKT pathway plays important roles in modulating neuroinflammation.

Title: Disc1 knockdown in mature astrocytes suppresses expression of the glutamate transporters, GLAST and GLT-1, and impairs cognitive function in mice

Authors: *A. V. SHEVELKIN[1,2], C. TERRILLION[2], V. MISHENEVA[2], Y. JOUROUKHIN[2], S.-H. KIM[2], D. FUKUDOME[2], A. SAWA[2], A. KAMIYA[2], M. V. PLETNIKOV[2,3]

Abstract: The role of a rare psychiatric genetic risk factor, Disrupted-In-Schizophrenia 1 (DISC1), in astrocyte physiology remains poorly understood despite the increasing appreciation of the contributions of astrocytes to neurotransmission and synaptic plasticity in a time- and brain region-dependent manner. We evaluated the effects of *Disc1* knockdown in mature astrocytes of the prefrontal cortex or hippocampus on expression of the glutamate transporters, GLAST and GLT-1, the markers of excitatory and inhibitory synapses within astrocyte areas, and associated learning and memory. Male and female 8-week-old C57BL6/j mice were injected with AAV-*Gfa*::GFP-miR30-*Disc1* (*Disc1* KD) or scrambled AAV-*Gfa*::GFP-mir30-Ctrl in the prefrontal cortex (PFC) or the CA1-2 areas of the hippocampus. 3 weeks later, a series of basic and cognitive tests was run followed by quantitative analysis of expression of GLAST and GLT-1 and the markers of excitatory and inhibitory synapses using Imaris software. *Disc1* KD in hippocampal or PFC astrocytes did not alter locomotor activity or anxiety-like behaviors but impaired the performance in Barnes maze. Unlike *Disc1* KD in PFC, *Disc1* KD in the hippocampus also reduced cue-dependent freezing in trace fear conditioning. These behavioral alterations were associated with decreased expression of GLAST and GLT1 in astrocytes and reduced density of excitatory ($Glut1^+$/$PSD95^+$ puncta) but not inhibitory ($VGAT^+$/$Gephyrin^+$ puncta) synapses within the GFP^+ astrocyte coverage areas. Reduced *Disc1* expression in mature brain astrocytes decreased levels of glutamate transporters and density of excitatory synapses within the astrocyte coverage zones and led to impaired learning and memory in a brain region-dependent manner. Our findings suggest that genetic risk factors could contribute to abnormal astrocyte functioning in a brain region-dependent manner, leading to cognitive impairment observed in major psychiatric disorders.

Title: The cytokine IL-27 shapes the properties of human astrocytes and neurons in the context of multiple sclerosis

Authors: *F. LEMAITRE[1], A. CARMENA MORATALLA[1], N. FARZAM-KIA[1], E. HADDAD[2], N. ARBOUR[1]

Abstract: Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system (CNS) characterized by immune cell infiltration, loss of myelin, and neuronal cell death. Several publications underscore altered gene expression profiles and perturbed functions of astrocytes and neurons associated with MS pathobiology. Notably, enhanced expression of multiple immune molecules by astrocytes and neurons in MS brains is observed. The impact of immune mediators produced by astrocytes and/or neurons on ongoing MS neuroinflammation is still incompletely resolved. The cytokine interleukin-27 (IL-27) triggers both pro and anti-inflammatory responses upon binding to its receptor (IL-27R). IL-27 can reduce disease severity in a mouse model of MS but its role in MS is still unknown. We previously showed that IL-27 expression is elevated in MS brains compared to controls and that human astrocytes both in MS lesions and *in-vitro* express this cytokine and its cognate receptor IL-27R. *We speculate that local CNS IL-27 production alters immune related functions of astrocytes and neurons in MS brains.* To answer this question, we use primary cultures of human astrocytes or neurons generated from fetal material. We demonstrated that IL-27 triggered signaling pathways including STAT1 phosphorylation and the NF-kB pathway in human astrocytes. We also observed that IL-27 enhanced protein expression of the immunoregulatory molecules PDL-1 and IDO-1, which could dampen T cell activation. IL-27 increased the surface expression of ICAM1, an adhesion molecule involved in T cell infiltration and astrocytes/T cell immunological synapse formation. Moreover, in response to IL-27, human astrocytes secreted key immune mediators such as CXCL9, 10 and 11, and IL-18BP. We also demonstrated that human neurons expressed IL-27R and responded to IL-27 *in-vitro* by triggering STAT1 phosphorylation. However, IL-27 induced a different response in neurons compared to astrocytes. Although IL-27 also augmented the expression of PD-L1 in neurons, it did not induce IDO-1 expression by neuronal cells. Our results support the notion that IL-27 distinctly alters immune functions of human astrocytes and neurons. Such alteration could have an impact on the immune responses in the brain of MS patients.

Title: Human neurons and astrocytes express NKG2D ligands and are susceptible to NKG2D-mediated immune responses

Authors: *A. CARMENA MORATALLA[1], L. LEGROUX[1], F. LEMAÎTRE[1], N. FARZAM-KIA[1], E. HADDAD[2], A. PRAT[1], N. ARBOUR[1]
[1]CRCHUM, Univ. de Montréal, Montréal, QC, Canada; [2]CHU Sainte-Justine, Montréal, QC, Canada

Abstract: Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS). MS pathological hallmarks include focal demyelination, axonal loss and immune cell infiltration. Our group has identified NKG2D as a relevant player in MS pathobiology. NKG2D is an activating co-receptor expressed by several immune effector cells. In humans, it binds to various ligands (NKG2DL), including MICA, MICB and ULBP (1 to 6) which are induced by environmental triggers such as inflammation. The expression of each of these ligands is controlled by different mechanisms, suggesting unique roles played by specific NKG2DL. Binding of NKG2DL to their receptor stimulates immune effector cells and triggers cytotoxic and inflammatory responses. We have shown that human oligodendrocytes express NKG2DL *in vitro* and the blockade of NKG2D reduced their killing by immune effector cells. Moreover, our group has previously shown MICA/B expression in MS lesions; however, other NKG2DLs have not been investigated. MS is characterized not only by myelin/oligodendrocyte destruction but also neuronal death and perturbed astrocyte functions. Therefore, we hypothesize that *human neurons and astrocytes exposed to inflammatory conditions also upregulate NKG2DL and consequently become susceptible to NKG2D-mediated responses by immune effector cells.* Our goal is to characterize the expression of each NKG2DL in MS brains and in primary cultures of human CNS cells and to determine the impact of such expression on the neural-immune cell interactions. We observed that both neurons and astrocytes express different NKG2DL at the mRNA level. Notably, only ULBP4 was detected by multiple techniques (FACS, western blot, immunocytochemistry) at the protein level on astrocytes and such expression was increased in the presence of inflammatory cytokines such as TNF and IFNγ. However, the expression of ULBP4 on neurons was more modest and not modulated by inflammation. ULBP4 was detected in MS brains. We are currently studying the functional impact of ULBP4 expression. Our results

suggest that not only oligodendrocytes, but also human neurons and astrocytes, can express specific NKG2DL and consequently become susceptible to NKG2D-mediated immune responses by effector cells such as CD8 T cells.

Abstract: Mechanisms of astrocytes' contribution to fetal neuroinflammation are poorly understood. α7 nicotinic acetylcholine receptor (α7nAChR) signaling may polarize glia towards a neuroprotective role under inflammatory conditions. Conversely, prenatal stress (PS) is accompanied by inflammation in the mother and offspring. PS increases expression of the Glu transporter VGluT1 resulting in higher levels of GLT1. We hypothesized (1) under exposure to lipopolysaccharide (LPS), α7nAChR agonist stimulation in fetal astrocytes augments their

neuroprotective profile, while the antagonistic stimulation reduces it; (2) a LPS double-hit (first in vivo, then in vitro) exacerbates these effects similar to microglia (PMID 28878260); (3) LPS exposure induces upregulation of glutamine transporters in glia akin to PS. Using an in vivo - in vitro fetal sheep model (PMID: 27856275), we validate these hypotheses via RNA-Seq analysis in primary fetal astrocyte cultures exposed to LPS in the presence of a selective α7nAChR agonist or antagonist. We compare these findings to the previously published results in identically conducted microglia experiments. Principal component analysis showed two transcriptome clusters: control, LPS single-hit and double-hit astrocytes pre-treated with α7nAChR agonist and LPS single-hit and double-hit astrocytes pre-treated with α7nAChR antagonist. The top down-regulated signaling pathway unique to LPS treatment was Ephrin A signaling (p-value 5.77E-04). α7nAChR agonist reduced this down-regulation (p-value 2.51E-02). α7nAChR antagonist had no significant effect. We used IPA to annotate VGLUT1 gene network with our findings to test for evidence that the network is being perturbed by LPS treatment. Across all treatment comparisons, two differentially expressed genes (DEGs) were identified in astrocytes: JAK1/2 (2.732 (log ratio) up-regulated, FDR 3.91E-05) and SLC1A2 (2.350 up-regulated, FDR 1.80E-04). In comparison, microglia exposed to LPS regardless α7nAChR manipulation showed a single DEG: SLC1A2 up-regulated 3.53 (FDR 5.17E-04). The LPS double-hit scenario did not change the overall pattern; α7nAChR agonist in astrocytes exposed to LPS in vivo also showed a -0.806 down-regulation of SH3GL1 (endophilin-A2, FDR 4.74E-02).Ephrin signalling contributes to a α7nAChR-dependent neuroprotective astrocyte phenotype. Low grade neuroinflammation results in changes similar to PS with regard to reprogramming glial cells to a higher glutamine uptake. PS and exposure to LPS may act synergistically to exacerbate the impairment of neuron-glial glutamatergic interaction.

Abstract: Astrocytes respond to diverse central nervous system (CNS) insults with functional changes that can range broadly from modulating inflammation to impacting on neural tissue remodeling and mediating neuroprotection. Genetic regulation of these responses is poorly understood. Here, using large scale genomic meta-analyses of mouse and human-derived data, we identified transcriptional regulators of astrocyte reactivity in multiple diverse CNS disorders. 25 transcriptional regulators were common across all eight disorders investigated. These regulators included both previously known molecules such as STAT3 and select SMADs, and newly identified molecules, whose critical roles are being validated by astrocyte-specific gene deletion in mouse models of CNS injury and disease. Numerous additional transcriptional regulators were found to be selective to subsets of disorders and some to only a single disorder. Notably, there was significant disorder selective bias of downstream molecules targeted by these regulators. Ontology and pathway analysis of downstream gene targets suggests that conserved transcriptional regulators may drive functionally-distinct gene regulatory programs in astrocytes depending on disease context. Our findings strongly support a model whereby astrocyte reactivity is highly diverse and disorder dependent rather than a stereotypic response constant across disorders. We provide a framework for understanding and potentially modulating the genetic control of astrocyte reactivity in different contexts. Abstract: Loss of function of the astrocyte specific protein MLC1 leads to the white-matter disease megalencephalic leukoencephalopathy with subcortical cysts (MLC). Patients have a high water content in the brain white matter. At the cellular level, the first occurrence in MLC is astrocyte swelling, followed by progressive myelin vacuolation. Previous studies on patient material and isolated cells from MLC mouse models show a role for MLC1 in astrocyte volume regulation and suggest that disturbed brain ion and water homeostasis is central to the disease. However, how astrocyte dysfunction in MLC affects neuronal networks is unclear.
Analysis of an extensive MLC patient inventory indicated that an early seizure onset is common in MLC. We studied the cellular basis of seizures in two mouse models for MLC (*Mlc1*-null and *Glialcam*-null mice). Although we did not observe spontaneous seizures in MLC mice, these mice exhibited a lowered threshold for kainate-induced seizures. Additionally, wireless local field potential recordings revealed epileptiform brain activity in MLC mice. Intrinsic excitability of pyramidal neurons, assessed with whole-cell patch-clamp recordings in brain slices, was unchanged in MLC mice. However, potassium rises in brain slices upon synaptic stimulation were increased in MLC mice. We are currently investigating whether synaptic transmission is altered in MLC mice, and how astrocyte swelling relates to epileptiform brain activity. In conclusion, our results indicate that astrocyte dysfunction in MLC leads to hyperexcitability of neuronal networks. These findings give important insight into the role of astrocyte volume regulation in neuronal network excitability and epilepsy.

Title: Regulation of the astrocytic response to neural injury by LZK

Authors: *M. CHEN[1], C. G. GEOFFROY[2], J. MEVES[3], A. NARANG[3], Y. LI[3], M. NGUYEN[3], V. KHAI[3], X. KONG[1], C. STEINKE[3], L. ELZIERE[3], M. GOLDBERG[1], Y. JIN[3], B. ZHENG[3]

Abstract: Reactive astrocytes impact recovery and repair after injuries, and contribute to disease pathogenesis in the central nervous system (CNS). The molecular regulation of astrocyte reactivity remains incompletely understood. Using genetic loss- and gain-of-function analyses *in vivo*, we identify leucine zipper-bearing kinase (LZK) as an activator of astrocyte reactivity after CNS injury. Deletion of LZK in adult astrocytes impairs astrogliosis and increases lesion size after spinal cord injury. Conversely, overexpression of LZK in adult astrocytes enhances astrogliosis and reduces lesion size. Remarkably, LZK overexpression is sufficient to induce widespread astrocyte reactivity and upregulation of known astrogliosis regulators SOX9 and STAT3, in the absence of injury. These findings have broad implications in understanding the multicellular response to injury and promoting CNS repair.

Title: Beneficial effects of low alcohol exposure, but adverse effects of high alcohol intake on glymphatic function

Authors: *I. LUNDGAARD[1,2], W. WANG[2], A. EBERHARDT[2], H. VINITSKY[2], B. REEVES[2], S. PENG[2], N. LOU[2], R. HUSSAIN[2], M. NEDERGAARD[2,3]

Abstract: Prolonged intake of excessive amounts of ethanol is known to have adverse effects on the central nervous system (CNS). Here we investigated the effects of acute and chronic ethanol exposure and withdrawal from chronic ethanol exposure on glymphatic function, which is a brain-wide metabolite clearance system connected to the peripheral lymphatic system. Acute and chronic exposure to 1.5 g/kg (binge level) ethanol dramatically suppressed glymphatic function in awake mice. Chronic exposure to 1.5 g/kg ethanol increased GFAP expression and induced mislocation of the astrocyte-specific water channel aquaporin 4 (AQP4), but decreased the levels of several cytokines. Surprisingly, glymphatic function increased in mice treated with 0.5 g/kg ethanol following acute exposure, as well as after 1 month of chronic exposure. Low doses of chronic ethanol intake were associated with a significant decrease in GFAP, with little changes in the cytokine profile compared with the saline group. These observations suggest that ethanol has a J-shaped effect on glymphatic system whereby low ethanol doses increase glymphatic function.

Title: Reactive astrocyte heterogeneity after stroke: Identifying new targets for neural repair

Authors: *A. J. GLEICHMAN[1], R. KAWAGUCHI[2], M. V. SOFRONIEW[3], G. COPPOLA[2], S. CARMICHAEL[4]
[1]Neurol., [2]UCLA, Los Angeles, CA; [3]UCLA Schl Med., Los Angeles, CA; [4]UCLA Sch. Med., Los Angeles, CA

Abstract: Stroke is one of the most common forms of death and disability worldwide, yet few treatment options exist. Tissue repair and recovery after injury is a complex process, involving both scar formation around the site of the injury that likely isolates the damage and prevents spread of immune-related damage molecules as well as remodeling of the neighboring and, in some cases, contralateral tissue. Astrocytes are central to these processes and respond differently in these distinct compartments. While it has long been clear that astrocytes respond to damage in a gradated fashion, the details of these responses are unknown. Here, we use morphologic and phenotypic tools to identify distinct zones of reactive astrocytes after stroke, which we used to inform a transcriptomic analysis to comprehensively map zone-specific astrocytic responses to both white matter and cortical stroke. We are using these transcriptomic maps to identify potential intervention points to promote repair and recovery, with a particular focus on astrocytic control of vascular development after white matter stroke.
In order to map the morphologic changes astrocytes undergo after stroke, we developed astrocyte-specific spaghetti monster reporter lentiviruses, injected them sparsely into the cortex or white matter at the time of stroke, and assessed individual astrocyte morphology at 7 days post-stroke. These studies revealed stereotyped changes in the morphology of both cortical and white matter astrocytes within defined regions surrounding the injury. We also assessed phenotypic changes in post-stroke astrocytes, using markers for proliferation, reactivity, and proteins previously identified as differentially regulated by stroke. Together, these studies were used to define zones of reactive astrocytes. To map the transcriptomic changes zone-specific astrocytes undergo after stroke, we used GFAP-Cre/Ribotag mice, in which astrocytic ribosomes are tagged, to selectively isolate astrocyte-enriched mRNA in laser captured zones. Astrocytes undergo dramatic, zone-specific changes in both stroke models; while some changes are

preserved between white matter and cortical stroke, others are not. In particular, cortical astrocytes appear to trigger greater angiogenesis and vessel maturation after stroke than do white matter astrocytes. Angiogenesis has been associated with increased recovery after gray matter strokes; therefore, we are exploring the function of astrocyte-induced angiogenesis in white matter stroke.

Title: Role of Orai1 in LPS-mediated cytokine production

Authors: *J. JIANG, H. HU
Drexel Univ., philadelphia, PA

Abstract: Ca^{2+} signals in astrocytes mediate a remarkable variety of cellular functions, such as glutamate release and cytokine production. Among the various mechanisms by which cellular Ca^{2+} signals are generated, store-operated calcium channels (SOCs) have recently emerged as a widespread pathway for regulating many Ca^{2+}-dependent functions. We have demonstrated that SOC proteins are expressed in astrocytes and activation of astrocytic SOCs results in cytokine production. However, whether SOCs are involved in cytokine production in a pathological condition is not clear. Lipopolysaccharide (LPS), a component of the Gram-negative bacterial cell wall, is the most well-established inducer for the experimental inflammation. Using the specific siRNAs against STIM2 and Orai1, two major components of SOCs, we observed that knockdown of STIM2 or Orai1 dramatically decreased LPS-induced TNF-α and IL-6 production. While we further confirmed that knockout of Orai1 drastically attenuated LPS-induced cytokine production, it remains unknown how Orai1 is involved in this process. LPS-induced Toll-like receptor4 (TLR4) signaling has been shown to activate a number of kinases including mitogen-activated protein kinases (MAPK). To characterize the signal transduction pathways in astrocytes, we tested effects of several MAPK inhibitors on LPS-induced activation of MARKs and cytokine production. MEK/ERK inhibitor PD 98059, JNK inhibitor SP600125 and p38 inhibitor SB202190 significantly attenuated LPS-induced cytokine production and abolished LPS-induced increases of phosphorylation of ERK, p38 and JNK, respectively. Consistently,

knockout of Orai1 markedly decreased LPS-induced activation of MAPKs. Interestingly, STIM2 and Orai1 were significantly increased in LPS-treated astrocytes compared to vehicle treated astrocytes. LPS-induced-downstream effects were blunted by a TLR4 antagonist. These results indicate TLR4 activation is functionally coupled to the SOC channel Orai1 in astrocytes. Our findings highlight an important role of SOCs in LPS-induced cytokine release and may suggest that SOCs are potential therapeutic targets to treat inflammatory diseases of the central nervous system.

Title: Modeling neuroinflammatory states associated with astrocyte function

Authors: *Z. S. JORDAN[1], A. M. MAROOF[2], K. THANGAMANI[3], C. HUTCHINSON[2], L. JOHNSON[2], M. C. VARELA[4], K. MEYER[2], A. KHAN[2], S. ALI[2]

Abstract: Astrocytes are essential for the functional maturation of neuronal circuits. Reactive astrocytes are found in neurodegenerative diseases (NDDs) at specific brain regions relevant to disease pathology. However, it's not clear whether reactive astrocytes are a cause or a consequence of NDD progression. Inducing a reactive state causes mouse astrocytes to change their function from neurotrophic to neurotoxic. We generated astrocytes from human induced pluripotent stem cells (hIPSCs), derived from NDD patients and healthy controls, and compared their quiescent and reactive states to primary human astrocytes to confirm astrocyte fate specificity and potential function. We treated astrocytes with the three cytokines: TNF-α, IL-1α, and IFN-γ, which are known to induce a reactive state in astrocytes *in vitro*. A panel of gene products known to be differentially regulated in the reactive state were assayed via immunocytochemistry and qRT-PCR in order to confirm a robust induction of the reactive state by cytokine treatment. Functional assessment of hIPSC-derived astrocytes will be assessed through glutamate uptake, calcium signal propagation, neuronal fate specification, synaptogenesis, synaptic phagocytosis, and neuronal survival. Therefore, we modeled the reactive astrocyte state *in vitro* with or without mature neurons. We used assays for astrocyte functions which support neuron growth and survival in order to determine the mechanisms in

which neurodegeneration may be initiated, following infection, traumatic brain injury, or other stressors that induces reactive astrogliosis.

Title: Synaptic refinement and glial engulfment in a mouse model of fragile X syndrome

Authors: *M. A. LEE[1], M. WEISENHAUS[2], P. JURAKHAN[4], M. SHIRASU-HIZA[2], C. MASON[3]
[1]Neurobio. and Behavior, [3]Dept. Pathology & Cell Biol., [2]Columbia Univ., New York, NY; [4]Barnard Col., New York, NY

Abstract: Fragile X Syndrome (FXS) is the leading monogenic cause of both autism and intellectual disability and results from the silencing of the *Fmr1* gene, which codes for the translational regulator, FMRP. FXS is characterized by structural and functional defects at the synapse. In particular, elongated dendritic spines and defects in LTD are hallmarks of the disorder, as well as structural defects in axons. Glia are known regulators of both synapse growth and elimination. Despite FMRP expression in glia and reports of glial defects such as altered astrocytic glutamate signaling in FXS, little is known about glial function and dysfunction in FXS. The Shirasu-Hiza lab has identified a defect in glial phagocytosis in the *Drosophila* model of FXS. This defect is associated with decreased levels of activated glia, marked by expression of Draper, the *Drosophila* homolog of the mammalian astrocyte phagocytic receptor, MEGF10. Whether such a defect occurs in vertebrates is unknown.
The mouse retinogeniculate system is a classic system in which to study synapse refinement. Retinal ganglion cell (RGC) axons extend from each eye to the dorsal lateral geniculate nucleus (dLGN), and their arbors and synapses from opposite side (contralateral) and same side (ipsilateral) eyes overlap. During the first postnatal week, excess branches and synapses are refined so that by postnatal day 10, each dLGN neuron only receives inputs from a single eye—

either contralateral or ipsilateral. Both microglial and astrocytic phagocytosis are known to participate in arbor and synapse refinement (Schafer et al, Neuron, 2012; Chung et al, Nature 2013). We are investigating the role of glial phagocytosis in synapse refinement in the mouse retinogeniculate system in FXS. We first examine gross synaptic refinement in the retinogeniculate system of the *Fmr1* KO mouse by labeling RGCs from each eye with anterograde tracers conjugated to different fluorophores and find developmental segregation of ipsilateral and contralateral RGCs is enhanced in the first postnatal week (P7) of *Fmr1* KO mice when compared to wild-type littermates. Subsequently, segregation in the *Fmr1* KO mutant is comparable to wild-type littermates at P14. By adulthood (P40), however, retinogeniculate inputs are less segregated in the *Fmr1* KO dLGN than in wild-type. In combination with CTB-labeling of RGCs, we are assessing astrocytic engulfment of presynaptic inputs in the *Fmr1* KO::Aldh1l1-eGFP mouse. We are also investigating RGC synapse number and structure. This work will help to advance our understanding of the role of FMRP in glial function and may elucidate the role of glia in development and adult-stage refinement of the visual system.

Title: Acute sensitivity of astrocytes in the Substantia Nigra to oxygen and glucose deprivation compared to the hippocampal CA1 region

Authors: *J. LIPSKI, R. N. KARUNASINGHE
Univ. Auckland, Auckland, New Zealand

Abstract: Astrocytes have a diverse spectrum of functions that are essential for regulating brain homeostasis. However, their role in brain ischemia still remains to be fully understood. The Substantia Nigra is a midbrain nucleus that is critical for movement control. Although its dopamine-producing neurons are implicated in the aetiology of Parkinsons disease, little is known of the acute effects of ischemia in this region. We recently reported that oxygen and glucose deprivation (OGD, 10 min) in brain slices, an *in vitro* ischemia model, generated a profound depolarization and swelling of neurons in the Substantia Nigra pars reticulata (SNr) but

not the dopaminergic neurons in the Substantia Nigra pars compacta (SNc). The SNr response resembled the phenomenon of 'anoxic depolarization,' known to also spread through the CA1 hippocampal region. The current study aimed to characterise the effects of OGD on astrocytes in the Substantia Nigra. Conventional intracellular recordings were made from astrocytes located at the border between SNc and SNr subregions in midbrain slices obtained from P21-23 rats. After fixing, immunoreactivity for the astrocyte-specific protein (GFAP) was also assessed. Nigral findings were compared with the relatively well-established astrocytic responses in the CA1 hippocampal region. OGD evoked a slow, then fast-phase depolarization of nigral astrocytes (n=13 cells from 9 rats), with the fast response developing during the anoxic depolarization and a rapid increase in extracellular K^+ ion concentration. This two-phased response resembled the OGD-evoked depolarization of hippocampal astrocytes (n=8 cells from 7 rats). However, unlike the prompt repolarization seen in hippocampal cells after returning O_2 and glucose, nigral astrocytes remained depolarized near 0 mV during reperfusion. In addition, immunoreactivity for the astrocytic protein GFAP markedly decreased in the Substantia Nigra after OGD (8 OGD *vs* 8 control slices submerged in standard ACSF, from 5 rats), while the hippocampus was unchanged (8 OGD and control slices, from 3 rats). These data indicate an acute post-ischemic withdrawal of astrocytic support in the Substantia Nigra.

Title: Effects of iron and tumor necrosis factor-alpha on astrocyte iron and glutamate homeostasis

Authors: *S. MUKEM[1,2], W. CHAIYANA[3], C. L. CHEEPSUNTHORN[4], P. CHEEPSUNTHORN[3]
[1]Biomed. Science, Chulalongkorn Univ., Grad. School-Interdisciplinary Program, Bangkok, Thailand; [2]Sch. of Medicine, Walailak Univ., Nakhon Si Thammarat, Thailand; [3]Dept. of Anatomy, Fac. of Medicine, Chulalongkorn Univ, Bangkok, Thailand, [4]Dept. of Biochemistry, Fac. of Med., Chulalongkorn Univ., Bangkok, Thailand

Abstract: Elevated levels of brain iron and pronounced inflammation have been correlated with neuropathological hallmarks of many degenerative brain disorders. Astrocytes are the most abundant cell type in the brain with diverse functions, including regulation of iron and glutamate homeostasis. This study sought to investigate the effects of iron and tumor necrosis factor-alpha (TNF-α) on the aforementioned functions of astrocytes using human 1321N1 astrocytoma cells.

Exposure to 50 ug/ml ferric ammonium citrate (FAC) increased calcein-chelatable iron content in 1321N1 cells, which was further enhanced when combined with 10 ng/ml TNF- α. These results correlated with a significant reduction in ferroportin mRNA levels and elevation of intracellular reactive oxygen species (ROS). TNF-α alone or, even better, in combination with FAC significantly stimulated the secretion of glutamate, as well as interleukin-6 (IL-6), from 1321N1 cells. Our findings suggest that astrocytes in degenerative brain disorders with iron accumulation and augmented inflammation are under stress due to their tendency to accumulate iron. Such astrocytes can release more of glutamate and IL-6, which together can drive neuronal cell death.

Title: Automated detection of markers of astrocyte activation

Authors: *L. G. FRANKLE, D. CARLYN, A. KOOTHAL, C. LU, R. CLEMENTS
Kent State Univ., Kent, OH

Abstract: Astrocyte activation is an important biomarker of multiple sclerosis (MS) and can be used to estimate severity of disease models. There are various ways to detect astrocyte activation including the concentration of proteins such as GFAP as well as morphological changes such as increased cell body size and altered cell body shape, and increased number, thickness, and branching of processes. While these morphological changes can be assessed manually with the aid of image processing software such as FIJI, automated programs could serve to increase the speed and ease of such assessments, potentially aiding in determinations of the extent to which mice being treated with cuprizone to mimic MS are being affected by it or conversely are being rescued by protective treatments. This would be a useful tool for future studies that use a mouse cuprizone model of MS, or any other mouse model that involves morphological changes to astrocytes. This plugin was developed using Java and works by selecting a seed point and using a region growing algorithm to expand throughout the cell. Processes are distinguished from the cell body by identifying whether a cubic radius surrounding each voxel includes only voxels belonging to the cell, and not background, in which case it's a body voxel. These methods segment astrocyte voxels from background voxels and body voxels from branches so determinations about cell body volume and process length and number can be reached. Data obtained by utilizing the plugin was compared to manual data to assess accuracy on metrics of

process counts and cell body volume. Manual data for the nuclear (DAPI) channel is also included to assess patterns in size and chromatin condensation as it correlates to cuprizone treatment and activation.

Title: The effects of medication on both non stepping and compensatory stepping responses to progressive external postural disturbances in individuals with Parkinson's disease

Authors: *C. P. HURT[1], D. J. KUHMAN[2], H. C. WALKER[3]
[1]Physical Therapy, Univ. of Alabama at Birmingham, Birmingham, AL; [2]Rehabil. Sci., Univ. of Alabama at Birmingahm, Birmingham, AL; [3]Neurol., UAB, Birmingham, AL

Abstract: Parkinson's Disease (PD) is associated with motor and non-motor symptoms. Among the motor symptoms is poor balance function, which increases fall risk. Medications (e.g., Levadopa) alleviate some, but not all, PD symptoms. For instance, effects of drug therapy on balance function have been equivocal. Our objective was to explore the effects of PD medication on a measure of balance function - the ability to resist stepping while experiencing progressive external disturbances to balance. This preliminary analysis of an ongoing study includes four participants with PD, Hoehn and Yahr 2 or 3. Each participant was tested after at least 12 hours off (OFF) and then on (ON) PD medication on the same day. We delivered progressively larger balance disturbances by increasing treadmill belt accelerations over 400 ms, starting at 0.5 m/s^2 and incrementing by 0.5 m/s^2 until a participant failed 4 times at a given acceleration (i.e., their step threshold). Participants stood quietly on the treadmill before each disturbance and were asked to avoid taking a step. We used motion capture to collect kinematic data for the feet and the body's center of mass (CoM). With these data, we calculated margin of stability (MoS), which considers CoM position and velocity with respect to the body's base of support (computed with kinematic data of the feet). Positive MoS suggests system stability and negative MoS suggests system instability. We found the minimum MoS (MoS_{min}) in the non-stepping trial immediately preceding the first trial where stepping threshold occurred ("sub-threshold trial"). For stepping trials, we found the MoS value at foot strike of the compensatory step (MoS_{fs}) and

the step distance. Step thresholds increased after administration PD medications in 3 individuals (3 to 5 m/s^2, 5 to 5.5m/s^2, 3.5 to 5.5 m/s^2) and did not change in 1 individual (5 m/s^2). MoS_{min} during sub-threshold trials were qualitatively different OFF (0.0 ± 2.0 cm) vs. ON (-3.1 ± 2.0 cm). That individuals were able to withstand a more negative MoS while ON indicates greater capacity for generating non-stepping compensatory responses. For trials in which a step occurred, both MOS_{fs} (OFF: 6.7 ± 8.7 cm; ON: 9.8 ± 11 cm) and step distance (OFF: 7.1 ± 9.0 cm; ON: 12.7 ± 10.0 cm) qualitatively increased with medication. These data indicated that PD medication enhanced compensatory stepping mechanics. In general, this preliminary analysis of an on-going study suggests that medications enhance balance function in individuals with PD. Going forward we will use joint kinetics to characterize improved internal muscular responses with medication.

Title: Dopamine d_1r or d_3r agonist exposure induces cross-receptor behavioral sensitization: Functional implications of d_1r-d_3r interactions

Authors: *K. E. LANZA, S. M. MEADOWS, K. CHEMAKIN, B. TOPPING, N. E. CHAMBERS, C. SAITO, C. R. BISHOP
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Parkinson’s Disease (PD) results in motor deficits which are symptomatically treated with L-DOPA. However, chronic use of L-DOPA inevitably leads to the development of L-DOPA-induced dyskinesia (LID) characterized by abnormal involuntary movements (AIMs). Though there are many mechanisms that contribute to LID, accumulating data have implicated the involvement of both dopamine (DA) D1 sensitization and D3 receptor upregulation (D1R and D3R, respectively). Importantly, D3R upregulation occurs largely on D1R-bearing cells and interactions between these receptors have been postulated to underlie LID development. Changes to D3R expression appear to depend on chronic stimulation of D1R. However, it is unknown

about whether and how repetitive D3R stimulation induces D1R behavioral sensitivity. The current investigation tested the functionality of putative D1R-D3R interactions by examining the presence of cross-agonism, hypothesizing that D1R or D1R agonist treatment would induce reciprocal behavioral sensitization. To this end, female adult Sprague-Dawley rats were rendered hemi-parkinsonian via a unilateral 6-hydroxydopamine lesion in the medial forebrain bundle. Three weeks later, rats were tested for off-treatment motor deficits with the Forepaw Adjusting Steps (FAS) test and subsequently organized into 4 equally motor impaired groups (n=8-10 per group). Thereafter, each group received 4 injections every 4-5 days of either saline, the D1R agonist SKF38393 (1.0 mg/kg) or the D3R agonist PD128907 (0.1 mg/kg). AIMs were monitored following each injection for 3 hours to track the development of dyskinesia. For the 5^{th} injection, each group received an acute injection of the opposite agonist to test for the possibility of cross-sensitization. AIMs were monitored for the same testing period. Results showed that subchronic administration of both SKF38393 and PD128907 induced the development of dyskinesia. More importantly, cross-agonism tests revealed reciprocal cross-sensitization; chronic treatment with either SKF38393 or PD128907 induced sensitization to a single administration of the opposite agonist. Therefore, the current study provides key behavioral data demonstrating the role of D3R in dyskinesia and provides behavioral evidence of D1R and D3R functional interactions.

Title: Cholinergic neurons in the rostral pedunculopontine nucleus contribute to dyskinesia in the hemi-parkinsonian rat

Authors: *N. E. CHAMBERS[1], J. SERGIO[1], M. COYLE[1], B. TOPPING[1], C. SAITO[1], K. E. LANZA[1], S. CLARK[3], C. R. BISHOP[2]
[2]Psychology, [1]Binghamton Univ., Binghamton, NY; [3]Univ. at Buffalo - The State Univ. of New York, Buffalo, NY

Abstract: Parkinson’s disease (PD) is associated with motor deficits and dopamine (DA) cell loss in the substantia nigra pars compacta. L-DOPA, the current standard treatment for PD, produces abnormal involuntary movements known as L-DOPA-induced dyskinesia (LID) within a decade of treatment. Although the causes of LID are multi-faceted, elevated cholinergic tone, to which the pedunculopontine nucleus (PPN) may contribute, has been implicated. Notably, the

PPN innervates basal ganglia structures, is implicated in parkinsonian motor deficits and drug-induced motor stereotypy, and displays upregulation of immediate early genes that contribute to dyskinesia expression in rats. Despite compelling evidence that the PPN is involved in movement and motor stereotypy, the role of cholinergic PPN neurons in dyskinesia is unknown. Thus, the goal of the current study was to examine the role of PPN cholinergic neurons in parkinsonian motor deficits and in LID and DA-agonist-induced dyskinesia in the hemi-parkinsonian rat model. In the current study, we employed a between-subjects design with four surgical groups. Diphtheria-urotensin II fusion toxin (DTX-UII) was used to selectively lesion cholinergic PPN neurons. Each group received a unilateral surgery targeting the PPN with either saline or DTX-UII and the medial forebrain bundle with either saline or the DA neurotoxin 6-OHDA. Gait analyses (via CatWalk), forepaw adjusting steps (FAS), and locomotor chambers were used to assay parkinsonian motor deficits and their reversal. Dyskinesia was measured via the abnormal involuntary movements test. Lesion severity and specificity was verified via PPN ChAT and NeuN and nigral TH expression. We hypothesized that dual lesion (DTX-UII + 6-OHDA) and DA lesion groups would show motor impairments, and that dual lesioned rats would show less dyskinesia compared to DA lesioned rats. The results of this study show that dual and DA lesioned rats displayed parkinsonian motor deficits. Importantly, dual lesioned rats exhibited less LID than DA lesioned rats. In addition, dual lesioned rats displayed less severe D1- and D2-receptor agonist-induced dyskinesia than DA lesioned rats. Taken together, this suggests that the PPN may contribute to dyskinesia through innervation of both the direct and indirect pathways. Interestingly, L-DOPA's motor efficacy was maintained in dual lesioned rats, supporting PPN cholinergic neuron modulation as a promising therapeutic target for reducing LID without interfering with motor benefits of L-DOPA.

Title: Optogenetic and chemogenetic induction of unilateral hemiparkinsonism is not associated with the risk of levodopa induced dyskinesias

Authors: *K. M. LE[1], S. CHINNIAH[1], V. IYER[1], N. PATEL[2], C. LIEU[1], M. PENNOCK[1], E. HANDLEY[1], A. ZENEROWITZ[1], E. DICKEY[1], S. SAVALIYA[1], T. SUBRAMANIAN[1], K. VENKITESWARAN[1]

Abstract: L-dopa provides effective symptomatic relief in Parkinson's disease (PD), but its long-term use causes levodopa-induced dyskinesias (LID). Loss of continuous dopaminergic stimulation (CDS) is an accepted hypothesis for the pathogenesis of LID. The "loss of CDS hypothesis" would predict that hemiparkinsonian (HP) patients and HP animals would develop unilateral LID. However, our studies show that HP rats and monkeys with preserved interhemispheric nigrostriatal fibers not develop LID. This suggests that loss of interhemispheric nigrostriatal connections may be critical for the genesis of LID. We tested the hypothesis that unilateral inhibition of the nigrostriatal pathway will lead to reversible hemiparkinsonism that will not be associated with dyskinesias. We used recombinant viral vectors to conditionally express Natronomonas halorhodopsin (NpHR3.0) and hM4Di, a Designer Receptor Exclusively Activated by Designer Drug (DREADD) to cause unilateral silencing of the nigrostriatal pathway. Experiments were performed in 2 separate model systems. In model #1, Sprague Dawley rats and in model #2 transgenic TH-Cre rats were used. In both models, recombinant viruses AAV5-Ef1a-DIO-eNpHR3.0-EYFP or AAV8-hSyn-DIO-hM4Di-mCherry was injected into the left substantia nigra pars compacta (SNpc). A cre-mediated switch, AAV2- Ef1a-mCherry-IRES-WGA-Cre, was injected unilaterally into left striatum in model #1 animal. Animals were repeatedly tested for onset and reversal of right HP (RHP) state. The eNpHR3.0 treated animals served as controls for the hM4Di treated animals and vice versa. Our results show that both eNpHR3.0 and hM4Di treated animals consistently developed RHP as characterized by mean unilateral reduction of vibrissae-evoked forelimb placement test scores by 75% ($p<0.5$). Striatal microdialysis indicated near complete diminution of dopamine levels that was temporally correlated with DREADD activation. In both models, RHP was completely reversible with no residual parkinsonism or adverse events. Repeatedly inducing RHP did not cause dyskinesias. Further, chronic treatment with L-dopa round the clock along with induction of RHP did not induce dyskinesias. No phototoxicity was noted. These experiments support the notion that unilateral inhibition of the nigrostriatal pathway with intact interhemispheric nigrostriatal connections does not lead to dyskinesias and chronic intermittent fluctuations of endogenous striatal dopamine is not associated with dyskinesias. These findings support the notion that preservation of interhemispheric nigrostriatal fibers and dopaminergic synapses will mitigate/prevent LID in PD.

Title: Muscarinic but not nicotinic agonists prevent increase in dyskinesias with optogenetic activation of striatal D1 medium spiny neurons in parkinsonian mice

Authors: *X. A. PEREZ[1], T. BORDIA[2]
[2]Ctr. for Hlth. Sci., [1]SRI Intl., Menlo Park, CA

Abstract: Dyskinesias are a disabling motor complication that arises with prolonged L-dopa treatment. Evidence indicates that direct pathway medium spiny neurons (D1 MSNs) play a primary role in the development of dyskinesias. Our previous work showed that D1 MSN stimulation induced dyskinesia-like abnormal movements in L-dopa naïve mice. L-dopa treatment alone induced dyskinesias (LIDs) to a greater extent than optical stimulation. However, combined L-dopa administration and stimulation resulted in an additive increase indicating that complex adaptive responses extending beyond activation of D1 and/or D2 receptors contribute to dyskinesias. Here, we used optogenetics to investigate whether nicotine treatment affects the direct control of striatal D1 MSN activity on dyskinesias in parkinsonian mice. Mice expressing cre-recombinase under the control of the D1 receptor promoter were unilaterally lesioned with 6-hydroxydopamine. AAV5-ChR2-eYFP or AAV5-control-eYFP was injected into the dorsolateral striatum, and optical fibers implanted. After stable virus expression, mice were optically stimulated and dyskinesias rated. The mice were subsequently treated with saline or L-dopa (until stably dyskinetic) and randomly assigned to saccharin or nicotine treatment. After a month of treatment, the effect of D1 MSN stimulation was assessed in all treatment groups. As previously, D1 MSN stimulation induced dyskinesia-like abnormal movements in L-dopa-naive animals and enhanced LIDs in L-dopa-primed mice. Nicotine decreased LIDs by ~50%, as before, but was unable to prevent the enhancing effect of D1 MSN stimulation. In fact, combined L-dopa and D1 MSN stimulation increased AIMs in the nicotine group to the same level as before nicotine treatment and equivalent to that observed in the saccharin group. These combined data suggest that nicotinic receptors (nAChRs) do not exert a direct control over D1 MSN activity to regulate LIDs. As recent studies have shown that enhancing muscarinic receptor type 4 (M4 mAChR) signaling decreases D1 MSN activity and ultimately reduces AIMs, we next examined the effect of VU0467154 on the effect of D1 stimulation on LIDs with and without nicotine treatment. VU0467154 reduced LIDs in saccharin but not nicotine-treated mice. Interestingly, it prevented the enhancement in LIDs with D1 stimulation in both groups. Overall,

the data indicate that while M4 mAChRs directly modulate D1 MSN activity to decrease LIDs, nAChRs may reduce them by indirectly affecting D1 MSNs and/or via additional mechanisms. Studies will now focus on examining the molecular mechanisms involved.

Title: The kappa opioid receptor antagonist nor-BNI accelerates development of L-DOPA-induced dyskinesia in a model of mild Parkinson's disease

Authors: *R. NAVA[1], A. J. FLORES[1], M. J. BARTLETT[1], M. R. SEXAUER[1], J. SIEGENTHALER[2], M. L. HEIEN[2], S. J. SHERMAN[1], F. PORRECA[3], T. FALK[1]

Abstract: Levels of the opioid peptide dynorphin, which is an endogenous ligand selective for kappa-opioid receptors (KORs), and its mRNA and peptide precursors are differentially dysregulated in Parkinson's disease (PD) and following the establishment L-DOPA-induced dyskinesia (LID). In the dopamine (DA)-depleted PD state, levels of dynorphin and its precursors are downregulated. In contrast, established LID is associated with levels of dynorphin and its precursors that are upregulated. It remains unclear whether these alterations contribute to the pathophysiological mechanisms underlying PD motor dysfunction and the subsequent emergence of LID, or whether they are compensatory. The KOR-antagonist nor-BNI has previously been shown to block sensitization in PD rats (Newman et al. 1997). Therefore, we set out to test if nor-BNI can change the development of LID during the priming period. To assess this, we have evaluated the effect of nor-BNI administration (3 mg/kg; *s.c.*) on the dose- and time-dependent development of abnormal voluntary movements (AIMs) in response to chronic escalating doses of L-DOPA treatment in a mild striatal 6-OHDA lesion rat LID model (70-80% DA depletion, compared to >95% in the standard LID model). Within this mild-dyskinesia paradigm, independent nor-BNI and vehicle-treated groups (n=6-7) were tested multiple times (2-4 times) across 5 escalating doses of L-DOPA (6, 12, 24, 48, 72 mg/kg*; i.p.*) and evaluated for

total limb axial and orolingual (LAO), and locomotor AIMs scores under blinded conditions. When cumulative AIMs scores were analyzed separately according to L-DOPA dose, we discovered that nor-BNI increased the expression of LAO AIMs only at the 12 (two-tailed t-test t=2.76 df=50, *p*=0.0081) and 24 mg/kg (two-tailed t-test, t=2.473 df=50, *p*=0.0169) L-DOPA doses. At the end of the experiment, after the 72 mg/kg L-DOPA dose, the AIMs levels were equal in both groups. When cumulative total locomotor AIMs scores were analyzed separately according to L-DOPA dose, at the 12 mg/kg dose a trend of an increased expression of locomotor AIMs after nor-BNI was seen (two-tailed t-test t=2.76 df=50, *p*=0.0733), and again locomotor AIMs were equal after the 72 mg/kg L-DOPA dose. In summary, nor-BNI significantly accelerated the rate of development of LAO but not locomotor LID in a mild striatal-lesion rat PD model, but did not increase the AIMs once LID was established. Given recent data showing that nor-BNI can increase DA release in the nucleus accumbens shell as measured with fast-scan cyclic voltammetry, it might be of interest to test if a similar increase in DA also occurs in the dorsolateral striatum and contributes to the described effect of nor-BNI.

Title: Striatal ΔFosB gene silencing reduces abnormal involuntary movements induced by L-DOPA in hemiparkinsonian rats

Authors: *G. BECK[1], J. ZHANG[2], K. FONG[3], M. M. MOURADIAN[4], S. M. PAPA[5]

Abstract: Long-term dopamine replacement therapy in Parkinson's disease (PD) leads to the development of motor complications including L-DOPA-induced dyskinesia (LID). Several studies have shown that the transcription factor ΔFosB, a truncated form of FosB, plays an important role in the development of dyskinesias. Specifically, our experiments in rodent models of PD demonstrated that the transgenic ΔFosB overexpression in the striatum induces rapid development of abnormal involuntary movements (AIMs) in the absence of the typically

required regular L-DOPA treatment. To confirm the key role of this transcription factor, here we investigated whether inhibiting ΔFosB expression reduces and/or delays AIMs development. rAAV-ΔFosB shRNA-GFP or the control virus rAAV-scrambled shRNA-GFP was injected into the left striatum of rats with 6-OHDA lesions of the left medial forebrain bundle (n = 24). After apomorphine test screening, animals were evaluated for their baseline motor responses to L-DOPA, and then started on L-DOPA daily administration for 2 weeks. The whole L-DOPA motor response (rotation, cylinder and stepping test performances) and AIMs were assessed every four days, using standardized rating scales for rodents.
AIMs scores were significantly reduced in the rats injected with rAAV-ΔFosB shRNA compared to animals injected with the control vector over the course of chronic L-dopa treatment. Rotation counts, and scores from cylinder and stepping tests were no different between the two groups, indicating that silencing the striatal ΔFosB gene had no impact on the antiparkinsonian action of L-DOPA. These results confirm the crucial role of ΔFosB in the underlying mechanisms of AIMs, and suggest that ΔFosB gene silencing could be a useful therapeutic approach for LID.

Abstract: The nitric oxide (NO) system has been proven to be a valuable modulator of L-DOPA-induced dyskinesia (LID) in parkinsonian rodents. Recent studies suggest that, under

certain circumstances, drugs with opposing pharmacological profiles may exhibit similar effects on LID. Our group has previously shown the anti-dyskinetic properties of NO synthase (NOS) inhibitor 7-Nitroindazole (7-NI) and of NO donor sodium nitroprusside (SNP) on reducing LID in hemiparkinsonian rats. This paradox effect is yet to be comprehended. Our aim was to investigate whether these drugs could have a common mechanism of action, perhaps by acting on different cyclic nucleotide systems in the lesioned striatum. For that, unilaterally 6-OHDA-lesioned rats with similar lesion intensity (as evaluated by the stepping test) were separated into groups and treated for 14 days with SAL (saline 0,9%, gavage, n=6), 7-NI/SAL (7NI 30 mg/kg i.p., n=6), SNP/SAL (NPS 4 mg/kg i.p., n=6), Veh/L-DOPA (L-DOPA 20 mg/kg, gavage, n=6), 7-NI/L-DOPA (7NI 30 mg/kg i.p., n=6) or SNP/L-DOPA (SNP 4 mg/kg i.p., n=6). We measured cAMP and cGMP levels in the dorsal striatum ipsilateral to the lesion, 10-15 min after last drug administration. We confirmed that 7-NI inhibited the manifestation of LID (P=0.0003). Our results also revealed the prolonged administration of SNP attenuated LID manifestation (U=12.08, P=0.0003). Chronic treatment with L-DOPA led to an increase in cAMP ($F_{1,30}$=15.98, P=0.0004) and cGMP ($F_{1,30}$=17.72, P=0.0002) levels in the lesioned dorsal striatum when compared to animals treated with SAL. Cyclic nucleotides levels were differentially regulated in animals that received 7-NI or NPS: 7-NI prevented the increase of both cAMP ($F_{2,30}$=21.00, P=0.0001) and cGMP levels ($F_{2,30}$=36.84, P=0.0001) whereas NPS prevented the increase of the cAMP levels ($F_{2,30}$=21.00, P=0.0001) and increased cGMP levels ($F_{2,30}$=36.84, P=0.0001) in L-DOPA-treated groups. In this way, our results revealed the reduction of cAMP levels might be a common mechanism in LID modulation by NOS inhibitor and NO donor. cAMP levels decrease might be an important mechanism to the antidyskinetic ability of the NO donor and the NOS inhibitor.

Title: The lack of Manf in the central nervous system causes activation of unfolded protein response without an effect on the dopamine system in mice

Authors: *E. PAKARINEN[1], V. VÕIKAR[2], P. PIEPPONEN[3], M. SAARMA[1], M. LINDAHL[1]
[1]Inst. of Biotech., [2]Neurosci. Ctr., [3]Fac. of Pharm., Univ. of Helsinki, Helsinki, Finland

Abstract: Neurodegenerative diseases, such as Parkinson's disease, share pathological features of protein aggregation and protein misfolding in cells. Accumulation of protein aggregates causes endoplasmic reticulum (ER) stress, which activates unfolded protein response (UPR) to reduce stress. Mesencephalic astrocyte-derived neurotrophic factor (MANF) is an ER-located protein secreted in response to ER stress. Moreover, MANF protects cells from ER stress both in vitro and in vivo. The deficiency of MANF in mice leads to pancreatic beta cell loss and diabetes caused by ER stress in beta cells. In the rodent model of Parkinson's disease MANF has shown both neuroprotective and neurorestorative actions. However, the role of endogenous MANF in the dopamine system in mice is still not understood. To examine whether MANF acts as a physiological trophic factor for dopamine neurons, we created MANF conditional knockout (cKO) mice with the deletion of Manf in the central nervous system by using transgenic Nestin Cre mice. In this study we aimed to characterize the morphology and function of the midbrain dopamine system of MANF cKO mice and examine the effect of MANF absence on ER stress levels in the brain. Results reveal chronic activation of one of the UPR pathways, IRE1, in the brains of MANF cKO mice. This activation, however, might provide protection, since no cell loss is observed in the dopamine system. Aged MANF cKO mice have normal number of midbrain dopamine neurons and unchanged dopamine levels in the striatum. Moreover, motor behavior stays similar to control mice during aging. Also, the functionality of dopamine neurons tested with amphetamine administration is unaffected in aged MANF cKO mice. In conclusion, mice with the deletion of MANF in the central nervous system have prolonged activation of UPR in their brains. Furthermore, MANF deficiency in mice is dispensable for the maintenance of dopamine neurons during aging.

Abstract: There is a great need to define the molecular changes associated with Parkinson's disease (PD) patients that develop L-Dopa-induced dyskinesia (LID). In the present research we have studied neurochemical processes in PD, and specifically LID, using MALDI-mass spectrometry imaging (MSI). We introduce a novel molecular-specific approach to image and quantify a large number of different neurotransmitters, their precursors and metabolites simultaneously directly in tissue sections using mass spectrometry (MS). Samples were obtained from a biobank of brain tissue (*Macaca mulatta*). Regional analysis (coronal sections) of neurotransmitters produced by the basal ganglia neurons in the PD and LID states were investigated by MALDI-FTICR MS imaging (Solarix 7T). Non-parametric test (Mann-Whitney U) as well as orthogonal correction partial least squares discriminant analysis (OPLS-DA) were performed in 21 selected brain regions. Using the novel MSI approach we were able to map almost the complete catecholamine neurotransmitter system, the precursors and most of their metabolites, directly in brain tissue sectionsin the PD and LID experimental model. L-Dopa and dopamine was significantly increased in most measured brain structures of the dyskinetic animals and the dopamine metabolites 3-MT and HVA were significantly increased in several cortex regions as well as the hippocampus. In summary, our methodology enables *in situ* mapping of patterns within and between neurotransmitter systems and showed novel neurotransmitter alterations in PD and LID. Quantitation of functional neurotransmitter balances may be a useful approach in studies of neurodegenerative disorders but also in drug development as a biomarker-based rationale for targeted modulation of neurotransmitter networks.

Abstract: Mutations in *TAF1*, the TATA-box binding protein associated factor that is central to RNA polymerase II function, can cause two different diseases. One, X-linked dystonia parkinsonism (XDP/DYT3), is characterized by neurodegeneration of the striatum with generalized dystonia and parkinsonism beginning in adulthood. XDP is linked to mutations near the 3'-end of *TAF1*, including an insertion of the retrotransposon SVA (SINE-VNTR-Alu) upstream of a neuron-specific *TAF1* exon. A second disease, X-linked intellectual disability syndrome (MRXS33), is linked to mutations in constitutive exons of *TAF1* that are located 5' to the SVA insertion. MRXS33 causes perinatal growth retardation, facial dysmorphology, psychomotor symptoms, and intellectual disability. To better understand the differences between XDP and MRXS33, we directly compared mRNA and protein expression patterns of the neuron-specific *TAF1* isoform (*N-TAF1*) and the constitutive isoform (*C-TAF1*). This is technically challenging because *N-TAF1* is distinguished from *C-TAF1* only by the inclusion of a six base-pair micro-exon (exon 34'), encoding alanine and lysine.
We used BaseScope™ probes against *C-* and *N-TAF1* for *in situ* hybridization in adult mouse brain, liver, and heart. *C-TAF1* was detected in all of these tissues, whereas *N-TAF1* was restricted to brain. Within the brain, *C-TAF1* was detected in mature neurons, glia, and dividing cells. By contrast, *N-TAF1* was enriched in post-mitotic neurons. We found similar differences in expression with antibodies that we generated against TAF1 peptides that included or excluded the microexon 34' sequence. Both C- and N-TAF1 were widely expressed in the brain including within nuclei of cortical neurons, striatal neurons, and dopamine-containing nigral neurons. However, double immunofluorescence for C- and N-TAF1 showed differential subnuclear localization within post-mitotic neurons.
Splicing factor nSR100/SRRM4 regulates inclusion of microexons in many neuronal genes, including *N-TAF1*. We compared the expression pattern of *nSR100* to *C-* and *N-TAF1* by *in situ* hybridization and immunolabeling. Like N-TAF1, nSR100 was widely expressed in post-mitotic neurons, but differentially enriched among them.
Our findings, together with previous work, suggest that the developmental symptoms of MRXS33 might be absent in XDP because of the restriction of N-TAF1 expression to post-mitotic neurons. However, the striking difference in subnuclear localization of C- and N-TAF1 indicates that other symptom differences are related to separate functions for these two TAF1 isoforms and shows that microexons can have a major impact on subcellular localization.

Title: Validation of a torsinA cerebellar knockdown model of DYT1 dystonia

Authors: *Y. LI[1], Y. LIU[1], E. RODRIGUEZ-LEBRON[2]
[1]Dept Neurol, [2]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL

Abstract: Dystonia is a movement disorder characterized by sustained or intermittent muscle contractions causing twisting, repetitive movements or abnormal postures. DYT1 dystonia is the most common genetic dystonia. About 60-90% of DYT1 patients carry heterozygous *DYT1 GAG* mutation causing a loss of a glutamic acid of the protein torsinA. Many studies suggest that the mutation results in a loss of function. But how the mutation causes dystonia remains largely unknown. The research in this area is hampered by the lack of overt dystonia-like phenotypes in most of the genetically modified mouse models developed. Recently, acute torsinA knockdown in the cerebellum using small hairpin RNAs (shRNAs) against torsinA mRNA has been demonstrated to induce overt dystonia-like phenotype in adult mice. However, shRNAs or small interfering RNAs (siRNAs) are known to have significant off-target effects that lead to altered expression of unintended genes. To validate the shRNA model of DYT1 dystonia, we generated an acute torsinA knockdown mouse model by bilateral stereotaxic injections of AAV5-CMV-Cre-GFP into the cerebellum of $Dyt1^{loxP/loxP}$ mouse. Expression of Cre led to cre-loxP-mediated recombination and eliminated the expression of torsinA in AAV-infected cells. The motor behavior of these mice was assessed by the dystonia scale at 3 weeks, 7 weeks and 13 weeks after injection, respectively. Thirteen weeks after AAV injection, mice were euthanized, and the brains were harvested. Green fluorescence could be seen only in the cerebellum and the torsinA level was quantified by western blot. Electrophysiological properties of the Purkinje cells were characterized using the cell-attached patch-clamp recording in the brain slices. Overt dystonia-like phenotypes were found in 5 out of 7 mice. However, an unexpected bidirectional circling was found in 3 of the most severely affected mice when the mice were lifted to examine hindlimb clasping. This resembles the vestibular deficits seen in other mutant mice such as vertigo 2 Jackson mice. Vertigo is not a typical symptom of DYT1 dystonia patients. Our findings are consistent with the previous results that acute cerebellar knockdown of torsinA expression can produce the overt dystonia phenotype, however, the vertigo phenotype we

observed questions the validity of the shRNA model as a phenotypic DYT1 dystonia mouse model.

Title: The role of BTBD9 in the pathogenesis of restless legs syndrome (RLS): Cortical and dopaminergic neurons

Authors: *S. LYU[1], A. DOROODCHI[1], Y. SHENG[1], K. DEXTER[1], B. SALVATO[1], M. DEANDRADE[2], M. MILLER[3], M. FEBO[1], R. XIAO[1], Y. LI[1]

Abstract: RLS is a prevalent sensorimotor disorder characterized by an urge to move due to uncomfortable sensations in the legs, often at night or at rest, which is generally relieved by movement. Genome-wide association studies have identified mutations in *BTBD9* to confer a higher risk of RLS. We developed *Btbd9* knockout (KO) mice as an animal model for the disease. RLS patients have been reported to show functional alterations in the cortex, especially sensorimotor cortex. Furthermore, the primary prescription for RLS patients are D2/D3 dopaminergic agonists and alterations in dopaminergic system have been widely found in both RLS patients and RLS animal models. Reduced expression of fly BTBD9 homolog in a subset of dopaminergic neurons can lead to sleep disruptions. Therefore, both cerebral cortex and dopaminergic system appear to be critical for the pathogenesis of RLS, with the exact functions of BTBD9 in these brain regions largely unknown. Here, we conducted manganese-enhanced MRI study in *Btbd9* KO mice and found increased neural activity in primary somatosensory cortex (S1) and rostral piriform cortex (PirR). Next, we performed behavioral studies with cerebral cortex-specific *Btbd9* conditional knockout mice (BCKO) and dopaminergic neuron-specific conditional knockout mice (BDATKO). We did not find motor restlessness and increased thermal sensation in BCKO or BDATKO mice. Instead, the BCKO mice showed a significant decrease of thermal sensation. Finally, we made use of the simple nervous system of *Caenorhabditis elegans* and studied egg-laying and locomotor behaviors to define the genetic

interactions between the worm BTBD9 homolog and the dopaminergic system. We found loss of *hpo-9*, the *C. elegans* homolog of *BTBD9*, resulted in hyperactive egg-laying behavior and altered responses to exogenous dopamine. Additionally, dopamine receptor mutation *dop-1* partially, but *dop-3* completely, suppressed the effect of *hpo-9* in egg-laying behavior. The function of HPO-9 in locomotion was modulated by *dop-1* and *dop-3*, with *hpo-9* and *dop-1* working in a similar way. Our finding is consistent with the previous study of increased D1 receptor (D1R) protein expression in the lumbar spinal cord of RLS animal models. Our results therefore indicate that systematic BTBD9 deficiency increases the neural activity of S1 and PirR. However, loss of BTBD9 only in cortical neurons or dopaminergic neurons is not sufficient to cause RLS-like phenotypes in mice. In *C. elegans*, HPO-9 deficiency altered the dopaminergic system by its interaction with dopamine receptors, especially *dop-1*. Taken together, our results revealed a complex mechanism by which mutation of BTBD9 can lead to RLS.

Title: Changes in motor cortical electrophysiological and two-photon Ca^{2+} responses during episodic dystonia in the tottering (tg/tg) mouse

Authors: A. NAIK[1], M. GRAY[1], *R. CARTER[1], L. GHANBARI[2], S. KODANDARAMAIAH[2], T. EBNER[1]
[1]Neurosci., [2]Mechanical Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Episodic ataxia type 2 (EA2) is a rare neurological disorder caused by a mutation in the *CACNA1A* gene, encoding the P/Q-type, voltage-gated Ca^{2+} channel important for initiating neurotransmitter release. Patients with EA2 exhibit both cerebral and cerebellar pathologies, including migraines, absence seizures, and episodic ataxia, which can be triggered by caffeine, stress, or alcohol. Several clinical studies have also reported dystonia occurring in EA2 patients. The *tottering* (*tg/tg*) mouse is a commonly used model for EA2 due an orthologous mutation in the *Cacna1a* gene, resulting in a phenotype similar to EA2, including absence seizures, ataxia, and transient episodes of dystonia. Previous research has implicated the cerebellum in the generation of the dystonic attacks, and it is well known that cerebellar output can help refine and coordinate motor commands. As a profound motor phenotype occurs during the dystonic attack,

we hypothesized there would also be changes occurring in the local cellular networks in the primary motor cortex (M1) of *tg/tg* mice. To investigate this, we recorded extracellular activity with a 16 channel multi-electrode array and two-photon (2P) Ca^{2+} imaging from awake, head-fixed *tg/tg* and wildtype mice on custom treadmills. Mice were either implanted with a chamber to accommodate the electrophysiology headstage, or injected with an AAV construct containing GCaMP6f in M1 and implanted with a 3D-printed, clear brain window for 2P imaging. Following a baseline recording period, the dystonic attacks were triggered by caffeine injections, and electrophysiology and imaging recorded pre-, during, and post-attack. Local field potential (LFP) analysis found generalized spike-and-wave discharges (GSWDs), a hallmark of absence seizures that *tg/tg* mice exhibit, were completely abolished during the dystonic attack and reappeared following an attack. This decrease in GSWDs was also paralleled with a decrease in gamma coherence during the attack, suggesting a decrease in thalamocortical activity. Alpha and beta coherence also decreased, which may be associated with a reduction in inhibitory synchrony that contributes to the dystonic movements. Preliminary results from the 2P imaging revealed an increased number of Ca^{2+} transients per neuron during the attack, however, the single unit recordings of basic firing properties (firing rate, CV, CV2) did not change during the attack. Overall, these results suggest that changes in local M1 coherence may contribute to the episodic dystonia in *tg/tg* mice. Further, the complete dissociation between GSWDs and the dystonic attacks shows that these two instabilities represent unique network states.

Abstract: DYT1 dystonia is an inherited movement disorder caused by a heterozygous trinucleotide deletion (GAG) mutation in DYT1/TOR1A, coding for torsinA. Growing evidence suggests that the cerebellum plays a role in the pathogenesis of dystonia. Brain imaging of DYT1

dystonia patients showed abnormal activity in the cerebellum. Cerebellum-specific knockdown of torsinA expression in adult mice leads to dystonia-like behavior. We and others reported previously altered dendritic structures in Purkinje cells in *Dyt1 Δ*GAG heterozygous knock-in (*Dyt1* KI) mouse models of DYT1 dystonia. To examine whether there are functional alterations of the Purkinje cells, electrophysiological properties of the Purkinje cell were characterized in the *Dyt1* KI mice using cell-attached patch-clamp recording in brain slices. Both the firing rate and the coefficient of variation (CV) were unchanged in the tonic type of Purkinje cells. However, in the non-tonic type of Purkinje cells in the *Dyt1* KI mice, although the firing rate was unchanged, the CV was significantly increased, suggesting abnormal firing of the non-tonic type of Purkinje cells in the *Dyt1* KI mice. To investigate how the altered Purkinje cell firing patterns contribute to DYT1 dystonia pathogenesis, we used Cre-dependent DREADD (designer receptors exclusively activated by designer drugs) to manipulate the Purkinje cell activity *in vitro* and *in vivo*. *Pcp2-cre*/DREADD double heterozygous mice were generated by crossing DREADD mice with L7/Pcp-2:Cre transgenic mice. Brain fluorescent imaging showed that DREADD was selectively expressed in Purkinje cells in *Pcp2-cre*/DREADD mice. Bath application of CNO (clozapine N-oxide), the DREADD agonist, could selectively excite or inhibit Purkinje cell firing in brain slice preparations. Behavioral tests were performed after intraperitoneal injections of either CNO or saline in *Pcp2-cre*/DREADD mice. Activation of Purkinje cells led to significant deficits in rotarod and beam-walking tests, but not when the Purkinje cells were silenced. None of these DREADD mice showed overt dystonia. The results demonstrated that altered Purkinje cell firing pattern, as seen in *Dyt1* KI mice, could potentially lead to motor coordination and balance deficits that have been reported in multiple genetic DYT1 dystonia mouse models. Taken together, our results support a role of cerebellum in the pathogenesis of DYT1 dystonia.

Abstract: Myotonic Dystrophy Type I (DM1) is a degenerative and hereditary disorder, its more typical symptoms are muscle weakness and hypotonia, which may lead to several complications like respiratory failure and cardiac arrest. DM1 has proven difficult to diagnose. It affects the quality of life of the patients and its symptoms could lead to different diagnostics that could be confused even with normal aging. For this reason it is important to find biomarkers that help in the assessment and in the follow up of treatment for this disease.The aim of this project is to find biomarkers that help us to characterize the evolution of this disorder. In the present work 37 DM1 patients and 35 healthy controls volunteer participants were matched by age, sex and level of education, then underwent an MRI session in a 3T Philips Ingenia scanner with a 32-channel head sense coil. Diffusion Tensor Images (DTI) were acquired with the following parameters: 33 diffusion directions, b=800 s/mm^2, isometric spatial resolution (2mmx2mmx2mm), TR=7103 ms, TE=60 ms, Gap=0, 70 slices. For the analyisis of data a t-test was applied for unpaired samples, and the FSL5.0.8 software was used. For the post processing DTI images were corrected by movement and eddy currents and TBSS script was applied. Clusters with statistical significance (P<0.05) were found in the regions of orbitofrontal white matter paths, anterior cingulate cortex white matter paths and corpus callosum. Atrophy in white matter paths is significant in frontal brain areas, which may imply that different control processes could be altered.

Title: Phenotyping cervical dystonia: using clinical video recordings and computer vision to capture triaxial head posture

Authors: Z. ZHANG[1], J. P. VU[1], Q. CHEN[1], E. CISNEROS[1], C. N. BENADOF[1], T. J. SEJNOWSKI[2], J. S. PERLMUTTER[3], G. T. STEBBINS[4], C. COMELLA[4], *D. A. PETERSON[5]

Abstract: The objective of this study was to test the hypothesis that computer-vision based video analysis software can capture abnormal head postures in cervical dystonia. Cervical dystonia (CD) is one of the most common forms of the adult onset focal dystonias. The most prominent phenotypic feature of cervical dystonia is abnormal head postures. These are usually quantified subjectively with the Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS), an ordinal clinical rating scale. Advances in computer vision have produced algorithms to infer head posture from conventional digital video recordings. But they have not been evaluated for measuring pathological head postures in CD. We analyzed digital videos from 21 patients recruited at Rush University Medical Center with isolated CD and a heterogeneous mix of abnormal head postures in each of the 3 axes of rotation: pitch (antero/retrocollis), roll (laterocollis, or "tilt"), and yaw (torticollis). We used OpenFace to estimate head orientation on each video frame, quantified as degrees of rotation in each axis. Mean orientation was calculated while patients were instructed to let their head drift to its most comfortable (dystonic) position with eyes closed. Of the 21 patients, 3 could not be evaluated because of extreme CD or facial hair which confounded face detection in OpenFace. For the remaining 18 patients, mean head orientation calculated from the videos was positively correlated with the ordinal severity ratings from the TWSTRS in each of the three axes of rotation (pitch $R = 0.85$, roll $R = 0.88$, and yaw $R = 0.69$, all $p < 0.005$). Our results demonstrate that computer-vision based video analysis software can capture abnormal head rotations in CD. This approach provides a measure of CD motor features that is inherently objective, critical to improving outcome measures for clinical trials of new treatments and regressors in human research on CD pathophysiology. In future

work, we plan to investigate heuristics for mitigating cases of extreme severity and excessive facial hair. We also plan to extend our analyses to a cohort of over 200 CD patients recruited from 10 sites in North America through the Dystonia Coalition's project to validate the Comprehensive Cervical Dystonia Rating Scale.

Abstract: The movement disorder dystonia can be caused by variants in the C-terminal domain (CTD) of the α3 subunit of collagen VI (COL6A3). Variants in other domains cause mechanistically unrelated muscular dystrophy phenotypes. To dissect this domain specificity, we generated mice expressing a truncated COL6A3, lacking only the CTD (*Col6a3*^{CTT} allele). Homozygous *Col6a3*^{CTT} mice had a dyskinetic phenotype, with impaired beam walk and rotarod performance, reminiscent of dystonia observed in patients with *COL6A3* CTD variants. Unlike a reported functional null allele, we observed no nonsense-mediated decay of the truncated transcript and no signs of muscular dystrophy. Within the brain, *Col6a3* is exclusively expressed in the septum and basal pontine nuclei (BPN). Given the critical role of the BPN in relaying corticocerebellar motor control and learning signals, we used whole cell patch clamp electrophysiology to investigate synaptic function in BPN neurons. BPN neurons of *Col6a3*^{CTT} homozygous mice have increased frequency of spontaneous and mini excitatory postsynaptic current (sEPSC and mEPSC) compared to age-matched wildtype controls, indicating enhanced

presynaptic excitatory tone. Neuroanatomical tracing indicated that excitatory input is primarily of cortical origin. We hypothesize that COL6A3 mediates corticopontine synaptic plasticity via an intrasynaptic interaction. Overactivation of the corticocerebellar pathway, consistent with the hyperkinetic nature of dystonia, represents a novel pathophysiological substrate for dystonia as well as a potential therapeutic target.

Title: The effect of EMG-based sensory feedback training of a trajectory-constrained self-feeding task on motor control for adolescents with secondary dystonia

Authors: *S. AMANO[1], E. AMBROSINI[2], E. BIFFI[3], A. GALBIATI[2], C. CASELLATO[4], A. PEDROCCHI[2], T. D. SANGER[1]
[1]Dept. of Biomed. Engin., USC, Los Angeles, CA; [2]Dept. of Electronics, Information, and Bioengineering, Politecnico di Milano, Milano, Italy; [3]Scientific Inst. IRCCS Eugenio Medea, Bosisio Parini, Italy; [4]Dept. of Brain and Behavioral Sci., Univ. of Pavia, Pavia, Italy

Abstract: While brain injury in early childhood or at birth not only immediately result in motor dysfunction, but also potentially cause a long-term consequence in motor learning, as sensory deficits, often observed in secondary dystonia, could result in motor learning deficit. Therefore, developing a novel intervention that can provide an augmented sensory feedback to reverse abnormalities in motor learning is imperative for children with secondary dystonia to have a better quality of life. The purpose of the study was to determine the effect of a 5-day motor training of a trajectory-constrained self-feeding task with our EMG-based sensory feedback in persons with secondary dystonia. Three subjects with secondary dystonia, whose ages ranged from 12 to 20, underwent two of a 5-day training of a self-feeding task; 1) with (BF+) and 2) without (BF-) a vibrotactile biofeedback device. On each day, each subject was instructed to transport a marble in a spoon between two targets, positioned 20cm apart along the sagittal plane, and to complete 10 repetitions without dropping a marble. Under BF+ condition, we attached a battery-powered wearable EMG feedback device on subject’s anterior or lateral

deltoid muscle. This device indicates the level of muscle activity at the site of our targeted muscle, by proportionate changes in the speed of a silent vibration motor. At baseline and following the training period, averaged movement time (MT) of 10 repetitions were recorded. To quantify the quality of movement, spoon trajectory was also collected at 100Hz to compute movement jerk (i.e., time derivative of acceleration normalized by duration and distance) during the task. The change scores after the training period in MT and normalized jerk were compared between BF+ and BF- condition. Improvement in MT after the training period appears to be negligible regardless of intervention (BF+: +.14±.70s, BF-: -.07±.23s). On the other hand, training with sensory feedback was beneficial to improve the quality of movement. In particular, after a 5-day training with the biofeedback device, all of three subjects reduced movement jerk (mean change: -267.4± 215.4). While average jerk across subjects also decreased (-67.6±450.0) under BF- condition, two of three subjects increased movement jerk. These results are consistent with the hypothesis that distorted or reduced sensory feedback or abnormal attentional mechanisms may perpetuate motor symptoms in children with dystonia. Most importantly, they provide evidence that correction of sensory deficits or task inattention can have direct beneficial effects. We are actively recruiting more children with secondary dystonia to confirm the hypothesis.

Title: Characterization of the stress response in the P/Q-type calcium channel knockout mouse model quirky

Authors: *M. GRÖMMKE[1], S. HERLITZE[2], M. D. MARK[3]
[1]Ruhr-Universität Bochum, Bochum, Germany; [2]Ruhr-University Bochum, Bochum, Germany; [3]Ruhr Univ. Bochum, Bochum, Germany

Abstract: The cerebellum is an important component of the motor system due to its involvement in coordination, optimization and execution of movements. Malfunctions within the cerebellar network cause several disorders with an immense impairment of motor behavior. Especially, mutations of the P/Q-type calcium channel result in motor related diseases like episodic ataxia type 2 (EA2) which is associated with ataxia and episodes of dyskinesia. A previous study demonstrated that conditional knockout of the P/Q-type calcium channel in cerebellar granule cells leads to cerebellar ataxia and dyskinesia in mice (*quirky*). Interestingly, stress is a common

trigger of dystonic events in EA2 patients as well as in *quirky* mice. In the cerebellum stress is predominantly associated with the release of the transmitter norepinephrine (NE) from neurons of the *Locus coeruleus* (LC). The activity of the LC, however, is to a great extent mediated by the corticotropin-releasing factor (CRF) and the LC is also known to release CRF as a co-transmitter. Since *quirky* mice display ataxia and dyskinesia triggered by stress it is of great interest to determine how NE and CRF have impact on stress-induced dystonic events and how the cerebellar network is affected in these mice. The short restraint stress-test which reliably induces dystonic events in *quirky* but not in C57BL/6 control mice was performed and the effect of intraperitoneally injected α_1-adrenergic receptor antagonist prazosin and CRF-receptor type 1 antagonist NBI-35965 was determined. The administration of prazosin reduced the occurrence of dystonic attacks in *quirky* mice whereas NBI-35965 had no beneficial effect indicating that the stress-response is mediated by NE and not CRF in these mice. Furthermore, *in vivo* electrophysiological recordings of cerebellar Purkinje cells (PCs) in anaesthetized mice were performed and the impact of NE on the spontaneous activity of PCs was investigated. Exogenous application of NE evoked a strong inhibition of the PC activity in *quirky* and C57BL/6 control mice. The NE-induced inhibition was stronger in *quirky* mice than in control mice and the additional application of prazosin led to a decrease of the NE-induced inhibition in *quirky* mice. These results demonstrate that the release of NE in the cerebellum leads to a greater inhibition of PC activity in *quirky* mice which in turn enhances the cerebellar output signal onto premotor areas of the brain leading to dyskinesia. It can be suggested that the NE-induced effect is primarily mediated by G_q-coupled α_1-adrenergic receptors located on cerebellar molecular layer interneurons and thus by a stronger inhibitory drive onto PCs.

Title: Chronic multi-electrode recordings of the basal ganglia-thalamocortical circuitry in children with generalized dystonia reveal functional mechanisms of deep brain stimulation

Authors: *E. ARGUELLES[1], M. ABOLFATH-BEYGI[2], R. DESHPANDE[2], D. FERMAN[1], T. D. SANGER[2]
[2]Biomed. Engin., [1]USC, Los Angeles, CA

Abstract: Dystonia is a movement disorder characterized by involuntary muscle contractions and abnormal postures. Dystonic symptoms have been associated with basal ganglia (BG) dysfunction, where abnormal neural activity causes a complex set of physiological changes

causing abnormal neural organization. Studies of the BG and thalamus in dystonia have focused on single electrode recordings under vary constrained conditions, making it difficult to study multi-neuronal function under natural behavior. Here we present single unit and local field potential data from 14 pediatric patients with generalized dystonia implanted with up to 100 microelectrodes and 60 macroelectrodes (Ad-Tech MM16C) distributed in multiple brain regions, including STN, GPi, Vo, VIM, and VPL. EMG was recorded from arm and leg muscles. Data were collected during one week, in which the patients performed different reaching tasks. Mutual information between single units and dystonic EMG was quantified and compared across the different brain areas. 9Hz stimulation was applied systematically to all implanted nuclei. Deep brain and cortical evoked potentials were recorded and analyzed to infer connectivity between the implanted regions. Permanent DBS targets were selected based on clinical improvement in motor symptoms with no negative side effects during high frequency stimulation. Our results show low firing rate neurons correlating with dystonic EMG. Mean firing rates of 5Hz or lower were found in all recording sites. Fast firing rate neurons >20Hz were poorly correlated with EMG. Deep brain evoked potentials were not present in all projected areas from the stimulation site, showing an inconsistent connectivity pattern with respect to the expected anatomical connections between the implanted areas, likely due to differences in the etiology and anatomical distribution of injury in each patient. Finally, the permanent implantation target varied between children, and in general, stimulation that ameliorate dystonic symptoms corresponded to nuclei in which neuronal activity was highly correlated with dystonic EMG and those that were able to propagate evoked potentials through the BG-thalamocortical loop. We hypothesize that nuclei with the highest relationship with EMG are those with dominant effect on the abnormal dynamic in the BG-thalamocortical circuit, given that dystonic EMG is associated with abnormal posture, unwanted movement, and overflow. Moreover, DBS is most effective when it can propagate through the circuit.

Title: Intracranial microelectrode recordings during deep brain stimulation correlate with sensory nerve evoked potentials to facilitate targeting

Authors: *R. DESHPANDE[1], E. ARGUELLES[1], D. FERMAN[2,4], T. D. SANGER[1,2,3,4]

Abstract: Deep brain stimulation (DBS) of the ventral intermediate nucleus (VIM) has been an effective treatment of the motor symptoms in movement disorders such as dystonia and essential tremor (ET). Recently, chronic peripheral nerve stimulation (PNS) has been demonstrated to be a non-invasive alternative for a subpopulation of patients with ET. In this study, we explore the effects of low frequency PNS in basal ganglia and thalamic nuclei. We present sensory evoked potential (SEP) data from 14 pediatric patients with generalized dystonia recorded from depth electrodes implanted in VIM, subthalamic nucleus (STN), ventral oral (Vo) and ventral posterolateral (VPL) nuclei. Patients were implanted temporarily with 8 or 10 Ad-Tech MM16C depth electrodes to simultaneously record single neuron activity and Local Field Potentials (LFP) from 80 or 100 micro contacts respectively. PNS at 9Hz was delivered using a standard clinical system (Xltek) to the median nerve. Artifact trigger average responses were computed and further analyzed. The results were contrasted with postoperative CT scans to confirm the location of the electrodes. The patients underwent the final DBS implants after this procedure, after a clinical decision was made taking into account this analysis and observed clinical benefits in the patients.
Our results show consistent SEPs in afferent sensory thalamic nuclei VIM and VPL, with smaller amplitudes in Vo. SEPs in STN were inconsistent or absent. These results are in consensus with studies in human SEPs done in the past using macro electrode recordings, and have helped to establish a relation between macroscopic SEP and cellular micro electrode recordings.High frequency LFPs overlapped in time with low frequency SEPs, and distinct peaks in frequency were observed at 1 kHz and 60Hz, after finding the Power Spectral Density (PSD) of the observed evoked response.
This method has low demands in terms of the necessary equipment. It can help in identifying the VIM as a target for DBS tremor suppression. It is also capable of distinguishing electrode locations in VIM, STN and Vo and can thus be used as an easy and reliable tool to assess the actual location of the depth electrodes with respect to the intended targets. The electrode locations can be corrected during the final implant surgery.

Title: Functional studies of the candidate gene, CACNA1G identified in essential tremor families

Authors: *S. SONTI[1], Z. ODGEREL[1], E. LOUIS[2,4,3], L. CLARK[1,5]
[1]Dept. of Pathology and Cell Biol., Columbia Univ. Med. Ctr., New York, NY; [2]Dept. of Neurol., [3]Ctr. for Neuroepidemiology and Clin. Neurolog. Res., Yale Sch. of Med., New Haven, CT; [4]Dept. of Chronic Dis. Epidemiology, Yale Sch. of Publ. Hlth., New Haven, CT; [5]Taub Inst. for Res. on Alzheimer's Dis. and the Aging Brain,, Columbia Univ., New York, NY

Abstract: Essential tremor (ET) is one of the most common neurological disorders. The primary motor feature of ET is a 4 -12 Hz kinetic tremor (i.e., tremor that is seen during voluntary movements such as eating or writing), which occurs in the arms and hands. Non-motor features can also include cognitive deficits, dementia and psychiatric manifestations. Emerging evidence suggests that ET is a disease or family of diseases of the cerebellum. The etiology of ET remains largely unexplained; however, genetic factors are thought to strongly contribute to the etiology of ET. Using a whole genome sequencing (WGS) approach, we identified mutations in *CACNA1G*, which encodes the T-type low-voltage activated calcium channel, $Ca_V3.1$, in three early-onset ET families (FASET; R01NS073872). $Ca_V3.1$ is expressed in various motor pathways and has been previously implicated in neuronal autorhythmicity and ET. High expression of $Ca_V3.1$ in Purkinje neurons and its active involvement in producing tremors characteristic of ET, make it a promising candidate gene. Electrophysiology studies by whole cell patch clamp recordings were performed in HEK293 cells expressing the $Ca_V3.1$ mutant channels. Significant differences in the gating of mutant $Ca_V3.1$ channels were observed compared to the wildtype channel. Although the effects on activation and inactivation kinetics were subtle small changes, a shift of steady state inactivation towards more positive voltages (+3.4mV) was observed for one of the mutations analyzed (p.Arg1235Gln) ($p<0.05$) . A shift of activation toward positive voltages has also been reported for the $Ca_V3.1$ p.Arg1715His mutation identified in a family with SCA42 (Coutelier et al., 2015). Computer simulation modeling for the $Ca_V3.1$ p.Arg1235Gln mutant channel or $Ca_V3.1$ p.Arg1715His mutation suggests that both mutations result in decreased neuronal excitability. To complement these studies, immunocytochemical studies are currently being performed in order to examine the possible changes in subcellular localization caused by each mutation. In summary, functional studies of the *CACNA1G* mutations identified in ET families suggest that *CACNA1G* is an ET gene and that ET may represent a family of disorders of neurological channelopathies. Further evaluation of ion channels as candidate genes for ET is warranted.

Title: Behavioral and electrophysiological characterization of harmaline-tremor in non-human primates

Authors: *E. M. BELLO[1], J. K. DAO[2], F. GUEDES[1], M. D. JOHNSON[1]
[1]Biomed. Engin., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Many of the recent advancements in deep brain stimulation (DBS) technology have leveraged the preclinical, MPTP-treated non-human primate model of Parkinson's disease. Preclinical animal models of Essential Tremor (ET) that display action and postural tremors have received much less attention. Studies from the early 1970s in non-human primates have indicated that administration of the MAO-inhibitor drug, harmaline, can induce transient 6-12 Hz action and postural tremors, which are broadly comparable to those in individuals with ET. What remains unclear for this preclinical animal model are: (1) the behavioral time-course of harmaline tremors, (2) whether the effects of harmaline habituate over time as reported for multi-dose harmaline-exposure in rodents, and (3) the electrophysiological responses to harmaline treatment in non-human primates. In this study, two non-human primates were treated with systemic, intramuscular harmaline in dosages ranging from 8 mg/kg to 12 mg/kg, while measuring limb tremor with a tri-axial accelerometer and while recording local field potentials (LFPs) from a chronically implanted DBS lead in the cerebellar-receiving area of motor thalamus. In comparison to the pre-drug state, administration of harmaline caused a broad increase in kinematic tremor power between 1-25 Hz and more focal spectral peaks centered at 13Hz in one subject. Thalamic LFPs also exhibited an increase in oscillatory activity between 5-10Hz, which was associated with the onset and duration of the harmaline-induced tremors. Consistent with previous reports, harmaline-induced tremor is a transient phenomenon with tremors subsiding approximately 2 hours after dosing. Additionally, these effects were found to be repeatable across multiple sessions over several weeks. The non-human primate model of action and postural tremor using systemic harmaline is likely to be a useful preclinical animal model for further development of novel neuromodulation technologies.

Title: Measuring tremor continuously and in real-world contexts using a wearable device during an essential tremor clinical trial

Authors: *B. J. FARLEY, A. E. BULLOCK, I. KAUL, D. P. NGUYEN, S. J. KANES, J. J. DOHERTY, M. C. QUIRK
Sage Therapeut., Cambridge, MA

Abstract: Essential tremor is a common movement disorder characterized by tremor, most commonly in the hand, during a voluntary movement or maintenance of a posture. The current standard for measuring tremor severity in clinical trials is clinical assessments, which has its inherent limitations of requiring clinic visits and infrequent sampling. Wearable devices, on the other hand, could provide significant additional value by measuring tremor continuously, both inside and outside of the clinic. Here, we present data from an open-label Phase 2a clinical trial evaluating the effects of SAGE-217, a GABA-A positive allosteric modulator, in patients with essential tremor. The objective of this analysis is to compare tremor measurements from a wearable wristband device (E4 wristband, Empatica, Milano) against clinical scales, and to determine whether the device can detect pharmacological modulation of tremor. At regular time intervals prior to and following SAGE-217 administration, subjects were assessed in the clinic with the TETRAS clinical scale and with a finger-worn accelerometer (Kinesia ONE, Great Lakes NeuroTechnologies, Cleveland) worn during defined tasks. The Empatica wristband device was continuously worn by patients during the trial and measurements from the device were captured both inside and outside of the clinic. In the majority of subjects, an oscillating signal within the expected tremor-frequency range (3-8 Hz) was clearly measurable from the wristband device. Custom algorithms were developed to derive a continuous, time-varying tremor score from the device. Across subjects, the mean wristband-derived tremor score over the trial correlated with both the TETRAS score ($r=0.68$, $p<0.01$) and the Kinesia score ($r=0.86$, $p<0.0001$). Treatment with SAGE-217 resulted in a reduction of tremor that was measurable based on the TETRAS, Kinesia, and from the Empatica wristband device. Additionally, treatment effects of SAGE-217 and their time course were also measurable from patients wearing the device outside of the clinic. These results support the notion that a wearable-device may be able to accurately and continuously measure tremor in clinical trial settings and could provide additional value by measuring tremor in real-world situations outside of clinical assessment windows.

Title: Deep brain stimulation in essential tremor: Tremor and dysmetria in the upper and lower limb

Authors: *A. CASAMENTO MORAN, S. DELMAS, S. L. BRACKSIECK, B. YACOUBI, M. S. OKUN, A. W. SHUKLA, D. E. VAILLANCOURT, E. A. CHRISTOU
Univ. of Florida, Gainesville, FL

Abstract: Essential tremor (ET) is one of the most common movement disorders in humans. The hallmark symptom of ET is a 4 to 8 Hz action tremor of the upper limbs. Deep brain stimulation (DBS) can reduce tremor amplitude and improve quality of life. However, it remains unknown whether DBS improves tremor and accuracy of goal-directed movements with the upper and lower limb. Here, we test whether DBS reduces upper and lower limb tremor and dysmetria (movement error) in ET patients. Nineteen ET patients treated with DBS (70.1 ± 8.1, 7 women) and 10 healthy (HC) age-matched controls (68.0 ± 6.2, 8 women) performed ballistic goal-directed movements with the wrist and ankle joint. ET performed the session twice, once with DBS on and once with DBS off (counterbalanced order). We quantified the tremor and dysmetria of the ballistic goal-directed movements. When DBS was switched off, ET exhibited greater tremor and dysmetria than healthy controls for both the wrist and ankle joints (all $P<0.05$). Turning on the DBS, reduced the tremor amplitude of the wrist ($P=0.04$) but not the tremor of the ankle *($P = 0.66$)* during ballistic goal-directed movements. In contrast, DBS did not reduce dysmetria for neither the wrist *($P = 0.3$)* nor ankle *($P = 0.08$)*. Our findings suggest that although DBS can reduce the tremor of the upper limb, it has no significant effect on lower limb tremor or upper and lower limb dysmetria.

Title: Towards a wearable sensor driven closed-loop deep brain stimulation paradigm for Tourette syndrome

Authors: *S. CERNERA[1], J. CAGLE[1], W. DEEB[2], M. OKUN[2], A. GUNDUZ[3]
[2]Neurol., [3]Biomed. Engin., [1]Univ. of Florida, Gainesville, FL

Abstract: Introduction Tourette syndrome (TS) is a neuropsychiatric disorder characterized by a combination of involuntary motor and vocal tics with symptoms potentially worsening into adulthood. Deep brain stimulation (DBS) has emerged as a potential treatment option for medically refractory TS. We hypothesize that DBS delivered in response to pathology can ameliorate symptoms and provide additional benefits, such as a longer battery life of the device and a reduction in side effects of prolonged stimulation. Herein, we demonstrate that external wearable sensors can provide a reliable control signal for closed-loop DBS. Additionally, we show that there are underlying differences within the muscle signal between voluntary and pathological movements. **Method** Data were collected from 3 TS subjects during routine monthly programming visits for DBS at the University of Florida Health Shands Hospital. During the visits, external wearable sensors recorded electromyography (EMG) and acceleration from muscles most afflicted by the subjects' tics. The subjects were instructed to perform a series of tasks that included mimicking their tics, volitional movements, or freely ticing. Each recording lasted between 3-4 minutes with intermittent periods of rest. Videos were concurrently recorded with wearable sensor data and labeled for movement onset by a movement disorder neurologist. Data were collected when DBS was off to minimize tic suppression. To align the data with movement onset, a trigger was sent and picked up by both the video and the wearable sensors. **Results** Frequency analysis demonstrated statistically significant differences in several EMG power bands, which were noted by computing the p-values (false-discovery rate corrected) between each type of movement for each feature band within each sensor. The top five significant features for both the left and right side of the body were corroborated using Receiving Operating Characteristic curves and inputted into a linear discriminant analysis classifier. Specificity (65-95%) and sensitivity (80-95%) were above chance level for each respective subject and side, suggesting that EMG characteristics can successfully distinguish between a tic and a volitional movement. Other analyses, such as cross-correlation, display significant differences in the delay of muscles during the two types of movements. This work has vast implications on the future of closed-loop DBS in not only TS, but also other movement disorders, such as Essential tremor. Overall, this research will lead to both a deeper

understanding of the effects of DBS on muscular physiology and a broader understanding of brain-muscle connectivity.

Title: Electrophsiology-guided deep brain stimulation targeting in tourette syndrome complements anatomical targets for improved outcomes

Authors: *J. CAGLE[1,2], E. OPRI[2], R. S. EISINGER[3], K. D. F. FOOTE, 32610[4], M. S. F. OKUN, 32610[5], A. GUNDUZ[2]
[2]Dept. of Biomed. Engin., [3]Neurosci., [4]Dept. of Neurosurg., [5]Dept. of Neurol., [1]Univ. of Florida, Gainesville, FL

Abstract: Tourette syndrome (TS) is a continuous lifelong condition that is highly prevalent and socially embarrassing. Although motor and vocal tics usually wane by the late teenage years, some individuals require medical or behavioral interventions. However, these may be ineffective and TS may persist into adulthood. Deep brain stimulation (DBS) has emerged as a promising treatment option for these tic conditions. In our patient cohort, two 4-contact macroelectrodes are placed during DBS surgery in the centromedian-parafascicular thalamic (CM-Pf) region bilaterally, which is known to suppress tic activity in TS patients. However, due to different imaging techniques and clinician preferences, the final target locations vary from patient to patient. In a previous study we identified neural correlates associate with tic onset in patients chronically implanted with Medtronic Activa PC+S neurostimulator, a highly novel next generation technology that can record brain activity while stimulation. Herein, we identify the anatomical correlates of Tourette syndrome using both imaging techniques and neurophysiological recordings from DBS electrodes for the better understanding of TS and improved targeting in future DBS interventions. To date, 6 TS patients are enrolled in the study, each having received bilateral Activa PC+S implants for chronic neural recordings. Tic features, a low frequency power in the theta-alpha ranges, is computed with respect to tic onset. Pre-operative T1 magnetic resonance imaging (MRI), inverted-T1 MRI, and post-operative computed tomography (CT) were obtained for each patient. The post-operative CT and pre-operative inverted-T1 MRI were co-registered to T1 MRI and the lead locations were identified.

Our results show that standard AC-PC coordinates do not reveal accurate lead placement due to the difference in brain size and neural anatomy from patient to patient. Both nonlinear MNI transformation and reverse linear atlas transformation shows similar lead locations with target location in anterior CM-Pf. In addition, for functional recordings, we identified one patient with an absence of tic features when initially implanted. After 4 months of treatment, the patient continued to experience less than 10% improvement in his tic severity. A review of his anatomical location showed deviated lead location. After replacement of this lead, we were able to identify the tic features and his tic improvement is on par with other patients. Therefore, with the identification of tic correlates functional recording may confirm target location after anatomical localization and intraoperative recordings with the DBS leads may improve DBS outcomes.

Title: Changes in joint coordination during gait in individuals with cerebral palsy

Authors: *J. PARK, P. PATHAK, K. KIM, D. XU
Dept. of Kinesiology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Motor dysfunction present in cerebral palsy (CP) patients has deemed to be the origin of instability in gait mechanics thereby increasing the risk of fall. Abnormal coordination of multiple joints with CP is often observed. Thus, proper organization of a redundant set of joints is critical to ensure the gait stability by stabilizing salient performance variables such as whole body center-of-mass (COM), head position, etc. Hence, the purpose of the current study was to examine the difference in COM and head stabilizing synergy during a gait cycle between CP patients and control subjects. 7 diplegic CP (GMFCS level II) patients and 10 age-& gender-matched controls were recruited. The subjects were asked to perform 3 trials with 4 strides per trial (12 cycles in total) walking at self-paced moderate speed and each cycle was normalized to 100%. The geometrical models included 11 & 5 sagittal plane segmental angles set as elemental variables for COM and head, respectively, whereas the sagittal plane coordinates of COM and

head as performance variables. The framework of uncontrolled manifold (UCM) analysis was utilized to quantify the indices of synergy (ΔV) for stabilization of the COM and head. The synergy indices in time-series were then divided into four phases and averaged across subjects: 1) double stance to left foot mid-swing, 2) left foot mid-swing to double stance, 3) double stance to the right foot mid swing & 4) right foot mid-swing to double stance. For the control group, there was a rise (i.e., stabilization) and drop (i.e., destabilization) in the ΔV trajectory with the transition from stance to swing phase. However, CP patients showed no systematic changes of ΔV in the sagittal plane for both COM and head stabilization. For phases divided dataset, a two-way ANOVA supported these findings setting factors as Group (2 levels: Control & CP) and PV (2 levels: COM & Head) for each phase separately. For phases 1 & 3, ΔV for control subject was larger than that for CP ($p<0.05$), and there was no difference between ΔV of COM and head for both groups. For phase 2, ΔV for control subject was larger than for CP ($p<0.05$), and ΔV of COM was larger than ΔV of the head ($p<0.05$). For phase 3, there were no significant differences between groups & PVs. Finally, there was no significant interaction of factors for all phases. These results imply that the ability to modulate co-variation patterns (e.g., destabilization for swing phase to stabilization for stance phase) among the segmental angles to stabilize the COM and head position during moderate speed walking were impaired in the individuals with CP, which may be caused by spastic contraction of a group of muscles within lower extremities.

Title: EEG study on chronic tic disorder patients

Authors: *M. MIYAKOSHI[1], K. TUNG[2], E. LLOYD[2], S. MAKEIG[1], S. LOO[2]
[1]Swartz Ctr. For Computat. Neuroscience, INC, UCSD, La Jolla, CA; [2]Semel Neuropsychiatric Institute, David Geffen Sch. of Med., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Measuring ongoing brain activity underlying chronic tic disorder (CTD) is difficult. Here, we applied the mobile brain-body imaging (MoBI) concept to collect data from 45 (8-12 yr) children (26 CTD, 19 Healthy Controls). EEG data for five children were unusable, leaving data for 40 children (23 CTD, 17 HC) in three conditions: Tic Freely, Suppress Tics without

reward, and Suppress Tics with reward in 5-min blocks embedded in 40-50 min recording sessions. EEG signals were recorded from 128 EGI hydrocel electrode channels. During Suppress Tics with and without reward, patients used a custom joystick to express their current intensity of tic urge. The EEG data for each subject in all three conditions were concatenated and processed using custom EEGLAB scripts. For the CTD subgroup, data cleaning retained 47.2 (SD 29.5, range 13-117) trials. Independent component analysis (ICA) decomposition was performed on data from each subject. Resulting independent components (ICs) were selected for group-level analysis if their equivalent dipole model was within the MNI template brain volume and the residual variance of their scalp map from the equivalent dipole projection was <=20%. The resulting 631 ICs from 20 CDT subjects were clustered based on equivalent dipole location into 15 clusters. IC tic event-related spectral perturbations (IC ERSPs) were computed, normalized, and collapsed into standard frequency bands. Non-zero ERSP band deviations were detected using one-sample t-tests with FDR. More non-zero time points were pre-tic than post-tic. Two frontal IC clusters exhibited pre-tic theta/alpha decreases, while several centro-parietal clusters had pre-tic beta/gamma decreases.were clustered based on equivalent dipole location into 15 clusters. Title: PRRT2 mutations lead to loss of function in the pathogenesis of paroxysmal kinesigenic dyskinesia

Authors: *Y. PAN[1], Q. LIU[2], Y. YANG[3], X. LI[3], S.-H. LI[4]
[1]Dept. of Human Genet., [2]Human Genet., Emory Univ. Sch. of Med., ATLANTA, GA; [3]Human Genet., [4]Dept Human Genet., Emory Univ., Atlanta, GA

Abstract: PKD (Paroxysmal Kinesigenic Dyskinesia) is a rare autosomal dominant inherited paroxysmal movement disorder, which is characterized by recurrent, brief attacks of abnormal involuntary movements induced by sudden voluntary movements. Our previously study had identified that mutations in the PRRT2 (proline-rich transmembrane protein 2) gene are associated with PKD and that the c.649dupC missense mutation is the major causative mutation. Since heterozygous mutations of PRRT2 in patients cause symptoms and may create truncated PRRT2, it remains unknown whether PRRT2 pathogenesis involves the gain of toxicity of mutant PRRT2. By generating PRRT2 KO and KI mice that express the hotspot c.649dupC mutation and by comparing WT and truncated PRRT2 resulted from the c.649dupC mutation, we have found that this mutation generates a truncated PRRT2 that is unstable and degraded rapidly. Furthermore, PRRT2 KO and KI mice are indistinguishable for their behaviors. Our studies demonstrate that PRRT2 mutations lead to the loss of function in the disease and suggest that its treatment requires the recovery of the normal function of PRRT2.

Title: Tracking ABCD1 expression using HA-tagged ABCD1 following intrathecal AAV9 delivery

Authors: *Y. GONG[1], A. BERENSON[1], F. LAHEJI[1], A. VOLAK[2], C. MAGUIRE[2], F. EICHLER[3]
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Massachusetts Gen. hospital, Boston, MA; [3]Massachusetts Gen. Hosptial | Harvard Med. Sch., Boston, MA

Abstract: Mutations in the gene encoding the peroxisomal ATP binding cassette transporter (ABCD1) cause elevations in very long chain fatty acids (VLCFA) and the neurodegenerative disease adrenoleukodystrophy. Previously we showed that gene correction in the Abcd1-/- mouse after intrathecal delivery of recombinant AAV9 encoding hABCD1 under the broadly active CBA promoter led to a 30% decrease of VLCFA levels in spinal cord. However, this gene and lipid correction was not achieved in dorsal root ganglia (DRG). To optimize detection of ABCD1 and better understand its biodistribution, we developed a method using hemagglutinin (HA)-tagged ABCD1 to track ABCD1 following AAV9 delivery. A C-terminal HA-tagged human ABCD1 cDNA was cloned into pAAV-CBA vector and packaged into rAAV9 in 293T cells.

When we treated 293T cells with AAV9-ABCD1-HA ($1X10^4$gc/cell and $1X10^5$gc/cell), there was a dose-dependent increase of ABCD1 protein expression using an anti-ABCD1 antibody; meanwhile, a strong signal was also detected using the HA-tag antibody, suggesting successful tagging of the ABCD1 protein. To confirm the localization of ABCD1 with HA-tag *in vitro*, we assessed mixed brain glial cells from postnatal mice treated with AAV9-ABCD1-HA at $5X10^5$gc/cell for 5 days. Immunostaining demonstrated exact co-localization of ABCD1 with the HA-tag. To corroborate the feasibility of using AAV9-ABCD1-HA to track ABCD1 *in vivo*, we carried out intrathecal delivery of AAV9-ABCD1-HA via an osmotic pump (IT pump). Tissues were harvested after 15 days of injection and then fixed for immunostaining using an HA-tag antibody. The results showed that delivery led to extensive expression of ABCD1-HA across different cell types in the spinal cord but was largely limited to neurons in DRGs.. To assess for functionality after AAV9-hABCD1 delivery, we measured VLCFA across different cell types *in vitro*. To our surprise, we could correct VLCFA levels in mixed brain glial cells but not in isolated DRG satellite cells. Cells treated with HA-tagged-ABCD1 were also collected for VLCFA analysis. In conclusion, AAV9-ABCD1-HA provides a more reliable way for tracking ABCD1 distribution after *in vivo* delivery. Compared with the less reliable ABCD1 antibody staining, HA-tag staining provides higher specificity and demonstrates that AAV9-ABCD1-HA localizes mainly to neurons in DRG. This result was corroborated with an AAV9 vector encoding GFP. Studies are pending to assess whether the HA tag still allows ABCD1 activity. These results may provide insight into our observation that we did not achieve VLCFA correction in DRG after AAV9-ABCD1 delivery, as the proper cell type was not transduced.

Title: Multidimensional analysis and detection of informative features in diffusion MRI measurements of human white matter

Authors: A. RICHIE-HALFORD[1], J. D. YEATMAN[2], N. SIMON[1], *A. S. ROKEM[1]
[1]The Univ. of Washington, Seattle, WA; [2]Speech and Hearing Sci., Univ. of Washington, Seattle, WA

Abstract: The white matter contains long-range connections between different brain regions. Tractometry uses diffusion-weighted magnetic resonance imaging (dMRI) data to quantify tissue properties along the trajectories of these connections in the human brain in vivo (Yeatman et al. 2012). In previous work, the results of tractometry were usually analyzed using mass univariate approaches: group comparisons or regression models computed separately for each point along every one of the tracts. Alternatively, tissue properties such as fractional anisotropy (FA) and mean diffusivity (MD) were computed for a specific tract of interest based on an a priori hypothesis. In the present work, we developed a method based on the sparse group lasso (Simon et al., 2013) that takes into account all of the tissue properties measured in all of the tracts, and selects informative features by enforcing sparsity, both at the level of individual tracts and tissue properties, but also across the entire set of tracts and all of the measured tissue properties. The sparsity penalties for each of these constraints is identified using a nested cross-validation scheme. Using data from a previous study that measured dMRI in patients with amyotrophic lateral sclerosis (ALS) and matched controls (Sarica et al. 2017), we demonstrate that this method is accurate, exceeding the previous results, that were based on a priori feature selection, in classifying patients and controls, with ~84% accuracy, an area under the receiver operating characteristic curve of 0.93, and an average precision of 0.95. Moreover, our method automatically identifies as important for this classification the parts of the white matter known to be affected by ALS within the corticospinal tract. In a regression setting, data from another previous study (Yeatman et al. 2014) can be used to accurately predict “brain age”. Thus, this multivariate analysis approach both (a) achieves high cross-validated accuracy for precision medicine applications of dMRI data and (b) identifies relevant features of brain anatomy to further our neuroscientific understanding of clinical disorders.

Title: Time-varying phase synchronization network within sensorimotor area in a patient with amyotrophic lateral sclerosis

Authors: *Y. FUJIMOTO[1,2], M. HIRATA[3]
[1]Endowed Res. Dept. of Clin. Neuroengineering, Global Ctr. for Med. Engin. and Informat,

Abstract: [Object/Background] Phase synchronization in oscillatory brain signals have been considered as a possible mechanism of functional integration and information transmission between different brain regions. However, local functional network within sensorimotor cortex have not been fully elucidated. The purpose of this study is to reveal phase synchronization network within sensorimotor area in a patient with amyotrophic lateral sclerosis. **[Methods]** In this study, we retrospectively analyzed the ECoG data obtained in our past clinical research carried out at Osaka University Hospital in 2013. One male patient with advanced-stage amyotrophic lateral sclerosis (ALS) participated in the research and clear written informed consent was obtained from the participant. The clinical research was approved by the Ethics Committee in Osaka University Hospital and the experimental protocol was carried out in accordance with the Declaration of Helsinki. ECoG data was recorded using custom-made 94ch high density ECoG electrodes which were designed to be located on the four anatomical regions within sensorimotor area on the left hemisphere: hand motor area (M1 hand), primary motor area other than hand motor area (M1), premotor area (PM), primary sensory area (S1). Phase synchronization network was assessed by two commonly used phase synchronization measures, inter-site phase clustering ISPC (which have originally termed as phase locking value PLV) and phase lag index PLI between all possible inter-electrode pairs (${}_{94}C_2 = 4371$) using morlet wavelet analysis with the center frequencies in alpha, beta, low and high gamma band range at every time-points around the onset of motor imagery task. **[Results]** Phase synchronization based all to all inter-electrode connectivity matrixes and time course of phase synchronization in subnetworks were examined. Grouping of electrodes based on the anatomical positions and the results of phase synchronization based connectivity between electrodes are highly corresponding to each other. Among the networks, some inter-regional synchronization showed characteristic increase and decrease around the timing of motor intention, whereas most of the intra-regional synchronization was relatively constant throughout the period. These findings are mostly apparent in beta frequency range and not obvious in other frequency band. **[Conclusion]** The present high-density micro ECoG study revealed time-varying transitions of phase synchronization network within sensorimotor area in a patient with ALS. Characteristic change around the timing of motor intention was obsearved in some inter-regional synchronization.

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease characterized by degeneration of neurons in the motor cortex (MCX), brain stem and spinal cord. About 90% of ALS cases occur sporadically with unknown genetic etiology, while the rest of cases are linked to genetic mutations mostly associated with familial ALS. We posit that vulnerability to ALS is rooted in a complex interaction between genetic mutations, genetic risk factors, and environmental insults. The latter have the potential to modify the genetic risk to ALS by affecting epigenetic modifications, thus causing dysregulation of gene expression networks and ultimately resulting in ALS-specific cellular pathophysiology. The goal of our work is to examine epigenetic signatures in MCX of ALS decedents in order to elucidate epigenetic correlates that may represent risk factors for ALS.
Epigenetic modulation occurs primarily at the level of the non-coding gene regulatory elements (GREs), such as gene promoters and enhancers, the latter being the most numerous GREs in the human genome. Although the position of enhancers cannot be easily inferred, both active promoters and enhancers are characterized by Histone 3 Lysine 27 acetylation (H3K27ac) modifications. Whereas considerable information exists for the functional epigenome in homogenate (i.e., cellularly heterogeneous) brain tissues from ALS decedents, the multicellular complexity of the brain precludes reliable annotation of cell-type-specific epigenomes from existing data sets. Therefore, cell-type-specific variations are likely to be missed in preparations of mixed cell types. Here we examined the epigenetic signatures of two major populations of brain cells (neurons and glia) in the MCX of ALS and control subjects, thereby significantly increasing the likelihood of detecting epigenetic correlates specific for ALS.
We applied fluorescence-activated nuclear sorting (FANS) with Alexa488-conjugated anti-NeuN antibodies and DNA-binding dye 7-AAD to separate neuronal and glia nuclei from diseased cases and controls. We then mapped neuron- and glia-specific GREs employing low-input native ChIP-seq assay for H3K27ac. The specificity of ChIP was confirmed using qPCR for sequences with known enrichment for H3K27ac and negative controls. Libraries were generated using NEBNext Ultra DNA Library Prep, KAPA-quantified, and sequenced using PE50 protocol and HiSeq 2500 instrument**.** ChIP-seq data analysis is currently in progress. This study will, for the first time, provide information on ALS-related epigenetic alterations unique to individual cell types.

Title: The stress granule response of wild-type and ALS FUS-mutant neurons to somatic and axonal stressors

Authors: *M. P. BENTHAM, N. BIRSA, C. BODO, C. MADURO, A. DEVOY, E. M. FISHER, G. SCHIAVO, P. FRATTA

Abstract: Stress granules (SGs) are cytoplasmic ribonucleoprotein aggregates which form in response to cellular stress and disassemble following the cessation of stress. Mutations in human SG proteins cause the neurodegenerative disease amyotrophic lateral sclerosis (ALS) and have been demonstrated to alter granule dynamics. Further, SGs have a compositional protein overlap with the post-mortem cytoplasmic inclusions that characterise ALS, suggesting that SGs may act as a precursors to, or seed, these inclusions.
We cultured primary neurons in compartmentalised devices, applying the oxidative stressor sodium arsenite to either the somal or axonal compartment, to investigate the kinetics of SG formation. We observed a delayed SG assembly response in neuronal somas when arsenite was applied axonally,
Further, we investigated the effect of ALS-causing mutations on the SG response, using a novel FUS-mutant mouse model. This model expresses a humanised C-terminal disease-causing mutation that results in a frameshifted amino acid sequence downstream of the mutation, eradicating the nuclear localisation signal of the FUS protein. This frameshift sequence allowed for the generation of antibodies able to distinguish between wild-type and mutant FUS. Using these antibodies, we observed that the normally predominately nuclear FUS protein significantly mis-localised to the cytoplasm in neurons heterozygous and homozygous for the mutation. Additionally, we demonstrated that the mutant protein is present in SGs at a significantly higher level than the wild-type protein.
As FUS binds a number of the other RNA-binding proteins present within SGs, we investigated the effect of this mutation on other granule components in wild-type, heterozygous and homozygous neurons and fibroblasts.

Our results demonstrate the ability of neuronal axons to respond to exogeneous oxidative stressors and highlight the importance of the SG response in ALS-mutant cells.

Abstract: Spinal muscular atrophy (SMA) is a motor neuron (MN) disorder and remains the most common genetic cause of infant mortality. SMA is caused by mutations in the survival motor neuron 1 gene (SMN1), which impairs the function and survival of MNs in the spinal cord. The reasons for the selective vulnerability of MNs linked to SMN reduction remain unclear. Therefore, we performed deep RNA sequencing on human SMA MNs derived from patients' induced pluripotent stem cells (iPSCs) to detect specific altered gene splicing/expression and to identify the presence of a common sequence motif in these genes. Many deregulated genes, such as the neurexin and synaptotagmin families, are implicated in critical MN functions. The overexpression of *NRXN2* was shown to improve human SMA-MN survival and increase motor axon length, suggesting a role as a modifier gene. Motif-enrichment analyses of differentially expressed/spliced genes, including neurexin2 (*NRXN2*), revealed a common motif, motif 7, which is a target of SYNCRIP. Interestingly, SYNCRIP interacts only with full-length SMN, binding and modulating several MN transcripts, including SMN itself. SYNCRIP overexpression rescued SMA-MNs due to the subsequent increase in SMN and their downstream target *NRXN2* through a positive loop mechanism. SMN/SYNCRIP complex through motif 7 may account for selective MN degeneration and represent a potential therapeutic

target. This study produced novel insights into the role of SMN loss in mRNA processing and its selective effects on human SMA-MNs, highlighting novel targets for therapeutic strategies.

Title: Proteomic analysis of cerebrospinal fluid from patients with C9orf72 hexanucleotide repeat expansion

Authors: *P. BARSCHKE, P. OECKL, P. STEINACKER, A. LUDOLPH, M. OTTO
Neurol., Ulm, Germany

Abstract: Aim: The hexanucleotide (GGGGCC) repeat expansion in the non-coding region of the *C9orf72* gene is the most common mutation associated with genetic amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Until now, it is unknown which factors define whether *C9orf72* mutation carriers establish ALS or FTD. Our aim is to identify protein biomarker candidates in the cerebrospinal fluid (CSF) from ALS and FTD patients with *C9orf72* mutations which differentiate between FTD and ALS and might be indicative for the outcome of the *C9orf72* mutation.
Methods: We analyzed the CSF proteome of symptomatic ALS (n=17) and symptomatic FTD (n=8) patients with *C9orf72* mutations and asymptomatic mutation carriers (CAR, n=11) by isobaric tags for relative and absolute quantitation (iTRAQ). CSF samples were digested with trypsin/LysC. After iTRAQ labeling the samples were pooled, fractionated by strong cation exchange (SCX) into six fractions and analyzed by LC-MS/MS. The MaxQuant and Perseus software were used for protein identification, quantification and data evaluation.

Results: In total, 2099 proteins were identified. By comparing the CSF proteome of ALS vs. FTD, ALS vs. CAR and FTD vs. CAR 468, 800 and 120 proteins were shown to be differentially regulated with a p-value lower than 0.05, respectively. Of these proteins 7, 17 and 2 proteins were at least two-fold up or downregulated.
Discussion and outlook: We identified an upregulation of neurofilament medium polypeptide and chitotriosidase-1 in the CSF of ALS patients compared to FTD and CAR, reflecting the neurodegeneration and neuroinflammation. However, we aim to identify new early biomarker candidates. We chose 17 promising protein candidates from our pool of differentially regulated proteins for further validation experiments. Currently targeted mass spectrometric approaches were established.

Title: An MRI-based structural covariance network approach to candidate gene discovery in motor neuron disorders

Authors: C. J. HUANG[1], *M. FLOETER[2]
[1]NINDS, NIH, Bethesda, MD; [2]NIH, Bethesda, MD

Abstract: Degeneration occurs differentially across cortical regions in amyotrophic lateral sclerosis (ALS) and primary lateral sclerosis (PLS). Atrophy and cortical thinning is greatest in the precentral gyrus, but typically affects other cortical regions. Correlated thinning between cortical regions could result from expression of common genes that render different regions more susceptible to triggers for degeneration. To examine this hypothesis, we constructed a precentral seed-based structural covariance network derived from MRIs in a cohort of healthy men and women using the Desikan-Killiany parcellations in FreeSurfer. Networks of patients with ALS and PLS were also constructed and were similar to healthy adults. The precentral network of healthy adults was used to query the gene expression database in the Allen Human Brain Atlas. A candidate set of 109 “risk factor” genes was identified that had log2 expression fold > 0.3 in the motor cortex and whose expression pattern across cortical regions was correlated with the precentral network, r>0.5. The biological functions included genes associated with excitability and synaptic function and gene expression regulation. There was no overlap of the candidate

gene set with a database of genes previously known to be associated with ALS (ALSoD). Ingenuity Pathway Analysis bioinformatic software showed that the candidate gene set was enriched in genes involved in neurodevelopmental pathways and in genes associated with neurodegenerative diseases compared to a control set of genes expressed in the motor cortex that were not correlated with the precentral network. There were numerous pathway interactions among the candidate gene set. Our MRI-based exploratory method for mining the Allen Human Brain Atlas has identified a set of genes that are candidates for further study of risk factors for neuronal vulnerability in motor neuron diseases. Title: DNA methylation in amyotrophic lateral sclerosis

Authors: *C. APPLEBY-MALLINDER[1], P. R. HEATH[2], R. HIGHLEY[2]
[2]Neurosci., [1]Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Introduction Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease causing degeneration and death of motor neurones (MNs). ALS can be sporadic (sALS) or familial, with a number genes having being implicated as being pathogenic including C9orf72 (C9ALS), which causes an intronic GGGGCC repeat expansion, and TDP43. DNA methylation is an epigenetic mechanism whereby a methyl (CH3) group is attached to a cytosine, usually resulting in gene expression repression. DNA methylation has been implicated in other neurodegenerative diseases, including Fragile X syndrome, but little work has been conducted in ALS. **Research objective and rationale** Initial studies conducted to investigate the role DNA methylation plays in ALS have been conducted on heterogeneous tissue types, but no studies have been conducted on the specific interaction between MNs from native tissue and DNA methylation. By conducting experiments on MNs extracted from native post-mortem human spinal cord tissue, we aim to elucidate the role of DNA methylation in MN decline, without the interactions from other cell types, which may mask MN-specific DNA methylation changes. **Methods** 5 control, 5 sALS and 6 C9ALS samples were used (n=16). Cases were age and sex matched, with sex differences being assessed. No significant differences were observed. MNs were extracted from the anterior horn of FFPE human cervical spinal cord tissue using laser capture microdissection (LCM). DNA was then extracted, and underwent bisulphite conversion. DNA methylation analysis was conducted using the Infinium HD Methylation assay, and analysed using RnBeads (Assenov *et al.* 2014). **Results** A positive correlation between TDP pathology and global methylation was observed, with C9ALS displaying the highest global methylation and TDP pathology levels. 61 genes and 74 promoters were found to be significantly differentially methylated in control versus disease. 43 of the gene hits, and 42 of the promoter hits displayed hypermethylation when compared to controls. When comparing the gene and promoter hits, 16 were found to be significantly differentially expressed in both genes and promoters, with 10 being hypermethylated. **Conclusions** Our studies suggest DNA methylation is a contributory factor in ALS.

Title: Transforming growth factor beta signaling in SOD1^{G93A} ALS

Authors: *C. BRAINE[1], D. CASTRO[2], T. MANIATIS[3], H. PHATNANI[4]
[1]Columbia Univ., New York, NY; [2]NEW YORK UNIVERSITY, NEW YORK, NY; [3]COLUMBIA UNIVERSITY, NEW YORK, NY; [4]NEW YORK GENOME CENTER, NEW YORK, NY

Abstract: Amyotrophic Lateral Sclerosis (ALS), also known as Lou Gherig's Disease, is a fatal neurodegenerative disease caused by the death of motor neurons in the spinal cord and brain. ALS is a genetically complex disease; diverse mutations cause motor neuron death by disrupting various interrelated pathways. To date no therapy targeting a single factor can rescue motor neuron loss. Transforming Growth Factor Beta (TGF-β) is upstream of many of the pathways changed in disease and has been shown to be dysregulated in ALS. Upregulation of TGF-β signaling has been identified as neuroprotective in many neurodegenerative disease models; however, there is conflicting evidence about the role of TGF-β signaling in ALS.
In this study, we use *in vitro* pharmacological and genetic approaches to manipulate different pathways within the TGF-β superfamily in co-cultured ES-derived motor neurons and astrocytes. Inhibition of the Classical and Activin arms of the pathway have differing effects on motor neuron survival. Furthermore, these effects vary depending on the ALS mutation carried by the motor neurons, suggesting that these signaling pathways play different roles in different models of ALS. To fully understand these phenotypes we put forward two objectives: 1. Characterize drug dependent changes in astrocytes and motor neurons independently; and 2. Determine how these changes are affected by the ALS mutations carried by these cells.
We also seek to understand how disease related changes in TGF-β signaling in the spinal cord directly affect motor neuron survival and gene expression in the SOD1^{G93A} model of ALS. We hypothesize that disease related disruption of TGF-β signaling in motor neurons contributes to their death. We will test this using cre lines or viral therapies to target two different TGF-β receptors in motor neurons or glia in the SOD1^{G93A} ALS animal model followed by gene expression profiling. These studies will help to define the role of TGF-β signaling in diseased and healthy motor neurons and begin to unravel how this pathway changes the motor neuron astrocyte relationship.

Title: Altered oxidative signaling impairs intracellular calcium dynamics in human ALS astrocytes

Authors: *V. GRANATIERO, C. KONRAD, K. BREDVIK, G. MANFREDI, H. KAWAMATA
BMRI, Weill Cornell Med. Col., New York, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is an untreatable, fatal disease leading to motor neuron degeneration and muscle paralysis. ALS astrocytes play a non-cell autonomous role in motor neuron death by secreting factors that modify the neuronal environment. In human induced pluripotent stem cell-derived astrocytes carrying the G93A SOD1 familial ALS mutation, but not in isogenic controls, we demonstrate an unprecedented connection between endoplasmic reticulum (ER) oxidative protein folding, H_2O_2 signaling, calcium dynamics, and cell secretion. In mutant astrocytes, slower ER oxidative protein folding and H_2O_2 production decrease Nrf2 signaling, and downregulate ER antioxidant enzyme expression. The decrease of these enzymes enhances ER calcium pump activity, resulting in excessive ER calcium accumulation and signaling. In turn, excessive ER calcium signaling triggers activation of mitochondrial energy metabolism and enhanced secretion of small molecules, such as ATP. These findings suggest that restoring hormetic H_2O_2 signaling in astrocytes could be a target for ALS therapy.

Title: The NINDS repository: Publicly available DNA and cell lines sampled from individuals diagnosed with neurological disorders

Authors: *L. SCHEINFELDT[1], S. HEIL[1], J. SANTANA[1], A. GREEN[1], A. AMBERSON[1], A. RESCH[1], R. ZHANG[2]
[1]Coriell Inst. For Med. Res., Camden, NJ; [2]NIH, Rockville, MD

Abstract: Neurological disorders present serious health concerns and challenges to health and health-related quality of life in the United States. Most neurological disorders are complex diseases involving genetic and environmental risk factors, many of which are not yet clearly

understood. The identification of reliable genetic risk markers will, therefore, contribute to preventive efforts, earlier diagnoses, disease management options, and new targeted therapeutics. To this end, The National Institute of Neurological Disorders and Stroke (NINDS) Repository offers a public resource containing DNA and lymphoblastoid cell lines with corresponding de-identified clinical and demographic data representing a diverse set of neurological disorders and neurologically normal controls. To date, NINDS Repository samples have been used in over 400 peer-reviewed scientific publications, including genome-wide association studies, case-control studies, whole-genome and whole-exome sequencing studies, structural variation studies, and candidate gene studies. The genetic and genomic data collected by these studies have been deposited in the Database of Genotypes and Phenotypes (dbGaP), a NIH/NLM sponsored repository for restricted-access data from studies investigating the contributions of genetic variation to phenotypic variation and disease (http://www.ncbi.nlm.nih.gov/gap). Since its establishment, specimens from over 39,000 individuals have been successfully banked and can be accessed through an online catalog (http://catalog.coriell.org/NINDS): individuals diagnosed with cerebrovascular diseases (N>12,100), Parkinsonism (N>5,600), motor neuron diseases (N>2,500), epilepsy (N>6,000), Tourette syndrome (N>4,100), Dystonia (N>2,600), and neurologically normal controls (N>7,400). More recently, over 2300 African American cerebrovascular disease and population control DNA samples from the REasons for Geographic and Racial Differences in Stroke (REGARDS) project were added to the NINDS Repository and are now available through the catalog to the scientific community.

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease of unknown etiology specifically affecting upper and lower motor neurons. Recent evidence from multiple cellular and animal models of ALS points at defects in nucleocytoplasmic transport (NCT) as central to the disease pathogenesis. NCT is a tightly regulated process that controls the cellular distribution of, among others, RNA-binding proteins (RBPs) involved in the regulation of mRNA processing. Notably, nuclear depletion of RBPs such as TDP-43 is a hallmark of ALS, suggesting a link between NCT, mRNA regulation, and ALS pathology. Here we investigate the possibility that mutations in PFN1, an actin binding protein associated with familial ALS, affect motor neuron survival via the disruption of NCT. Our data suggest that disruption of actin homeostasis due to mutant PFN1 expression alters the stability and function of the nuclear pore, leading to nuclear depletion and cytoplasmic accumulation of RBPs. Furthermore, we investigate the functional consequences of these defects in the regulation of RNA metabolism and the relevance of theses defects to ALS pathology. Collectively, our data support the hypothesis that cytoskeletal dynamics and mRNA regulation are two pathways linked through the function of NCT, and that disruption to NCT itself may play a central role in multiple forms of ALS.

Abstract: The hexanucleotide repeat expansion GGGGCC (G4C2)n in the *C9orf72* gene is the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Recent findings indicate that dysfunction of nuclear-cytoplasmic transport of RNA binding proteins is disrupted in C9orf72 (C9). Similarly, we have identified that the RNA editing enzyme Adenosine Deaminase Acting on RNA 2 (ADAR2) is significantly mislocalized in C9orf72 repeat expansion mediated ALS. ADAR2 is responsible for adenosine (A) to Inosine (I) editing of double stranded RNA and its function has been shown to be essential for survival in ADAR2 knock out mice, which die shortly after birth. Additionally, altered ADAR2 function due to downregulation has been associated with sporadic forms of the disease. We provide evidence to suggest the mislocalization of ADAR2 in human induced pluripotent stem cell derived neurons (hiPSNs) of C9 patients, a C9 mouse model and C9 ALS post mortem tissue. To begin to understand the mislocalization specific to C9orf72 ALS, we have preliminary evidence that ADAR2 is mislocalized in the presence of the Arginine containing RAN translated dipeptides GR and PR. Surprisingly, we do not see any editing deficits at the GluA2 Q/R site in C9 cells and patient tissue. Current efforts are focused on discovering the overall impact of global A to I RNA editing deficits in C9 disease pathogenesis. Analysis of editing at over 400,000 known RNA editing sites indicates that there are vast RNA A to I editing deficits in Sporadic and C9orf72 mediated ALS. We have identified RNA editing aberrations in many pathways including the crucial EIF2 signaling pathway and the protein ubiquitination pathway. Our findings suggest that the mislocalization of ADAR2 which predominantly occurs in C9orf72 mediated ALS is responsible for the alteration of RNA processing events that may impact vast cellular functions.

Title: Dysregulation of Mdm2 and Mdm4 alternative splicing underlies motor neuron death in spinal muscular atrophy

Authors: *M. VAN ALSTYNE[1], C. M. SIMON[1], P. SARDI[2], L. S. SHIHABUDDIN[2], G. Z. MENTIS[1], L. PELLIZZONI[1]
[1]Columbia Univ., New York, NY; [2]Sanofi, Framingham, MA

Abstract: Spinal muscular atrophy (SMA) is a neurodegenerative disorder caused by ubiquitous deficiency in the Survival Motor Neuron (SMN) protein. Reflecting the emerging multiple roles of SMN in RNP assembly and post-transcriptional gene regulation, disruption of several distinct SMN-dependent RNA pathways has been proposed to contribute to SMA pathogenesis. However, proving clear mechanistic links between select SMN-dependent RNA processing events and specific, clinically relevant features of SMA remains an outstanding challenge. We sought to address this issue by focusing on the molecular mechanisms of motor neuron death - the classical hallmark of SMA in both patients and mouse models. We recently demonstrated that p53 is a key driver of motor neuron degeneration in SMA mice, but the molecular mechanisms linking SMN deficiency to p53 activation and motor neuron death are unknown. Here, we demonstrate that the function of SMN in the assembly of spliceosomal snRNPs regulates alternative splicing of Mdm2 and Mdm4, two non-redundant repressors of p53. We show that decreased inclusion of critical regulatory exons of Mdm2 and Mdm4 - which is most prominent in vulnerable SMA motor neurons - acts as a key biological switch governing initiation of the p53 response in SMA mice. Furthermore, we directly link snRNP dysfunction to the dysregulation of Mdm2 and Mdm4 alternative splicing and upregulation of p53. Importantly, increased skipping of Mdm2 and Mdm4 exons regulated by SMN is necessary and sufficient to synergistically elicit robust p53 activation in wild type mice. Conversely, correction of either deficit by restoration of full-length Mdm2 or Mdm4 is sufficient to suppress p53 induction and motor neuron degeneration in SMA mice. These findings reveal that loss of SMN-dependent regulation of Mdm2 and Mdm4 alternative splicing underlies p53-mediated death of motor neurons in SMA, establishing a causal link between snRNP dysfunction and neurodegeneration.

Title: Short interference peptides as blockers for TDP-43 phosphorylation prevent TDP-43 aggregation and cell death

Authors: *J. ZHU[1], W. JIA[2], M. S. CYNADER[3]
[1]Vancouver, BC, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Brain Res. Ctr., The Univ. of British Columbia, and, Vancouver, BC, Canada

Abstract: Background: Detergent insoluble inclusions of TDP-43 protein are the signature neuropathology in over 90% of amyotrophic lateral sclerosis (ALS) cases and approximately half of frontotemporal dementia (FTLD-TDP) cases. In TDP-43 proteinopathy disorders, neurons contain aggregates of TDP-43 protein. TDP-43 in the aggregates is extensively post-translationally modified, with phosphorylated TDP-43 (pTDP) being the most consistent and robust marker of pathological TDP-43 deposition. Since phosphorylated TDP-43 is not observed in the absence of neurodegeneration, abnormally phosphorylated TDP-43 has been hypothesized to mediate TDP-43 toxicity in these neurodegenerative disease states. Casein kinase I delta (CK-1δ) has been reported to phosphorylate TDP-43. TDP-43 phosphorylation sites targeted by CK-1δ correspond to the sites identified in Sarkosyl-insoluble fractions of brains from ALS patients.
Objective: The overall objective is to understand the role of TDP-43 phosphorylation in forming aggregates and how it mediates neuronal toxicity.
Methods: In our study, high density peptide array analysis was used to identify the interaction regions between TDP-43 and CK-1δ. We designed potential peptide-based kinases blockers to effectively interfere with TDP-43 and CK-1δ association. Immunocytochemistry and Western blots were used to quantify the effects of peptides. LDH and MTT assays were used to confirm cell death rate in an Ethacrynic acid (in vitro) model which also caused TDP-43 aggregation.
Results: we found that the endogenous TDP-43 could be phosphorylated and tended toward aggregation following CK-1δ overexpression but did not translocate from nucleus to cytoplasm. We found that the peptides we designed to block CK-1δ -TDP-43 interactions prevented TDP-43 phosphorylation and aggregation caused by either CK-1δ overexpression or Ethacrynic acid treatment. In addition, the peptides reduced the cell death induced by Ethacrynic acid in both SY5Y cells and primary cultured cortical neurons.
Conclusions: The above results indicate that TDP-43 phosphorylation may play an important role in the progress of these neurodegenerative diseases. Our interference peptides which block TDP-43 phosphorylation could be a useful strategy for developing potential new therapeutics.

Abstract: The hexanucleotide repeat expansion GGGGCC (G_4C_2) found in the non-coding region of the *C9orf72* (C9) gene represents the most common genetic abnormality in amyotrophic lateral sclerosis (ALS) (40-50%) and frontotemporal dementia (FTD) (10-30%). ALS and FTD patients have genetic, pathologic and symptomatic overlap. Therefore, understanding the molecular mechanisms of disease pathogenesis in this ALS/FTD disease spectrum could lead to the development of novel therapeutic strategies. Cognitive decline as seen in normal ageing or Alzheimer's disease (AD) is characterized by changes in neuronal morphology, spine density and progressive synapse loss. We hypothesize that similar mechanisms are responsible for the dementia symptoms caused by the C9 mutation and that these events arise early during disease progression before any neurodegeneration has occurred. Furthermore, based on recent findings in AD and FTD, we hypothesize that this synaptic dysfunction may involve the neural-immune complement pathway. Here we present preliminary data supporting this hypothesis using C9-ALS/FTD patient-derived human induced pluripotent stem cells differentiated into motor neurons (hiPSC-MNs) and cortical neurons (hiPSC-CNs), in addition to C9 mouse models. We found significant changes in dendritic branching, dendritic length, spine density and detected alterations in the expression pattern of synaptic proteins in hiPSC neurons. We also observed changes in neuronal excitability using longitudinal micro-electrode array analysis. Similar changes in dendritic arborization and dendritic length were observed in homozygous C9orf72 $^{-/-}$ knockout mice. In addition, increased complement pathway activation and decreased expression of pre-synaptic markers were observed in this C9 mouse model. Our data suggest that synaptic deficits are present in C9 ALS/FTD which might be triggered by aberrant neural-immune interactions. These synaptic dysfunctions are hypothesized to contribute to cognitive impairment and neuronal cell death found in C9orf72 patients and therefore provide first mechanistic insights into the dementia symptoms caused by this mutation.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a progressive heterogeneous neurodegenerative disorder with fatal outcome and with no curative treatment available. ALS is characterized by the degeneration of motor neurons, with 97 % of ALS patients displaying a common histopathological phenotype in disease-affected tissues, namely aggregation of the TAR-DNA binding protein (TDP)-43 in the cytoplasm of motor neurons. Accumulating evidence from unrelated studies suggest that lower levels of naturally occurring autoantibodies (NAbs) towards pathological proteins are implicated in the impaired clearing mechanism in neurodegenerative diseases. The aim of the study was therefore to investigate the affinity of anti-TDP-43 NAbs in plasma and cerebrospinal fluid (CSF) from 41 ALS patients in comparison with 41 healthy individuals.Using ELISA competition assay we explore the affinity of the binding between antibodies and TDP-43 in plasma and CSF. We have utilized the ability of high binding antibodies to form more stable bonds with their antigen compared with lower binding antibody. By incubating plasma samples with increasing concentrations of free TDP-43 monomer and a subsequent measurement of free antibodies on plates with immobilized TDP-43 protein, we were able to separate anti-TDP-43 NAbs into low and high affinity fractions that probably present distinct epitope specificities.The results show significantly reduced levels of high-affinity anti-TDP-43 NAbs in plasma samples from ALS patients. Further, we measured global antibody levels and relative levels of anti-TDP-43 NAbs within the immunoglobulin (Ig)G-subclasses and IgMs in plasma and CSF samples. We found a significant decrease in relative plasma levels of anti-TDP-43- IgG3- and IgM Nabs, and a significant increase of anti-TDP-43 IgG4 Nabs in ALS patients compared to healthy subjects. A significant increase of anti-TDP-43 IgG2 Nabs and global levels of IgG1s, IgG3s, IgG4s and IgMs in CSF samples from ALS patients were also

observed. Additionally, we observed significant increase in IgG Nabs-TDP-43 complexes in ALS plasma samples compared to healthy subjects. These results indicate that a TDP-43 immune aberrancy is apparent in ALS patients and could explain the toxic aggregation of TDP-43. We hypothesize that an immune deterioration may be an important reason for low affinity anti-TDP-43 antibody binding properties in ALS patients resulting in ineffective clearance of TDP-43-antibody complexes containing low affinity antibodies. Data generated in this project can contribute to further development of immune-based therapeutic strategies in ALS.

Title: Strategy for personalized medicine based on ALS patient-derived stem cells using CRISPR/Cas9-mediated genome editing

Authors: *Y. YUN[1], D. BAEK[1], J. KIM[2], S. BAE[3], Y. HA[1]
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Stem Cell Res. Ctr., Daejeon, Korea, Republic of; [3]Hanyang Univ., Seoul, Korea, Republic of

Abstract: Purpose Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that causes dysfunction of the motor neuron. Motor neuron which is responsible for controlling voluntary muscles movement in the spinal cord, brainstem and brain progressively deteriorate and die. It leads to muscle weakness, paralysis and eventually respiratory failure to death. The precise cause of ALS is not known, only 5% to 10% of cases are known as associated with genetic problem. Considering various novel genetic mutations have been reported and poorly understood pathophysiology of ALS, the development of personalized therapy that target the patient's own genetic mutation and restore motor neuron function would provide the most promising treatment. Material and methods From a case of male patient presenting with ALS, Next generation sequencing (NGS) discovered a point mutation in a gene named ATP7A which encodes a transmembrane copper-transporting ATPase. In order to assess the genotype-phenotype, impaired ATP7A trafficking, patient-derived fibroblast was directly reprogrammed to generate induced neural stem cell (iNSC). Gene correction of point mutation in ATP7A using CRISPR/Cas9 system was performed in patient-derived induced pluripotent stem cells (iPS). To target the precise mutated sequence, we designed specific sgRNA and donor DNA as well as

proper transfection methods. Results Whole genome sequencing of ALS patient and his parents revealed maternally inherited variant in ATP7A gene. We investigate the pathophysiology in patient-derived cells and impaired ATP7A trafficking phenotype caused by a point mutation. iNSC revealed the cellular dysfunction such as proliferation and apoptosis compared to normal cell line. Similarly, patient-derived iNSC showed less responsiveness to copper compare to normal cell line. We obtained isogenic cell line with ATP7A corrected iPS. Investigation of pathophysiology between patient-derived cells and gene corrected cells revealed that ATP7A function is partly rescued and cellular function such as proliferation and neural differentiation is improved. Conclusion Reprogrammed stem cells from patient somatic cell are suitable to investigate the mechanism, pathology and gene-editing. NGS can give the genetic evidence and candidates of disease. The CRISPR/Cas9 system can target the sequence precisely and homology directed repair (HDR)-mediated gene editing allows a correction of point mutation. As a result, these new technologies are capable of precise genomic analysis in patient genetic background and this strategy would be the most promising approach to personalized precision medicine.

Title: Role of neurodegeneration causative genes SMN and C9orf72 in genome instability

Authors: E. KARYKA[1], C. WALKER[1], S. HERRANZ-MARTIN[1], S. EL-KHAMISY[1], *M. AZZOUZ[2]
[1]Univ. of Sheffield, Sheffield, United Kingdom; [2]The Univ. of Sheffield, Sheffield, United Kingdom

Abstract: The most common motor neuron diseases (MNDs) are amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (SMA). While SMA, a childhood MND, is caused by mutations in a single gene (*survival motor neuron* or *SMN1*), ALS has been linked with several causative genes. Intronic GGGGCC repeat expansions in C9orf72 are considered the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), though the mechanisms by which such expansions cause neurodegeneration are poorly understood. Two major pathologies stemming from the RNA expansions have been identified in postmortem tissue: intracellular RNA foci and repeat-associated non-ATG dependent (RAN)

dipeptides, though it is unclear how these and other hallmarks of disease contribute to the pathophysiology of neuronal injury. Adeno-associated virus (AAV) was used to model C9orf72 pathology in neuronal cells and rodent. We report that AAV viral vectors encoding 10 pure, 102 interrupted GGGGCC repeats or 69 V5-tagged DPRs delivered into the cerebrospinal fluid via cisterna magna of wild type mice led to transgene expression in multiple areas of the CNS and cause neurodegenerative phenotype[1.2]. Virus-mediated expression of C9orf72-related RNA and dipeptide repeats in the mouse central nervous system increases double strand breaks and ATM defects and is associated with neurodegeneration. We also report elevated levels of DNA-RNA hybrids (R-loops) and double strand breaks in rat primary neurons, human cells and C9orf72 ALS patient spinal cord tissues.
We also report significant increase in DNA breaks in Smn-depleted motor neurons as well as postmortem spinal cord sections derived from SMA patients. We show that the DNA damage is transcription-dependent as we detect significant decrease in DNA breaks after RNA polymerase II inhibition. These findings suggest that SMN and C9orf72-mediated neurodegeneration is driven, at least partly, by genomic instability.

Title: ALS Cell Atlas: An online resource to infer gene activity in nine major CNS cell types in ALS patients and mouse models

Authors: N. SKENE[1], M. ALABRUDZINSKA[1], P. LÖNNERBERG[1], A. DOMANIKU[3], *S. A. LEWANDOWSKI[1,2]
[1]Karolinska Institutet, Solna, Sweden; [2]Dept. of Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden; [3]Bahcesehir Univ., İstanbul, Turkey

Abstract: We still know very little about how various central nervous system (CNS) cell types contribute to ALS onset or progression. Our goal is to infer the timecourse of activity for nine major CNS cell types in spinal cord tissue from end-stage ALS patients and during disease progression in *SOD1*^{G93A} mouse model with the use of single-cell transcriptomes applied to interpret whole tissue expression data. The resulting dataset will be released as an open, interactive online resource.
Our resource will include gene expression specificity rankings for nine major cell types (pyramidal neurons, interneurons, astrocytes, microglia, oligodendrocytes, endothelium, pericytes, vascular smooth muscle and vascular leptomeningeal cells). In order to observe the dynamics of cell activity we analyzed respective cells at pre-symptomatic (28, 42, 56, 70 days) and symptomatic stages (98, 112, 128 days) in *SOD1*^{G93A} mice together with post mortem ALS patient tissue.
We would like to present a demonstration version of the online resource features for genes associated with microglial cells which allowed us to identify novel genes activated during ALS in these cells. Our resource will help to stimulate interest in specific cell type contribution in ALS. It will also help to discover novel drug targets specific for given cell type population in symptomatic and pre-symptomatic stages of ALS progression. In the long run we hope our resource will stimulate drug discovery research and benefit ALS patients.

Title: Determining the potential roles of G4 Resolvase1 in ALS

Authors: *A. E. CHAMBERS[1], A. E. RICHARDSON[2], S. N. SANDWITH[2], D. W. SAUNDERS[1], H. M. RAIMER[3], J. P. VAUGHN[4], Y.-H. WANG[3], M. A. SMALDINO[1], P. J. SMALDINO[1]
[2]Biol., [1]Ball State Univ., Muncie, IN; [3]Univ. of Virginia, Charlottesville, VA; [4]Nanomedica, Inc., Winston-Salem, NC

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease. This disease is relentlessly progressive, leading to the inability to eat, speak, move, and breathe. There is no cure, and 80% of all people with ALS will succumb to the disease within 5 years of diagnosis. A

better understanding of the molecular underpinnings of ALS is necessary for the development of effective future therapies. A dramatic increase in the number of GGGGCC-repeat units in the first intron of the *C9orf72* (*C9*) gene causes the most common subset of familial ALS. Healthy individuals harbor between 2 and 30 repeats, while *C9* ALS patients typically have >30 and often hundreds to thousands of the repeat unit. The guanine (G)-rich nature of the *C9*-repeat sequence allows it to fold into secondary DNA structures, termed G-quadruplexes. Expansion of *C9*-repeat DNA leads to transcription of truncated *C9* RNAs that aggregate into toxic foci and sequester essential RNA-binding proteins. *C9*-repeat RNAs are translated into toxic dipeptide repeats, and the net effect is neuronal death. Therefore, *C9* ALS is foundationally a DNA G-quadruplex disease, and identifying the proteins that modulate these structures is essential for understanding and treating *C9* ALS. The enzyme that accounts for the majority of all G-quadruplex helicase activity is G4 Resolvase 1 (G4R1) (aliases: RHAU, DHX36). We hypothesize that G4R1, as the major G-quadruplex helicase, is dysregulated in *C9* ALS. We are testing this hypothesis by comparing G4R1 expression in ALS patient cell lines compared to age-sex matched controls. Our results indicate a significant increase in G4R1 expression in *C9* ALS cell lines compared to matched controls. These findings demonstrate a potential role for G4R1 in *C9* ALS and further investigation is being conducted.

Title: ALS associated mutations in Matrin 3 alter protein-protein interactions and impede mRNA nuclear export

Authors: *A. BOEHRINGER[1], D. MEDINA[1], K. GARCIA-MANSFIELD[2], N. BAKKAR[1], P. PIRROTTE[2], R. BOWSER[1]
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]Translational Genomics Inst., Phoenix, AZ

Abstract: Mutations in Matrin 3 have recently been linked to ALS, though the mechanism that induces disease in these patients is unknown. To define the protein interactome of wild-type and ALS-linked MATR3 mutations, we performed immunoprecipitation followed by mass spectrometry using NSC-34 cells expressing human wild-type or mutant Matrin 3. Gene ontology analysis identified a novel role for Matrin 3 in mRNA transport centered on proteins in the TRanscription and EXport (TREX) complex, known to function in mRNA biogenesis and nuclear export. ALS-linked mutations in Matrin 3 led to its re-distribution within the nucleus, decreased co-localization with endogenous Matrin 3 and increased co-localization with specific TREX components. Expression of disease-causing Matrin 3 mutations led to nuclear mRNA export defects of both global mRNA and more specifically the mRNA of TDP-43 and FUS. Our findings identify a potential pathogenic mechanism attributable to MATR3 mutations and further link cellular transport defects to ALS. Our current work investigates the role of specific protein domains in the interactions between Matrin 3 and TREX proteins, and will explore mRNA export defects in motor neurons derived from patient induced pluripotent stem cells (iPSC).

Title: Identification of a genetic mutation in microvilli protein EBP50, a new cause of hereditary peripheral neuropathy

Authors: *G. SONG[1], D. P. GUPTA[2], M. RAHMAN[2], H. PARK[3], M.-G. LEE[2], K. SUK[2]
[1]Inst. for Transnational Neuroscience, Dept. of Medial Sci., Catholic Kwangdong Univerity, Incheon, Korea, Republic of; [2]Dept. of Pharmacol., Kyungpook Natl. Univ. Sch. of Med., Daegu, Korea, Republic of; [3]Col. of Med, Dong-A Univ., Pusan, Korea, Republic of

Abstract: We have identified a novel EBP50 gene mutation in a family with peripheral neuropathy. EBP50 is highly expressed at the tip of Schwann cells and at nodes of Ranvier. The expression of EBP50 in sciatic nerve significantly increased during Schwann cell maturation and myelination, while its expression was significantly downregulated in animal models of peripheral neuropathy, suggesting its important role in peripheral nerve system. In addition, heterozygous knockout mice (EBP50 +/-) exhibited distinctive features of peripheral neuropathy such as abnormal myelin formation and decreased motor function. Knocking-down the expression of

EBP50 in Schwann cells reduced the length of cell protrusion and cell motility. Mutations in the EBP50 gene reduced NRG-induced AKT phosphorylation and Schwann cell mobility. In conclusion, we have established a loss-of-function mutation in the EBP50 gene responsible for hereditary peripheral neuropathy in this study. This new discovery will be the basis for the development of genetic peripheral neuropathy therapies.

Title: Dysfunction of VEGF-mediated mechanisms at different disease stages of $SOD1^{G93A}$ mice model

Authors: *N. REI[1,2], J. A. RIBEIRO[1,2], S. H. VAZ[1,2], C. VALENTE[1,2], A. M. SEBASTIAO[1,2]

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the progressive degeneration of motor neurons in corticospinal tract, leading to muscle weakness, atrophy, paralysis and death. Recent studies support that vascular endothelial growth factor (VEGF) has a neuroprotective function, protecting motor neurons from degeneration in ALS models. VEGFA binds both VEGF-R1 and VEGF-R2, but with more affinity to VEGF-R1, which may negatively regulate VEGF function, preventing its binding to VEGF-R2. VEGFB binds only to VEGF-R1. We now evaluated if there are any changes in the levels of VEGF proteins (VEGFA and VEGFB), and VEGF receptors (VEGF-R1 and VEGF-R2) at the cerebral cortex (CTX) and spinal cord (SC) of a model of ALS, SOD1(G93A) mice.A qReal-time PCR was used to evaluate mRNA levels (n=3-7) and an ELISA assay (n=4-6) was performed to evaluate the expression of VEGF and VEGF receptors protein levels. Pre-symptomatic (4-6 weeks old) and symptomatic (12-14 weeks old) mice were analysed and data compared with age-matched wild type mice. Significant differences were considered at $p<0.05$. Concerning mRNA expression of VEGF and its receptors, at the CTX of pre-symptomatic mice, there was an

increase in the expression of mRNA levels for VEGFA and VEGFB with no significant change in the expression of mRNA for VEGF receptors. Interestingly, in CTX of symptomatic mice there was a decrease of the mRNA expression for VEGFA and VEGF-R2 and an increase of VEGFB. At the SC of pre-symptomatic mice there was an increase in mRNA levels of VEGF-R1 and VEGFB and a decrease of mRNA levels of VEGFA and VEGF-R2 in the SC of symptomatic mice. Regarding the protein levels, there are no significant changes for VEGFA expression at both, CTX and SC and there is a significant increase of VEGFB at SC of pre-symptomatic mice. Concerning the VEGF receptors, there is an increase at SC of pre-symptomatic mice of both receptors (VEGF-R1 and VEGF-R2) and a decrease at CTX of symptomatic mice.Overall, the data suggest an early dysfunction of VEGF-mediated mechanisms, with an enhanced expression at pre-symptomatic stage, which reverses to a decrease at the symptomatic stage.

Title: Optogenetic enhancement of TDP-43 intermolecular interaction triggers its cytoplasmic mislocalization and inhibits axon outgrowth of spinal motor neurons

Authors: *K. ASAKAWA[1,2], K. KAWAKAMI[1,3]
[1]Natl. Inst. of Genet., Mishima / Shizuoka, Japan; [2]Dept. of Genet., [3]SOKENDAI, Mishima/Shizuoka, Japan

Abstract: Cytoplasmic aggregation of TDP-43 characterizes degenerating motor neurons in most cases of Amyotrophic lateral sclerosis (ALS). However, exact mechanisms of TDP-43 neurotoxicity that lead to neuronal dysfunction and degeneration remain elusive. Here, we show that enhancement of TDP-43 intermolecular interaction is sufficient to trigger its cytoplasmic mislocalization and toxic to spinal motor neurons. We develop an optogenetic approach by which intermolecular interaction of a TDP-43 variant can be enhanced by light illumination in zebrafish larvae. The photo-responsive TDP-43 (optoTDP-43) can function as TDP-43 since it rescues TDP-43 knockout phenotypes under an ambient light condition. In contrast, upon illumination of blue light, optoTDP-43 gradually loses its nuclear-specific localization and

becomes dispersed throughout the nucleus and cytoplasm. Crucially, transient light illumination that causes cytoplasmic mislocalization of optoTDP-43, but not its cytoplasmic aggregate formation, is sufficient to diminish subsequent axon outgrowth of spinal motor neurons. Our results suggest that excessive intermolecular interaction is a fundamental basis of TDP-43 neurotoxicity in spinal motor neurons. Therefore, optoTDP-43 provides a potential avenue for recapitulating pathologies of ALS and other TDP-43 proteinopathies in a spatiotemporally regulated fashion by light illumination.

Inst., [6]Neurol., [7]Brain Sci. Inst., Johns Hopkins Univ., Baltimore, MD; [8]Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal, progressive neurodegenerative disease characterized by the degeneration of cortical and spinal motor neurons. An intronic G_4C_2 hexanucleotide repeat expansion (HRE) in the *C9orf72* gene is the most common cause of familial ALS, as well as frontotemporal dementia (FTD). Increasingly, glial cell dysfunction is recognized as a pathogenic mechanism that contributes to ALS pathology and motor neuron death. Furthermore, *C9orf72* promoter activity is enriched in C9-ALS-affected cell types: motor neurons and oligodendrocytes, suggesting that intrinsic changes in these cells may influence disease progression. Oligodendrocytes, the glial cell type responsible for producing myelin and for providing metabolic support to neurons, degenerate early in the gray matter of the mutant SOD1 ALS mouse model as well as in human ALS patients. Subsequently, a downstream proliferative cascade of oligodendrocyte progenitor cells (OPCs) takes place; however, these OPCs are unable to fully differentiate and recapitulate the functions of lost oligodendrocytes. Importantly, the mechanisms underlying these changes, and whether these same events take place in C9-ALS, is unknown. Our group and others have recently demonstrated that

nucleocytoplasmic transport, the critical bidirectional process occurring at the nuclear pore complex (NPC), is disrupted in *C9orf72* animal models as well as in C9-ALS patients. Given that nuclear transposition of transcription factors is critical to oligodendrocyte development, disruption of nucleocytoplasmic transport in these cells may impair their ability to differentiate and support neurons in C9-ALS conditions. Here, we assess whether oligodendrocyte degeneration and impaired OPC differentiation occur in C9-ALS patient tissue and in C9-BAC transgenic mouse models expressing the HRE. We also examine whether NPC pathology and nucleocytoplasmic transport deficits are found in oligodendrocytes and OPCs in these models. Together, these novel experiments shed light on disease-relevant pathways that may be therapeutically amenable, as well as expand on the complex biology of the NPC in specific CNS cell types.

Title: Macrophages accumulate at neuromuscular junctions coincident with denervation in the $SOD1^{G93A}$ mouse model of amyotrophic lateral sclerosis

Authors: *M. LYON, P. AROUNLEUT, C. MILLIGAN
Neurosci., Wake Forest Univ. Grad. Sch., Winston Salem, NC

Abstract: Macrophages are cells associated with tissue homeostasis and the innate immune system and provide a primary, phagocytic response to infectious agents or injured cells. This response is often isolated or directed toward a specific site in a tissue to prevent the spread of infection of injury. Macrophages can exhibit phagocytic, neuroprotective, proinflammatory characteristics or a combination of these, with examples of these activities coming from classic studies of perihperal nerve injury, where myeloid cells have been shown to mediate myelin clearance (phagocytic) and promote axonal regeneration (neuroprotective). Amyotrophic lateral sclerosis (ALS), a disease characterized by the progressive denervation of neuromuscular junctions (NMJs) and the death of motoneurons, provides an intriguing disease model to study macrophage response in, as motoneuron pathology in the disease is present in both the central and peripheral environments. For example, the earliest pathological hallmarks in the $SOD1^{G93A}$

mouse model, those seen in the first postnatal month, include synaptic changes in the spinal cord, vacuolated mitochondria in the dendrites, cell body, axons, and presynaptic terminals. Initial denervation of NMJs and differences in motor behavior are also observed in the first 30 postnatal days. Evidence demonstrating a phagocytic response of tissue macrophages to injured neurons has been shown peripherally in the disease with macrophages accumulating on the sciatic nerve, and centrally with microglia responding to late-stage degeneration of motoneuron cell bodies in the spinal cord, however, potential macrophage responses coincident with early NMJ denervation in muscles have not been explored. Here we show accumulation of macrophages targeting presynaptic terminals and intramuscular axons as early as postnatal day 30 in the tibialis anterior of $SOD1^{G93A}$ mice that undergoes denervation compared to $SOD1^{G93A}$ soleus (that does not undergo denervation) and wildtype, age-matched controls. The macrophages are associated with these structures prior to denervation, but numbers increase with NMJ denervation and axon retraction. These findings suggest that macrophages in the peripheral muscle play a role in disease progression. Potential protective and degenerative roles will be explored and discussed.

Laboratory, Sch. of Psycology, Univ. of New South Wales, Sydney, Australia; [4]Dementia Res. Ctr., Macquarie Univ., Sydney, Australia; [5]The Jenner Inst., Univ. of Oxford, Oxford, United Kingdom

Abstract: Amyotrophic lateral sclerosis (ALS) is a debilitating and fatal disease characterised by progressive loss of motor function, which is now recognised to exist on a disease continuum with frontotemporal dementia (FTD), the second most common form of dementia. Growing evidence suggests that excitotoxity is a major disease mechanism in ALS contributing to the degeneration of motor neurons. A common pathological feature of both ALS and FTD is the cytoplasmic mislocalisation and aggregation of TAR DNA-binding protein 43 (TDP-43) in neurons, occurring in over 90 percent of ALS patients and approximately 50 percent of FTD patients. Furthermore, pathological mutations in *TARDBP* gene encoding TDP-43 have been identified in

ALS/FTD families. As well as progressive motor deficits reminiscent of ALS, we have previously reported cognitive decline and hippocampal atrophy in our inducible mutant TDP-43 mouse line (iTDP-43^{A315T}). To understand the mechanisms underlying this cognitive decline, we first performed RNASeq analysis on hippocampal brain tissue of pre-symptomatic iTDP-43^{A315T} and non-transgenic littermate controls and found up-regulation of several genes involved in synaptic transmission. To see if these differences in mRNA profile translated into functional changes in synapses, we performed electrophysiological recordings on brain slices of iTDP-43^{A315T} mice and their littermate controls and found differences in the amplitude and decay time constant of excitatory postsynaptic current, suggesting alterations in glutamate uptake in iTDP-43^{A315T} mice. Since excitotoxicity is a common feature of ALS patients, we induced excitotoxic seizures with pentylenetetrazole (PTZ) and found that iTDP-43^{A315T} mice had differences in latency to seizure and seizure severity compared to non-transgenic littermates. Taken together, these results suggest novel network aberrations in iTDP-43^{A315T} mice which are consistent with our previously published phenotypic characterisation of these mice, and which may lead to an understanding of important mechanisms underlying the onset and progression of ALS/FTD.

Title: Mechanisms underlying neuronal dysfunction in *C. elegans* single-copy/knock-in models for FUS ALS

Authors: *S. N. BASKOYLU[1], N. CHAPKIS[1], K. SCHUCH[2], B. UNSAL[1], J. SIMON[1], D. SAVAS[1], A. C. HART[1]
[1]Neurosci., [2]MCB, Brown Univ., Providence, RI

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disorder marked by the progressive loss of glutamatergic and cholinergic motor neurons, muscle atrophy and paralysis. It is the most common motor neuron disorder affecting adults, and often leads to death within 3-5 years after disease onset. A number of genes with diverse roles in RNA and protein homeostasis have been associated with ALS, including fused in sarcoma (FUS). FUS encodes a ribonucleoprotein involved in mRNA transcription, splicing, transportation and stress

granule formation. However, it is unclear how mutations in FUS lead to ALS. In patient motor neurons, mutant FUS forms cytoplasmic aggregates with several other proteins implicated in ALS. This, and other evidence, suggest that mutant FUS may function in a common neurodegenerative pathway with other ALS-linked genes. To examine the mechanism of ALS FUS dysfunction, we generated the first single-copy/knock-in models of ALS FUS in *C. elegans* using CRISPR/Cas9-mediated genome editing. Introduction of patient amino acid changes R524S and P525L into the *C. elegans* orthologous gene *fust-1* lead to stress-induced locomotion defects, neurodegeneration and aggregation. Furthermore, single-copy ALS FUS models had defective neuromuscular signaling. Investigation of ALS FUS neuromuscular dysfunction lead to our discovery of several modifier ALS genes in *C. elegans* single-copy/knock-in models of ALS FUS. Notably, loss in an autophagy-related gene fully rescued neuromuscular signaling defects in *C. elegans* ALS FUS models. Currently, we are examining autophagy in *C. elegans* motor neurons. Combined, our findings in single-copy/knock-in models, and other published work on ALS FUS, implicate defective proteolysis pathways as a significant contributing factor in ALS pathogenesis.

Title: Sonic hedgehog signalling pathway during regenerative processes in a mouse model of spinal motoneuronal loss

Authors: *M. GULISANO[1], N. VICARIO[2], A. COSTANTINO[3], M. A. S. GIUNTA[2], F. M. SPITALE[2], R. PARENTI[2], R. GULINO[3]
[1]Dept. of Drug Sci., [2]Dept of Biomed. and Biotechnological Sciences, Lab. of Cell. and Mol. Physiol., [3]Dept of Biomed. and Biotechnological Sciences, Lab. of Neurophysiol., Univ. of Catania, Catania, Italy

Abstract: Background - Neuronal loss represents the consequence of direct or indirect insults to neurons, as well as one of the major factors mediating persistent disability. Gliosis, neuroinflammation and neurodegeneration are processes in which different cell populations have an interplay mediating both hostile microenvironment and self-repairing mechanisms. Sonic hedgehog (Shh) signaling, which has been indicated as an important pathway in central nervous

system development and neural stem cells (NSCs) function, may have a role in prompting the repairing and modulating actions of endogenous and/or exogenous NSCs in neurodegenerative conditions. **Methodology** - Somatic NSCs were obtained from the subventricular zone (SVZ) of 8 week old female 129/Sv mice. We studied the Shh pathway on NSCs both *in vitro* and in a mouse model of spinal motorneuronal degeneration induced by cholera toxin B conjugated to saporin (CTB-Sap) injection into the gastrocnemius muscle. **Results** - NSCs were derived, expanded and characterized *in vitro*. We analyzed the effects of Shh signaling pathway modulation on NSCs *in vitro*, finding a significant increase of the NSCs growth rate (2.98±0.58 *vs.* 5.26±0.57, $p<0.05$) and neurospheres diameters (109.9±2.4μm *vs.* 129.6±3.7μm, $p<0.01$) upon Shh pathway activation. We then characterized Shh signaling activation in CTB-Sap mice analyzing neuronal loss, gliosis, inflammation and compensatory self-repairing mechanisms, compared to intact control mice. **Conclusions** - Our results suggest a crucial role of Shh signaling during regenerative processes and NSCs as a potential strategy to support recovery after spinal motoneuronal degeneration, thus representing a promising approach for neurodegenerative disorders.

Title: Autophagolysosome disruption in *Drosophila* models of ALS/FTD caused by C9orf72 expansion mutations

Authors: *K. CUNNINGHAM[1], K. ZHANG[1], H. SUNG[1], J. T. PHAM[2], M. SENTURK[3], K. MAULDING[1], J. D. ROTHSTEIN[4], H. J. BELLEN[5], T. E. LLOYD[1]
[1]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Neurol., The Johns Hopkins Sch. of Med., Baltimore, MD; [3]Baylor Col. of Med., Houston, TX; [4]Brain Sci. Inst., Johns Hopkins Univ., Baltimore, MD; [5]Dept Molec & Human Genet., Howard Hughes Med. Inst., Houston, TX

Abstract: A GGGGCC hexanucleotide repeat expansion (G4C2 HRE) in the C9orf72 gene is the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia

(FTD). In an RNAi screen for modifiers of HRE-mediated degeneration, our lab previously identified a key role for nucleocytoplasmic transport (NCT) disruption in C9-ALS/FTD (Zhang et al., Nature, 2015). We are investigating pathways that mediate neurodegeneration downstream of nucleocytoplasmic transport disruption. In our screen, we identify two key regulators of autophagy, p62/SQSTM1 and Mitf/TFEB as modifiers of neurodegeneration. In a *Drosophila* model of C9-ALS expressing $(G4C2)_{30}$, we find that p62 is upregulated and forms large aggregates in motor neurons. p62/SQSTM1 plays a key role in autophagy by binding ubiquitinated proteins and delivering them to the autophagosome for degradation via the lysosome. Surprisingly, we find that knockdown of Ref(2)p, the fly homologue of p62/SQSTM1, rescues degeneration in the fly eye and in motor neurons, while knockdown of Mitf enhances neurodegeneration. Immunofluorescence and western blot analysis of autophagy and lysosome markers demonstrates an impairment in autophagosome biogenesis but expansion of dysfunctional lysosomes. Using electron microscopy of the *Drosophila* eye, we observe a remarkable accumulation of expanded multilamellar bodies and autolysosomes that precedes neurodegeneration. Due to these lysosomal defects, we hypothesize that mislocalization of Mitf from the nucleus downstream of NCT defects may cause dysregulation of lysosomes and autophagy. Indeed, we find that Mitf is mislocalized to the cytoplasm in G4C2-expressing cells and in iPS neurons derived from C9-ALS/FTD patients. We also find that genetic and pharmacological induction of lysosomal genes downstream of Mitf rescues neurodegeneration. We propose that C9orf72-HRE expression causes Mitf/TFEB mislocalization from the nucleus and contributes to a feed-forward disruption between NCT disruption and protein aggregation. This study suggests that drugs targeting lysosomal proteostasis pathways may have therapeutic potential for C9orf72-mediated ALS and FTD.

Title: Herpes zoster induced brachial plexopathy affecting whole branches, a case report

Authors: *S. KANG
Chung-Ang Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The most common neurologic complication of herpes zoster is chronic pain, and motor paralysis is a less common complication. Until now, a few cases have been reported about

motor paralysis as brachial plexopathy (BPI) after herpes zoster infection. In this case report we report a patient with brachial plexopathy involving whole branch confirmed by needle electromyography. Case A 88 year old female patient visited the hospital with bullous skin lesion in neck, right whole arm. She complained tingling sense, pain, and swelling on the involved area. Under diagnosis of Herpes zoster, she took the anti-viral agents (famciclovir, loxoprofen, epinastine, levosulpiride), and 3 days later, the bullous skin lesion in hands is proceeded to the proximal part of body. Her symptoms were improved with proper medication and two months later, pain was much improved and the skin lesion was changed to chronic scar. However, she was referred for electrodiagnostic study through the orthopedics because she reported that weakness on this right upper extremity had started. On physical examination, muscle power on elbow flexion was grade 4, elbow extension was grade 4, wrist extension was grade 4, finger flexion was grade 3, finger abduction was grade 3, finger extension was grade 3, and finger DIP was grade 3. She showed difficulties in fine motor control and during performing fine motor task she showed mild tremor. In motor nerve conduction study, conduction velocity of median, ulnar and radial nerve was decreased. Amplitude of sensory responses was decreased in median, ulnar, superficial radial, lateral antebrachial cutaneous, and medial antebrachial cutaneous nerve. Needle electromyography showed abnormal spontaneous activities in the muscles innovated from axillary, musculocutaneous, median, ulnar, and radial nerves.
Synthesizing the clinical symptoms, physical examination and eletromyography, she was diagnosed as the brachial plexopathy, whole branch involved, after herpes zoster infection. We performed magnetic resonance imaging (MRI) study, and it showed diffuse swelling of entire right brachial plexus. The patient was enrolled to the occupational therapy and continued medication (steroid). After one month of rehabilitation, weakness and sensory symptoms were much improved. Whole branch involving BPI after herpes zoster infection is a rare case, and electrodiagnostic study is helpful for accurate diagnosis. Proper rehabilitation program would be needed also to improve the motor weakness.

Title: Mitochondrial hyperfusion connects GDAP1 pathophysiology in Charcot-Marie-Tooth disease with MNF2

Authors: *A. METHNER[1], C. WOLF[1], A. POUYA[1], A. PFEIFFER[1], D. BUENO[1], H. VON PEIN[1], J. SCHWIRZ[2], K. REHBACH[3], M. PEITZ[3], O. BRÜSTLE[3]
[1]Johannes Gutenberg Univ. Mainz, Mainz, Germany; [2]IMB, Mainz, Germany; [3]Inst. of Reconstructive Neurobio., Bonn, Germany

Abstract: Charcot-Marie-Tooth (CMT) disease is a hereditary polyneuropathy caused by mutation of GDAP1 or MFN2, two mitochondrial proteins that exert opposite effects on mitochondrial shape; GDAP1 is a glutathione-S-transferase which causes mitochondrial fission while MFN2 causes fusion. Both proteins regulate mitochondria-endoplasmic reticulum (ER) contact sites, important cellular signaling hubs, and MFN2 controls mitochondrial hyperfusion, a cellular stress response. No common pathway underlying the disease has yet been identified. We found that neuronal cells from patients with autosomal-recessive CMT4A caused by GDAP1 mutation and GDAP1 knockdown cells have elongated mitochondria and an increased mitochondrial membrane potential. Knockdown uncouples mitochondrial respiration from ATP production, increases mitochondrial turnover, and reduces mitochondria-ER contact sites and mitochondrial [Ca2+]. Interestingly, GDAP1 and MFN2 reside in the same multi-protein complex in the presence of oxidized glutathione and over-expression of wildtype, but not enzyme-dead or mutated GDAP1, inhibits redox-mediated mitochondrial hyperfusion. Our data suggest that GDAP1 regulates mitochondrial hyperfusion via its enzymatic activity, which links CMT4A pathophysiology with MFN2.

Title: *In vivo* translational profiling of motor neurons in mouse models of Charcot-Marie-Tooth type 2D

Authors: *E. L. SPAULDING[1], R. W. BURGESS[1,2]
[1]The Jackson Lab., Bar Harbor, ME; [2]Grad. Sch. of Biomed. Sci. and Engin., Univ. of Maine, Orono, ME

Abstract: Charcot-Marie-Tooth disease (CMT) is a collection of debilitating peripheral neuropathies caused by mutations in over 80 genes. The heterogeneity of the disease, as well as the technical challenge of studying the mammalian peripheral axon *in vivo*, both contribute to the lack of a cure. Dominant mutations in glycyl-tRNA synthetase (*GARS*), the enzyme responsible for both cytosolic and mitochondrial charging of tRNAs with the amino acid glycine, cause Charcot-Marie-Tooth Type 2D (CMT2D). How mutations in *GARS* cause neurodegeneration is unclear, but impaired translation has emerged as a potential toxic gain-of-function mechanism based on work with *Drosophila* models of CMT2D. To test this mechanism in mice, we are profiling translation in motor neuron cell bodies of the spinal cord and axons of the sciatic nerve in mice with mutations in *Gars* that are validated as CMT2D models. *In vivo*, cell type-specific, fluorescent non-canonical amino acid-tagging (FUNCAT) has revealed reduced global translation in mutant motor neuron cell bodies of $Gars^{P278KY/+}$ and $Gars^{C201R/+}$ mice. In contrast, Puromycin labeling of newly synthesized protein in an unaffected tissue, the liver, reveals normal translation in 3 *Gars* mouse models. Surprisingly, an increase in newly synthesized protein is seen in $Gars^{P278KY/+}$ motor axons with FUNCAT, a signature that resembles regenerating motor axons in wild type mice following a sciatic nerve crush. To complement the protein analysis, i*n vivo* ribosome-tagging from $Gars^{P278KY/+}$ and $Gars^{C201R/+}$ motor neuron cell bodies was used to identify mRNAs undergoing translation. This revealed an upregulation of transcripts associated with the integrated stress response, including Activating transcription factor 4 (Atf4) and several of its gene targets. This gene expression signature has been previously associated with metabolic stress in tissues like liver, but has not been described in neurons. Using RNAScope in situ hybridization, we show that activation of the stress response genes occurs in approximately 70% of mutant motor neurons and does not occur in any other cell types of the spinal cord. Thus, a cell autonomous, gain-of-function impairment in translation may contribute to motor neuron degeneration in mouse models of CMT2D.

Title: Investigating the role of a mitochondrial deacetylase in spinal and bulbar muscular atrophy

Authors: J. MAZUK, E. HEINE, K. HAN, D. SIMPSON, D. EXLER, D. GARCIA-CASTRO, *H. L. MONTIE
Bio-Medical Sci., Philadelphia Col. of Osteo. Med., Philadelphia, PA

Abstract: Spinal and bulbar muscular atrophy (SBMA, Kennedy's Disease) is an X-linked neuromuscular disease affecting men. This late onset disease is caused by an expansion of a CAG tract in the androgen receptor (AR) gene, which encodes a glutamine (Q) tract in the protein. Disease is critically dependent upon AR ligands. As mitochondrial dysfunction is a component of SBMA pathogenesis, we have been studying the role of a mitochondrial deacetylase in SBMA. We have modulated this protein genetically and pharmacologically in a number of SBMA cell models. Up-regulating its activity protects cells from the toxic effects of polyQ-expanded AR. We are currently investigating the molecular mechanism(s) of its protection. Continued studies will include *in vivo* modulation of this mitochondrial deacetylase to determine whether it can abrogate motor dysfunctions, as well as other components of SBMA pathology.

Title: Efficacy of gene therapy using allele-specific RNAi in a precision humaninzed model of a dominantly-inherited peripheral neuropathy

Authors: K. H. MORELLI[1], L. B. GRIFFIN[2], N. K. PYNE[3], L. M. WALLACE[3], A. M. FOWLER[3], A. ANTONELLIS[2], S. Q. HARPER[3], *R. W. BURGESS[4]
[1]The Jackson Lab., Bar Harbor, ME; [2]The Univ. of Michigan, Ann Arbor, MI; [3]Nationwide Children's Hosp., Columbus, OH; [4]Jackson Lab., Bar Harbor, ME

Abstract: Charcot-Marie-Tooth disease type 2D is a dominantly inherited axonal neuropathy that leads to loss of motor and sensory innervation in the periphery. The disease is caused by mutations in glycyl tRNA synthetase (*GARS*), the essential, non-redundant enzyme that charges glycine onto its cognate tRNAs for translation. Although the disease mechanism remains unclear,

previous results from mouse models of *Gars*/CMT2D suggest that effective treatments need to decrease the mutant forms of *GARS*, whereas bolstering wild type *GARS* does not mitigate the neuropathy. To accomplish this allele-specific-reduction, we have used RNAi, processed through a mir30 micro-RNA cassette, and delivered using adeno-associated virus 9 (AAV9). Testing an RNAi that targets an existing dominant allele of *Gars* in mice indicated that this strategy is successful. Delivery of the AAV9 into the central nervous system could almost completely prevent the disease if administered pre-onset, and still had significant benefit when delivered post-onset. These effects were dose-dependent, and persisted for at least a year. To test the translational potential of this approach, we introduced a human disease-associated allele of *GARS* into the mouse genome. This mutation is a *de novo* mutation and has not been previously described. The mice carrying this allele developed a neuropathy by a few weeks of age, validating its pathogenicity. Delivery of an RNAi specifically targeting this allele produced similar results, with an almost complete prevention when delivered pre-onset, and lesser, but still significant improvement when delivered at post-onset time points. This project demonstrates the utility of precision animal models for the validation of human genetic variants and for preclinical studies. It also demonstrates that viral delivery of RNAi for allele-specific knockdown is a viable therapeutic strategy for dominantly inherited neuromuscular diseases.

Title: Disturbances of the homeostasis of the neuro-muscular complex in contractures of individuals with Cerebral Palsy

Authors: *J. PINGEL[1], J. B. NIELSEN[2]
[1]Dept. of Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen N, Denmark; [2]Univ. Copenhagen, Kobenhavn N, Denmark

Abstract: Abstract Muscle contractures are common in individuals with cerebral palsy (CP), but the mechanisms responsible for the development of contractures are still unclear. Here we propose that changes in tissue homeostasis within the neuro-muscular-tendon tissue-complex are at the heart of the development of contractures. In order to unravel the neural, mechanical and metabolic factors, as well as genetic and transcriptional factors in muscle contractures, several

different studies have been conducted. **Changes at tissue level:** Our recent results reveal that some individuals might be genetically predisposed to become contractures. Furthermore, a significant correlation was observed between the passive stiffness of skeletal muscle and the expression of HSPG2, PRELP, RYR3, COL5A3, ASPH and COL4A6. **Systemic differences:** When levels of CRP, TGF-β and IL-6 was measured in serum of children with CP, adults with CP and healthy adults, it was observed that Children with CP has significantly higher systemic levels of CRP and TGF-β. Whether inflammation affects the growth of the muscles or might have other negative adverse effects in children with CP needs further investigation **Effect of treatments:** While micro-architectural analyses still are under investigation in humans, our animal studies have shown, that BoNT/A injections damages the microstructure of both the non-fibrillar and the fibrillar tissue and impairs the motor control of the gait in rats, and causes an increased collagen turnover in the muscle tissue. In summary, the present results indicate that muscle contractures might be caused by multiple factors, and we therefore suggest that it is necessary to reconsider of how and why muscle contractures develop.

Title: Abnormal motor axon potassium currents in a mouse model of hereditary neuropathy

Authors: *C. KRARUP[1], S. ALVAREZ[1], D. KLEIN[2], R. MARTINI[2], M. MOLDOVAN[1]
[1]Rigshospitalet, Kobenhavn O, Denmark; [2]Univ. of Wuerzburg, Wuerzburg, Germany

Abstract: Charcot-Marie-Tooth neuropathy type 1A (CMT1A) resulting from peripheral myelin protein 22 KDa (PMP22) overexpression is the most common hereditary motor and sensory neuropathy in humans. The transgenic PMP22 (PMP22tg) mouse line C61 carrying 4 copies of the human PMP22 gene, has a slowly progressing neuropathy with thin myelin, immature Schmidt-Lanterman incisures and supernumerary Schwann cells, phenotypically similar to CMT1A. PMP22tg nerves showed activated macrophages leading to axon-myelin compartment disruption and maldistribution of K+ channels (Kohl B et al, Am J Pathol. 2010; 176: 1390), although the pathophysiological significance of these changes remains unclear. The aim of this study was to investigate the motor axon excitability in PMP22tg heterozygotes as compared to wild-type (WT) littermates. Multiple measures of motor axon excitability under anesthesia were

carried out by stimulation of the tibial nerve at ankle and “threshold-tracking” of the plantar CMAP responses. At age 3 months, when the post-developmental maturation was nearly complete in the WT, the PMP22tg CMAP showed an increase in latency by 29%. The CMAP amplitude was decreased by 36% although the mean motor unit size (MScan motor unit number estimation method) appeared unchanged. These conduction abnormalities were paralleled by marked abnormalities in excitability. PMP22tg showed a larger rheobase, an increased strength-duration time constant, a reduced minimum I/V slope (input conductance) and larger than normal deviations during threshold electrotonus. At age 6 months, the CMAP latency of PMP22tg was increased by 70% as compared to WT. In contrast to this marked conduction slowing along the tibial nerve from 3 to 6 months of age, further progression of excitability changes at ankle appeared modest. Nevertheless, when pooling data from 3 to 6 months, the increase in PMP22tg latency was correlated (Spearman $P<0.05$) with an increase in accommodation half-time during depolarizing electrotonus (+40% of threshold) from 29 to 35 ms and a reduction of the late subexcitable period of the recovery cycle from 16 to 9% of threshold, both changes consistent with a redistribution of K+ currents. Our data suggest that in the PMP22tg CMT1A model, a functional, thus potentially reversible, nodo-paranodopathy, accumulates along the nerve and aggravates the conduction impairment due to demyelination.

Title: Mir-486 is an epigenetic regulator of duchenne muscular dystrophy disease pathology

Authors: *R. HIGHTOWER[1], G. V. HALADE[2], M. S. ALEXANDER[3]
[1]Pediatric Neurol., The Univ. of Alabama at Birmingham, Birmingham, AL; [2]Cardiovasc. Dis., Univ. of Alabama at Birmingham, Birmingham, AL; [3]Pediatric Neurol., Children's of Alabama, Birmingham, AL

Abstract: Duchenne muscular dystrophy (DMD) affects 1 in 5000 live male births making it the most common form of muscular dystrophy worldwide. Patients with this X-linked neuromuscular disorder develop muscle loss, ambulation loss, cardiac arrhythmias, and respiratory complications which irreversibly progress throughout their lifespan. DMD is caused by mutations in the *DYSTROPHIN* (*DMD*) gene that result in non-functional dystrophin protein.

Dystrophin is critical for maintaining muscle structure and integrity; therefore, loss of dystrophin ultimately results in neuromuscular junction disintegration, myofiber membrane breakdown, myofiber death, and whole muscle atrophy. Although all patients experience many similar clinical disease manifestations, there remains a wide spectrum of phenotypic variability between them regarding onset and severity of symptoms. This clinical variability suggests dysregulation of secondary signaling pathways that may be influencing progression of disease. Dysregulated secondary signaling pathways in DMD have yet to be elucidated. MicroRNAs have shown to play a key role in muscle development and maintenance and have been implicated as biomarkers in various neuromuscular diseases. Our laboratory has previously shown that expression of a muscle-enriched microRNA, miR-486, is significantly decreased in both DMD patients and mouse models. In addition, our lab has demonstrated that overexpression of miR-486 in dystrophin-deficient mice can ameliorate neuromuscular disease pathology. From this, we hypothesized that miR-486 is a significant epigenetic regulator of DMD disease progression. Locomotive, histological, and metabolic analyses were used to assess muscle-specific transgenic overexpression of miR-486 in dystrophin-deficient mice. Global knockout of miR-486 in both WT and dystrophin-deficient mice was also investigated. We observed that miR-486 overexpression improved serum creatine kinase levels, improved muscle architecture, reduced centralized myonuclei, and increased physical activity in dystrophin-deficient adult male mice. MiR-486 global knockout resulted in significant disruption of skeletal muscle architecture, decreased physical activity, and defects in brain, cardiac, and metabolic function compared to WT controls. Future experiments focused on the detailed mechanism of miR-486 and its mRNA targets that will help to define the role of miR-486 in dysregulated secondary signaling pathways in DMD pathology. Overall, our findings suggest that miR-486 is a valuable biomarker for DMD and may serve as a novel therapeutic target for the treatment of dystrophin deficiency.

Abstract: Background: Duchenne muscular dystrophy (DMD) is an X-linked devastating progressive muscle disease. Death is usually secondary to cardiorespiratory complications. Preclinical /early detection of cardiac autonomic disturbances prior to identification by standard techniques of cardiac assessment may help in timely initiation of cardio-protective therapy. **Methods:** A prospective study in **36** DMD boys and 23 age-matched healthy controls was conducted. ECG analysis, Heart rate variability - HRV, blood pressure variability(BPV) and baroreceptor sensitivity -BRS, were analysed and correlated with disease severity and genotype according to Multiplex Ligation-dependent Probe Amplification (MLPA). **Results:** In the DMD group**,** the mean age at first presentation to neuromuscular clinic was 8.22 ± 2.3 years, mean age at onset of illness was 3.8 ± 2.1 years and mean duration was 4.6 ± 2.7 years. The mean age at onset was 3.94 ±2.2 years. MLPA showed deletions in 32 (89.1%) and duplications in 4 (11.1%) patients. The mutation was distal in 27 and proximal in 9 cases. The mean heart rate was significantly higher in DMD children compared to controls (100 ± 10.22 /min vs 86.23 ± 12min). All the BPV parameters assessed were significantly reduced except diastolic, mean BP and coefficient of variation with increase in aortic impedance in the DMD group. The BRS parameters were also significantly impaired. A positive correlation was found between duration of illness and abnormalities in BPV parameters. There were no significant changes between proximal and distal mutation pattern with ECG/ HRV/BPV/BRS changes. **Conclusion:** This study shows a definite early impairment of neuro-autonomic control in DMD before the onset of clinical symptoms. These simple non-invasive tests like HRV, BPV and BRS can be used to identify pre-clinical cardiac dysfunction.

Title: Characterizing chemotherapy-related somatosensory impairment

Authors: *J. HOLST-WOLF, L. TURCOTTE, J. KONCZAK
Univ. of Minnesota, Minneapolis, MN

Abstract: Chemotherapy-induced peripheral neuropathy is an unwanted side effect of treatment affecting patients and survivors of pediatric cancers. Peripheral neuropathy is known to cause impairments in haptic perception and proprioception. Currently, there is no gold-standard means of measuring these somatosensory impairments. Consequently, the extent of sensory impairment

during chemotherapy and recovery after treatment is unknown. Given that these senses are crucial for motor development and for performing activities of daily life, it seems imperative to obtain accurate measures of how chemotherapy affects these senses in patients with pediatric cancers. We here present two novel, simple assessments that yield objective measures to characterize sensory impairment associated with chemotherapy. The first assessment measures haptic discrimination, specifically the ability of an individual to discriminate between curvatures explored by active touch with the index finger. The second assessment measures proprioceptive acuity of the elbow by measuring an individual's ability to match a passively presented forearm position with the contralateral forearm. Eleven individuals (ages 6 to 25 years old) diagnosed with extracranial cancers such as acute lymphoblastic leukemia, Hodgkin and non-Hodgkin lymphoma, and Ewing sarcoma who are undergoing or have recently completed chemotherapy have completed at least one of these assessments. Preliminary data demonstrate the efficacy of the haptic assessment for measuring somatosensory dysfunction in pediatric patients treated with chemotherapy as 9 of 11 patients have haptic acuity thresholds in the 4th quartile of an the age-matched normative cohort. Regression analysis has identified a relationship between haptic discrimination threshold and the cumulative dosage of chemotherapeutic agent types. These results indicate the haptic discrimination assessment has sufficient resolution to characterize the effects of chemotherapeutic agents on somatosensation.

Title: MitCHAP-60 and SPG13 arise from an inactive hsp60 chaperonin that fails to fold the ATP synthase b-subunit

Authors: *J. M. BHATT, J. WANG, A. ENRIQUEZ, J. LI, R. BERNAL
Chem., Univ. of Texas At El Paso, El Paso, TX

Abstract: The human mitochondrial heat shock protein (hsp60) functions as a chaperonin, folding proteins that are destined towards the mitochondrial matrix. Mutations in Hsp60 have been shown to lead to neurodegenerative diseases, namely, MitCHAP60 and SPG13. A D3G mutation in hsp60 leads to MitCHAP60, an early onset neurodegenerative disease characterized by muscle weakness, limb spasticity and involuntary eye movement. Another hsp60 mutation, V98I, has been linked with SPG13, a form of hereditary spastic paraplegia, characterized by progressive weakness, spasticity in the lower limbs, impaired vision, deafness, and cognitive impairment. The β-subunit of the mitochondrial ATP synthase has been shown to interact with Hsp60, however, the biological effects of the interaction have not been studied. We hypothesized that hsp60 is important in folding the β-subunit and that the mutant hsp60 complexes would be deficient in folding the β-subunit; leading to the neurodegenerative diseases. We expressed and purified Wt. and mutant hsp60 complexes from bacteria and analyzed them via electron microscopy and biochemical assays. Our data suggests that hsp60 plays a crucial role in folding the ATP synthase β-subunit and that the mutant complexes are unable to fold it in *in-vitro* protein-folding assays.

Title: *In vitro* recapitulation of the dysfunctional neuromuscular junction in Charcot-Marie-Tooth disease

Authors: *R. R. BESSER, R. MACIEL, I. CLAURE, A. ALASSAF, D. CARBONERO, M. SAPORTA, A. AGARWAL
Univ. of Miami, Miami, FL

Abstract: Neuromuscular junction (NMJ) dysfunction has been identified in several forms of Charcot-Marie-Tooth disease (CMT). We seek to design a multi compartment cell culture system comprised of CMT patient iPSC derived neurospheres, aligned axons, and engineered anisotropic skeletal muscle tissue to model NMJ dysfunction in CMT using a human *in vitro* platform. Upon validation, this platform will enable mechanistic studies of CMT, as well as discovery of novel therapeutics. Mouse skeletal muscle cells and human neurospheres were co-cultured on a 2-phased hydrogel in maturation media. The hydrogel was fabricated by crosslinking gelatin (10% w/v) with microbial transglutaminase (mTg) (4%) and micromolded. A solution of laminin (10 μg/mL) and mTg (4%) was then incubated on top of the hydrogels.

During hydrogel fabrication one of two patterns were stamped onto the gel: 20 µm x 10 µm grooves for standard co-culture or a compartmentalized design. Our 2-phase biomaterial allowed enhanced myotube growth and alignment. The muscle cells were immunostained for α-sarcomeric actinin, which revealed mature myotube formation with organized sarcomeres. Additionally, neurospheres adhered and extended axons after seeding on the gelatin-laminin hydrogel. The addition of neurosphere media to skeletal muscle cultures enhanced the percentage of myoblasts that differentiate into myotubes from 30% to 85%. Both co-cultures and compartmentalized systems were imaged using immunofluorescence. Co-localization of the terminal end of an axon and acetylcholine clusters indicates the presence of a neuromuscular junction. To confirm the existence of neuromuscular junctions, further functional studies are underway. Gelatin-laminin micromolded hydrogels, which utilize biomimetic extracellular matrix components, are an optimal substrate to co-culture iPSC-derived neurospheres and muscle cells. These engineered hydrogels promote myotube formation and axonal growth. Additionally, micromolded gelatin-laminin hydrogels can be utilized to engineer a multi compartment culture system.

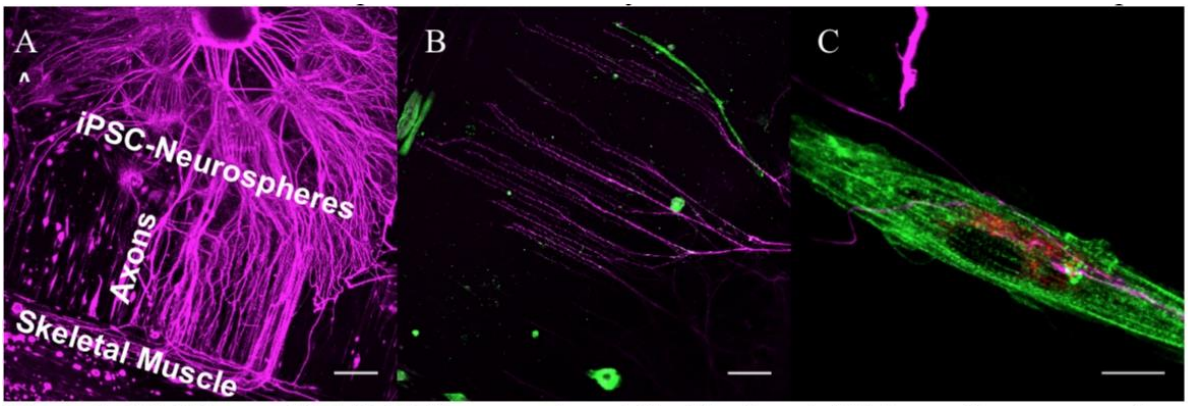

Figure 1. (A) Micromolded Gel-LN compartmentalized hydrogel. (B) Axons from neurosphere following channels and connecting with muscle cell. (C) Co-localization of acetylecholine receptor clusters (red) and terminal axon (magenta) indicates presence of a neuromuscular junction. Scale bar (A) and (B) is 500 µm, scale bar (C) is 50 µm.

Title: The homeostatic adjustment of intrinsic excitability plasticity & spontaneous presynaptic neurotransmitter release in motor neurons and interneurons of severe spinal muscular atrophy mice

Authors: *J. SUN, M. A. HARRINGTON
Biol., Delaware State Univ., Dover, DE

Abstract: Spinal muscular atrophy (SMA) is the leading genetic cause of death in infants and toddlers. Studies with animal models have demonstrated increased excitability and loss of afferent proprioceptive synapses on motor neurons in severe type SMA mice. To further understand the functional changes of the motor neural network in SMA, we studied the intrinsic excitability and synaptic transmission of both motor neurons and interneurons in the ventral horn of the lumbar spinal cord in the SMNΔ7 mouse model. We found that the resting membrane properties of motor neurons were significantly changed in SMA mice, including a hyperpolarized resting membrane potential, increased input resistance and decreased membrane capacitance, while more interneurons in SMA mice fired spontaneously and at higher rates than in littermate controls. The properties of the action potential (AP) in motor neurons were also changed, including a decreased rheobase current, increased amplitude and increased after depolarization potential. The relationship between AP firing frequency and current did not change in either motor neurons or interneurons, but the threshold current was reduced in motor neurons. These changes in the passive membrane and AP properties suggest an overall increase in the excitability of both motor neurons and interneurons. The plasticity of intrinsic excitability changed differently in motor neurons and interneurons. The percentage of neurons showing long-lasting potentiation was increased in motor neurons but decreased in interneurons, while long-lasting depression showed the opposite changes in SMA mice. For spontaneous inhibitory synaptic currents (sIPSC), the amplitude was significantly reduced in motor neurons, while the frequency was increased in interneurons of SMA mice. Interestingly, for miniature synaptic currents mEPSC frequency increased in motor neurons, and both mEPSC and mIPSC frequency increased in interneurons. These data suggest that in SMA-affected mice, defects in the network of interneurons induce homeostatic adjustments of intrinsic and synaptic properties in motor neurons. More research is needed to determine if this modulation contributes to the pathophysiology or is a compensatory response that helps preserve the function of the motor network.

Title: Cytoskeletal alterations in motor neurons derived from inducedcytoskeletal alterations in motoneurons derived from induced pluripotent stem cells (iPSCs) of patients with Brown-Vialetto-Van Laere (BVVL) syndrome can be rescued by riboflavin and N-acetyl-cysteine treatments

Authors: *A. NICEFORO[1], S. PETRINI[2], F. COLASUONNO[1], E. BERTINI[3], S. MORENO[1], C. COMPAGNUCCI[3]
[1]Dept. of Sci., Univ. Roma Tre, Roma, Italy; [2]Confocal Microscopy Core Facility, [3]Neuromuscular and Neurodegenerative Disorders, Bambino Gesù Children's Hosp., Rome, Italy

Abstract: Brown-Vialetto-Van Laere syndrome (BVVL) is a rare childhood disorder characterized by progressive sensorineural deafness and selective degeneration of ponto-bulbar motor neurons (MNs)[1]. The disease is caused by mutations in *SLC52A3* or *SLC52A2* genes, encoding for the human Riboflavin Transporters RFT2 and RFT3. Riboflavin (vitamin B2), as a precursor of FMN and FAD, is a crucial micronutrient for growth and normal cellular functions, particularly involving energy metabolism pathways driven by flavoproteins[2]. Induced pluripotent stem cells (iPSCs), derived from reprogramming of somatic cells are increasingly used to reproduce rare diseases. We therefore took advantage of this approach, using iPSCs obtained from fibroblasts of BVVL patients, to characterize molecular and cellular aspects of the disease. To study the cell type mostly affected in patients, we differentiated iPSCs into motor neurons, focusing on the cytoskeleton, whose dynamics is fundamental to drive the morphological and functional changes occurring in these cells, extending their neurites for long distances[3]. While patients' iPSCs showed no abnormalities in microtubule organization, when differentiated into MNs, these cells displayed deranged cytoskeletal components. Indeed, both immunofluorescence and RT-qPCR analyses demonstrated altered expression and distribution of α-/β-tubulin and NFH intermediate filaments in BVVL motoneurons. Considering the role of riboflavin in redox homeostasis[2], we explored possible beneficial effects of excess vitamin and/or the antioxidant molecule N-acetyl-cysteine (NAC). Treatment with riboflavin resulted in improved cytoskeletal features in patients' derived motor neurons, suggesting that redundancy of transporters may rescue neuronal functionality, when adequate concentrations of the vitamin are present in the microenvironment. This finding supports empirical data of patients' symptoms amelioration following riboflavin-based therapies[4]. Even more importantly, supplementation of culture medium with NAC, particularly in combination with riboflavin, restored normal cytoskeletal arrangement in patients' iPSCs-derived motoneurons. Our data, while supporting the use of

iPSCs for *in vitro* modeling of BVVL syndrome, highlights the pathogenic role of cytoskeletal abnormalities, which can be rescued by riboflavin and NAC treatments, thus suggesting possible therapies based on these molecules. 1. Title: Modeling hereditary spastic paraplegias with patient-specific stem cell-derived cortical and spinal neuron co-cultures

Authors: *Y. MOU[1], Y. DONG[3], S.-C. ZHANG[3], X.-J. LI[1,2]
[1]Dept. of Biomed. Sci., Univ. of Illinois, Rockford, IL; [2]Dept. of Bioengineering, Univ. of Illinois, Chicago, IL; [3]Waisman Ctr., Univ. of Wisconsin, Madison, WI

Abstract: Hereditary spastic paraplegias (HSPs) are a heterogeneous group of neurogenetic disorders characterized by axonal degeneration of cortical motor neurons (MNs), a group of large projection neurons (PNs). How the connections between cortical PNs and their targets, spinal MNs, are affected in HSPs remain largely unknown. We have previously generated iPSCs from fibroblasts of an SPG3A patient with mutation of Atlastin-1 (*ATL1*, p.S342PP342S). Here, we first generated SPG3A isogenic human pluripotent stem (hPSC) cell (hPSC) lines by knocking in a mutation (*ATL*161 line, p.A161P) and correcting the mutation in the SPG3A hPSC line (p.S342P). The mutation of *ATL-1* (p.A161P) induced the axonal defects, including decreased axonal outgrowth, increased axonal swellings and impaired axonal synaptophysin transport in cortical PNs. Moreover, the correction of SPG3A mutation rescued the axonal defects, confirming the cause-effect relationship between the *ATL-1* mutations and disease phenotypes of cortical PNs. Next, we seek to determine the synaptic defects in HSP by establishing a co-culture model for SPG3A. We generated the channel rhodopsin 2 (ChR2)-EYFP expressing hPSC lines using CRISPR/Cas9-mdeiated homologous recombination. These normal, SPG3A iPSCs or isogenic cell lines were differentiated into cortical PNs (ChR2+), which were then co-cultured with spinal MNs derived from their corresponding regular pluripotent stem cells (without ChR2).

After the immunostaining, we observed a dramatic decrease in the numbers of the Synapsin+/EYFP+/PSD95+ synaptic clusters in the SPG3A (p.PS342PS) and ATL161 (p.A161P) co-cultures comparing to control coculture of cortical PNs and spinal MNs. Furthermore, the electrophysiological analysis revealed that the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) recorded in SPG3A spinal MNs decreased significantly comparing to control coculture group after the activation of ChR2-expressing cortical PNs using blue light stimulation, indicating the impaired functional synaptic connections between co-cultured cortical PNs and spinal MNs in SPG3A cell model. Taken together, our data reveal that the mutation of Atlastin-1 induced the axonal defects of cortical PNs and the impaired synaptic connections between cortical PNs and spinal MNs in a SPG3A co-culture model, which can serve as a unique system to study the pathogenic mechanism and explore the treatment for HSPs.

Title: RGMa inhibition ameliorates the severity of localized model of neuromyelitis optica

Authors: *K. HARADA[1], Y. FUJITA[1], T. OKUNO[4], S. TANABE[5], Y. KOYAMA[2], H. MOCHIZUKI[3], T. YAMASHITA[1]
[1]Dept. of Mol. Neurosci., [2]Dept. of Neurosci. and Cell Biol., [3]Neurol., Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan; [4]Res. Inst. for Microbial Diseases, Osaka Univ., Osaka, Japan; [5]WPI Immunol. Fronteir Res. Center, Osaka Univ., Osaka, Japan

Abstract: Background: Neuromyelitis optica (NMO) is an autoimmune disease associated with NMO-IgG, an antibody that selectively binds to aquaporin-4. Because of its association with this disease, passive transfer of NMO-IgG has been used to develop rodent models of NMO. But, previous models causes damage to multiple neuronal circuits, making it difficult to determine if the clinical deficits can be directly caused by a defined neuronal tract system. NMO and multiple sclerosis (MS) are immune-mediated neurodegenerative diseases with broadly comparable symptoms; thus, they may share some underlying molecular mechanisms. Systemically treating models of MS with RGMa-antibodies significantly improved function, reduced microglial lesion

size, enhanced axon regeneration into the lesion, and produced signs of remyelination.
Objectives: To study whether neutralizing the effect of RGMa could prevent the disease progression of a localized NMO model, and to obtain a deeper insight into the mechanism.
Rat model of NMO: Wistar rats (8 weeks) were used. Laminectomy was performed at thoracic 9/10 vertebral level and a micro-syringe attached to a pulled-glass micro-capillary needle was used to infuse a single injection of NMO-IgG or Control-IgG (20 μg) at the 10^{th} thoracic vertebrae. Animals were randomly and evenly divided (n = 10 per group): non-NMO rats, Control mAb-treated NMO rats, and anti-RGMa mAb-treated NMO rats. For the NMO groups, anti-RGMa mAb or Control-IgG was injected intravenously (10 mg/kg) after the NMO-IgG injection (day 0) and then every 7 days.
Immunohistochemistry: Primary antibodies includes: anti-AQP4, anti-GFAP, anti-Iba-1, anti-CD45, anti-MBP, and anti-SMI-312.
Results: The rats received a single 20-μg injection of NMO-IgG in the dorsal column of the thoracic spinal cord, which induced a well-demarcated single inflammatory lesion in the spinal cord. The weekly injections of anti-RGMa mAb significantly attenuated the severity of the clinical signs after day 12. We then examined the involvement of RGMa in T-cells in order to understand the mechanism of alleviated symptoms observed in our NMO rat. Interestingly, anti-RGMa mAb-treated NMO rats displayed a sharp reduction in the $IL17A^+$ T-cell population. The treatment might have brought about this effect by suppressing the enhanced production of $IL17A^+$ T-cells, which subsequently reduced axonal and astrocyte loss. Furthermore, the inhibition of RGMa promoted restoration of injured neural networks, presumably leading to a delay in the progression of the secondary phase of NMO.
Conclusions: We propose that humanized anti-RGMa mAb may help in preventing and attenuating the neurological symptoms of NMO.

Title: The polyglutamine protein FAM171B localizes to neuronal cytoplasm

Authors: D. RAJAGURU, M. BAUER, D. S. SHARLIN, *G. M. GOELLNER
Biol., Minnesota State Univ- Mankato, Mankato, MN

Abstract: Expansion mutation within polyglutamine (polyQ) tract proteins is known to underlie a number of severe neurodegenerative disorders such as Huntington's Disease and Spinocerebellar Ataxia. Using a bioinformatics approach, we have identified a novel protein, FAM171B, that contains a stretch of 14 consecutive glutamines. Using *in situ* hybridization and immunohistochemistry experiments, our data strongly suggests that FAM171B is widely expressed in the brain with abundant expression in the hippocampus, cortex, and cerebellum. To begin elucidating FAM171B sub-cellular location we are using confocal fluorescence imaging of GFP-fusion tagged FAM171B and anti-FAM171B antibodies *in vitro*. Our findings indicate that FAM171B displays a punctate/vesicular staining pattern throughout the cytoplasm of human glioblastoma tissue culture cells and primary mouse cortical neurons. FAM171B localization is particularly enriched in the peri-nuclear region and adjacent to the plasma membrane. Current studies are utilizing organelle specific markers to verify sub-cellular locale and live-cell imaging to assay whether FAM171B may traffic between intracellular compartments.

Title: Hippocampal granule cell loss in human chronic alcohol abusers

Authors: *T. WARDI LE MAITRE[1], G. DHANABALAN[2], N. BOGDANOVIC[3], K. ALKASS[1], H. DRUID[4]
[1]Oncology-Pathology, Karolinska Institutet, Stockholm, Sweden; [2]Dept. of oncology and pathology, Karolinska Inst., Stockholm, Sweden; [3]Karolinska Univ. Hosp., Neurogeriatric Clin., Stockholm, Sweden; [4]Forensic Medicine, Karolinska Institutet, Stockholm, Sweden

Abstract: Chronic alcohol abuse often causes cognitive impairment, which both experimentally and in human studies has been associated with neurodegeneration and volume loss in the hippocampus. Here, we hypothesize that alcohol reduces the number of granule cells in the human dentate gyrus and consequently contribute to the observed volume loss. Hippocampal samples were isolated from deceased donors with a history of chronic alcohol abuse and from controls with no alcohol overconsumption. From each case, a sample from the mid-portion of hippocampus was sectioned, immunostained for the neuronal nuclear marker NeuN, and counter stained with hematoxylin. Granule cell number and volume of granular cell layer in the dentate gyrus were estimated using the optical fractionator method of stereology. We found a considerable reduction in granule cell number and also a significantly reduced volume of the granular cell layer of chronic alcohol abusers as compared to controls. In controls there was a slight age-related decline in the number of granule cells and volume of granular cell layer in line with previous studies. This was not observed among the alcoholics, possibly due to a larger impact of alcohol abuse than age on the degenerative changes in the dentate gyrus. Loss of neurons in the alcoholic group could either be explained by an increase of cell death or a reduced number of new cells added to the granular cell layer. However, there is no convincing support for an increased neuronal death by chronic alcohol exposure, whereas a growing body of experimental data indicates that neurogenesis is impaired by alcohol. In a recent study, we reported that alcoholics show a reduced number of stem/progenitor cells and immature neurons in the dentate gyrus, hence that alcohol negatively affects hippocampal neurogenesis. The present results further suggest that such impairment of neurogenesis by chronic alcohol abuse also results in a net loss of granule cells in the dentate gyrus of hippocampus.

Title: Electrophysiological impairment and K^+ dyshomeostasis in retinal ganglion cell axonopathy

Authors: *R. A. FISCHER[1], M. L. RISNER[2], A. L. ROUX[2], R. M. SAPPINGTON[1,2]
[1]Dept. of Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Dept. of Ophthalmology and Visual Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Axonopathy is a common feature among many neurodegenerative disorders. In axonopathy, functional deficits, such as axon transport dysfunction, occur prior to structural degeneration of the axon. Axon degeneration is then followed by degeneration of the soma. This temporal sequence of events is often accompanied by spatial progression, where clusters of neighboring neurons exhibit a similar rate of degeneration. Spatial progression of axonopathy suggests that external cues in the immediate milieu of degenerating neurons may play an important role in disease progression. To determine how neurons in the early stages of axonopathy differ from those in surrounding areas with no overt signs of axonopathy, we compared electrophysiological function with axon transport deficits in retinal ganglion cells (RGCs) in a mouse model of optic neuropathy. In this model, pressure-related stressors induce axonopathy in clusters that ultimately spread to encompass larger areas of the retina and optic nerve. We assessed electrophysiological function of RGCs with and without axon transport deficits, as measured by uptake and anterograde transport of the neural tracer cholera toxin beta (CTB). We found that RGCs with deficits in CTB uptake possess a more depolarized resting membrane potential (Vm), compared to RGCs with intact uptake ($p<0.05$). Despite similar K^+-induced depolarization of Vm ($p>0.05$), the K^+-induced spike rate decreases as the $[K^+]_e$ increases in RGCs with deficient CTB uptake. This is opposed to RGCs with intact CTB transport, where increased $[K^+]_e$ induces a reciprocal increase in spike rate. At the same $[K^+]_e$, the spike rate of RGCs with deficient CTB uptake is significantly lower than that for RGCs with intact CTB uptake ($p<0.05$). *In vitro* studies confirm a disrupted K^+ homeostasis surrounding RGCs exposed to pressure-related stressors. In primary, purified RGCs, elevated pressure leads to increased $[K^+]_e$ in the culture media ($p<0.005$) and a significant decrease in cation influx ($p<0.05$), as compared to control condition. Gene expression and protein localization studies in the optic neuropathy model indicate that this K^+ dyshomeostasis may arise from decreased expression of Na/K-ATPase, particularly in RGCs ($p<0.05$). Our data suggest that axon transport deficits in RGCs are accompanied by electrophysiological impairment that involves failure to re-establish the electrochemical gradients of ions required for maintenance of spiking frequency. This impairment may be linked to K^+ dyshomeostasis secondary to altered expression of the Na/K-ATPase and could contribute to spatiotemporal progression of pathology between neighboring RGCs.

Title: Loss of neuritin accelerates RGC loss and retinal degeneration in adult mice following optic nerve injury

Authors: *Y. AZUCHI[1,3], K. NAMEKATA[1], T. SHIMADA[2], X. GUO[1], A. KIMURA[1], C. HARADA[1], A. NISHIGAKI[3], K. YAMAGATA[2], T. HARADA[1]

Abstract: Glaucoma is one of the major causes of blindness and is characterized by progressive degeneration of retinal ganglion cells (RGCs) and their axons. The optic nerve injury (ONI) model mimics some aspects of glaucoma, including RGC death induced by excitotoxicity and oxidative stress, and therefore, it is a useful animal model for glaucoma. Previous studies have shown that neurotrophins, such as brain-derived neurotrophic factor, protect RGCs in an ONI model. Neuritin, also known as candidate plasticity gene 15 (CPG15), was first identified as one of the activity-dependent gene products in the brain. Neuritin is an extracellular, glycosylphosphoinositide-linked protein, which can be secreted as a soluble form by various cells including neuronal and glial cells. Neuritin induces neuritogenesis, neurite arborization, neurite outgrowth and synapse formation, which are involved in the development and functions of the central nervous system. In addition, it is recently thought to be a kind of neurotrophin that regulates neural cell survival. Here, we investigated the function of endogenous neuritin following ONI using *neuritin* knockout (KO) mice. We first examined *neuritin* mRNA expression levels in the mouse retina before and after ONI. ONI induced slight upregulation of *neuritin* mRNA in the retina of WT mice. Next, we investigated developmental abnormalities and severity of ONI-induced degeneration in the *neuritin* KO mouse retina. *In vivo* retinal imaging and histopathological analyses demonstrated that there is no difference in the retinal

structure and number of RGCs between *neuritin* KO and WT mice under normal condition. However, ONI caused more severe RGC death and inner retinal degeneration in *neuritin* KO mice compared with those in WT mice, over the course of 2 weeks following ONI. We also investigated if neuritin has any stimulatory effects on cell survival signaling pathways in the retina following ONI. Previous studies have reported that exposure of cerebellar granule neurons to neuritin markedly induced phosphorylation of Akt and ERK in part by activating the insulin receptor signaling. Akt and ERK signaling pathways are known to promote RGC survival after ONI. In present study, immunoblot analyses revealed that ONI-induced phosphorylation of Akt and ERK were suppressed in *neuritin* KO mice. Our findings suggest that neuritin has neuroprotective effects via Akt and ERK signaling pathways after ONI and may be useful for treatment of glaucoma.

Title: Possible involvement of vwc2l, a constituent of the AMPA receptor complex, in the functioning of neuronal and non-neuronal tissues

Authors: *S. I. TOMAREV[1], N. NAKAYA[2], A. SULTANA[3], J. SCHWENK[4], B. FAKLER[5]
[1]SRGCB, LRCMB, NEI, NIH, Bethesda, MD; [2]SRGCB/LRCMB, Natl. Eye Inst., Bethesda, MD; [3]NIH, Bethesda, MD; [4]Inst. of Physiology, Univ. of Freiburg, Freiburg, Germany; [5]Inst. of Physiol., Freiburg, Germany

Abstract: Vwc2l (also known as brorin-like) is a secreted protein considered to be a chordin-like BMP antagonist. Vwc2l is a component of the ionotropic AMPA-type glutamate receptor (AMPAR) complex but its function in the complex unknown. Previous proteomics data indicated that vwc2l, together with olfactomedin 1 (Olfm1), Olfm2, Olfm3, vwc2, and neuritin may interact with extracellular parts of the AMPAR core subunits. The objective of this study was to investigate possible functions of vwc2l using mouse and zebrafish models. Quantitative proteomics demonstrated that the amount of vwc2l assembled with AMPARs was strongly reduced in immunoprecipitates obtained with GluA1-4 antibodies from *Olfm1* null brain or retina

membrane fractions compared with wild-type samples, indicating that the integration of vwc2l in native AMPAR complexes is largely mediated by Olfm1. Indeed, mouse and zebrafish vwc2l were co-precipitated with Olfm1 from lysates of COS7 cells transiently transfected with corresponding expression constructs indicating direct interaction of Olfm1 and vwc2l. Overexpression of vwc2l during early zebrafish development induced by an injection of *vwc2l* mRNA into zebrafish eggs resulted in severe developmental defects, mainly in the posterior part of larvae. These defects were remarkably reduced when the *vwc2l* mRNA was injected into *olfm1* knockout eggs, indicating that the effects of vwc2l over- or mis-expression may be modulated by Olfm1. Overexpression of vwc2l may affect TNFα signaling as suggested by the results of RNAseq analysis of zebrafish larva heads 24 hours post-fertilization. TNFα signaling is known to be involved in neuronal degeneration in brain and eye diseases and glutamate toxicity. Moreover, glia-derived soluble TNFα was shown to be a major inducer of retinal ganglion cell death through the activation of Ca^{2+}-permeable AMPA receptor. Another potential target of vwc2l overexpression is SREBP, a transcription factor responsible for synthesis of cholesterol and other lipids. Cholesterol synthesis is known to be important for maintaining healthy neuronal membrane structure in axons and dendrites as well as lipid rafts in synapses. Our data sugest that vwc2l has multiple functions in both neural and non-neural tissues.

Abstract: HIV infection induces synaptodendritic injury in the brain. As HIV does not efficiently infect neurons, its influence on neurons is largely due to the effect of infected/activated glial cells. Previous studies implicate the contribution of activated microglia to neuronal damages. However, how microglia are activated in response to HIV remain elusive. We used the transgenic mice expressing gp120, a HIV glycoprotein contributing to neurocognitive disorders, to study microglia turnover. Single cell RNA-Seq was performed on 10000 cells dissociated from the cortex of 2-, 4- and 8- month wide type and gp120-transgenic mice. Our results indicate the chronologic differentiation of microglial subtypes with potential activity in phagocytosis, demyelination, gliosis, or proliferation in the transgenic mice. The findings reveal previously unknown microglial plasticity induced by HIV and the trajectory of potential microglial differentiation that may contribute to synaptodendritic injury.

Title: Increased chemokines and chemokine receptors contribute to neurodegeneration in postmortem human alcoholic brain

Authors: *L. QIN, R. P. VETRENO, F. T. CREWS
Bowles Ctr. Alcohol Studies, Univ. North Carolina, Sch. Med., Chapel Hill, NC

Abstract: Chemokines and chemokine receptors are associated with neuroinflammation and their expression is induced by inflammatory mediators. In the current study, qPCR and immunohistochemistry were used to study expression of chemokines and chemokine receptors in post-mortem human orbital frontal cortex (OFC) tissue samples from moderate drinking controls and alcoholics. In the alcoholic OFC, we found significant increases in mRNA levels of C-C motif chemokines (CCL2 [MCP1; 163%], CCL8 [MCP2; 346%], CCL7 [MCP3; 152%], CCL13 [MCP4; 289%], and CCL5 [RANTES; 237%]) and C-X-C motif chemokines (CXCL8 [IL-8; 306%] and CXCL12 [SDF-1; 291%]), compared to moderate drinking control subjects. We also observed an approximate two-fold increase in protein levels of IL-8 in the alcoholic OFC. We also observed significant increases in mRNA levels of C-C motif chemokine receptors (CCR1 [146%], CCR2 [245%], and CCR8 [221%]), C-X-C motif chemokine receptors (CXCR1

[252%], CXCR2 [264%], CXCR3 [210%], and CXCR4 [235%]), and the C-X3-C chemokine receptor for fractalkine CX3CR1 (337%) in the alcoholic OFC, relative to moderate drinking control subjects. Interestingly, expression of these chemokines and chemokine receptors in the human OFC were correlated with each other, and negatively correlated with age of drinking onset such that an earlier age of drinking initiation (~18 years of age) was associated with greater expression levels of these chemokine signaling molecules. Gene expression of the chemokines CCL3 (MIP-1α), CCL4 (MIP-1β), CCL19 (MIP-3β), CXCL10 (IP-10), and CX3CL1 (fractalkine) were unchanged in the alcoholic OFC. To evaluate the association of increased chemokines and chemokine receptors with neurodegeneration in the post-mortem alcoholic OFC, we investigated caspase-3, -7, -8, -9 mRNA, and activated caspase-3 protein expression. We found significant increases in mRNA levels of caspase-3 (158%), -7 (193%), -8 (166%), and -9 (181%) as well as increased activated caspase-3+IR (155%) in the alcoholic OFC, compared to moderate drinking controls. Expression of caspase signaling molecules were negatively correlated with age of drinking onset, and positively correlated with expression of chemokines and chemokine receptors. Together, these data suggest that the enhanced expression of chemokines and chemokine receptors in human alcoholic brain could contribute to chronic ethanol-induced neuroinflammation and neurodegeneration.

Abstract: Gray Matter (GM) atrophy is one of the best predictors of long term disability in multiple sclerosis (MS) and recent evidence has further revealed that localized GM atrophy in MS is associated with clinically relevant disabilities. However, the mechanisms underlying GM atrophy remain largely unknown. In this report, we used voxel-based morphometry (VBM) to characterize the pattern of GM atrophy in the early stages of the most widely used animal model of MS, experimental autoimmune encephalomyelitis (EAE). We identified GM atrophy throughout the cerebral cortex, cerebellum, caudoputamen, and thalamus of mice with EAE compared to healthy controls, consistent with previous literature. Our investigation revealed that axonal damage and loss in the spinal cord was strongly correlated with voxelwise GM atrophy within motor and sensory regions of the cortex. We believe this is the first report to use VBM in EAE in mouse and to associate specific pathology with localized GM atrophy in EAE. This finding suggests that axonal damage and loss plays a key role in permanent GM atrophy. Understanding the relationship between cellular pathology and GM atrophy may lead to the development of better neuroprotective therapies for patients with MS.

Abstract: Autophagy is a degradative pathway for removing aggregated proteins, damaged organelles, and parasites. Evidence indicates that autophagic pathways differ between cell types. In neurons, autophagy plays a homeostatic role, compared to a survival mechanism employed by starving non-neuronal cells. We investigated if sphingosine kinase 1 (SK1)-associated autophagy differs between two symbiotic brain cell types—neurons and astrocytes. SK1 synthesizes sphingosine-1-phosphate, which regulates autophagy in non-neuronal cells and in neurons. We found that benzoxazine autophagy inducers upregulate SK1 and neuroprotective autophagy in neurons, but not in astrocytes. Starvation enhances SK1-associated autophagy in astrocytes, but not in neurons. In astrocytes, SK1 is cytoprotective and promotes the degradation of an autophagy substrate, mutant huntingtin, the protein that causes Huntington disease. Overexpressed SK1 is unexpectedly toxic to neurons, and its toxicity localizes to the neuronal soma, demonstrating an intricate relationship between the localization of SK1's activity and neurotoxicity. Our results underscore the importance of cell type-specific autophagic differences in any efforts to target autophagy therapeutically.

Title: Characterization of the brain innate immune system in an animal model of Wernicke-Korsakoff syndrome

Authors: *B. GARCIA-BUENO[1], M. MOYA[2], A. BALLESTA[2], A. RODRIGUEZ GONZALEZ[2], M. SANCIO[2], D. SAN FELIPE[2], M. LOPEZ-GALLARDO[2], R. GOMEZ DE HERAS[2], F. RODRIGUEZ DE FONSECA[2], E. M. MARCO[2], L. ORIO[3]

Abstract: Wernicke-Korsakoff syndrome (WKS) is the consequence of a severe deficiency of thiamin (B1 vitamin) that is typically related to alcohol abuse. The clinical course of WKS begins with Wernicke's Encephalopathy (W), characterized by ataxia and cognitive dysfunction,

and may continue with the Korsakoff syndrome (WK), characterized by irreversible brain damage. The molecular mechanism responsible of the transition between both stages is unknown, although some evidences suggest a role for neuroinflammation and oxidative/nitrosative stress.
We characterized an animal model of both pathological states, investigating also alterations on innate immune Toll-like receptor 4 and tested a potential approach to manage such alterations based on the systemic administration of the anti-inflammatory oleylethanolamide (OEA).
W was induced by feeding the animals with a thiamine-deficient diet and administration of a thiamine antagonist (pyrithiamine, 0.5mg/Kg, ip,). WK was then triggered by the intravenous administration of a glucose overdose (5g/Kg). For the characterization of the model, general activity was analyzed in the open field and motor coordination in the rotarod test. OEA (10 mg/kg, i.p.) was daily administered during the last 6 experimental days.
W animals showed a loss of body weight starting from day 12, reaching around the 10% of the body weight loss at the end of the experiment. In the rotarod test, an impaired performance was exhibited by W animals. Some W and WK animals, by the end of the study displayed rigid movements, splayed legs, hunched posture and sometimes tremors and jerking seizures. We also shown a concomitant increase of the TLR4 ligand lipopolysaccharide plasma levels and an up-regulation of TLR4 signaling pathway in the WK animals. OEA recovered WK animals' performance in the rotarod test. Similarly, OEA seems also to revert the increased anxiety levels observed in W and WK animals in the elevated plus-maze (EPM).
The pharmacological modulation of innate immunity could be an attractive therapeutical strategy to manage the transition between reversible to irreversible structural and functional damage in the Wernicke-Korsakoff syndrome.

Title: Lead exposure during lactation increases the levels of quinolinic acid in blood and quinolinic acid immunoreactive cells in the brain of young rats

Authors: *K. M. KHAN[1,2], M. S. RAO[3], A. RAHMAN[4]
[2]Anat., [1]Kuwait Univ. Fac. of Med., Safat, Kuwait; [3]Anat., [4]Food Sci. and Nutr., Kuwait Univ., Safat, Kuwait

Abstract: Lead (Pb) is a neurotoxicant, which is particularly toxic to the developing brain. Quinolinic acid (QA), a metabolite of the kynurenine pathway of tryptophan metabolism, is also a known neurotoxicant, affecting hippocampal, striatal and cortical neurons. Pb and QA share certain features of neurotoxicity; both produce oxidative stress and induce tau hyperphosphorylation. Production of QA in the brain is increased by oxidative stress. We have previously shown that exposure to Pb or intraventricular infusion of QA lead to learning and memory deficits in young rats. The purpose of this study was to investigate whether exposure to low levels of Pb during lactation has an effect on the levels of QA in blood and QA immunoreactive neurons in different brain regions of young rats. Wistar rat pups were exposed to 0.2% Pb-acetate via their dams' drinking water from postnatal day (PND) 1 to 21(Pb-exposed group, n=10). The control group (C, n=10) was given regular tap water. QA level in serum was measured by ELISA on PND45 and PND60. QA-immunoreactive neurons in cerebral cortex, thalamus and hippocampus (dentate gyrus, CA3 and CA1 areas) of Pb-exposed and control rats were quantified in the brain sections immunostained for QA on PND45 and PND60. Pb exposure did not affect the level of QA in serum in the PND45 rats (5.74±0.77ng/ml in control vs 6.43±0.35 ng/ml in Pb-exposed, $p>0.05$), whereas, in PND60 rats, Pb exposure significantly increased QA levels as compared to control group (5.72±0.80 vs 9.01±1.0; $p<0.001$). Pb-exposed rats had significantly higher number of QA-immunoreactive cells in all the areas examined at both PND45 ($p<0.05$) and PND60 ($p<0.01$), with the exception of the thalamus in the PND45 rats, where the difference between Pb-exposed and control rats was not significant. These results show that Pb exposure increases the levels of QA in the blood and QA immunoreactive cells in brain regions. This increase in QA levels may be the cause for Pb-induced learning and memory deficits, which we reported earlier

Title: C9ORF72 poly-GA inclusions promote phosphorylated TDP-43 aggregation *in vitro* and *in vivo*

Authors: *T. NONAKA, M. HASEGAWA
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Amyotrophic lateral sclerosis and frontotemporal lobar degeneration are neurodegenerative diseases characterized by accumulation of insoluble aggregates of phosphorylated 43-kDa TAR DNA-binding protein (TDP-43), and linked with abnormal expansion of a hexanucleotide repeat in an intron of chromosome 9 open reading frame 72 (*C9ORF72*). However, the relationship between *C9ORF72* mutations and TDP-43 aggregation remains unknown. Non-ATG-dependent translation of *C9ORF72* repeats produces dipeptide repeat (DPR) proteins, which form p62-positive aggregates in cerebral cortex and cerebellum of patients. Here, we show that the formation of poly-GA protein inclusions induced intracellular aggregation of endogenous and exogenous TDP-43 in cultured cells. Poly-GA aggregation preceded accumulation of phosphorylated TDP-43. These inclusions induced intracellular aggregation of phosphorylated TDP-43, but not tau or alpha-synuclein. Formation of phosphorylated TDP-43 aggregates depends on the number of poly-GA repeats. Detergent-insoluble fraction from cells co-expressing poly-GA and TDP-43 could function as seeds for further TDP-43 aggregation. We also present *in vivo* evidence that poly-GA inclusions elicit intracellular aggregation of endogenous TDP-43 and neurodegeneration in mice expressing poly-GA, without formation of nuclear RNA foci containing GGGGCC repeat expansion or loss-of-function of the C9ORF72 protein. These findings suggest a novel pathogenic mechanism that poly-GA protein aggregation directly promotes pathogenic changes of TDP-43, leading to disease-associated neurodegeneration in patients with *C9ORF72* mutations.

Title: Neuroprotective role of sigma-1 receptors in amyotrophic lateral sclerosis relevant to nucleocytoplasmic transport

Authors: *P.-T. LEE[1], T.-P. SU[2]
[1]Cell. Pathobiology Section, Integrative Neurosci. Res. Br., IRP/NIDA/NIH, Baltimore, MD;
[2]Cell. Pathobiology Section Integrative Neurosci. Br., NIDA-IRP, NIH, Baltimore, MD

Abstract: Expanded hexanucleotide G_4C_2 repeats lead to the nucleocytoplasmic transport defect in the nuclear pore complex (NPC). G_4C_2 RNA repeats were shown to interact with Ran GTPase-

activating protein 1 (RanGAP1) at the NPC and impaired the conversion of RanGTP to RanGDP, causing the former to accumulate in the cytosol of neurons from *C9orf72*-related amyotrophic lateral sclerosis (ALS) patients. Missense mutation at amino acid E102Q of sigma-1 receptor (Sig-1R) chaperons was reported in familial ALS. The molecular action of Sig-1Rs in ALS is unknown even though Sig-1Rs exist at the nuclear envelope. Here, we examined the relationship between G_4C_2 RNA repeats, Sig-1Rs, and RanGAP1. Immunoprecipitation assay and fluorescence confocal microscopy reveal that Sig-1Rs associate with RanGAP1 in the NPC. Sig-1Rs partly colocalize with Cy3-labeled C_4G_2 RNA probe in the perinuclear region by using RNA fluorescence *in situ* hybridization (i.e., RNA-FISH). Interestingly, the recombinant glutathione S-transferase (GST)-tagged full-length Sig-1R proteins (amino acids 1-223) from both human and mouse physically interact with biotin labeled G_4C_2 RNA repeats in the biotinylated RNA pull-down assay. To identify the G_4C_2 RNA-protein interacting domains on the Sig-1R, we purified three truncated fragments of GST-tagged Sig-1R including amino acids 1-70, 71-150 and 151-223. The results demonstrated that protein fragments including amino acids 71-150 and 151-223 of Sig-1R are important for the Sig-1R-G_4C_2 RNA interaction. Furthermore, the Sig-1R E102Q mutation, reported to cause ALS, causes a decrease in its affinity with G_4C_2 repeats. The overexpresson of Sig-1Rs reduces the cytoplasmic accumulation of Ran GTPase while knockdown or knockout of Sig-1Rs exacerbates the cytosolic accumulation. Further, we found that Sig-1Rs bind to FG-repeats-containing nucleoporins of NPC and stabilize those NPC proteins. Thus, our results suggest dual neuroprotective roles of Sig-1Rs in the G_4C_2 subtype of ALS: one by enhancing the nucleocytoplasmic transport by stabilizing the NPC and the other by sponging away the toxic G_4C_2 repeats. Sig-1R drugs may thus benefit the G_4C_2 subtype of ALS patients. (Supported by IRP, NIDA, NIH/DHHS)

Title: Carboxypeptidase E/neurotrophic factor-α1 is a novel neuroprotective protein functioning independently of its prohormone processing enzymatic activity

Authors: *L. XIAO, X. YANG, V. K. SHARMA, D. ABEBE, A. PELTEKIAN, Y. P. LOH
Section on Cell. Neurobiology, NICHD, NIH, Bethesda, MD

Abstract: Carboxypeptidase E (CPE) also known as Neurotrophic factor-α1 (NF-α1), was first identified as an exopeptidase and is highly expressed in the nervous and endocrine systems. It

functions intracellularly as a prohormone/proneuropeptide processing enzyme. Recent studies show that CPE/ NF-α1 plays a critical role extracellularly, as a trophic factor to mediate neuroprotection, stem cell differentiation and neurite outgrowth *in vitro*. To show that these neurological functions are independent of its enzymatic activity, we generated a CPE/NF-α1 knockout (CPE-KO) and a mouse model with a CPE E342Q point mutation which obliterates the enzymatic activity. We found that both CPE-KO and E342Q mice exhibited increased body weight and glucose levels due to lack of processing of prohormones and neuropeptides to yield insulin and peptides that affect feeding. Brain morphology studies by Nissl staining revealed that the CPE-KO mice had significant degeneration of CA3 regions of hippocampus, while E342Q mice had an intact hippocampus, similar to wild-type (WT) animals. In addition, doublecortin positive cells (neuroblast marker) in CPE-KO mice were significantly decreased in dentate gyrus, but there was no difference between E342Q and WT mice. Microtubule-associated protein 2 staining showed degeneration of dendrites in the hippocampal CA3 region in CPE-KO mice, but there was no difference between E342Q and WT mice. To investigate the effect of E342Q mutation on various behaviors, open field, forced-swim test, and Morris water maze tests were performed on the mice. The results showed that WT and E342Q mice exhibited a gradual decrease in escape latency during the 5-day training in the Morris water maze test, while CPE-KO mice demonstrated an abnormal acquisition curve. In probe test, both WT and E342Q mice spent twice as much time in the target quadrant than other quadrants, unlike the CPE-KO mice. These results suggest E342Q mutant mice maintain normal learning and cognitive ability despite the loss of CPE enzymatic function; in contrast learning and memory function were compromised in CPE KO mice. This study provides *in vivo* evidence that CPE/NF-α1 is a novel trophic factor that functions in neuroprotection, independent of its enzymatic role in prohormone processing.

Title: Layer-dependent time course of neuronal death following ultraviolet light irradiation of the cerebral cortex

Authors: *M. NAKATA[1,2], M. SHIMODA[3], S. YAMAMOTO[1]
[1]AIST, Tsukuba, Japan; [2]JSPS Res. fellow, Tokyo, Japan; [3]Dept. of Pathology, Keio Univ., Tokyo, Japan

Abstract: Ultraviolet (UV) light irradiation applied to living cells induces a variety of reactions including inflammation, DNA damage, and cell death. We previously reported that the destructive features of UV light can be used to create focal brain lesions on the cerebral cortex. In that study, almost no neurons were observed within an inverted bell-shaped UV lesion at 5 days after irradiation. The present study investigated the processes underlying neuronal degeneration after UV exposure. Adult Wistar rats were anesthetized and irradiated with UV light (UV-A; wavelength 365 nm, 2.0 mWh) through an optic cannula (flat circle, 400 µm in diameter) that was in contact with the dura mater at a targeted brain site (anterior parietal cortex; bregma -3.7 mm, 2.0 mm from the midline). The rats were perfused for histological analyses at six different timepoints after the irradiation: 2 h, 6 h, 12 h, 24 h, 3 days, and 5 days. Immunohistochemistry for NeuN, which is a neuronal marker, revealed that neuronal degeneration began in the bottom half of the lesion within 6 h after irradiation. At 24 h after irradiation, almost all neurons in the bottom half of the lesion had disappeared and there was an evident decrease in the number of neurons in the top half. At 3 days after irradiation, only a cluster of neurons in layer II/III remained, in the central part of the lesion. At 5 days after irradiation, almost no surviving neurons were observed. Terminal deoxynucleotidyl transferase (TdT) dUTP nick-end labeling (TUNEL) staining to detect apoptotic cell death revealed that apoptosis began at 2 h and that the neurons surviving at 3 days had already initiated this process. Taken together, the present results indicate that UV irradiation induced apoptotic cell death in the cerebral cortex, and that not all of the neuronal degeneration within the lesion occurred simultaneously. These findings suggest that neuronal tolerance to UV irradiation varies among the cortical layers.

Title: Attenuation of excitotoxicty induced molecular changes by NMDAR inhibitors

Authors: *M. KUMAR[1], S. PAUL[1], M. JOHN[1], M. MAYADEVI[1], J. JAMES[2], R. V. OMKUMAR[1]

Abstract: Over activation of Ca^{2+} channels cause excitotoxicity induced neuronal death in various neurodegenerative diseases. Molecular mechanisms leading to cell death under excitotoxic conditions are still not completely understood. In this study we are observing the changes at the level of protein expression as well as their post translational modifications upon exictotoxic insults through acute NMDA treatment via intracerebroventricular (ICV) injection and chronic monosodium glutamate (MSG) treatment via intraperitoneal (i.p) injection in adult male rats. Activation of calcium signaling by NMDA receptor is expected upon the above mentioned treatments. Methodology involves bilateral ICV injections of NMDA to rats for the acute treatment that was accompanied with prior ICV administration of NMDAR inhibitor, MK801 or CaM kinase inhibitor, KN93 or the vehicle. Chronic excitotoxic insult was caused by 15 days of MSG injection by i.p route to adult male rats, which were also orally administered with either vehicle or an NMDAR inhibitory plant extract. A group of animals were also fed with a known NMDAR inhibitory drug, dextromethorphan. Analysis by Morris water maze (MWM) test showed that the behavioral impairment caused by MSG administration could be ameliorated by simultaneous treatment with one of the NMDAR inhibitors, either the plant extract or dextromethorphan. We have shown increased p-GluN2B by immunoblotting in hippocampal and cortical tissues in both NMDA and MSG treated animals which were found to be attenuated by MK801 and the NMDAR inhibitory plant extract respectively. We have seen reduction of p-AKT and p-TrkB upon excitotoxic insults. Changes in the levels of other proteins related to calcium signalling and cell survival such as p-CREB and caspases are also being analyzed. Data from this study might provide new insights on signaling pathways during excitotoxic insults.

Title: Molecular mechanisms of neurodegeneration through the altered circadian clock

Authors: *Y. CHANG, M. CHOI, J. KIM
Cityu of Hong Kong, Hong Kong, Hong Kong

Abstract: Circadian clock, a cell-autonomous oscillator, presents in most of the cells to drive a 24-h cycle in biological and behavioral processes. The core clock mechanism is composed of a transcriptional negative feedback loop, where the transcription factor BMAL1-CLOCK drives the expression of their target genes including their own inhibitors, Period (PER) and Cryptochrome (Cry), as well as other circadian output genes. As several lines of epidemiological evidence have indicated a bidirectional linkage between altered circadian rhythms and neurodegeneration, we take effort in exploring the underlying mechanisms in this association. In this study, we found that circadian clocks were altered in the presence of neurotoxic stimuli via a decline activity of transcription factors BMAL1-CLOCK in primary neurons. In addition, focal adhesion pathway and intracellular tension signaling relating to cytoskeleton were identified as the affected processes by neurodegeneration through RNA sequencing analysis. Taken together, our works aims to provide a comprehensive insight into a relationship between circadian clock and neurodegeneration.

Abstract: Development of treatments for neurodegenerative disorders demands understanding the mechanisms that contribute to synaptic plasticity and the loss thereof. This in turn, requires methods to quantify the connectivity of a neuronal network with high accuracy and throughput. To meet this demand, we have established a microscopy-based assay that integrates morphological (nuclei, neurites, pre- and postsynaptic markers) and functional (spontaneous synchronous calcium activity) correlates of neuronal connectivity in mouse primary and human iPSC-derived neurons [1, 2, fig 1]. Using supervised and unsupervised classification approaches, we were able to establish a signature of neuronal maturation in primary cultures, that integrated a diverse set of connectivity features. We found that dilution of B27 medium supplement induced a gradual connectivity impairment as evidenced by a shift in the maturation signature. Dysregulation of microtubule stability, induced by pharmacological means or by MAPT-(P301L) overexpression, resulted in much more pronounced impairment [3]. Using a focused compound screen, we discovered that inhibition of dual leucine zipper kinase activity rescued the connectivity defects witnessed in both adverse conditions. This underscores the neuroprotective effect that has been described for this compound [4]. Our results illustrate that image-based profiling enables sensitive interrogation of neuronal connectivity. Therefore, the current approach holds promise for identifying pathways and treatments that preserve or rescue neuronal connectivity in neurodegenerative disorders.

Abstract: Phosphatidylinositol-binding clathrin assembly protein, *PICALM*, has been validated to be associated with Alzheimer's disease (AD). PICALM has an important biological role in facilitating the clearance of amyloid-β through the blood-brain barrier, as well as maintaining brain homeostasis. In developing neurons, PICALM provides proper function of synaptic transmission by regulating the size and density of synaptic vesicles. Studies have shown that protective *PICALM*-associated single-nucleotide polymorphism (SNP) $rs3851179^{A}$ is correlated with increased enthorhinal cortical thickness when compared to $rs3851179^{G}$ SNP. Here, we crossed $Picalm^{+/-}$ male with $Picalm^{+/-}$ female mouse and collected brains from $Picalm^{-/-}$, $Picalm^{+/-}$ and $Picalm^{+/+}$ embryos at E12.5, E15.5 and E18.5 developmental stage. At E15.5 and E18.5, we observed microcephaly in $Picalm^{-/-}$ embryos when compared to their $Picalm^{+/+}$ littermates, leading to their premature death *in utero*. However, $Picalm^{+/-}$ embryos do not exhibit any signs of degeneration and have similar phenotype as $Picalm^{+/+}$ embryos. Furthermore, we

found drastic differences in distribution of special AT-rich sequence binding protein 2 (SATB2), COUP-TF-interacting protein 2 (CTIP2) and T-box brain 1 (TBR1), transcription factors involved in post-mitotic differentiation of developing neurons and the thickness of neocortex was decreased by 50% in *Picalm*$^{-/-}$ when compared with *Picalm*$^{+/+}$ embryos. *In vitro* experiments with primary neuronal cultures further showed different patterns in neuronal maturation in *Picalm*$^{-/-}$ and *Picalm*$^{+/+}$ cells. Because PICALM plays a crucial role in endocytosis, PICALM deficiency has strong negative effect on the developing brain that is highly sensitive to protein turnover. Overall, our data demonstrate that PICALM has crucial role in the embryonic brain development.

Title: Smcr8 depletion disrupts lysosome function and induces inflammation in the immune system and nervous system

Authors: *C. LIANG[1], M. YANG[2], Q. SHAO[2], L. MA[2], J.-K. LEE[1], J. CHEN[2]
[1]Univ. of Georgia, Athens, GA; [2]USC, Los Angeles, CA

Abstract: Hexanucleotide repeat expansion in the first intron of *C9ORF72* gene causes the most common forms of familial FTD and ALS. We and other groups have previously identified that SMCR8 forms a protein complex with C9ORF72 and regulates autophagy initiation and flux. However, the *in vivo* function of SMCR8 is unknown. Here, we report that *Smcr8* knockout mice developed splenomegaly and lymphadenopathy. Mutant spleens exhibited increased numbers of CD68-positive macrophages and increased expression of inflammatory cytokines, including IL-1β, IL-6, TNF-α and IFN-1β. These phenotypes resemble the phenotypes observed in *C9orf72* null mice, therefore suggesting that SMCR8 and C9ORF72 not only physically interact but may also have similar functions. Indeed, both *C9orf72*-/- and *Smcr8*-/- mice displayed increased numbers of astrocytes in the hypothalamus. SMCR8 was previously identified as a component of purified lysosomes and *Smcr8* null MEFs displayed defects in lysosome-dependent autophagy. Using *Smcr8* depleted peritoneal macrophages, we found accumulation of enlarged autolysosomes without tubulation. Furthermore, mutant macrophages failed to disassemble

autophagosomses during long-term starvation and displayed a significant increase in cells with Lamp1 and LC3 double-positive autolysosomes. This suggests that depletion of SMCR8 disrupts autophagy lysosome reformation and impairs lysosomal degradation. Similar results were found within the hypothalamus of *Smcr8* knockout mice, which displayed accumulation of Lamp1-positive organelles. SMCR8 was previously identified to form a stable cognate protein complex with C9ORF72 that protects each other from degradation. Therefore, it is tempting to speculate that haploinsufficiency of C9ORF72/SMCR8 in FTD/ALS diseases leads to impaired lysosomal degradation, dysfunction of macrophages and astrocytes, and contributes to neurodegeneration.

Title: Transcriptomics analysis highlights the sexually dimorphic mechanical pain hypersensitivity mechanisms

Authors: *A. CHERNOV[1], S. K. HULLUGUNDI[2], K. A. EDDINGER[2], J. DOLKAS[2], A. G. REMACLE[1], M. ANGERT[2], B. JAMES[1], T. L. YAKSH[2], A. Y. STRONGIN[1], V. I. SHUBAYEV[2]
[1]Sanford-burnham-Prebys Med. Res. Inst., La Jolla, CA; [2]Dept. of Anesthesiol., Univ. of California San Diego, La Jolla, CA

Abstract: Females more frequently than males suffer from chronic pain. The sexual dimorphism mechanisms underlying the experience of pain from non-painful tactile stimuli (mechanical allodynia) have started to emerge. Here, we report a novel murine model of sexually dimorphic mechanical allodynia induced in female, but not male mice, by sciatic nerve injection of myelin basic protein 84-104 fragment (IS-MBP). Our RNA-seq analysis of the sciatic nerve, dorsal root ganglia (DRG) and the dorsal spinal cord transcriptomes in female and male mice exposed to IS-MBP revealed the sexually dimorphic regulation patterns in: (1) lipid metabolism signaling; (2) cell-mediated immunity signaling; (3) nociceptive, including glutamate and Ca2d1/calcium, (4) anti-nociceptive, including opioid and cannabinoid, receptor, signaling; (5) X-chromosome-linked TIMP-1 gene; (6) maternally-imprinted IL6, H19 and IGF2 genes and (7) non-coding

RNAs, including, the X-linked XIST, microRNA. The overall high variation in the expression of gene isoforms suggests a possible regulatory role of splice variants and UTRs. The greatest number of the sexually dimorphic gene regulation was dominant in DRG and spinal cord. Mitochondrial dysfunction and unfolded protein response were differentially induced by IS MBP relative to the controls. The present study offers a novel model and, to our knowledge, the first global molecular database of sexual dimorphism of neuropathic pain.

Title: Regulation of microglial function in aging brains by CSF-1 and GM-CSF

Authors: *V. CHITU, P. WANG, D. ZHENG, H. KETCHUM, E. R. STANLEY
Albert Einstein Col. of Med., Bronx, NY

Abstract: Adult onset leukoencephalopathy with axonal spheroids and pigmented glia (ALSP) is an adult onset dementia caused by dominantly-inherited inactivating mutations in the CSF-1 receptor kinase (CSF-1R). Our studies in the *Csf1r*$^{+/-}$ mouse model of ALSP suggest that aberrant activation of microglia by GM-CSF (also known as CSF-2) plays an important role in the pathology of ALSP. Indeed, removal of a *Csf2* allele rescued the cognitive and olfactory phenotypes of the *Csf1r*$^{+/-}$ mice, but not the loss of motor coordination. Unexpectedly, these studies showed that *Csf2*$^{+/-}$ mice exhibit olfactory, cognitive and motor phenotypes. However, these were milder than those of *Csf1r*$^{+/-}$ mice. To determine how reduction in *Csf1r* or *Csf2* expression alone, or in combination, affect microglial function in aged mice, we analyzed changes in the transcriptome of cerebral Tmem119^{+} microglia compared to wild type controls (n=3, females, 21 months of age). *Csf1r* heterozygosity led to the differential expression of 496 genes. Bioinformatic analysis indicated that *Csf1r* heterozygosity did not produce a neurotrophic defect or overt inflammatory activation of microglia. Rather, the transcriptional profile predicted a maladaptive phenotype characterized by changes in membrane proteins (40% of differentially expressed genes (DEGs)), unresponsiveness to deactivating stimuli and mitochondrial dysfunction that could result from changes in lipid metabolism. *Csf2* heterozygosity affected the

expression of 1168 genes in microglia. Similar to *Csf1r* heterozygosity, the neuropathology in *Csf2*$^{+/-}$ mice was not associated with a neurotrophic deficit or with inflammatory activation of microglia. Instead, GM-CSF insufficiency caused the activation of antioxidant and lipid metabolic pathways that are expected to be neuroprotective. However, it also promoted the expression of components of the complement system that has a well-established role in synapse loss in neurodegenerative disease. Examination of microglia isolated from *Csf1r*$^{+/-}$;*Csf2*$^{+/-}$ mice revealed a substantial reduction in DEGs (254) and restoration of most signaling pathways and biological processes affected by either single heterozygosity. Together, these data suggest that balanced signaling by CSF-1R and GM-CSF in microglia is critical for brain homeostasis during aging and that regulation of the redox status and lipid metabolism are converging targets.

Title: Functional characterization of TMEM163 single nucleotide polymorphisms

Authors: V. B. SANCHEZ, S. ALI, *M. P. CUAJUNGCO
Biol. Sci., California State Univ. Fullerton, Fullerton, CA

Abstract: Mucolipidosis type IV (MLIV) is a genetic lysosomal storage disorder caused by the dysfunction of Mucolipin-1 (TRPML1) ion channel. We previously reported an elevation of zinc within lysosomes of MLIV cells and identified Transmembrane (TMEM)-163 protein, a putative zinc transporter, as an interaction partner for TRPML1. Both proteins co-localize on the plasma membrane and lysosomal compartments. The function of TMEM163 is yet to be fully elucidated; however, it is predicted to have six transmembrane domains (TMD) and our data show that TMEM163 is an efflux transporter. To further study its function and how it might be involved in certain human diseases like MLIV, we used the single nucleotide polymorphism database (dbSNP) from the National Center for Biotechnology Information website to study specific sequence variations within the *TMEM163* gene. We identified SNPs that produce amino acid substitution (non-synonymous) when compared with the wild-type TMEM163 protein sequence. We then used bioinformatics to predict the topology of TMEM163 protein, and found that some non-synonymous SNPs are located in areas of the protein that could affect post-translational

modification and change its structure and function. Thus, we hypothesize that SNPs that affect post-translational modifications will disrupt the zinc efflux transport function of TMEM163 in cultured cells over-expressing the protein. To accomplish this study, we performed site-directed mutagenesis using In-Fusion homologous recombination cloning technique to systematically replace specific nucleotides corresponding to the SNPs located within or in proximity of N- and C-termini, as well as between TMD-1 and TMD-6. Upon sequence verification, we tested the effect of each SNP-associated mutant by transfecting them into cultured HEK-293 cells. Twenty-four hours post transfection, the cells were exposed to zinc chloride (10 μM) and zinc pyrithione (1 μM) and assayed for zinc flux using the zinc-specific, membrane impermeable FluoZin-3 AM dye. Our results confirmed that TMEM163 is a zinc efflux transporter and we found that the non-synonymous SNP mutants showed markedly lower zinc efflux relative to the wild-type control. Additional experiments using zinc specific dyes with different affinity are being conducted. Understanding the function of TMEM163 could explain the nature of its interaction with TRPML1 and its potential role on the observed zinc dyshomeostasis in MLIV cells.

Title: LncRNA NEAT1 in ethanol induced neuronal cell death

Authors: L. SHI[1], B. ZHENG[1], Y.-Y. MO[2], *J. WANG[1]
[1]Dept. of Pathology, [2]Dept. of Pharmacol. and Toxicology, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Background: Our previous work has demonstrated that ethanol increase the expression of Kruppel-like factor 11 (KLF11), a neuronal cell death mediator in brain of rodent treated with alcohol by binge or chronic feeding. Our preliminary data suggest that KLF11 functionally interacts with the Nuclear Enriched Abundant Transcript 1 (NEAT1), a long non-coding RNA playing roles in cell proliferation, growth. **Objectives**: The current work is to generate the stable expressing CRISPR/Cpf1 and NEAT1 dual gRNAs to decipher the role of the two isoforms of NEAT1 in this ethanol induced and KLF11 mediated neuronal cell death **Methods**: 1) Construct vectors that contain the nuclease AsCpf1 and gRNAs specifically

targeting to the interesting genes; 2) Establish stable NEAT1-1 or NEAT1-2 knockout cells by our recently established CRISPR/Cas mediated dual gRNAs technique; 3) Determine the role of NEAT1-1 and NEAT1-2 in ethanol treated cells; 4) Identify the interaction of NEAT1-1 and NEAT1-2 with KLF11 in ethanol induced cells death. **Results**: Our genotyping analysis indicated that we have successfully established a stable transfected CRISPR-Cpf1 SH-SY5Y cells which completely KO the NEAT1-1 from the genome with abolishing both transcripts of NEAT1-1 and NEAT1-2, suggesting that both isoforms share the same promoter; Treatment with 100mM or 150mM EtOH significantly increased the expression of NEAT1-2, but not NEAT1-1 in SH-SY5Y cells; There exists the interaction between NEAT1-2, but not NEAT1-1 with KLF11; The treatment of 100mM or 150mM EtOH disrupted the combination of KLF11 with NEAT1-2, without changing the co-localization between KLF11 and NEAT1-1. **Conclusion:** Our study demonstrates that this dual gRNA guided CRISP-Cpf1 system is a reliable approach to specifically knock out the lncRNA NEAT1. Establishment of NEAT1 isoform specific cell models provides a critical research tool for better understanding of how NEAT1 and its interaction with KLF11 are involved in ethanol induced neural cell death. As a result, NEAT1 may serve a therapeutic target for intervention.

Title: Contribution of the neuronal and microglial lineages to the behavioral phenotypes of $Csf1r^{+/-}$ ALSP mice

Authors: *F. BIUNDO[1], V. CHITU[2], G. S. SHLAGER[2], E. S. PARK[2], M. E. GULINELLO[2], K. SAHA[2], H. KETCHUM[2], E. R. STANLEY[2]
[1]Albert Einstein Col. of Med., Bronx, ; [2]Albert Einstein Col. of Med., Bronx, NY

Abstract: Adult onset leukoencephalopathy with axonal spheroids and pigmented glia (ALSP) is a dementia caused by dominantly-inherited mutations in *CSF1R* gene that result in CSF-1R kinase inactivation or disrupt expression. A *Csf1r* heterozygous mouse model of ALSP mimics the clinical symptoms, radiological and histological changes observed in human patients. In addition, we found an early olfactory impairment, as reported in other neurodegenerative disorders. Histological examination of brains from $Csfr^{+/-}$ mice revealed microgliosis and

elevation of several pro-inflammatory cytokines and chemokines, suggesting that microglial expansion and activation may have an important role in disease. Apart from microglia, the CSF-1R is also expressed by neural progenitors and subpopulations of cortical and cerebellar neurons. It is upregulated in hippocampal neurons in response to excitotoxic insult and cell-autonomously confers survival. Furthermore, the transient increase in cortical layer V neurons observed in young *Csf1r*$^{+/-}$ mice, followed by their normalization with age, suggest that CSF-1R supports the survival of aging neurons. Together, these data imply that *Csf1r* heterozygosity affects both microglial activation and neuronal survival. To explore the contribution of reduced neuronal and microglial CSF-1R signaling to neurodegeneration in ALSP, we employed two lineage-specific Cre deletion systems, *Nestin*^{Cre}, for the neural lineage and *Cx3Cr1*^{Cre}, for the microglial and monocytic lineages. *Csf1r*$^{fl/+}$*;Nes*^{Cre}/+ and *Csf1r*$^{fl/+}$*;Cx3Cr1*^{Cre}/+ mice were tested in a longitudinal battery of behavioral tasks to assess olfaction, memory, motor coordination and depression-like behavior (blinded studies of males and females, ≥14/genotype, followed from 7 to 18 months of age). Reduced *Csf1r* expression in microglia was sufficient to reproduce the olfactory and short-term memory deficits observed in *Csf1r*$^{+/-}$ mice. In contrast, neither lineage-specific deletion alone was sufficient to phenocopy the depressive behavior, long-term memory, or locomotor coordination deficits observed in *Csf1r*$^{+/-}$ mice. These data suggest that while dysregulation of microglia alone is sufficient to some behavioral phenotypes, alterations in both neuronal cells and microglia are necessary for others. Current studies are focused on addressing the cellular and molecular mechanisms involved.

Title: Microglial TREM2 mediatesTDP-43 protein aggregate clearance & neuroprotection in a mouse model of ALS

Authors: *M. XIE[1], Y. LIU[1], M. P. MATTSON[2], L. WU[1]
[1]Mayo Clin., Rochester, MN; [2]Lab. of Neurosciences, NIA Biomedial Res. Ctr., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease, which is characterized by the progressive loss of both upper and lower motor neurons in the brain and spinal cord, leading to muscle weakness and paralysis. Although it is generally believed that the disease onset is initially derived from selective motor neuron degeneration, the non-cell-

autonomous nature of this disease emphasizes the contribution of glia cells in disease progression. The TAR-DNA binding protein 43 kDa (TDP-43) is an RNA binding protein which was discovered to be the main component of intracellular, insoluble protein aggregates found within motor neurons in ALS pathology. Studies from rodent models of ALS demonstrate dynamic states of microglial morphology across different stages of ALS pathology, including a neuroprotective state in the early disease stage. However the underlying molecular mechanisms are still largely unknown. Triggering receptor expressed on myeloid cell 2 *(TREM2)* is a surface receptor that is exclusively expressed on microglia in the brain and plays a crucial role in microglial proliferation, migration and phagocytosis. Heterozygous expression of *TREM2* variants has been linked to increased risk for neurodegenerative diseases, including ALS. We recently generated an ALS-like motor neurodegenerative mouse model using viral overexpression of hTDP-43 protein in neurons (AAV9-CAG-hTDP43) or control vector (AAV9-CAG-GFP). In WT mice, overexpression of hTDP-43 resulted in progressive motor neuron loss, motor dysfunction and microglia activation. Reactive microglia cleared TDP-43 aggregates, preventing the spread of hTDP-43 proteinopathy to nearby neurons. On the other hand, the absence of TREM2 significantly increased neuronal loss and worsened motor dysfunction. Using two-photon *in vivo* imaging, we observed the direct response of microglia to hTDP-43 protein following a stereotaxic injection into the motor cortex, dramatically increasing their process motility after hTDP-43 injection. Our results reveal a TREM2-mediated neuroprotective role for microglia in the hTDP-43 overexpression model of ALS-like motor neuron degeneration.

Title: Extracellular vesicular transport in HIV-1 Tat protein and morphine directed microRNA changes in astrocytes on HIV-associated neurocognitive disorders (HAND)

Authors: *K. CHEN[1,2], L. SARDO[1], S. MITA[1], Z. A. KLASE[1]
[1]Dept. of Biol. Sci., Univ. of the Sci., Philadelphia, PA; [2]Philadelphia Col. of Osteo. Med., Philadelphia, PA

Abstract: HIV-associated neurocognitive disorder (HAND) impacts nearly one-half of HIV-infected patients. Astrocytes harbor latent HIV-1 that can produce appreciable amounts of

neurotoxic viral proteins, such as HIV-1 Tat. Evidence for Tat protein and morphine have both been implicated in exacerbation of HAND. We predict aberrant microRNA intracellular changes in astrocytes impair their ability to support neurons and moreover act as a driver for ongoing neuroinflammation through extracellular vesicles (EVs) to bystander cells. Tat protein can inhibit Dicer endoribonuclease cleavage necessary for miRNA maturation. Our objective is to determine the role of miRNAs altered by Tat and morphine in HAND through EVs. We cultured astrocytes and 293Ts, transfected with Tat plasmid, and treated with morphine. Luciferase reporter assay was used to quantify β-catenin activity, a neuroprotective pathway in astrocytes and biological activity of Tat EVs in TZMbl cells. We then profiled changes of 380 miRNAs by RT-qPCR on Tat and morphine treated cells. Cell supernatant was collected and processed for EVs. In astrocytes, morphine increased the suppressive ability of Tat on β-catenin activity compared to Tat alone in a dose-specific manner. We found that 90 miRNAs were uniquely dysregulated by a 3-fold change or more in combined Tat and morphine treatment. We found significant activation of the HIV-1 LTR in our TZMbl assay after treatment with our extracellular Tat-EV isolates and found Tat to be stable in EVs for over 20 days stored in 4 degrees Celsius. We observed morphine's ability to increase the suppressive ability of Tat on β-catenin activity in a dose-dependent manner. Our finding suggests worsening neuropathology in joined Tat and morphine interactions. Continuing experimentation and data will include miRNA profile in EVs, the relationship between intracellular and extracelluar miRNA changes, and biological impact of these EVs on neuroinflammatory related pathways in uninfected cells.

Abstract: Despite combined antiretroviral therapy (cART) effectively inhibiting HIV viral replication and extending life, about 50% of all HIV+ individuals develop HIV-Associated Neurocognitive Disorders (HAND). HIV infection of perivascular macrophages, microglia, and astrocytes in the brain occurs early in disease, and has been linked to persistent neuroinflammation and cognitive impairment even when peripheral viral loads are suppressed. HAND symptoms have also been linked to upregulated expression of the primary glutamate-synthesizing enzyme, glutaminase, which may contribute to observed excess glutamate production in the brain leading to aberrant excitatory neurotransmission, excitotoxicity, and impaired cognitive function. Glutaminase inhibition may thus represent a novel drug target to confirm treatment of HAND. We recently developed JHU083, an orally available, brain penetrant prodrug of the glutaminase inhibitor 6-diazo-5-oxo-l-norleucine (DON). Here, we show that JHU083 reduces excess glutamate levels in the central nervous system, normalizes microglia glutaminase activity and restores cognitive function in HIV-infected mouse models. Therefore, glutaminase inhibition can reduce toxic glutamate levels and may serve as a novel target for HAND treatment.

Title: HIV-1 and HIV proteins interact with morphine to induce loss of KCC2 and GABAergic dysfunction in primary human neurons in a NMDAR and CCR5 dependent manner

Authors: *A. J. BARBOUR[1], J. M. BALINANG[1], A. R. MCQUISTON[1], K. F. HAUSER[2], P. E. KNAPP[3]
[2]Pharmacol. & Toxicology, [3]Dept Anat & Neurobio., [1]Virginia Commonwealth Univ., Richmond, VA

Abstract: Despite the introduction of combined antiretroviral therapy, the CNS remains highly susceptible to insult from HIV-1 and inflammatory factors which cause sublethal damage to bystander neurons, providing the neural basis of HIV-associated neurocognitive disorders (HAND). Opiate use is often comorbid with HIV infection and these patients show exacerbated HAND symptomology. Little is known about electrophysiological changes associated with HIV ± morphine co-exposure. We addressed this question by developing a dissociated primary human model derived from differentiating human neural progenitor cells (hNPC) into a mixed neuron-astrocyte culture containing glutamatergic and gamma-aminobutyric acid-(GABA)ergic neurons. Optical techniques were used for electrophysiological experiments, thus circumventing the biohazard of sharp electrodes in the presence of HIV. With genetically encoded voltage indicators (GEVI), Flicr1/Archon1, and genetically encoded calcium indicator (GECI), GCaMP6f, we measured primary human neuron electrophysiological and calcium activity to elucidate changes in excitatory-inhibitory balance due to HIV ± morphine exposure. We determined that HIV and morphine both dysregulate neuronal $[Cl^-]_i$ resulting in hyperexcitability. K-Cl cotransporter 2 (KCC2) maintains low $[Cl^-]_i$ necessary for $GABA_AR$-induced hyperpolarization. Thus, we hypothesized that both HIV and morphine decrease expression/activity of KCC2 leading to dysregulated $[Cl^-]_i$ and loss of subsequent $GABA_AR$ hyperpolarization. This was confirmed by immunostaining experiments that showed significant loss of KCC2 in neurons exposed to supernatant from HIV-infected monocytes (250-500 pg/mL p24) and 500nM morphine in the absence of neuron death. We have further determined that the viral proteins transactivator of transcription (Tat) and glycoprotein 120 (gp120; R5-tropic) contribute to KCC2 loss. These results correlate with significant defects of GABA-ergic signaling in primary human neurons exposed to HIV, or HIV proteins ± morphine. KCC2 expression and response to GABA were rescued by co-exposure with KCC2 activity enhancer, CLP257. Our data identify KCC2 and upstream activity as a promising, novel target for therapeutic intervention to alleviate functional changes underlying HAND ± opiate use.

Abstract: Opiates exacerbate HIV-induced neuropathogenesis within vulnerable regions of the central nervous system. Within the hippocampus of mice expressing doxycycline-inducible HIV-1 protein *transactivator of transcription* (Tat), 2 weeks of Tat exposure reduced apical dendritic spine density on dentate gyrus (DG) granule cells ($p = 0.008$), CA1 pyramidal neurons ($p < 0.001$), and CA3 pyramidal neurons ($p < 0.001$) *in vivo*, while simultaneous morphine exposure (escalating s.c. injection b.i.d., 10-40 mg/kg) did not have a significant effect. *In vitro*, prolonged (72 h) exposure to Tat (100 nM) reduced primary murine hippocampal neuron survival, particularly GAD67+, GABAergic cells ($p < 0.001$). Acute Tat exposure increased neuronal intracellular calcium concentration ($[Ca^{2+}]_i$) by 193.9 ± 53.9% compared to controls, which was exacerbated by morphine (312.0 ± 31.5%) and reversed by $GABA_A$ agonist muscimol (100 nM, three-way interaction, $p < 0.001$). $[Ca^{2+}]_i$ returned to baseline within 20 min in Tat-exposed cells (114.4 ± 30.3%); however, $GABA_A$ antagonist bicuculline (20 µM) prolonged Tat-induced elevation of $[Ca^{2+}]_i$ in the presence of morphine (208.0 ± 22.8%, $p < 0.001$). To identify key sources of Tat-induced calcium influx, potential extracellular [NMDAR (MK-801), AMPAR (CNQX), L-type Ca^{2+} channels (nimodipine, isradipine)] and intracellular [$RyR_{1,3}$ (dantrolene), σ_1R (BD-1063)] calcium sources were blocked pharmacologically. Tat-induced $[Ca^{2+}]_i$ was significantly reduced by nimodipine (10 µM, $p < 0.001$) and MK-801 (20 µM, $p < 0.001$), but not BD-1063 (1 µM, $p = 0.381$). Morphine-induced calcium influx was reduced by isradipine (5 µM, $p = 0.009$) and BD-1063 ($p = 0.038$). Bicuculline and morphine interactive effects within Tat-exposed cells were reduced by CNQX (500 nM, $p < 0.001$). Overall, these data indicate morphine, $GABA_AR$, and HIV-1 Tat elevate $[Ca^{2+}]_i$ within hippocampal neurons through both independent (i.e., AMPAR, NMDAR, RyR, σ_1) and shared (i.e., $Ca_v1.2$) calcium sources. While 2 wks morphine exposure showed limited additive impact on dendritic spine density in vivo, the morphine-dependent alterations in calcium homeostasis may ultimately contribute to structural deficits within hippocampal neurons. GABAA signaling ameliorates Tat-induced [Ca2+]i as shown by muscimol, which could ultimately contribute to structural and behavioral outcomes in vivo. We hypothesize that the potential loss of the vulnerable GABAergic interneuron subpopulation within the hippocampus may exacerbate opiate- and HIV-induced neuropathology.

Title: Role of dopamine in the modulation of macrophage-mediated inflammation: Implications for NeuroHIV and neurodegenerative disorders

Authors: *R. NOLAN[1], R. MUIR[2], S. MATT[1], E. NICKOLOFF[1], K. RUNNER[1], E. K. HADDAD[2], P. J. GASKILL[1]
[1]Pharmacol. and Physiol., [2]Med., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Despite the success of combination anti-retroviral therapy (cART), around 50% of HIV-infected individuals still display a variety of neuropathological and neurocognitive sequelae known as NeuroHIV. Current research suggests these effects are mediated by long-term changes in CNS function in response to chronic infection and inflammation, and not solely due to active viral replication. Among these changes are alterations in dopaminergic signaling and increased inflammation in dopamine-rich brain regions. In the post-cART era, drug abuse is one of the most prominent risk-factors for the development of NeuroHIV. All drugs of abuse increase extracellular dopamine in the CNS, and our lab has shown that dopamine can increase HIV infection of primary human macrophages and increase the production of inflammatory cytokines. These and other studies showing correlations between dopaminergic dysfunction and severity of NeuroHIV suggests that elevated dopamine could enhance the development of HIV-associated neuropathology. However, the precise mechanism(s) by which elevated dopamine could exacerbate the progression of NeuroHIV, particularly in chronically-infected, virally suppressed individuals, remain unclear. Within the CNS, the primary targets for HIV are myeloid lineage cells, such as microglia and perivascular macrophages. Thus, to determine the connection between dopaminergic alterations and HIV-associated neuroinflammation, we have examined the impact of dopamine exposure on inflammatory functions of macrophages and microglia. Our data show that dopamine treatment of human macrophages isolated from healthy and cART-treated donors promotes a inflammatory phenotype in these cells by inducing production of inflammatory mediators including IL-1β, IL-6, CCL2, CXCL8, CXCL9, and CXCL10. Further, dopamine-mediated modulation of specific cytokines is correlated with macrophage expression of dopamine-receptor transcripts, particularly DRD5, which we show to be expressed at significantly higher levels than other dopamine-receptor subtypes. Dopamine exposure in human macrophages also activates inflammatory pathways such as caspase1, leading to downstream

activation of the inflammasome, potentially via epigenetic modulation. Moving forward we are focused on elucidating the effect of dopamine on production of cytokines and neurotrophic factors, as well as inflammasome activation in iPSC-derived microglia. Overall, these data will provide more understanding of the role of dopamine in the development of NeuroHIV, and may suggest new molecules or pathways that can be useful as therapeutic targets during HIV infection.

Title: Dopamine increases macrophage susceptibility to HIV infection through activation of non-canonical signaling pathway

Authors: *P. J. GASKIL[1,2], E. A. NICKOLOFF[2], R. NOLAN[3], K. RUNNER[2]
[2]Pharmacol. & Physiol., [3]Neurobio. and Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Despite the success of antiretroviral therapy (ART), the neurological effects of HIV infection remain a major health issue. The constellation of neuropathologies, behavioral, cognitive and motor impairments now collectively known as NeuroHIV, affects around 50% of infected individuals. These effects are driven by infection and subsequent dysfunction in myeloid cells, such as macrophages and microglia, which are the primary targets for HIV in the CNS. Our studies show myeloid cells exposed to the neurotransmitter dopamine have an increased susceptibility to HIV infection, potentially enhancing the spread of infection within the brain. The number of myeloid cells exposed to dopamine is greatly increased in the CNS of drug abusers, a common comorbidity with HIV infection. Although drugs have different mechanisms of action, all drugs of abuse exert their addictive and reinforcing effects through elevation of CNS dopamine. In addition, dopaminergic therapeutics, such as those for depression, Parkinsons, Alzheimers, diabetes and some cancers could also elevate CNS dopamine. As myeloid cells are exposed to dopamine due to spillover during neurotransmission, the effects of exogenously induced changes in dopaminergic tone could exacerbate the development of NeuroHIV. Our research demonstrates that dopamine concentrations of 10^{-8}M or higher significantly increase the entry of HIV into primary human macrophages. This increase is due to the activation of either D1-like or D2-like dopamine receptors, suggesting that in MDM, both types of receptors may act

through a common pathway. Canonically, D1-like receptors couple to $G_{\alpha s}$ to activate cyclic AMP (cAMP), resulting in phosphorylation of PKA, while D2-like receptors couple to $G_{\alpha i}$ to inhibit cAMP. Our data show that in MDM, this pathway is not active, and that dopamine receptors act through an alternative pathway mediated by $G_{\alpha q}$ or $G_{\beta\gamma}$ activation of PLC and PKC, increasing IP_3 and Ca^{2+} release. This pathway seems to be mediated, at least partially, by DR5, which is the most prominently expressed DRD transcript in these cells. Further, inhibition of this pathway by blocking Ca^{2+}release with Dantrolene completely abrogates the impact of dopamine on HIV infection in these cells. These data indicate dopamine mediates its effects on HIV infection through elevations in intracellular Ca^{2+}, and indicate that HIV infection involves previously unknown cellular pathways. Further, these data indicate that dopamine signaling in macrophages is biased toward a non-canonical signaling pathway and suggest that this pathway could be a novel therapeutic target to ameliorate the impact of drug abuse on NeuroHIV.

Title: Effects of S-Equol on norepinephrine and dopamine receptor mRNA expression in the HIV-1 transgenic rat prefrontal cortex

Authors: *A. K. COOK[1], K. A. MCLAURIN[2], H. LI[3], C. F. MACTUTUS[4], R. M. BOOZE[5]

Abstract: HIV-1 infection affects over 36 million people worldwide, and despite combination antiretroviral therapy, neurocognitive disorders such as mild cognitive impairment persist along the trajectory of the disease. HIV-1 is known to alter neurochemistry, however, there is no known treatment for this neurochemical disruption. Forming the gut-brain axis, gut microbiota acts through neurotransmitter systems and immune interactions to affect emotional and social behavior as well as cognitive processing. S-Equol is produced naturally by gut microbiota in most individuals, acting as a beta estrogen receptor agonist. It is thought to alter neurochemistry

through the mesolimbic noradrenergic system and dopamine system, producing a neuroprotective effect. Previous studies have shown that S-Equol treatment is effective in promoting neurorecovery against Tat, an HIV-1 viral protein, as well as preventing HIV-1 Tat induced apoptosis. Testing the effectiveness of S-Equol on HIV-1 transgenic rats, treatment was given during a formative period of PD 28 through PD 90 at a dose of 0.2 mg/day. After a history of operant training, an innovative RNA *in situ* hybridization assay (RNAScope) was used to label mRNA expression of the norepinephrine receptor, alpha-2, and the dopamine receptor, DrD1, in the prefrontal cortex. Preliminary results suggest a sex dependent shift towards higher cell scores in alpha-2 mRNA transcript levels in females, independent of genotype; an effect not observed in males. A sex and genotype dependent shift in DrD1 mRNA levels was also found, shifting the cell scores of the HIV-1 transgenic rats treated with S-Equol towards their placebo treated control counterparts. By examining the neural mechanism of S-Equol, potential therapeutic uses of this treatment may be identified. Funded by NIH grants DA013137, HD043680, MH106392, NS100624.

Title: HIV-associated cognitive deficits; sex and regional specific outcomes correlate with changes in activity-regulated cytoskeleton (Arc) expression

Authors: *Y. K. HAHN[1], W. D. MARKS[2], S. R. NASS[2], S. KIM[1], J. J. PARIS[3], K. F. HAUSER[2], P. E. KNAPP[1]

Abstract: The introduction of combined and highly active anti-retroviral therapies (cART) has transitioned HIV from a disease with short-term survival into a chronic disease and has changed the profile of HIV-associated neurocognitive disorders (HAND). While severe neurocognitive deficits leading to dementia are now rarely found, the prevalence of mild and moderate cognitive and motor deficits has remained constant or increased, even among patients with systemic viral suppression. This phenomenon likely reflects inefficient penetration of current antiretroviral drugs through the blood brain barrier, which allows the central nervous system (CNS) to exhibit

low levels of persistent infection. HIV-infected patients commonly show neurocognitive deficits that affect memory, attention/concentration, mood, and fine motor skills. Furthermore, although the percentage of women in the HIV-infected population has increased, sex-related effects on memory/cognition deficits in HIV patients remain unclear. We utilized a transgenic mouse model of HIV (conditionally expressing HIV-1 Tat_{1-86} protein in CNS) and examined both males and females for changes in cognitive behavior and for expression of biochemical markers related to memory and learning, especially the Arc protein. Arc is an immediate early protein, and its expression can be induced by any environmental experience leading to learning and memory. Altered Arc expression is involved in disruption of memory after radiation therapy. The induction of Arc occurring after contemporaneous acoustic/odor stimuli was reduced by HIV-1 Tat exposure in both sexes, although Arc expression remained significantly higher in Tat^+ females compared to males. Multiple cognitive behavioral tests showed that only Tat^+ males exhibited significant deficits in spatial memory, increased anxiety and altered extinction of fear. Sex-specific differences were also found in both Arc cell signaling pathway proteins and other memory-associated proteins such as Homer1 and Zif268 in hippocampal lysates. We also examined spine density in different brain regions, male Tat^+ mice showed significant reductions of spine density in hippocampus and striatum, but not in amygdala. Parallel results were seen in levels of Arc protein expression *in vivo*. Interestingly, treatment with BDNF for 4 h significantly increased Arc levels in hippocampal organotypic slice cultures +/- Tat exposure. Overall, our results indicate that sex may influence HIV-1 Tat protein-related effects on cognition and anxiety, and that some sex-related outcomes correlate with regionally specific changes in Arc-associated cell signaling.

Title: Sexual dimorphism in the gene expression of cerebrocortical neurotransmitter systems in hiv gp120 transgenic mice

Authors: *N. Y. YUAN[1], A. B. SANCHEZ[2], M. KAUL[3,4]
[1]Biomed. Sci., UCR Sch. of Med., Riverside, CA; [2]Dept. of Psychiatry, Univ. of California San

Diego, La Jolla, CA; [3]Biomed. Sci., SOM, Univ. of California Riverside, Riverside, CA; [4]Infectious and Inflammatory Dis. Ctr., Sanford Burnham Prebys, La Jolla, CA

Abstract: Human immunodeficiency virus (HIV)-associated neurocognitive disorder (HAND) is estimated to affect around half of the HIV-positive population. The neurocognitive symptoms of HAND affect not only survival and quality of life but can also impact everyday functioning. Despite advancing strategies to suppress the virus through combination antiretroviral therapy (CART), HAND has persisted in these individuals. Studies in our laboratory utilize transgenic mice expressing the viral envelope protein gp120 under the control of a modified GFAP promotor in astrocytes (gp120tg mice). These mice (C57BL/6 x SJL background) exhibit neuronal damage and differential gene expression resembling that observed in brains of patients with HAND.

In humans, males and females exhibit neurochemical sex differences which have been implicated in diseases that differentially affect men and women. The global proportion of men vs women has been approximately 50% (UNAIDS) since the late 1990s. However, the predominance of HIV among men in the United States (CDC: 76% vs 24%) has led to an underrepresentation of women in clinical and preclinical studies. Evidence from previous small-scale studies indicates that HIV-positive women may have an increased risk for neuropsychological impairment. Thus, increasing the understanding of how biological sex affects HAND can provide essential information required for future development of improved personalized treatment strategies.

In this study, we describe the sex differences observed at RNA level in both the dopamine/serotonin and GABA/glutamate neurotransmitter systems in the cerebral cortex of 6 month old mice with and without transgenic expression of viral gp120 protein. Among wild type (WT) males without gp120, there is a lower expression of many genes in the dopamine/serotonin pathway (Drd5, Slc18a1, Arrb1, etc; p&lt0.05) compared to WT females. In gp120+ males, there is a similar downregulation of the dopamine/serotonin pathway but with discrete changes in the genes (Drd4, GFAP, Htr6, etc; p&lt0.05). In the GABA/glutamate system, there were significant differences in WT males; both upregulation (Gria2, Gabra1, Gabra5, etc; p&lt0.05) and downregulation (Gabre, Grin2c, Grik5, etc; p&lt0.05) when compared to WT females. In gp120+ males, most alterations were upregulated compared to gp120+ females (Gria2, Gabrg1, Gabra1; p&lt0.05). These findings indicate that there are substantial sex differences in the cerebrocortical RNA expression profiles of major neurotransmitter systems in both WT and gp120 transgenic animals.

Title: Homeostatic changes in CA1 pyramidal neurons of the hippocampus from HIV transgenic rats

Authors: *I. V. SOKOLOVA[1], A. SZÜCS[2], P. P. SANNA[3]
[1]Immunol., The Scripps Res. Inst., San Diego, CA; [2]UCSD, La Jolla, CA; [3]Mol. and Cell. Neurosci., Scripps Res. Inst., La Jolla, CA

Abstract: We used HIV transgenic (Tg) rats and the patch-clamp technique to study the effect of chronic low-level expression of HIV viral proteins on CA1 pyramidal neurons of the hippocampus. Electrophysiological properties of CA1 pyramidal neurons in acute slices from both dorsal and ventral areas of the hippocampus from HIV rats were compared to those in their counterparts from wild-type control rats. We found increased excitatory inputs onto pyramidal neurons in the two hippocampal regions. However, these increases were mediated through distinct mechanisms in the dorsal and ventral hippocampi. CA1 pyramidal neurons in the dorsal hippocampus of HIV Tg rats displayed elevated rate of excitatory postsynaptic currents (EPSCs), while CA1 pyramidal neurons in the ventral hippocampus of HIV Tg rats showed increased EPSC amplitudes. The enhanced excitatory input onto CA1 pyramidal neurons in HIV rats was associated with overall decrease of neuronal intrinsic membrane excitability. Neurons of HIV Tg rats were significantly more hyperpolarized than the control neurons. In experiments using conventional protocol of neuronal stimulation by current injection, the minimal stimulation current in neurons of HIV Tg rats was significantly higher than that in control neurons. The action potential (AP) rise time and the AP ½ width in HIV neurons were increased. The finding of reduced excitability was confirmed in experiments in which the dynamic clamp protocol was used to stimulate neuronal spiking activity. In both areas of the hippocampus, the minimal synaptic conductance required to trigger neuronal firing was higher in HIV neurons. We used neuronal modeling to examine whether diminished I_h in HIV neurons could account for their reduced excitability. Enhanced glutamatergic inputs and reduced excitability in CA1 pyramidal neurons of HIV rats may represent coordinated homeostatic changes aimed at stabilizing firing rates in the hippocampus of HIV Tg rats.

Title: Voltammetric analysis of escitalopram treatment in the HIV-1 transgenic rat: Implications for comorbid HIV and depression

Authors: *A. DENTON[1], S. BERGER[2], C. F. MACTUTUS[3], S. B. HARROD[4], P. HASHEMI[1], R. M. BOOZE[5]
[1]Univ. of South Carolina, Columbia, SC; [2]Univ. of South Carolina, Columbia, SC, SC; [3]Psychology, Univ. of South Carolina Dept. of Psychology, Columbia, SC; [5]Dept Psychol, [4]Univ. South Carolina, Columbia, SC

Abstract: HIV-1 infection is a serious condition affecting approximately 37 million people as of 2015. Despite the advent of combination antiretroviral therapy (cART), approximately 50% of seropositive individuals report some degree of clinical depression. The HIV-1 transgenic (Tg) rat contains seven of the nine genes that comprise the HIV viral genome and represents a non-infectious rodent model of HIV-1. The present study examined the effects of chronic escitalopram treatment on dopamine (DA) and serotonin (5-HT) in the HIV-1 Tg rat. Escitalopram is a selective serotonin reuptake inhibitor (SSRI) that is commonly prescribed for the treatment of clinical depression. In order to evaluate the release and reuptake kinetics of DA and 5-HT, fast-scan cyclic voltammetry (FSCV) was employed. Adult male and female HIV-1 Tg and F344/N control animals were subcutaneously implanted with an escitalopram pellet (4 mg) or placebo pellet. At least 2 weeks following pellet implantation, animals were anesthetized and a stimulating pin was placed in the medial forebrain bundle and a recording carbon-fiber microelectrode was placed in the nucleus accumbens for DA. For 5-HT, the recording carbon-fiber was placed in the hippocampus. Consistent with our previous findings using ex vivo brain slice preparations, impaired DA release and reuptake was found in HIV-1 Tg rats relative to controls; however, chronic treatment with escitalopram did not attenuate the dopaminergic deficits. Impaired 5-HT release was found in the HIV-1 Tg rat hippocampus. Although escitalopram treatment did not increase 5-HT function in HIV-1 Tg rats, a temporal shift in peak 5-HT was observed. Collectively, these findings suggest that escitalopram treatment in HIV-1 Tg rats did not alter DA kinetics, but alterations in 5-HT suggested a mechanism for antidepressant actions in HIV-1 infected patients.

Title: Disruption of timing: NeuroHIV progression in the post-cART era

Authors: *K. A. MCLAURIN, H. LI, R. M. BOOZE, C. F. MACTUTUS
Dept. of Psychology, Univ. of South Carolina, Columbia, SC

Abstract: By 2030, approximately 73% of HIV-1 seropositive individuals will be 50 years or older, heralding an examination of the progression of HIV-1 associated neurocognitive disorders (HAND). A longitudinal experimental design was used to assess progression of the core components of executive function across the functional lifespan in the HIV-1 transgenic (Tg) rat, resembling HIV-1 seropositive individuals on lifelong combination antiretroviral therapy. At the earliest assessment (i.e., approximately 2 months of age), the factor of biological sex was the driving factor for observed differences in task acquisition, tapping learning, and signal detection, tapping sustained attention [HIV-1 Tg (*N*=20 litters; male: *n*=37, female: *n*=33); F344/N Control (*N*=17 litters; male: *n*=34, female: *n*=33)]. Despite the "savings" afforded by repeated testing, HIV-1 Tg animals exhibited progressive, relative impairments in the completion of signal detection and the detection of shorter signal durations; deficits which became most prominent in male HIV-1 Tg animals at 18 months of age. A reversal task, tapping flexibility and inhibition, revealed marked impairment in HIV-1 Tg rats, with sex-dependent deficits in task acquisition and the detection of shorter signal durations. Examination of dendritic spine branch order in layers II-III pyramidal neurons of the medial prefrontal cortex revealed a profound distributional shift, with a greater relative frequency of spines on lower order branches, in HIV-1 Tg animals relative to controls, supporting an alteration in synaptic connectivity. Both neurocognitive alterations and synaptic dysfunction were independent of neuroinflammation. A differential relationship between dendritic spine branch order and signal detection during reversal in HIV-1 Tg and control animals supports a primary mechanism for HAND. Thus, even in the absence of comorbidities, HAND is a neurodegenerative disease characterized by sex dependent, progressive neurocognitive impairments across the functional lifespan; impairments which may be due, at least in part, to alterations in synaptic connectivity. Title: Impaired neurogenesis in the HIV-1 transgenic rat and recovery with physical activity

Authors: J. LAPOINTE, M. CRANSTON, V. MADORMO, C. MACTUTUS, S. HARROD, *R. M. BOOZE
Dept Psychol, Univ. South Carolina, Columbia, SC

Abstract: Prior evidence suggests that the HIV-1 associated protein Tat affects neuronal proliferation and substantially inhibits neurogenesis. Similarly, the HIV-1 envelope protein gp120 can affect progenitor proliferation, potentially affecting neurocognitive processes involved in HIV-1 Associated Neurocognitive Disorders (HAND). Physical activity is known to increase dentate gyrus hippocampal adult neurogenesis. In the current study, we examined if voluntary nocturnal wheel running would promote neurogenesis and neuronal maturation of the dentate gyrus in HIV-1 Tg rats compared to F344/N controls. Adult HIV-1 Tg female animals (n=20) and F344/N female control animals (n=20) were compared to adult HIV-1 Tg male animals (n=20) and F344/N male controls (n=20). All animals were provided nocturnal access to a running wheel for 67 minutes/day for a minimum of 85 consecutive days, with half of the running wheels immobilized (sedentary condition). Following wheel running, animals were immediately sacrificed and brain slices were evenly divided, with alternating hippocampal slices processed for either doublecortin (DCX) immunostaining or with ballistically-delivered DiI, followed by 3-dimensional dendritic spine analysis. In female HIV-1 Tg animals, wheel running significantly increased the number of DCX+ granule cells in the dentate gyrus and decreased DCX+ numbers in HIV-1 Tg males ($p \leq .05$). The number of less mature DCX+ cells (without dendrites) was significantly decreased in HIV-1 Tg animals ($p \leq .05$). DCX+ granule cells with dendrites (more mature than DCX+ soma-only granule cells) showed significant differences between the sexes ($p \leq .05$), and a significant interaction between running condition and animal sex ($p \leq .05$). Dentate granule cell spine morphology differed between HIV-1 Tg and control animals, with increased spine length, head diameter, and volume in the HIV-1 Tg wheel running

animals compared to sedentary HIV-1 Tg animals. Thus, HIV-1 impairs adult hippocampal dentate granule cell neurogenesis and interferes with the integration of newborn cells into the dentate gyrus and this integration may, in part, be restored by physical activity.

Title: Behavioral analysis of escitalopram treatment in the HIV-1 transgenic rat

Authors: A. U. LATEEF, A. K. COOK, N. G. QUAN, A. R. DENTON, *C. F. MACTUTUS, S. B. HARROD, R. M. BOOZE
Psychology, Univ. of South Carolina, Columbia, SC

Abstract: As of 2015, 37 million people worldwide are living with HIV-1, with nearly forty-thousand new cases of HIV-1 infection occurring in the United States alone. Despite the relative success of combination antiretroviral therapy (cART) in treating the illness, roughly half of all individuals suffering from HIV-1 infection will experience comorbid depression. The present study seeks to examine the effects of chronic exposure to escitalopram (14.76 mg pellet) upon behavioral markers of depression and apathy in the HIV-1 transgenic (Tg) rat. Escitalopram is a selective serotonin reuptake inhibitor (SSRI) that is commonly prescribed for depression and is recognized as a safe addition to cART treatment. In order to evaluate depressive symptoms in HIV-1, a battery of behavioral tests were administered to adult male and female HIV-1 Tg and F344/N control rats. To evaluate startle response, prepulse inhibition of the acoustic and visual startle was employed. Apathy, a core component of depression was evaluated using a five-bottle sucrose preference test. Both a modified hole board test and an elevated plus maze test was used to evaluate exploratory behaviors. Consistent with our previous reports, significant prepulse inhibition deficits were found in HIV-1 Tg, relative to F344/N control rats. Escitalopram had limited effectiveness in attenuating this deficit. Sex differences were observed in exploratory behaviors, but escitalopram did not appear to modify exploratory behaviors in either HIV-1 Tg

or F344/N control rats. Finally, although escitalopram treatment did not appear to shift sucrose preference in HIV-1 Tg or F344/N control rats, a curvilinear dose-response shift across sucrose concentration was observed in the HIV-1 Tg rats, suggesting motivational alterations. Collectively, these findings show that escitalopram may have limited effectiveness in mitigating behavioral markers of depression in the HIV-1 Tg rat.

Title: HIV-1 Tat alters anterior cingulate cortex morphology and executive functioning in a transgenic mouse model of neuro-HIV

Authors: *S. R. NASS[1], Y. HAHN[2], N. VARSHNEYA[3], P. E. KNAPP[2], K. F. HAUSER[3]
[1]Dept. of Pharmacol. and Toxicology, Virginia Commonwealth Univ. Hlth. Syst., Richmond, VA; [2]Dept. of Anat. & Neurobio., [3]Pharmacol. & Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Although combined antiretroviral therapies (cART) have improved the mortality and quality of life of HIV patients, approximately 30-50% develop neurocognitive impairments, including deficits in executive functioning, such as attention problems and impulsivity. In the central nervous system HIV-1 proteins, such as HIV-1 trans-activator of transcription (HIV-1 Tat), can be expressed leading to deleterious effects on neuronal morphology and function, and may underlie the development of neurocognitive deficits. The present study tested the hypothesis that HIV-1 Tat disrupts behavior and neuronal dendrite morphology associated with executive functioning. CNS expression of HIV-1 Tat under the control of a glial fibrillary acidic protein-driven, *tet*-on promoter was induced by administering doxycycline for 2-8 weeks in adult male, transgenic mice. A relatively short duration (2 weeks) of HIV-1 Tat induction decreased the density of dendritic spines on apical, but not basal dendrites, on layer 5 pyramidal neurons in the anterior cingulate cortex (ACC). Apical dendrites in the ACC receive “top-down” afferents from higher cortical areas; whereas basal dendrites receive “bottom-up” afferents from lower cortical and sensory areas, suggesting HIV-1 Tat may interfering with cortical feed-back input.

Interestingly, the morphological changes at 2 weeks of HIV-1 Tat expression did not coincide with changes in compulsive or coping behaviors. However, longer-term HIV-1 Tat exposure (6-8 weeks) increased feeding in the novelty suppressed feeding test, while decreasing prepulse inhibition, indicating that Tat may cause impulsivity in situations of competing motivation (e.g. drive to feed vs. fear of novel brightly lit areas) and attention deficits. Further, long-term Tat exposure affects coping behavior in the forced swim test. Ongoing experiments examining the effects of HIV-1 Tat on dendritic morphology in interconnecting brain areas and neuronal function are being conducted to elucidate the structural and functional deficits in specific neurocircuits underlying HIV-1 Tat-induced alterations in executive functioning.

Abstract: Cerebral aneurysm formation is a complex interplay among environmental exposures, biomechanical features, cellular and molecular characteristics, and genetic predisposition. Aneurysmal subarachnoid hemorrhage (aSAH) is usually the result of these mixed factors and the triggers for aneurysmal aSAH remain poorly understood while mounting evidence suggests that genetic factors contribute both to aneurysm formation and aneurysm rupture. In this study, we focused on the association of SERPINE1 gene with aSAH and its sequelae, clinical vasospasm, and delayed cerebral ischemia (DCI). Six single nucleotide polymorphisms (SNP) of

SERPINE1 gene (rs2227631, rs1799889, rs6092, rs6090, rs2227684, rs7242) were investigated. The SERPINEI gene encoded PAI-1 protein, which is antifibrinolytic and responsible for the controlled degradation of blood clots.
Blood samples from 195 subjects (145 aSAH patients and 50 controls) ages 21-88 years were collected for genetic analysis. Exclusion criteria were age under 19 years and abnormalities in cerebral vasculature. The control group was composed of trauma patients with unremarkable CT angiograms of cerebral aneurysm or other vascular malformation, and without known genetic risk factors for cerebral aneurysm formation. Both aSAH patients and controls were enrolled within 72 hours of admission. Patients were treated in accordance with guidelines for the management of aSAH and surveillance for clinical vasospasm and DCI. Weight of evidence (WOE) and information value (IV) are used for initial screening of variables for aSAH, clinical vasospasm and DCI. Follow up logistic regression showed that individuals with diabetes ($P < 0.0001$), hypertension ($P=0.015$), rs2227631 G allele ($P=0.017$), and higher age ($P=0.035$) are associated with aSAH.
Individuals with hypertension (>140/90) ($P=0.02$), hyponatremia ($P=0.03$), and ventriculoperitoneal shunt (VPS) treatment ($P=0.04$) were associated with increased risk of DCI. Haplotype analysis showed that G5AGGT carriers (4% haplotype frequency) were associated with aSAH ($P=0.05$), smaller aSAH size ($P=0.004$), lower Hunt and Hess scale ($P=0.05$) and lower Fisher CT scale ($P=0.01$). Recessive G5GGGT carriers (32% haplotype frequency) were associated with DCI ($P=0.01$) and clinical vasospasm ($P=0.02$).
Recessive A4GGAG carriers (32% haplotype frequency) were associated with larger aneurysm size ($P=0.016$) and has longer hospital stay ($P=0.05$). Haplotypes are in the order of rs2227631, rs1799889, rs6092, rs6090, rs2227684 and rs7242. These results demonstrate the importance of SERPINE1 genetic polymorphism in predicting aSAH.

Title: Gene expression profiling in whole blood of patients with ischemic stroke and cigarette smoking

Authors: *X. CHENG, F. HAMADE, N. SHROFF, H. HULL, G. JICKLING, B. ANDER, B. STAMOVA, F. SHARP
UC Davis, Sacramento, CA

Abstract: Though previous studies suggested that cigarette smoking-related genes may be linked to ischemic stroke (IS), no specific biomarkers have been identified in whole blood for patients who suffer IS and also smoke.
In this study, we performed whole genome mRNA expression study on Affymertrix HTA 2.0 microarrays using whole blood from 219 subjects (including 42 IS current smoker patients, 68 IS never smoker patients, 23 control smokers, 86 control never smokers). The significantly regulated genes were identified using ANOVA with p-value of 0.005 and |fold change|>1.2. The related functional pathway of identified genes was analyzed using Exploratory Gene Association Networks (EGAN) software.
Our data showed 63 (51 up and 12 down) genes were significantly altered in IS smoker patients *vs* IS never smoker patients, and 58 (48 up and 10 down) genes significantly altered in control smokers *vs* control never smokers. We also found three genes (GPR15, LRRN2 and CLDND1) associated with IS smoker patients were overlapped with non-IS control smokers. Based on 60 genes specifically associated with smoking and IS, the significantly related functional pathways include chemokine signaling pathway, T-cell receptor signaling pathway, cytokine-cytokine receptor pathway, iCOS-iCOSL signaling in T helper cells, as well as Th2 pathway.
In summary, we found that the alteration of inflammatory genes may provide direct evidence for explanation of health hazard of smoking before and/or after ischemic stroke and significance of smoking cessation, especially for people at high risk of IS.

Title: Nicotine & e-Cig exposure alters brain glucose utilization in ischemic stroke

Authors: *A. E. SIFAT, B. VAIDYA, M. A. KAISAR, L. CUCULLO, T. J. ABBRUSCATO
Pharmaceut. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: Use of electronic cigarettes (e-Cig) is a growing health concern in both smoking and nonsmoking populations and rigorous studies are needed to investigate the effects of the nicotine exposure via e-Cig on the neurovascular unit (NVU) and stroke outcome. Previous studies by our lab have shown that nicotine exposure significantly decreases glucose transport across the blood-brain barrier (BBB) in ischemia-reperfusion. In the present study, we investigated the effects of both short-term and long-term nicotine exposure on neuronal glucose utilization in ischemic conditions. To extend this study, we also looked at the effects of in vivo e-Cig vaping on ischemic brain glucose utilization. In vitro primary cortical neurons were exposed to nicotine (10 μM) & cotinine (5 μM) for 1 or 5 days and then subjected to 2 h oxygen-glucose deprivation (OGD) followed by 24 h reoxygenation to mimic ischemic conditions. Neuronal glucose utilization was measured by radiolabeled deoxy-D-glucose uptake. Immunocytochemistry (ICC) was done to investigate glucose transporter 1 & 3 (glut1, glut3) and nicotinic acetylcholine receptors (nAChRs) expression while MTT assay measured neuronal viability. Neuronal glycolytic flux and mitochondrial respiration were measured by seahorse flux analyzer. Nicotine was also administered to male 6 months old mice by e-Cig vapor (2.4% nicotine) delivered by an electronic nicotine delivery system for 7 days. Brain deoxy-D-glucose uptake was also determined in brain slices exposed to 30 min OGD followed by 2 h reoxygenation utilizing an acute brain slices (ABS) technique. Glucose transporters expression in brain slices were investigated by western blotting. Nicotine & cotinine did not show any neuronal toxicity except for 1000 μM nicotine. 1 & 5 days of nicotine & cotinine exposure significantly decreases neuronal glucose utilization in OGD-reoxygenation conditions which were reversed by a non-specific nicotinic acetylcholine receptor (nAChR) antagonist, mecamylamine (20 μM). Nicotine & cotinine also decreases neuronal glut1 expression which were correlated with α7 nAChR upregulation in OGD-reoxygenation. Further, this decreases neuronal glycolytic flux and mitochondrial respiration in ischemic condition. E-cig exposure for 7 days also decreases glucose uptake under normoxic and OGD-reoxygenation conditions with corresponding decrease of glut1 & glut3. These data support, from a cerebrovascular perspective, that nicotine & e-Cig vaping exposure creates an enhanced glucose deprived state and dysregulates glucose metabolism at the NVU which could lead to enhanced ischemic brain injury.

Title: Influence of the cerebral and spinal nicotine signaling in the development of central post-stroke pain

Authors: *S. TOKUYAMA[1], W. MATSUURA[2], S. HARADA[1]
[1]Kobe Gakuin Univ., Kobe, Japan; [2]Kobe Gakuin Univ., Kobe City/Hyogo, Japan

Abstract: Central post-stroke pain (CPSP) is one of the complications of cerebral ischemia and of neuropathic pain syndrome. The treatment of CPSP remains incomplete due to its resistance to both pharmacological and non-pharmacological therapies in approximately half of CPSP patients. Although CPSP is a serious condition, details pertaining to underlying mechanisms are not well known, making current standard treatments only partially effective. Nicotine and its receptor have recently been shown to be critical in the modulation of nociceptive transduction following peripheral neuropathy. Especially, it has been reported that a nicotinic acetylcholine receptor (nAchR) subtype as α4β2 and α7 have regulated the induction of several pain behaviors. We have been suggested that cerebral or spinal nicotine might be involved in the induction of CPSP. The aim of this study is to determine that the involvement between nicotine signaling and CPSP.
Male ddY mice were subjected to 30 min of bilateral carotid artery occlusion (BCAO). The development of hind paw mechanical allodynia was measured using the von Frey test. On day 3 after BCAO, mice were intracerebroventricular (i.c.v.) or intrathecal (i.t.) injected nicotin (10, 20 nmol/mouse), dihydro-β-erythroidine (a selective α4β2 nAchR antagonist; 20 nmol/mouse) and/or methyllycaconitine (a selective α7 nAchR antagonist; 20 nmol/mouse).
The number of escape behaviors, one of mechanical allodynia, against the stimulation induced by the von Frey filament was significantly increased on day 3 after BCAO compared with that in the sham group. The BCAO-induced mechanical allodynia was significantly suppressed by i.c.v. and i.t. injection with nicotine. Suppressive effect of nicotine (i.c.v. or i.t.) was significantly channeled by i.c.v. or i.t. injection of dihydro-β-erythroidine or methyllycaconitine. On the other hand, expression levels of α4 nAchR did not changed by BCAO as compared with sham operation.
Taken together, we conclude that nicotine and its receptors such as α4β2 and α7 nAchR are directly involved in the pathogenesis of CPSP. Our findings are helpful for better understanding of the pathological mechanism in CPSP.

Title: CD36 deficiency alters the composition of monocyte-derived macrophages in the brain following ischemic stroke

Authors: *K. PARK[1], M.-S. WOO[1], M. BALKAYA[1], J. YANG[1], M. FEBBRAIO[2], S. CHO[1]
[1]Burke-Cornell Med. Res. Inst., White Plains, NY; [2]Dept. of Dent., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Although the inflammatory nature of CD36 expressed in monocytes/macrophages (MM) in acute stroke has been documented, their role during recovery phase of stroke is less clear. The present study investigates a role of MM CD36 in trafficking into the injured brain and MM subset composition in chronic stroke. C57 male mice (12 weeks old) were subjected to transient focal ischemia and brain immune cells were collected at 7day (d) and 2 month (m). Using a flow cytometer, CD11b+ cells were further distinguished by $CD45^{Hi}$ and $CD45^{Low}$ subsets, which conventionally represent infiltrating MMs and resident microglia respectively. The extent of MM trafficking was determined by an intravenous infusion of GFP+ splenocytes in the stroked animals 1d prior to sacrifice. Stroke caused the presence of $CD45^{Hi}$ subset at 7d and 2m only in the ipsilateral hemisphere. $CD45^{Low}$ populations were presented in both hemispheres with significant increase in the stroked hemisphere. Adoptive transfer of GFP+ splenocytes into stroked mice resulted in GFP+ cells in both $CD45^{Hi}$ and $CD45^{Low}$ subsets at 7d and 2m. Protein expression of CD36 and lysosomal acid lipase (LAL), M2 and phagocytic markers, were increased at 7d and the increase was higher at 2m. Immunohistochemical analyses showed CD36 expression in infiltrated GFP+ MMs in the ipsilateral hemisphere. In mice with myeloid specific deletion of CD36 ($CD36KO^{MM}$), GFP+ cells were absent in $CD45^{HI}$ subset but largely presented in $CD45^{Low}$ subsets, although the total number of GFP+ cells into the stroked brain were similar between the genotypes. There was no difference in infarct size at 3d (Wt vs cKO, n= 11/group, ns). The present study showed the persistent infiltration of MMs during acute and recovery stages. The absence of infiltrated GFP+ cells in $CD45^{Hi}$ subset in $CD36KO^{MM}$ mice further suggest an involvement of MM CD36 in balancing pro-inflammatory ($CD45^{Hi}$) and microglia-like ($CD45^{Low}$) subsets in the post-stroke brain. <!--EndFragment-->

Title: TRIM9-mediated resolution of neuroinflammation confers neuroprotection against ischemic stroke in mice

Authors: *J. ZENG[1], Y. WANG[2], Z. LUO[3], L.-C. CHANG[4], X. XIE[2], B. DEVERMAN[5], V. GRADINARU[5], S. GUPTON[6], B. ZLOKOVIC[2], Z. ZHAO[2], J. JUNG[4]

Abstract: Excessive and unresolved neuroinflammation is a key component of the pathological cascade in brain injuries such as ischemic stroke and timely resolution of neuroinflammation is critical for the recovery and repair after brain injury. The nuclear factor-κB (NF-κB) signaling plays a central role in neuroinflammation through transcriptional induction of proinflammatory genes. In the aged brain, without any evident disease, there are chronically increased levels of NF-κB activity and pro-inflammatory cytokines. We report that TRIM9, a brain-specific TRIpartite motif (TRIM) protein, is highly expressed in the peri-infarct areas shortly after ischemic insults and governs the resolution of NF-κB-mediated neuroinflammation, which is considerably abrogated in aged brain. Mechanistically, TRIM9 sequestered β-TrCP from Skp-Cullin-F-box ubiquitin ligase complex, blocking IκBα degradation and thereby dampening NF-κB-dependent proinflammatory mediator production and immune cell infiltration. Consequently, *Trim9* deficient mice were highly vulnerable to ischemia, manifesting uncontrolled neuroinflammation and exacerbated neuropathological outcomes. Systemic administration of recombinant TRIM9 adeno-associated virus-PHP.B, allowing brain-wide enriched TRIM9 expression, effectively resolved neuroinflammation and alleviated neuronal death, especially in aged mice. This reveals that TRIM9 is essential for resolving NF-κB-dependent neuroinflammation for the recovery and repair after brain injury and TRIM9-potentiation based therapy may offer a new treatment of stroke and inflammation-related neurological disorders.

Title: Specific action mediated by spinal HMGB1 signaling in the ischemic stress-induced mechanical allodynia in mice

Authors: *W. MATSUURA[1], S. HARADA[1], K. LIU[2], M. NISHIBORI[2], S. TOKUYAMA[1]
[1]Kobe Gakuin Univ., Kobe, Japan; [2]Okayama Univ., Okayama, Japan

Abstract: [Aims]We have previously shown that spinal high-mobility group box-1 (HMGB1) plays a key role in the induction of central post-stroke pain (CPSP). It has been also reported that HMGB1 exacerbates inflammation and pain condition through its receptors such as toll-like receptor 4 (TLR4) or receptor for advanced glycation end products (RAGE). Furthermore, it has been reported that HMGB1 regulates activation of glial cells and nitric oxide synthetase (NOS) involved in pain through TLR4 and RAGE. In this study, we investigated whether the interaction between spinal glial cells and HMGB1 signaling, including its receptors, is directly involved in the induction of CPSP. **[Methods]**Bilateral carotid arteries of male ddY mice (5 weeks old) were occluded for 30 min (BCAO). Mechanical allodynia was evaluated by a von Frey filament test on day 3 after BCAO. On day 3 after BCAO, anti-HMGB1 monoclonal antibody (mAb), lipopolysaccharides from *Rhodobacter sphaeroides* (LPS-RS, a TLR4 antagonist), low-molecular-weight heparin (LMWH, a RAGE antagonist) and N^G-nitro-L-arginine methyl ester (L-NAME, a nonselective NOS inhibitor) intrathecally (i.t.) injected. Glial cells expression levels and NOS activity on day 3 after BCAO were measured using immunostaining and colorimetric assay, respectively. **[Result]**On day 3 after BCAO, intrathecal injection of anti-HMGB1 mAb, LPS-RS and LMWH significantly blocked mechanical allodynia. BCAO-induced upregulation of spinal Iba1-positive cells (microglial marker) and GFAP-positive cells (astrocyte marker) were suppressed by i.t. injection of anti-HMGB1 mAb and LPS-RS, but not LMWH. In addition, i.t. injection of L-NAME significantly blocked mechanical allodynia on day 3 after BCAO. Furthermore, i.t. injection of anti-HMGB1 mAb, LPS-RS and LMWH significantly inhibited the increase of NOS activity in the spinal cord on day 3 after BCAO.

[Conclusion]These results showed that spinal HMGB1/TLR4/glial cells/NOS and HMGB1/RAGE/NOS signaling are directly involved in the induction of CPSP.

Sciences, Univ. of Copenhagen, Copenhagen, Denmark; [5]Munich Cluster for Syst. Neurol. (SyNergy), Muenchen, Germany

Abstract: Stroke is one of the leading cause of death and disability in today's world[1]. Apart from the acute neuron death and degeneration, neuroinflammation, which involves with infiltration of peripheral immune cells, has been recognized as a major secondary injury mechanism after stroke[2]. The lymphatic system is critical for immune responses although until recently, the brain was considered to be devoid of any lymphatic vessels. The discovery of brain lymphatic vessels[3] indicates a potential immune cell trafficking route between the CNS and the rest of the body. However, standard histology is not an ideal method to study meningeal vessels as their connections are largely destroyed when the brain is harvested.
To overcome this hurdle and to image details of intact meningeal vessels, we used DISCO clearing of whole mouse body, which allows us to image the subcellular details through bones and highly autofluorescent tissues. Using DISCO panoptic imaging, we readily visualized intact brain meningeal vessels with immune cells in their native environment. Applying middle cerebral artery occlusion (MCAO) model of stroke in LysM-EGFP line transgenic mice (labeling monocytes and macrophages), we observed the invasion of LysM GFP+ cells into the brain

parenchyma especially in the peri-infarct region. Furthermore, we detected significant increase of LysM GFP+ cells in the brain meningeal structures after stroke in MCAO mice. This finding suggests that the meninges might be an additional invasion route of immune cells differently from the disrupted blood brain-barrier and the choroid plexus[4]. In summary, DISCO panoptic imaging of intact mouse bodies provides a powerful and unique methodology for studying the meningeal structures both in health and disease and it is readily applicable in diverse fields of biomedical research.

Title: Pericyte contribution to scar after stroke

Authors: *T. PHAM, S. CARMICHAEL
Neurol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Stroke is the leading cause of adult disability. Pericyte, a less-well-understood cell type of the brain, is a heterogeneous population of perivascular cells that regulates development and maintenance of structural elements of the blood brain barrier, vascular stability, and angiogenesis. The role of pericytes after stroke has not been well characterized. Most work on

pericytes in the brain in general and in stroke have focused on their role in regulating blood flow. Our previous data indicates that pericytes after stroke experience bursts in proliferation and unique migration patterns away from blood vessels to form populations of fibroblast-like cells at the infarct margin. This suggests that pericytes take part in active tissue remodeling adjacent to the stroke. Pericyte contributions to fibrotic scar after injury has been a topic of debate in recent years. The controversy stems from the use of different transgenic mouse lines to fate-track and different injury models with different biology. Here, using novel dual-pericyte-specific viral systems that tightly label pericyte populations before and after stroke, we phenotyped fate-tracked post-stroke pericytes. We found that post-stroke pericytes migrate away from vasculature, heavily proliferate, start to express fibroblast markers, and take residence inside the infarct core. Surprisingly, meningeal fibroblasts sharing the same pericyte markers did not contribute to the formation of the fibroblast scar in the infarct core. Our result confirms the pericyte origin of fibrotic scar in the central nervous system after stroke, and suggest the multiple roles this heterogeneous cell type plays in tissue repair and regeneration.

Title: Inhibition of miR-34b/c rescues hippocampal CA1 neurons and memory deficits in global ischemia

Authors: *J.-Y. HWANG, H.-R. BYUN, F. PONTARELLI, M. PORCH, B. L. COURT VAZQUEZ, R. S. ZUKIN
Dept Neurosci, Albert Einstein Col. Med., Bronx, NY

Abstract: Transient global ischemia arising as a consequence of cardiac arrest in humans causes selective, delayed death of hippocampal CA1 pyramidal neurons and cognitive impairment. Effective treatments to ameliorate the neurodegeneration and cognitive dysfunction associated with global ischemia are an unmet need. Emerging evidence points to a widespread role for microRNAs (miRNAs) as key modulators of target gene expression in neurons. Accordingly, dysregulation of miRNAs are implicated in the pathophysiology of neurodegenerative disease

and neurological disorders. Our findings, derived *via* miRNA-seq, indicate that expression of a subset of microRNAs are altered in postischemic CA1 including miR-34b/c, miR-21, miR-331, miR-181 and miR-29. Ingenuity pathway analysis reveals that miR-34b/c is the leading miR candidate implicated in cell death and survival. Dysregulation of miR-34 has been implicated in pathophysiology of neurological disorders such as Parkinson's disease and epilepsy. However, a role for miR-34 in the pathogenesis of global ischemia is, as yet, unclear. Here we show ischemia induces p53-dependent activation of miR-34b/c and downregulation of its target genes, which together promote neuronal death in selectively vulnerable hippocampal CA1 *in vivo*. Consistent with this, inhibition of miR-34b/c affords neuroprotection, rescues impaired synaptic plasticity and reduces memory deficits in global ischemia. These findings document a causal role for p53-dependent activation of miR-34b/c in neuronal death and identify a novel therapeutic target for amelioration of the neurodegeneration and cognitive deficits associated with ischemic stroke.

Title: miRNA miR-7a-5p ameliorates ischemic brain damage by targeting alpha-synuclein

Authors: *T. KIM[1], S. MEHTA[1], M. LOPEZ[1], R. SULLIVAN[2], K. MORRIS-BLANCO[1], H. KIM[1], C. KIM[1], R. VEMUGANTI[1]
[1]Neurolog. Surgery, [2]Comparative Biosci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Transient focal ischemia is known to induce extensive temporal changes in rodent cerebral miRNAome. We previously showed that of those altered, miR-7a-5p (miR-7) was found to be significantly decreased in a sustained manner during the acute phase after focal ischemia. Functionally, miR-7 was shown to inhibit the expression of several proteins including alpha-synuclein that play detrimental roles in neurodegenerative diseases. Thus, we presently evaluated the therapeutic efficacy of miR-7 after cerebral ischemia in rodents as per Stroke Treatment Academic Industry Roundtable criteria. Rodents were subjected to transient middle cerebral

artery occlusion. miR-7 was injected via either intracerebrally or systemically through the retro-orbital sinus. miR-7 levels and protein levels were measured by either qPCR or Western Blots. The post-ischemic motor deficit was evaluated with rotarod, beam walk, and adhesive removal test, and brain damage was measured on cresyl violet stained brain sections. Cellular changes after ischemia were examined using immunofluorescence staining. We found that miR-7 expression was decreased in both young/adult and aged rats of both sexes after ischemia. Pre- or post-ischemic treatment with miR-7 mimic decreased the infarct volume and promoted functional recovery in both sexes and ages studied. Furthermore, systemic injection of miR-7 mimic into post-ischemic mice resulted in significant decrease in the infarct volume with minimal peripheral toxicity. The miR-7 mimic treatment significantly reduced the post-ischemic induction of alpha-synuclein which is known to induce mitochondrial fragmentation, apoptosis, oxidative stress and autophagy that promote post-stroke neuronal death. Therefore, out studies indicate that miR-7 is a potential therapeutic agent to minimize post-stroke brain damage.

Title: The microRNA-210/TET2 axis mediates neuroinflammation in neonatal hypoxic-ischemic brain injury

Authors: *Q. MA, C. DASGUPTA, L. ZHANG
The Lawrence D. Longo, MD Ctr. for Perinatal Biol., Loma Linda Univ., Loma Linda, CA

Abstract: Neonatal hypoxia-ischemia (HI) is a leading cause of acute mortality and chronic brain injury in newborns with a high risk of hypoxic-ischemic encephalopathy. MicroRNA-210 (miR-210) is "*the Master Hypoxamirs"* and has been reported to be involved in physiological and pathological processes in response to hypoxia. Our previous study demonstrated that the inhibition of miR-210 provided neuroprotection in neonatal HI brain injury. However, the underlying mechanisms remain elusive. Our data shows that Tet methylcytosine dioxygenase 2 (TET2) is a putative downstream target of miR-210, which plays a critical role in regulating inflammatory gene expression after neonatal HI in mice. The miR-210 inhibitor complementary locked nucleic acid oligonucleotides (LNA-miR-210) or LNA scramble was stereotaxically injected into the ipsilateral hemisphere of postnatal day 7 (P7) male and female mouse pups

intracerebroventricularly. Twenty-four hours later, mouse pups were subjected to ligation of unilateral common carotid artery followed by hypoxic treatment (8% O_2). The immunoblot assay found that miR-210-LNA rescued brain TET2 protein levels after HI insult, as compared to LNA scramble. Moreover, the delivery of miR-210 mimic into the mouse brain resulted in downregulation of brain TET2 protein levels as compared to scramble control. To investigate the role of TET2 in regulating inflammatory response in neonatal HI brain injury, mouse pups (P7) were injected with TET2 silencing RNA intracerebroventricularly followed by HI insult 48 hours later. The results showed that TET2 knockdown significantly increased the vulnerability of the neonatal brain to HI insult and resulted in exacerbated neurological deficits. Moreover, TET2 knockdown time-dependently upregulated the transcription levels of pro-inflammatory cytokines, as compared to scramble control. Thus, our results demonstrate that the miR-210/TET2 axis mediates the regulation of neuroinflammatory response in neonatal HI brain injury. (Supported by NIH NS103017)

Title: Do microRNAs change expression in oligodendrocytes after perinatal hypoxia ischemia in mice?

Authors: M. H. BASHIR[1], S. C. CHAPMAN[2], *R. W. DETTMAN[3], M. L. V. DIZON[4]
[1]Pediatrics, Northwestern Univ., Chicago, IL; [2]Neonatology, US Naval Hosp. Okinawa, Okinawa, Japan; [4]Neonatology, [3]Anne and Robert H Lurie Children's Hosp., Chicago, IL

Abstract: In the postnatal brain, neural progenitors within the cortex and subcortical white matter predominantly produce cells of oligodendroglial lineage. These cells are particularly vulnerable to hypoxic-ischemic injury (HI) resulting in the loss of mature oligodendrocytes (OL) or defects in myelination. MicroRNAs (miRs) are short, non-coding RNAs that modify gene expression. We previously observed increased expression of miR-138 and mir-338 after perinatal HI in P7 mouse pups. Conditional ablation of Dicer in NG2-expressing neural progenitors protected against myelin loss and loss of motor function in mice indicating that miRs play a role in the response of the brain to perinatal HI. Here, we further evaluated changes to expression of miR-9, mir-21, miR-138, miR-338 after perinatal HI using quantitative real-time polymerase chain reaction (qRT-PCR) 24h, 48h, 72h, 7d, 14d and 28d post-HI compared to age-matched

shams. We observed that in total hemispheric RNA, pri-miR-9 peaked at 24h (Fold Change (FC)=2.06) and mature miR-9 peaked at 7d (FC=2.91) relative to sham. For miR-21, pri-miR-21 peaked at 24h (FC=1.82) and mature miR-21 peaked at 72h (FC=4.78) relative to sham. For miR-138, pri-miR-138 peaked at 72h (FC=1.87) and mature miR-138 peaked at 7d (FC=3.76) relative to sham. For miR-338, pri-miR-338 peaked at 72h (FC=1.48) and mature miR-338 peaked at 7d (FC=2.3) relative to sham. Thus, these miR's all increased in response to perinatal HI. To test if these miRs increased in neural progenitors we employed MIRAP (**mi**cro**R**NA tagging and **a**ffinity **p**urification). We generated NG2Cre^{ERTM}; tAgo2 mice and subjected them to perinatal HI at P7. MIRAP was performed at 72h post-HI. Here, qRT-PCR was performed using the locked nucleic acid technology developed by Exiqon using miR-103 as the control transcript. We observed that mature miR-9 and miR-138 were decreased relative to sham (FC=0.53 and FC=0.57). miR-338 was not detectable by MIRAP at 72h. Mature miR-21 was increased in neural progenitors at 72h (FC=2.2). These findings indicated that 72h after HI, only mature miR-21 is increased in neural progenitors. To test this further we performed *in situ* hybridization for mature miR-21 and observed that miR-21 was increased in the corpus callosum of mice exposed to perinatal HI 48h after injury. Together, we found increases to miRs at different times after perinatal HI. The presence of mature miRs always followed accumulation of pri-miRs indicating that tissues undergo a period of time before RNAs are packaged into RISC. MIRAP provides a basis for distinguishing between miRs that accumulate in neural progenitors versus other cell types of the perinatal brain.

Title: Anti-cancer drugs (CX-4945 and MS-275) protective of WM against ischemic injury differentially regulate miRNA expression

Authors: *S. BRUNET[1], C. BASTIAN[1], S. BALTAN[2]
[1]Cleveland Clin. Fndn., Cleveland, OH; [2]Dept. of Neurosciences, Cleveland Clin., Cleveland, OH

Abstract: We have shown that two cancer drugs (CX-4945 and MS-275) are protective of white matter (WM) against ischemic injury. These compounds have two different mode of action. CX-4945 is a selective Casein Kinase 2 (CK2) inhibitor and MS-275 is a selective Class I HDAC inhibitor. Could alteration in miRNAs, noncoding RNAs that regulate gene expression, mediate some of the protective actions of these cancer drugs on WM from ischemic injury? The aim of this study was **1)** to identify miRNA expressed in mouse optic nerve, **2)** to determine miRNA regulated by OGD and **3)** to determine if CX-4945 and MS-275 alter the miRNA expression in a mouse model of WM ischemic injury. RNA was isolated from the mouse optic nerve (MON) from control, following oxygen glucose deprivation (OGD) with and without CX-4945 or MS-275. A quantifiable miRNA profiling technique (NanoString) was used to determine the expression of 610 miRNAs. Mean expression levels and fold change were determined. In control condition, NanoString analysis revealed that 280 miRNAs were expressed above background levels and that 12 miRNAs were expressed at high levels (> 10 000 sequence counts) in MONs. OGD resulted in the up-regulation of four miRNAs (miR-501-3p, miR-201, miR-1959, miR-146b) and the down-regulation of two miRNAs (miR-1937a and miR-1937b) compared to control conditions. OGD with CX-4945 treatment resulted in the up-regulation of two miRNAs (miR-1937a, miR-1937b) and the downregulation of three miRNAs (miR-501-3p, miR-200b and miR-mo1-2). Note that miR-501-3p, miR-1937a and miR-1937b showed differential expression between OGD and OGD with CX-4945. Finally, OGD with MS-275 resulted in the alteration of more miRNAs. Specifically, the upregulation of five miRNAs (miR-376b, miR-2140, miR-2141, miR-2146 and miR-487b) and the downregulation of five miRNAs (miR-501-3p, miR-190, miR-1959, miR-27a and miR-M1-7-3p). Note that miR-501-3p and miR-1959 showed differential expression between OGD and OGD with MS-275 treatment. Interestingly miR-501-3p was a common target but differentially regulated between OGD and OGD with CX-4945 or OGD with MS-275 . Our findings provide the first evidence that WM ischemia modulates miRNA and that CX-4945 and MS-275 regulate WM miRNA, providing a common mechanism by which CX-4945 and MS-275 confer protection to axon function and WM integrity against an ischemic injury. In addition, these findings may pave the way for treating WM by targeting specific miRNAs, leading to improved axonal function, decreased disability and ultimately increased quality of life of stroke patients.

Abstract: Repetitive waves of cortical spreading depression/depolarization (CSD) are spontaneously evoked in acute ischemic injury. CSD is linked to a sharp increase of extracellular K^+ that induces a long-lasting suppression of neural activity. CSD induces secondary irreversible damage in the ischemic brain suggesting that K^+ homeostasis might constitute a novel therapeutic strategy. Here, we found that asynchronous astrocytic Ca^{2+} activity appears after CSD**.** Adrenergic receptor (AdR) antagonism suppressed this aberrant astrocytic Ca^{2+} activity and accelerated normalization of extracellular K^+, resulting in faster recovery of neural activity. Remarkably, systemic adrenergic blockade before or after stroke facilitated functional locomotor recovery and reduced infarct volume, paralleling to the preservation of the water channel aquaporin-4. Our results suggest that AdR blockers promote cerebrospinal fluid exchange and rapid extracellular K^+ clearance, representing a novel and potent intervention for acute stroke.

Title: Multiscale simulation of spreading depolarization in ischemic stroke

Authors: *A. NEWTON[1,2], A. H. SEIDENSTEIN[4], M. L. HINES[1], R. A. MCDOUGAL[1,5], W. W. LYTTON[2,6,3]
[1]Dept. of Neurosci., Yale Sch. of Med., New Haven, CT; [2]Physiol. and Pharmacol., [3]Dept. of Neurol., State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [4]Sch. of Engin., NYU, Brooklyn, NY; [5]Ctr. for Med. Informatics, Yale Univ., New Haven, CT; [6]Dept. of Neurol., Kings County Hosp. Ctr., Brooklyn, NY

Abstract: Occlusion of a blood vessel in the brain triggers a cascade of changes, including: 1. synaptic glutamate release, related to excitotoxicity; 2. elevated extracellular potassium, leading to spreading depolarization (depression); 3. edema due to cell swelling, reducing the extracellular volume and increasing the tortuosity; 4. production of reactive oxygen species, which gives rise to inflammation and direct cellular damage. These cascades occur over multiple time-scales, with the initial rapid changes in cell metabolism and ionic concentrations triggering several damaging agents that may ultimately lead to cell death. At the tissue scale coincident diffusion may divide ischemic tissue into distinct patterns of pathology, with the ischemic core surrounded by several types of ischemic penumbrae, with cells that are damaged but salvageable.
We developed models of ischemic stroke at molecular, cellular and tissue scale, using multiscale coupling of electrophysiology, intracellular molecular alterations, neuronal network activity, and bulk tissue alterations mediated by extracellular diffusion. We used these models to evaluate the hypotheses of multiple penumbrae and patterning of cell damage.
We considered several toxic substances released from the ischemic core as contributors to penumbral damage, on top of a background ischemic field in the watershed areas. Differences in the rates of production, release, diffusion and clearance of the substances could give rise to multiple distinct penumbrae about the ischemic core. In addition to the tissue patterning, the individual cells may show differential susceptibility to damage due to differences in morphology and physiology, such as the surface area to volume ratio or the intracellular calcium dynamics. We investigated this by placing biophysically detailed models of cortical pyramidal neurons in the penumbrae, with intracellular Ca^{2+} dynamics and Na^{+}/K^{+}-ATPase pumps. Such differential cellular damage could also lead to alterations in cell morphology and function in contexts of low-level repeated ischemia, potentially leading to ischemic dementia.

Title: Zn^{2+} entry through the mitochondrial calcium uniporter (MCU): Critical role in mitochondrial dysfunction and neurodegeneration after neuronal Zn^{2+} loading and during ischemia

Authors: *S. G. JI, Y. V. MEDVEDEVA, J. H. WEISS
Neurol., Univ. of California, Irvine, Irvine, CA

Abstract: In addition to Ca^{2+}, Zn^{2+} contributes to ischemic neurodegeneration. During ischemia, Zn^{2+} is released at synapses, where it can enter postsynaptic neurons, and from cytosolic buffering proteins (where it is normally bound). Prior studies suggest that Zn^{2+} can enter mitochondria through the mitochondrial calcium uniporter (**MCU**) and disrupt their function. Yet key questions remain. **(1) Validation of MCU dependent mitochondrial Zn^{2+} entry and dysfunction.** Prior studies were limited by the incomplete specificity of MCU blockers. Using MCU knockouts (**KO**), we were able to confirm Zn^{2+} entry through this route. We further examined effects of MCU deletion on Zn^{2+}-induced mitochondrial dysfunction. In cultured neurons subjected to mild exogenous Zn^{2+} loads combined with partial disruption of endogenous buffering, we found Zn^{2+}-induced mitochondrial depolarization and swelling both to be attenuated in MCU KO. **(2) MCU dependence of Zn^{2+}-triggered reactive oxygen species (ROS) production.** Despite prior studies showing that acute Zn^{2+}-triggered ROS generation largely depends upon mitochondrial Zn^{2+} uptake, we found increased Zn^{2+}-induced ROS production in MCU KO, likely reflecting induction of the cytosolic ROS generating enzyme NADPH oxidase as a previously unknown compensatory effect. **(3) MCU targeted interventions.** To assess the potential therapeutic utility of targeting the MCU, we examined effects of adding MCU blockers immediately after Zn^{2+} exposure, and found this to significantly attenuate mitochondrial dysfunction. **(4) MCU in Zn^{2+}-induced and ischemic cell death.** Finally, we examined the neuroprotective utility of targeting the MCU. In cultured neurons, both MCU KO and delayed MCU blockade attenuated Zn^{2+}-triggered cell death. Additionally, in hippocampal slices we found evidence that Zn^{2+} entry through the MCU contributes to cell death in a model of ischemia, likely via disrupting mitochondrial function. The strong correlations between preservation of mitochondrial function and neuroprotection in both models support the idea that mitochondrial Zn^{2+} uptake via MCU contributes directly to injury. These findings show a new role of MCU in Zn^{2+}-triggered and ischemic neurodegeneration and support the utility of delayed MCU blockade as a novel neuroprotective strategy.

Title: Transient global ischemia induces early progressive Zn^{2+} accumulation in CA1 mitochondria that may contribute to mitochondrial structural disruption and neurodegeneration

Authors: H.-L. WANG, H. Z. YIN, G. TIAN, S. G. JI, Y. V. MEDVEDEVA, A. BAZRAFKAN, N. MAKI, Y. AKBARI, *J. H. WEISS
Dept. of Neurol., Univ. of California Irvine, Irvine, CA

Abstract: Despite high morbidity of ischemic stroke, there are as of yet no neuroprotective interventions with efficacy in humans. Whereas most prior efforts targeted Ca^{2+}, recent findings have highlighted contributions of Zn^{2+}. *In vitro* studies by us and others support the hypothesis that mitochondria are important sites of injurious Zn^{2+} effects; after entering neurons, Zn^{2+} can enter mitochondria, triggering mitochondrial dysfunction (including reactive oxygen species production, depolarization, and swelling), contributing to cell death. We have also used hippocampal slices subjected to oxygen glucose deprivation (**OGD**) to model ischemia, and found that early neuronal Zn^{2+} accumulation and entry into mitochondria both appear to precede and contribute to sharp Ca^{2+} rises associated with acute neurodegeneration. In addition, after sublethal OGD, there is long lasting Zn^{2+} accumulation in CA1 mitochondria that appears to contribute to delayed mitochondrial dysfunction. To address the above hypothesis in an *in vivo* translational model of global ischemia, rats were subjected to 8-9 min asphyxial cardiac arrest, resuscitated, then perfused after either 1 or 4 h recovery. Examining the hippocampal slices, we observe the following: (1) Vanadium acid fuchsin staining revealed substantial neuronal injury to hippocampal CA1 and CA3 pyramidal neurons after global ischemia, with significantly greater impact on CA1. (2) Examination of immunolabeled mitochondria under confocal microscopy indicated mitochondrial swelling in both CA1 and CA3 neurons. (3) To assess redistribution of labile (or loosely bound) Zn^{2+} after ischemia, we labeled reactive Zn^{2+} using the Timm's sulfide silver technique (in which Na_2S precipitates reactive Zn^{2+}, and electron dense silver associates with the precipitates), and examined the slices using electron microscopy. We found that ischemia caused substantial Zn^{2+} accumulation in CA1 mitochondria, which correlated strongly with disruption of mitochondrial structure and was far worse with 4 h than with 1 h recovery. This study provides the first ultrastructural examination of Zn^{2+} redistribution after *in vivo* global

ischemia, and lends support to the hypothesis that early and progressive mitochondrial Zn^{2+} accumulation after ischemia contributes to mitochondrial dysfunction and neuronal death.

Abstract: Cardiac arrest is the leading cause of natural death in the United States. Patients successfully resuscitated from cardiac arrest will often die from the neurologic damage induced by lack of blood flow to the brain. Reperfusion of the brain, set in motion by the requisite resuscitation of the patient, causes significant mitochondrial dysfunction, exacerbating neuronal death. Mitochondria quality control depends on the delicate balance of fission, fusion, and targeted autophagy of unthrifty mitochondria (mitophagy). Proper mitochondrial dynamics can be perturbed by a variety of factors and are an imperative determinant of cell viability, often faltering under the stress of reperfusion. To better understand the molecular mechanisms of mitochondrial fragmentation during reperfusion injury, we have put forth a focused strategy to manipulate the mitochondrial fission protein, Dynamin-related protein-1 (Drp1) in a mouse model of cardiac arrest and resuscitation.
Mitochondrial fission is regulated by Drp1, which is recruited to the outer mitochondrial membrane to constrict mitochondria. Under duress, such as ischemia-reperfusion, the mitochondrial dynamic state becomes unbalanced, tending towards fragmentation, resulting in cell death. Using our novel mouse model of cardiac arrest/resuscitation in combination with a neuron specific Cre recombinase (CamK2a-ERT2) and floxed Drp1, we are able to induce Drp1 knockout in vulnerable neurons to elucidate the role of Drp1 induced fission in neuronal injury following cardiac arrest.

Title: Disruption of mitochondrial quality control following ischemic brain injury

Authors: *T. H. SANDERSON, K. MAHERAS, A. ANZELL, J. WIDER
Emergency Med., The Univ. of Michigan, Ann Arbor, MI

Abstract: The primary cause of morbidity and mortality in post-cardiac arrest patients is brain injury caused by global ischemia/reperfusion injury. While the return of spontaneous circulation is essential to preserve the ischemic tissue, it also significantly exacerbates brain injury. Mitochondria play a central role in the pathophysiology of post-cardiac arrest injury. Furthermore, maintenance of mitochondrial integrity through quality control is critical to maintaining mitochondrial function. This process is achieved through the specific fragmentation and removal of dysfunctional mitochondria or mitochondrial segments. Although this process is known to play a pivotal role in the maintenance of healthy neurons, much controversy exists with regards to the role of mitochondrial quality control in the progression of post-ischemic brain injury. Recent development of a novel binary-based fluorescence assay for mitophagic flux (mito-QC) has permitted a rigorous analysis of mitochondrial quality control in cells. Expression of tandem mCherry and GFP fused to the targeting sequence of the outer mitochondrial membrane protein, Fis1 allows temporal resolution of this process. During stable conditions, both red and green fluorophores are localized to mitochondria. When a mitochondrion undergoes mitophagy, mCherry fluorescence remains stable, while GFP is quenched. Thus, the red/green fluorescence ratio can be utilized to quantify mitochondrial quality control flux in physiologic and pathologic contexts. Utilizing this transgenic mouse model in conjunction with our novel mouse model of cardiac arrest/resuscitation, we investigated disruption of the mitochondrial network and mitochondrial quality control balance after ischemic brain injury. Global brain ischemia during cardiac arrest induces extensive mitochondrial network fragmentation during reperfusion, which is followed by induction of regulated cell death. This mitochondrial fragmentation is associated with disruption of normal mitochondrial quality control flux in the CA1 hippocampus of mito-QC mice. These novel models allow a refined analysis of mitophagy in the brain during ischemia/reperfusion injury and suggest the manipulating mitophagic flux after ischemia could provide a novel means of therapeutic intervention.

Title: Pharmacological calcium/calmodulin-dependent kinase (CAMKII) inhibition protects against Purkinje cell damage following cardiac arrest and cardiopulmonary resuscitation in mice

Authors: *N. QUILLINAN[1], N. CHALMERS[1], O. PATSOS[1], K. STEKLAC[2], P. S. HERSON[3]
[1]Anesthesiol., Univ. of Colorado, Aurora, CO; [2]Colgate Univ., Hamilton, CO; [3]Anesthesiol., UC Denver, Aurora, CO

Abstract: Introduction: Ischemic brain damage is triggered by glutamate excitotoxicity resulting in neuronal cell death. While the specific cascade of events leading to injury is complex, previous research has demonstrated that NMDA receptor activation triggers downstream calcium-dependent signaling pathways, specifically Ca2+/calmodulin-dependent protein kinase II (CaMKII). Focal and global ischemia studies have shown that inhibiting CaMKII is protective against hippocampal damage, but there is little known about cerebellar cell death mechanisms. The aim of this study is to examine the neuroprotective potential of inhibition of CaMKII in Purkinje cells using a global ischemia model. **Methods:** C57BL/6 male adult mice were subjected to 8 minutes of cardiac arrest followed by cardiopulmonary resuscitation (CA/CPR). Mice were randomized to receive tat-CN19o or control peptide (tat-SCR), 30 minutes after CA/CPR. We performed a dose-response for tat-CN19o and cerebellar injury was analyzed at 7 days after CA/CPR. Acute signaling was assessed at 6 hours after CA/CPR using western blot analysis of cerebellar homogenates. Antibodies recognizing phosphorylated and total CAMKII and DAPKI were used, and integrated volume of bands was quantified. Statistical analyses were performed using ANOVA tests, with a $P<0.05$ considered significant. **Results:** We observed increased phosphorylation of the T286 residue of CAMKII at 6 hours after CA/CPR, suggesting increased autonomous activation. Analysis of Purkinje cell density revealed a decrease in cell density at 7 days after CA/CPR that was prevented with tat-CN19o at doses of 0.1 and 1 mg/kg. A dose of 0.1 mg/kg was able to prevent gait abnormalities 7 days after CA/CPR. Western blot analysis of cerebellum revealed that cardiac arrest reduced DAPK1 phosphorlyation, which was not observed in mice that received tat-CN19o (0.1 mg/kg). **Conclusions:** These data demonstrate that autonomous activity of CAMKII is increased by ischemia in the cerebellum that contributes to cell death. Neuroprotection in the cerebellum with tat-CN19o required doses that were 10-fold higher than what was needed for neuroprotection in

the hippocampus (Deng, Cell Reports, 2017). Importantly, we have identified DAPK1 pathway was activated following CA/CPR and CAMKII inhibition reduced this activation. Future studies will address whether cerebellar injury is DAPK1-dependent and whether these pathways are also activated in a CAMKII-dependent manner in the hippocampus. In summary, our findings indicate that inhibition of autonomous CaMKII activity is a promising therapeutic approach that is effective across multiple brain regions.

Title: Contribution of large-conductance Ca^{2+}-activated potassium (BK) channels to the evolution of spreading and anoxic depolarization

Authors: *R. FRANK, Á. MENYHÁRT, F. BARI, E. FARKAS
Dept. of Med. Physics and Informatics, Univ. of Szeged, Szeged, Hungary

Abstract: Anoxic depolarization (AD) is a permanent event, and indicates primary brain damage in the ischemic core. In contrast, spreading depolarization (SD) is a transient wave of mass depolarization that causes secondary lesion growth in the penumbra. Although the profound extracellular K^+ elevation has served as the hallmark of these events for decades, further investigation is needed to identify the ion channels that mediate the cellular K^+ efflux during AD and SD. Our aim was to examine the contribution of large-conductance Ca^{2+}-activated potassium channels (BK channels) to AD and SD evolution.
Anesthetized C57Bl/6 mice (n=15) were used for the in vivo assessment of cerebrocortical local field potential (LFP), $[K^+]_e$, and local cerebral blood flow (CBF); or Sprague-Dawley rats (n=13) to prepare in vitro oxygen-glucose deprived (OGD) or control brain slice preparations for LFP recording. SDs were evoked by high concentration K^+ in vivo or electric stimulation in vitro, while AD occurred spontaneously in response to OGD in vitro. Half of the preparations were topically treated with paxilline (500 nM).
Paxilline decreased SD amplitudes both in vivo (11.00±5.3 vs. 19.3±4.5 mV, paxilline vs.

control) and in vitro (9.1±5.3 vs. 17.2±5.5 mV paxilline vs. control), and AD amplitude in vitro (2.4±1.4 vs. 5.8±2.6 mV, paxilline vs. control). The relative shift of $[K^+]_e$ with SD was also markedly reduced by paxilline in vivo (12.7±7.5 vs. 22.2±2.7 mM, paxilline vs. control). Finally, paxilline completely diminished SD-related hypoperfusion in 6 of 7 mice, in which $[K^+]_e$ prior to SD initiation was experimentally elevated over 10 mM.
These observations indicate the fundamental role of BK channels in the evolution of SD and AD. Moreover, we propose that K^+ efflux via BK channels effectively contributes to vasoconstriction in response to SD.

Title: Altered expression pattern of gene associated with retinoid-interferon induced mortality-19 (GRIM-19) following transient global cerebral ischemia in the mouse hippocampus

Authors: S.-N. HWANG[1,2], J.-C. KIM[1,2], *M.-Y. LEE[3,2], S. KIM[1,2]
[1]Dept. of Pharmacol., [2]Catholic Neurosci. Inst., [3]Catholic Univ. Med. Col., Seoul, Korea, Republic of

Abstract: Gene associated with retinoid-interferon-induced mortality-19 (GRIM-19) has been well known as a tumor suppressor gene in cancer research and a subunit of the mitochondrial respiratory chain complex I, required for mitochondrial ATP production. Brain ischemia, the leading cause of death and disability in developed countries, results in an abrupt increase of reactive oxygen species (ROS) that finally leads to cell death. GRIM-19 is a composition of the mitochondrial respiratory chain complex I where ROS is predominantly produced. In addition, ROS overproduction after ischemic insult has been considered as one of major causes of ischemia/reperfusion injury. Thus, the role of GRIM-19 in brain ischemia will help to clarify the mechanism of ischemia-induced brain damage. However, to date, there has been no report about the immunohistochemical expression pattern of GRIM-19 following brain ischemia, which is necessary to understand the pathophysiological role of GRIM-19 in cerebral ischemia. Therefore, in the present study, we examined the expression pattern of GRIM-19 in the adult mouse hippocampus after transient global cerebral ischemia. Male C57BL/6 mice (11 weeks old) were subjected to a 40-min of bilateral common carotid artery occlusion (BCCAO) followed by 3 days of reperfusion. Sham-operated animals received the same procedure without occlusion of the

common carotid arteries. To identify the cell types expressing GRIM-19, double immunofluorescence staining was performed using antibodies against GRIM-19 and either NeuN (a neuronal cell marker), GFAP (an astrocyte marker) or Iba-1 (a microglia marker). In sham-operated animals, GRIM-19 was expressed in most NeuN-positive cells but not in GFAP- and Iba-1-positive cells. In the BCCAO group, neuronal cell death and reactive astrocytes and microglial cells were observed in the hippocampal CA1 regions. It is noteworthy that the numbers of double-labeled cells for GRIM-19 and astrocytes or microglial cells were significantly increased in the non-pyramidal cell layer of the hippocampus, whereas there was a substantial loss of GRIM-19 immunoreactivity in the pyramidal cell layer. This is the first report showing immunohistochemical expression pattern of GRIM-19 in the hippocampus following transient global cerebral ischemia. These results raised the possibility that GRIM-19 plays a role in the reactive astrocytes and/or microglia following transient global cerebral ischemia. Further studies are needed to clarify the function of GRIM-19 in astrocytes and microglia under this pathophysiological condition.

Title: TrkB activation attenuates gephyrin misfolding induced by activity blockade and hypoxia ischemia in developing neurons

Authors: C.-C. HUNG, S.-P. HSU, W.-H. CHIEN, C.-Y. LEE, Y.-L. GAN, *Y.-H. LEE
Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Gephyrin is a scaffolding protein involved in clustering postsynaptic $GABA_A$ receptors for mediating inhibitory neurotransmission. Our previous study revealed that gephyrin misfolding occurs in protein kinase C (PKC) inhibition or neuronal activity blockade, as observed in neonatal hypoxia-ischemia (HI), due to the dephosphorylation of growth-associated protein 43 (GAP43) at serine 41 (S41). Activation of tyrosine receptor kinase B (TrkB) by brain-derived neurotrophic factor is known to mediate activity-dependent neuronal survival and plasticity involving PKC activation. Here, we investigated whether TrkB activation could rescue the activity blockade-induced gephyrin misfolding. We found that activity blockade-induced misfolded gephyrin was transported to aggresomes through association with histone deacetylase 6 and ubiquntin-K63. TrkB-activator, LM22A, attenuated S41 dephosphorylation of GAP43,

GAP43-gephyrin interaction, and gephyrin misfolding caused by blocking neuronal activity in developing neurons. Moreover, LM22A attenuated GAP43 dephosphorylation induced by oxygen-glucose deprivation in cultured cortical neurons and by hypoxia-ischemia in neonatal rat brains. Thus, these results suggest that TrkB activation is effective in ameliorating activity blockade-induced GAP43-gephyrin interaction and subsequent gephyrin misfolding in developing neurons, which may protect GABAergic synapse formation against neonatal HI injury.

Title: Neuronal activity associated with hypoxic-ischemic injury in neonatal mice

Authors: *D. SKWARZYNSKA[1], P. WAGLEY[1], J. KAPUR[3], J. BURNSED[2]
[1]Univ. of Virginia, Charlottesville, VA; [2]Univ. of Virginia, Crozet, VA; [3]Dept Neurol., Univ. Virginai Hlth. Sci. Ctr., Charlottesvle, VA

Abstract: Background: Hypoxic-ischemic encephalopathy (HIE) affects 1.5/1000 newborns annually and is associated with deficient cerebral blood flow (ischemia) and oxygen supply (hypoxia). HIE is a major cause of neonatal seizures, cerebral palsy, behavioral and cognitive defects. Neuronal circuits involved in HI-induced acute seizures are unknown. Further understanding of neuronal activation following HIE may lead to improved prognostic tools and new therapeutic strategies. **Objective:** Examine neuronal activation following HI-induced seizures in a neonatal "TRAP" mouse. **Methods:** HI was created using the Vannucci model (unilateral carotid ligation+45 min of 8% FiO2) in Cre-tamoxifen transgenic mice (TRAP) on postnatal day (p)10. 30 min later, mice were injected with 4-hydroxytamoxifen (4OHT) to allow expression of fluorescent protein in activated cells during the 1-2 hrs prior. Sham mice (neck incision+anesthesia, no ligation or hypoxia) and HI mice were perfused 7 days after injection. 200µm tissue sections were processed using the tissue clearing CLARITY method, then immunostained for NeuN. Imaging was performed on Zeiss 780 confocal microscope. Imaris 9.1 software was used to analyze images using the "ImarisColoc" function to determine the percentage of green (NeuN) and red (tdTomato) voxels that overlap. **Results:** CLARITY and

confocal microscopy allowed detection of activated neurons in the TRAP mice following HI-induced acute seizures. We observed selective neuronal activation in bilateral somatosensory cortex, ipsilateral (to carotid ligation) entorhinal cortex, dentate gyrus, CA3, lateral thalamic structures and striatum in HI mice compared to sham mice. Our data show that the ipsilateral hemisphere contains significantly more colocalized voxels compared to the contralateral hemisphere ($p<0.00001$) and sham mice ($p<0.00001$). **Conclusions:** CLARITY tissue clearing and confocal microscopy allowed visualization of neuronal activation following HI-induced seizures in neonatal "TRAP" mice. More activated neurons were present in the cortex ipsilateral to ligation as well as the hippocampal structures. The future goal is to examine if the neuronal activation in ipsilateral hippocampus is associated with deficits in memory function in neonatal HI-treated "TRAP" adult mice.

Title: Hyperglycemia drives increased superoxide production by peri-lesional microglia after permanent ischemia

Authors: *S. WON, S. GHOSH, A. HUYNH, R. A. SWANSON
Neurol, UCSF and SFVAMC, San Francisco, CA

Abstract: Hyperglycemia commonly occurs after stroke as part of a systemic stress response, even in non-diabetic patients. Hyperglycemia after stroke worsens outcome both in patients and in animal models of stroke, but the mechanism(s) of this effect are not defined and it remains uncertain whether patients should have hyperglycemia aggressively normalized. In other settings, hyperglycemia can promote tissue injury by fueling production of superoxide by NADPH oxidase. Here we evaluated superoxide production in a mouse photothrombotic model of permanent ischemia. Forty-eight hours after ischemia onset, hyperglycemia (blood glucose of 300-400 mg/dL; 15-20 mM) was induced by i.p. injection of glucose. Dihydroethidium (DHE) was infused at the same time. Three hours later brains were harvested for assessment of superoxide formation in the peri-infarct region by evaluating oxidation of DHE to fluorescent species. Hyperglycemia was found to significantly increase superoxide formation. The oxidized DHE was localized primarily to Iba1/CD11b positive cells (microglia/macrophages). The experiment was then repeated in $p47^{phox-/-}$ mice, which cannot form an active NADPH oxidse-2

complex. In contrast to wild-type mice, hyperglycemia did not produce an increase in peri-lesional superoxide formation in the $p47^{phox-/-}$ mice. These results suggest that hyperglycemia occurring many hours after ischemia can increase oxidative stress in peri-infarct tissues by fueling NADPH oxidase activity in reactive microglia/macrophages, and by this mechanism may contribute to worsened outcome.

Title: Intranasal insulin attenuates hypoxic-ischemic brain damage and sensorimotor behavioral disturbances in neonatal rats

Authors: C. P. TALATI, J. W. LEE, S. LU, N. B. OJEDA, Y. PANG, *A. J. BHATT, L.-W. FAN
Pediatrics, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Hypoxic-ischemic (HI) encephalopathy (HIE) causes significant morbidity and mortality in affected newborns. Current therapies have limited use and efficacy. There is an urgent need for additional therapies to improve these outcomes. Recent animal and clinical studies suggest that insulin may function as a neuroprotective agent, but its effect against HI brain injury is unexplored. Intranasal insulin (InInsulin) has been shown to have neuroprotective effects in adult stroke and Alzheimer's disease studies. The intranasal route is beneficial as it has a more direct CNS distribution and minimal systemic side effects. We tested a novel hypothesis that InInsulin is neuroprotective against HI brain injury in newborn rats. The objective of the current study is to examine whether InInsulin attenuates HI-induced brain injury and neurobehavioral dysfunction in neonatal rats.
At postnatal day 10 (P10), Sprague-Dawley rat pups were randomly divided into four groups of 8 pups per group: HI+Insulin; HI+Vehicle (Veh); Sham+Insulin; Sham+Veh. The male to female ratio was kept equal. Pups either had HI exposure by permanent ligation of right carotid artery followed by 90 min of hypoxia (8% oxygen) or sham surgery followed by room air exposure. Immediately after HI or Sham, pups received either intranasal recombinant human insulin (25 μg) or an equivalent volume of Veh in each nare. The Sham+Veh served as control. A panel of sensorimotor neurobehavioral tests was performed by a blinded observer on P11. A blinded

examiner evaluated the microscopic brain injury by estimations of brain damage following Nissl staining and Fluoro-Jade C staining (a marker for degenerating neurons) at P11. Statistical analysis was performed via two-way ANOVA followed by Student-Newman-Keuls method. The sample size was determined to find a difference of 30% between means with the power of 85% and significance of $p < 0.05$.
Our results showed that InInsulin attenuated HI-induced sensorimotor behavioral disturbances as seen in negative geotaxis, wire hanging, hind limb suspension, and righting reflex tests at P11 ($p<0.002$). There were no differences between the sexes. Rat pups exposed to HI had ipsilateral brain damage and Fluoro-Jade C positive cells compared with Sham+Veh group ($p<0.001$). InInsulin treatment reduced the HI-induced ipsilateral brain damage volume ($p<0.001$) and the Fluoro-Jade C positive cells in the neonatal brain ($p<0.002$). These results suggest that InInsulin may provide protection against neonatal HI exposure-induced sensorimotor behavioral disturbances and that these protective effects are associated with reduced brain damage.

Title: Endothelial activation of caspase-9 during hypoxia-ischemia regulates vascular integrity and neuronal survival

Authors: *M. I. AVRUTSKY[1], Y. Y. JEAN[1], C. W. CHEN[1], A. J. WHITE[1], S. K. YUEN[1], J. M. LAWSON[1], F. N. MORALES[1], A. M. POTENSKI[1], E. CANEPA[1], S. SNIPAS[2], G. S. SALVESEN[2], C. M. TROY[3]
[1]Pathology, Columbia Univ., New York, NY; [2]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [3]Dept Pathol & Neurol, Columbia Univ. Medl Ctr., New York, NY

Abstract: Introduction: Ischemic injury in central nervous system (CNS) tissues features neuronal dysfunction, inflammation and breakdown of vascular integrity.
Methods: To determine the mechanistic relation of these phenomena, we employed clinically relevant *in vivo* imaging—fluorescein angiography, optical coherence tomography (OCT) and focal electroretinogram (ERG)— in a mouse model of retinal vein occlusion (RVO). RVO was achieved by tail-vein injection of rose bengal, followed by laser photocoagulation of retinal veins using the Micron Phoenix IV system.
Results: RVO induced neuronal cell death and nonapoptotic activation of caspase-9 and caspase-7 in endothelial cells. Human brain tissue from patients with cerebral ischemia showed caspase-9 activation in blood vessels. Inhibition or genetic deletion of endothelial caspase-9 in RVO provided morphologic and functional neuroprotection. Topical application (eyedrops) of a cell penetrating specific caspase-9 inhibitor attenuated retinal edema, reduced leukocyte infiltration and preserved neuroretinal function following RVO.
Conclusion:These results reveal a nonapoptotic function of caspase-9 in endothelial cells which regulates blood-retinal barrier and neuronal survival and identify endothelial caspase-9 as a tractable target for treatment of hypoxic and ischemic injury.

Title: Temporal therapeutic window for calcium release-activated calcium (CRAC) channel inhibition in experimental stroke

Authors: *R. KACIMI[1], A. MIZUMA[2], K. KURISU[2], K. STAUDERMAN[3], M. J. DUNN[3], S. HEBBAR[3], M. A. YENARI[2]
[1]VA Med. Center, Neurol. Dept. (N127), Univ. of California San Francisco, San Francisco, CA; [2]Neurol., Univ. of California, San Francisco and Veterans Affairs, San Francisco, CA; [3]CalciMedica, San Diego, CA

Abstract: Purpose: Inflammatory responses after ischemic stroke contribute to the worsening of brain injury. Calcium release-activated calcium (CRAC) channels contribute to inflammation in brain ischemia and injury. We previously reported that CM-EX-137, a novel small molecule CRAC channel inhibitor improved outcomes in experimental stroke. In that study, treatment was begun minutes after stroke onset. In order to understand the translational potential of this compound, we now explore whether this inhibitor can be delayed hours after stroke onset.
Subjects and Methods: C57/BL6 male mice, aged 2months were exposed to distal middle cerebral artery occlusion (dMCAO). Some were treated with CM-EX-137 (5mg/kg/d IP) or vehicle (maximum 7days). CM-EX-137 treatment was delayed 1, 4 and 6h after dMCAO. Mice treated with vehicle or inhibitor given immediately after dMCAO were included for comparison. Mice were survived 14d. Neurological functions were evaluated using a modified Bederson score, elevated body swing test, and corner test before surgery and 1, 3, 7, 14d post dMCAO. Ischemic lesion was evaluated from hematoxylin & eosin staining. Microglia/monocyte/macrophage activation was assessed via isolectin B4 and CD68 staining.
Results: All mice exposed to dMCAO survived out to 14 days (n=6-7/ group). Neurological functions were significantly improved in the 1h and 4h delayed treatment group ($p<0.001$), but not at 6h. CM-EX-137 treatment within 4h also significantly reduced infarct volume ($p<0.05$) and microglia/monocyte/macrophage activation in the 1h and 4h delay groups($p<0.01$), but not in

the 6h delay group. **Conclusion**: CRAC channel inhibition by CM-EX-137 appears to have a temporal therapeutic window between 4-6h. As acute interventions in humans appears to be effective for recombinant tissue plasminogen activator (rt-PA) within 4.5h, and mechanical thrombectomy within 24h, future studies should include whether combination treatment with CM-EX-137 can further improve outcomes or lengthen the temporal therapeutic window of revascularization treatments.

Title: Suppression of inflammation by a novel calcium release-activated calcium (CRAC) channel inhibitor improves outcome in female mice exposed to experimental stroke

Authors: *A. MIZUMA[1], R. KACIMI[2], K. STAUDERMAN[3], M. J. DUNN[3], S. HEBBAR[3], M. A. YENARI[1]
[1]Neurol. UCSF and VAMC, San Francisco, CA; [2]VA Med. Center, Neurol. Dept. (N127), Univ. of California San Francisco, San Francisco, CA; [3]CalciMedica, San Diego, CA

Abstract: Purpose: The calcium release-activated calcium (CRAC) channel is a novel channel identified on immune and other cells. They comprise two subunits, STIM1 and Orai1, which sense changes in intracellular calcium, and have been studied indirectly through non-specific calcineurin inhibitors such as cyclosporine A and FK506. In immune cells, these calcium changes lead to activation of immune responses. Acute immune responses following stroke are known to worsen outcome. We have studied a new small molecule class of CRAC channel inhibitor that in preclinical and pilot clinical studies appears to be safe, well-tolerated and lacks the toxicities seen with calcineurin inhibitors. We previously reported that such a novel CRAC channel inhibitor specific to this channel improved outcome in male animals subjected to experimental stroke. Here, we explore responses in female animals. **Methods**: C57/BL6 female mice (n=7/group), aged 2 months were subjected to distal middle cerebral artery occlusion (dMCAO) and some were given CRAC channel inhibitor CM-EX-137 (5mg/kg/d IP, CalciMedica; dMCAO-CM) or vehicle (dMCAO). Mice were studied during the same phase of

the estrus cycle (diestrus). CM-EX-137 was injected immediately after dMCAO and at 24 & 48h. Mice were survived 3d. Neurological functions were evaluated by modified Bederson score, elevated body swing test, adhesive removal test, and corner test before surgery, 24 and 72 hours post dMCAO. Lesion volumes were evaluated by cresyl violet staining. Adjacent sections were stained with isolectin B4 (IB4), macrophage marker CD68 and inducible nitric oxide synthase (iNOS) to assess inflammation as well as CRAC channel components STIM1 and Orai1. **Results**: Neurological assays at 1 and 3d post-dMCAO were significantly improved in dMCAO-CM group ($p<0.001$), compared with dMCAO-vehicle. CM-EX-137 also significantly reduced infarct volume ($p<0.001$). Stroke-induced microglia & monocyte activation was suppressed by CM-EX-137 ($p<0.001$; IB4, CD68). iNOS expression was induced after brain ischemia and was significantly reduced by CM-EX-137 ($p<0.01$). Double staining with CRAC channel components STIM1 and Orai1 plus the macrophage marker CD69 showed reduction of these components with CM-EX-137 treatment ($p<0.001$). **Conclusion**: Female mice respond to CRAC channel inhibition in a manner similar to males.

Title: Regional responses of the brain water accumulation and blood-brain barrier disruption to conivaptan treatment after experimental stroke in mice

Authors: *E. ZEYNALOV[1], S. M. JONES[1], J. ELLIOTT[2]
[1]Swedish Med. Ctr., Englewood, CO; [2]Colorado Brain and Spine Inst., Englewood, CO

Abstract: Background: Stroke is associated with multiple devastating complications such as brain edema, disruption of blood-brain barrier (BBB), hyponatremia, and others. Conivaptan is a mixed V1a and V2 vasopressin receptor antagonist used to correct syndrome of inappropriate anti-diuretic hormone (SIADH)-induced hyponatremia. Our recent studies in mice showed that conivaptan can reduce stroke-evoked brain edema formation and BBB disruption in mice. Possible mechanisms of this beneficial effect are: 1) V1a receptor blocking effect may prevent vasoconstriction and improve cerebral blood flow; and 2) V2 receptor blocking can facilitate excretion of water by the kidneys, rise of plasma sodium creating osmolar gradient between the brain and the vascular compartment. Study rationale and objective: Stroke patients do not receive

treatment until the confirmation of diagnosis. Stroke-triggered severity of changes in the brain may be variable depending on the proximity to the occluded vessel. This study was designed to evaluate regional stroke-evoked brain edema formation and blood-brain barrier disruption in the context of the timing of conivaptan therapy initiation in mice. Methods: Mice underwent a 60-minute MCAO followed by reperfusion. Continuous infusion of conivaptan was initiated via an IV catheter at 3 and 5 hours after MCAO and administered for 48 hours. Animals were sacrificed, and the brains were harvested and divided into two hemispheres. Each hemisphere was further separated into three regions: anterior penumbra (AP), core (C) and posterior penumbra (PP). Brain edema was evaluated by measuring brain water content (BWC) using wet-to-dry ratio. Blood-brain barrier (BBB) disruption was assessed by the Evans Blue (EB) extravasation technique at the end point as well. Results: Continuous IV infusion with conivaptan initiated 3 hours of reperfusion reduced BWC in all regions of the brain: AP, C, and PP when compared to NS. However, 5-hour delay of conivaptan treatment was ineffective at reducing BWC in those regions. Conivaptan reduced BBB disruption after MCAO only in the AP at 3- and 5-hour delay. C and PP regions were unaffected by the treatment. Conclusions: Conivaptan treatment initiated at 3 hours after stroke reduces brain edema in all brain regions: AP, C, and PP. Further delay in treatment initiation up to 5 hours after stroke loses this beneficial effect of conivaptan. Conivaptan treatment initiated at 3 and 5 hours after MCAO attenuates BBB disruption only in AP, but not in C or PP regions. This diverse effect of conivaptan on BBB could be due to the vascular anatomy in mice. These findings may potentially be used in patients to improve recovery after stroke.

Title: Circular RNA TLK1 aggravates brain infarction and long-term neuronal dysfunction via miR-335-3p/TIPARP after ischemic stroke

Authors: *F. WU, B. HAN, S. WU, H. YAO
Dept. of Pharmacol., Sch. of Medicine, Southeast Univ., Jiangsu, China

Abstract: Circular RNAs (circRNAs) are highly expressed in the brain and involved in regulating physiological and pathophysiological processes. However, the potential role of circRNAs in neuronal damage and functional recovery in stroke remains largely unknown. Here, we demonstrated that circular RNA TLK1 (circTLK1) levels were significantly increased in ischemic brain tissues after transient middle cerebral artery occlusion (MCAO) in mice and up-regulated in plasma from acute ischemic stroke (AIS) patients. Knockdown of circTLK1 expression significantly decreased infarct areas, attenuated neuronal deficits, and promoted neuronal plasticity and long-term recovery in ischemic stroke mice. Mechanistically, circTLK1 functions as an endogenous microRNA-335-3p sponge to inhibit miR-335-3p activity, which subsequently caused the increased expression of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)-inducible poly (ADP-ribose) polymerase (TIPARP), with subsequent inhibition of neuronal survival and plasticity. Taken together, our results indicate that circTLK1 and its coupling mechanisms are involved in cerebral ischemia, thus indicating that circTLK1 may serve as a novel biomarker or therapeutic target for stroke.

Title: A novel mouse model with motor and cognitive deficit

Authors: *M. MORENO GARCIA, O. PATSOS, C. SCHROEDER, N. QUILLINAN
Anesthesiol., Univ. of Colorado Denver Anschutz Med. Cam, Aurora, CO

Abstract: Objective: Each year in the U.S. there are an estimated 20,000 strokes resulting in cerebellar infarction. The neurological impairments observed in these patients include motor coordination and motor learning impairments. Surprisingly, cerebellar stroke patients also exhibit cognitive impairments that affect memory and language. Establishing a model of cerebellar stroke that recapitulates aspects of human cerebellar infarction will allow for us to perform mechanistic studies of brain injury and identify therapeutic targets to improve recovery in stroke

patients. The goal of this study was to develop and characterize a photo-thrombotic mouse model of focal cerebellar stroke.
Methods: Adult male and female mice were head-fixed in a stereotaxic frame, were administered Rose Bengal (150 ug/g) and the superior cerebellar artery (SCA) was illuminated for 15 minutes with a cold white LED light source. Stereological analysis of lesion volume was performed at 1 and 7 days after surgery. Behavioral testing of motor and memory function was performed in mice subjected to sham procedure or photo-thrombosis at 7 days following surgery. Motor testing included gait, balance beam and paw preference analysis. Cognitive performance consisted on evaluation of spatial memory via a contextual fear conditioning assay.
Results: Cerebellar stroke volumes were larger at 1 day (2.4 mm^3) than 7 days (0.964 mm^3), likely do to edema at the earlier time point. Lesion volumes were similar between males and females at both time points. Increased blood brain barrier permeability at 1 day and glial reactivity at 7 days were observed in the infarct region. Interestingly, infarction of anterior lobules of the cerebellar cortex resulted in gait abnormality, motor coordination and ipsilateral limb impairments; whereas infarction of posterior lobules resulted in spatial memory deficits.
Conclusion: In conclusion, we have developed a reproducible model of cerebellar stroke that not only displays the pathophysiology of infarction but also presents motor and cognitive impairments previously evaluated in a clinical setting. This tool can help us understand the alterations that occur in the cerebellum as a result of cerebellar infarction and will become key to finding therapeutic targets to diminish the severity of behavioral outcomes.

Title: Targeting PTPσ enhances axonal regeneration, remyelination and functional recovery after intracerebral hemorrhage in mice

Authors: *H. SUN[1,4], M. YAO[1], H. LAI[1], S. RUXANDRA BADEA[2], Y. GAO[2], J. HUANG[1,3], G. K. LEUNG[1], W. WU[1]

China; [3]State Key Lab. of Brain and Cognitive Sci., The Univ. of Hong Kong, Hong Kong, China; [4]Dept. of Neurosurg., Zhujiang Hospital, Southern Med. Univ., Guangzhou, China

Abstract: Introduction:
One reason for limited recovery from intracerebral hemorrhage (ICH) may be the development of a glial scar at the border between normal and damaged tissue. The glial scar, which contains reactive astrocytes and associated extracellular matrix (ECM) proteins such as CSPGs, not only suppresses axon regeneration, but also results in demyelination due to oligodendrocyte death in both the immediate vicinity of the injury site, thereby interfering with long-term anatomical and functional recovery. CSPG inhibition of axonal regeneration,oligodendrocyte outgrowth and myelination are partially mediated by the protein tyrosine phosphatase sigma (PTPσ) receptor. Intracellular sigma peptide (ISP), a newly developed membrane permeable peptide which binds to PTPσ and relieves CSPG-mediated inhibition, has been used to promote regeneration and functional recovery after spinal cord injury and ischemic heart attack.
Aim: We hypothesize that treatment with ISP would lead to functional recovery by enhancing axon regeneration and remyelination after intracerebral hemorrhage.
Methods: Experimental ICH model in male mice was induced by intrastriatal injection of Collagenase IV. The functional recovery was evaluated weekly until 8 weeks post-ICH using rotarod test and Cylinder test following daily ISP (10μM) subcutaneous injection for the same period of time. Axon regeneration and remyelination weres assessed by histological staining, three-dimensional (3D) histological methods as well as immunoblot.
Results: Increased axonal sprouting and improved remyelination in the immediate vicinity of the injury site as well as functional recovery were observed in ICH mice treated with ISP.
Conclusions: These results suggest that modulation of PTPσ by ISP represents a potential therapeutic strategy for hemorrhagic stroke.

Title: Nitrosonifedipine ameliorates neurological symptoms and prolongs the surival in malignant stroke-prone spontaneously hypertensive rats

Authors: *Y. IZAWA-ISHIZAWA, M. IMANISHI, Y. ZAMAMI, K. TAKECHI, T. TAMAKI, K. ISHIZAWA
Tokushima Univ., Tokushima, Japan

Abstract: A malignant stroke-prone spontaneously hypertensive rat (M-SHRSP) is a model animal showing high rate of cerebral stroke. The onset and progressions of stroke are known to be involved in oxidative stress. Nitrosonifedipine (NO-NIF) is photolytic metabolite of nifedipine, an anti-hypertensive drug. We have revealed that NO-NIF possesses potent radical scavenging activity and protective effects against several pathological conditions involving oxidative stress. Therefore, we investigated the effects of NO-NIF on the onset and progressions of stroke in M-SHRSP in the present study. M-SHRSPs were treated with NO-NIF (30 mg/kg/day, i.p.) or vehicle from the age of five weeks. Neurological symptoms were observed every day and scored by severity of general status and disordered motility of anterior/posterior limbs. The day of the stroke onset was determined by neurological symptoms and the change in body weight. Brain was harvested after death and histologically analyzed. For in vitro study, nerve growth factor (NGF)-induced neurite elongation and intracellular signaling pathway was investigated using PC12 cells. Contrary to our expectations, NO-NIF could suppress neither the incidence nor the timing of stroke onset compared to control group. However, NO-NIF prolonged the lifespan of M-SHRSP. The periods until 50% rats died from stroke were extended for 29 days in NO-NIF group compared to control. In control rats, the neurological score showed linear worsening after stroke onset. However, its exacerbation was significantly suppressed in NO-NIF treated group. Consistently, NO-NIF treated rats showed less pathological lesion, such as hemorrhage, thrombus, and liquefaction degeneration in brains. In PC12 cells, NGF-induced neurite elongation was enhanced by NO-NIF existence. Moreover, NO-NIF prolonged the co-localization of NGF receptor and flotillin, a lipid raft marker, and the activations of intracellular signaling molecules, such as Akt and ERK1/2. In our previous study, we have already showed that NO-NIF affects the fluidity of cellular membrane. Therefore, it was considered that NO-NIF enhanced NGF signaling by changing the cellular membrane fluidity and localization of NGF receptor. In the present study, we demonstrated that NO-NIF could prolong the lifespan after stroke induced by malignant hypertension. It was also suggested that NO-NIF elongated neurite by enhancing NGF-stimulated intracellular signaling activities and finally improved the stroke-related neurological symptoms in M-SHRSP.

Title: Effects of glibenclamide against early brain injury after subarachnoid hemorrhage

Authors: *R. KAJIMOTO[1], T. IGARASHI[2], N. MORO[3], H. OSHIMA[4], T. SUMA[4], A. YOSHINO[5]
[1]Itabashi Hosp., 30-1 Oyaguchikamimachi, Itabashiku,, Japan; [2]Nihon Univ. Sch. of Medicine., Tokyo, Japan; [3]Neurosurg., [4]Nihon Univ. Sch. of Med., Tokyo, Japan; [5]Nihon Univ. Sch. Med., Tokyo, Japan

Abstract: Subarachnoid hemorrhage (SAH) is a devasting condition with high morbidity and mortality rate. Early brain injury (EBI), which is mainly caused by an increased intracranial pressure, occurring within 72 hours after SAH, has been considered as a prognostic factor and as a new therapeutic target. It has been reported that sulfonylurea receptor 1 (SUR1) is upregulated in neurons, glial cells and vascular endothelial cells in the early period after brain injury. It is known that the upregulation of SUR1 promotes influx of sodium and calcium into the cells through ion channel that will lead to cell swelling and causes cell death. It also has been reported that the excess upregulation of SUR1 causes inflammatory changes, although the mechanism in detail has not been elucidated yet. Glibenclamide is a therapeutic agent for diabetes mellitus that is used worldwide to decrease blood sugar level by acting to SUR1 on beta cell of the pancreas. Furthermore, it is reported that glibenclamide will reduce cerebral edema and decrease mortality rate in a middle cerebral artery occlusion model. However, the effects of glibenclamide against EBI after SAH has not been elucidated. In this study, we examined the effects of glibenclamide against EBI in a rat SAH model.
Male Sprague-Dawley rats were randomized into three groups, Sham group (n=3), SAH-control group (n=8) and SAH-glibenclamide group (n=8). Dimethyl sulfoxide (DMSO) was used as a control. Glibenclamide or DMSO was subcutaneously administrated via osmotic pump starting immediately after SAH. Brains were removed 24 hours after SAH. Brain edema was measured by dry-wet method. In the cortex, putamen and hippocampus, the expression of inflammatory cytokines was measured by polymerase chain reaction. In addition, 9 different rats (3 per group) were used to evaluate the expression of microglia by immunohistological method.
Brain edema in the SAH-glibenclamide group significantly decreased compared to the SAH-control group. SAH caused significant increase of interleukin-1 beta (IL-1β), tumor necrosis factor alpha (TNFα) and nuclear factor-kappa B in the cerebral cortex. In the SAH-glibenclamide group, IL-1β and TNFα levels were significantly suppressed compared to the SAH-control group. Activation of microglia was suppressed by glibenclamide administration.
Glibenclamide suppressed brain edema formation, activation of microglia and suppressed the release of inflammatory cytokines in a rat model of SAH.

Title: Treating cerebral ischemia and reperfusion induced neuronal injury with a cysteine precursor in mice

Authors: Y. LIU, J.-W. MIN, K. SUBEDI, *H. WANG
Univ. of South Dakota, Vermillion, SD

Abstract: Oxidative stress aggravates brain injury following ischemia/reperfusion (I/R). We previously showed that ubiquilin-1 (Ubqln1) protects brains against oxidative stress and I/R induced brain injury. Here, we demonstrate that a small molecule compound, L-2-oxothiazolidine-4-carboxylate (OTC) that functions as a precursor of cysteine, upregulated Ubqln1 and is a potential therapeutic reagent in both the cell and mouse models of ischemic stroke. In cultured neuronal cells, OTC elevated Ubqln1 protein level and reduced oxygen glucose deprivation-caused cell death in a dose-dependent manner. In an ischemic stroke mouse model, OTC (100 mg/kg) administered via the tail vein at 1 or 3 hours after reperfusion, significantly attenuated brain infarct injury and improved behavioral outcomes. Administration of OTC in stroke mice also restored reduced-glutathione level and suppressed the elevation of oxidized-glutathione. OTC treatment in stroke mice also decreased both superoxide production and the oxidized protein levels in the penumbral cortex at 24 hours following ischemic stroke. Consistently, OTC also upregulated Ubqln1 protein level in in the penumbral cortex following stroke, which was associated with increased glutathione S-transferase (GST) level. Moreover, we demonstrated that Ubqln1 interacted with and stabilized GST in cell cultures. These results suggest that OTC upregulates Ublqn1 and other antioxidant molecules and is a potential therapeutic reagent for stroke.

Title: The AVP antagonist conivaptan prevents early inflammatory responses following stroke in mice

Authors: *S. M. JONES[1], E. ZEYNALOV[1], J. P. ELLIOTT[2]
[1]Neurotrauma Res., Swedish Med. Ctr., Englewood, CO; [2]Colorado Brain and Spine Inst., Englewood, CO

Abstract: Background: Stroke and traumatic brain injury are major causes of death and disability world-wide, and more research into mechanisms of cell death and treatments to improve recovery are necessary. Arginine vasopressin (AVP) exacerbates edema and promotes blood brain barrier breakdown and neural damage following ischemia or traumatic brain injury. Following brain injury, AVP is elevated in plasma and brain tissue.
We have previously shown that the V1/V2 receptor blocker conivaptan prevents edema and blood brain barrier (BBB) breakdown in a mouse model of stroke. Breakdown of the BBB following injury has been linked to increased neuro-inflammation. This study was designed to determine whether treatment with conivaptan reduces stroke-induced neuro-inflammation in mice.
Methods: Mice (C57/Bl6) were subjected to 60-minute focal middle cerebral artery occlusion (MCAO) followed by reperfusion and continuous infusion treatment with conivaptan or saline. Five hours after MCAO, qPCR analysis on harvested brain tissue (ipsilateral and contralateral) was performed to examine the induction of the AVPR1a receptor as well as inflammatory markers TNFα, CXCL1 and CCL2. In separate sets of mice, survival time was 24 hours and the extravasation of FITC-albumin and CD68 staining was examined.
Results: Our studies revealed increased ipsilateral expression of the V1a receptor (AVPR1a), TNFα and CXCL1 within 5 hours of occlusion, which were prevented by conivaptan treatment. After 24 hours, FITC extravasation was reduced and CD68 labelled cells were significantly less numerous in mice receiving conivaptan treatment following MCAO. In cultures of primary astrocytes, oxygen glucose deprivation (OGD) induced the expression of AVPR1a but had no effect on TNFα, CXCL1 or CCL2 expression.
Conclusion: The activation of these early cellular responses to injury initiate a cascade of processes leading to secondary inflammation and the infiltration of neutrophils and monocytes, which have been shown to contribute to edema, BBB disruption and cellular damage.

Conivaptan is currently FDA approved for the treatment of hyponatremia. Our data indicate that conivaptan may have additional beneficial effects by reducing the induction of an early inflammatory response following stroke.

Title: Limiting hematoma growth by red cell microparticles following intracerebral hemorrhage

Authors: *K. DAVE[1], A. K. REHNI[2], H. NAVARRO[4], C. BIDOT, Jr.[4], V. SHUKLA[4], S. KOCH[4], M. A. PEREZ-PINZON[3], Y. S. AHN[4], W. JY[4]
[1]Neurol., Univ. Miami Sch. Med., Miami, FL; [2]Neurol., [3]Univ. of Miami Sch. of Med., Miami, FL; [4]Univ. of Miami, Miami, FL

Abstract: Spontaneous intracerebral hemorrhage (sICH) is the deadliest stroke sub-type. No effective treatment is available so far. Preventing hematoma extension, and/or prevention of continued bleeding in sICH are attractive therapeutic targets. It has been shown *in vitro* that red blood cell-derived microparticles (RMP) enhance platelet function and accelerate coagulation, augmenting both primary and secondary hemostasis. In the present study, we determined the efficacy of RMP in reducing hematoma expansion in a rat model of sICH. RMPs were prepared from human RBCs using a high-pressure extrusion method. sICH was induced in male Sprague Dawley rats by injection of collagenase into the right striatum. Rats were randomly divided into various experimental groups. At ~24 hours post-collagenase injection, neurological scores were evaluated, rats were sacrificed, and the hematoma areas on images of brain sections were measured. Induction of sICH and evaluation of hematoma area and neurological score was carried out by an investigator blinded to the experimental conditions. To determine dose of collagenase required to create moderate hematoma, we performed a dose response curve. Mean hematoma volume for 0.12 U / rat (n = 5), 0.17 U (n = 4), and 0.22 U (n = 5) collagenase treated animals was 40.6 ± 3.44, 72.0 ± 3.40 ($p<0.001$ vs 0.12 U group), and 79.1 ± 7.13 mm^3, respectively. We chose 0.17 U collagenase for subsequent studies. Next, we determined optimal RMP dose required to lower hematoma growth following sICH. Placebo (vehicle-treated) and three RMP-treated groups (low dose, medium dose, and high dose received total of 7.19×10^9, 2.55×10^{10}, and 9.48×10^{10} particles / kg b.w., respectively) were included in the study. We observed that hematoma volume for placebo, low dose, medium dose, and high dose group was

71 ± 4 (n = 19), 59 ± 5 (n = 10), 43 ± 2 (n = 10, p<0.001 vs placebo group), and 67 ± 5 (n = 10), respectively. The hematoma volume was lower by 17, 40 (p<0.001 vs placebo group), and 6% in low dose, medium dose, and high dose treated groups when compared to placebo group, respectively. We observed that neurological score was lower in low dose (9.4 ± 0.4, n = 10, p < 0.005), medium dose (9.3 ± 0.4, n = 10, p < 0.001), and high dose (9.4 ± 0.5, n = 10, p < 0.005) groups as compared to placebo group (10.8 ± 0.2, n = 19). Our results indicate that a medium RMP dose had maximum effect on hematoma expansion. Our results also demonstrate that although low and high RMP dosages had no effect on hematoma volume, both of these dosages did lower neurological score when evaluated at 24 h post-collagenase injection. Our results indicate that RMPs have potential to lower hematoma growth in sICH patients.

Title: Dual-function injectable angiogenic biomaterial for the repair of brain tissue following stroke

Authors: *L. R. NIH[1], S. CARMICHAEL[2], T. SEGURA[3]
[1]Dept. of Neurology, David Geffen Sch. of Med., Univ. of Los Angeles, California, Los Angeles, CA; [2]Neurol., UCLA Sch. Med., Los Angeles, CA; [3]Duke Univ., Durham, NC

Abstract: Stroke is the primary cause of adult disability due to the brain's limited ability to regenerate damaged tissue. After stroke, an increased inflammatory response coupled with severely limited angiogenesis and neuronal growth result in a necrotic lesion that compartmentalizes the degraded tissue within a physical empty cavity. Although the vascular endothelial growth factor (VEGF) appears as the best candidate for therapeutic angiogenesis, its administration after stroke has been limited by poor penetration across the blood-brain barrier, a short half-life time, and severe side effects due to its ability to promote vascular permeability. Recent advances in biopolymer hydrogels have developed gels with extracellular matrix motifs that not only support cell infiltration when injected directly in the stroke cavity but also allows a time and space-controlled delivery of growth factors. We hypothesized that the brain administration of an engineered immuno-modulating angiogenic biomaterial directly to the stroke cavity can promote tissue formation de novo by modulating post-stroke inflammatory response and angiogenesis. For this, male adult mice were subjected to an ischemic stroke and injected with a hyaluronic acid-based hydrogel containing heparin nanoparticles and covalently bound VEGF. This biomaterial generates a vascularized network of regenerated functional neuronal connections within previously dead tissue and reduces the post-stroke inflammation in and around the stroke site. These results are lost with the absence or reduction of bound VEGF where only the immuno-modulator effect is observed, and with the absence or reduction of heparin particles where angiogenesis is no longer associated with axonal sprouting. This work lays the groundwork for the use of dual immuno-modulator and angiogenic materials to repair other neurologically diseased tissues.

Title: Liposomal formulation of novel dual cox-lox inhibitor protects brain from cerebral ischemia induced neuronal injury

Authors: *V. GUPTA, A. KUMAR
Pharmacol. Division, Univ. Inst. of Pharmaceut. Sci., Panjab Univ., Chandigarh, India

Abstract: Objective: To investigate the neuroprotective potential of liposomal formulation of licofelone against global cerebral ischemia induced brain injury in Wistar rats.
Methods: Bilateral common carotid artery occlusion was performed for 30 minutes in male wistar rats for the induction of global cerebral ischemia. Post treatment with liposomal formulation of licofelone (2.5 and 5mg/Kg; *i.p.*) was done at every 12 hour interval. After 48 hours of reperfusion period, behavioral assessments were done, animals were sacrificed and brains were harvested for biochemical, mitochondrial and histological assessments.
Results: Post treatment with licofelone restored the behavioral function (as assessed by locomotor activity, rota rod performance, hanging latency and neurological score), arrested oxido-nitrosative stress (as assessed by lipid peroxidation, reduced glutathione, superoxide dismutase, catalase and nitrite), decreased neuroinflammation (as assessed by TNF-α), decreased apoptosis (as assessed by caspase-3), lowered mitochondrial damage (as assessed by enzyme complexes I-IV), decreased infarct area (as seen by TTC staining) and recovered histological alterations (as seen by H&E staining).
Conclusion: Post treatment with liposomal formulation of licofelone protects the brain from neuronal damage after global cerebral ischemia in wistar rats.

Title: Robotic rehabilitation and chemogenetic activation of serotonergic neurons for post stroke functional recovery

Authors: *S. CONTI[1], C. SPALLETTI[2], N. GIORDANO[2], S. LAI[1], A. GIORGI[3], M. PASQUINI[1], M. PASQUALETTI[3], M. CALEO[2], S. MICERA[1,4]

Chair in Translation Neuroengineering, Ctr. for Neuroprosthetics and Institu, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Abstract: Stroke is one of the leading causes of long-term motor disabilities. Re-acquisition of motor skills is a priority for stroke survivors, yet currently available rehabilitative therapies are not completely effective. Modern strategies aim to enhance motor rehabilitation by promoting neural plasticity, which is widely accepted to support functional recovery following brain damage. Serotonin, because of its neuroplastic properties, is a major candidate to drive the observed recovery. Here, we have investigated the role of serotonin and physical training in neuroplasticity and recovery after stroke. To this aim, we combined enhanced endogenous serotonin release with robotic rehabilitation and characterized motor recovery in a mouse model of stroke.We exploited a chemogenetic model for controlled serotonin release via systemic administration of clozapine-N-oxide (CNO) in transgenic mice expressing DREADD receptors specifically in serotonergic neurons. C-Fos expression in raphe neurons, together with increased serotonin transporter in peri-infarct cortex, demonstrated efficient and prolonged activation of the serotonergic system.We combined chemogenetic stimulation with robotic rehabilitation in stroke mice. Animals underwent unilateral photothrombotic lesion within the primary motor cortex (caudal forelimb area); 5 days after, they received daily doses of CNO and were rehabilitated using a robotic platform which allows quantitative assessment of forelimb flexion. Forelimb motor function was tested with two classical motor tests: Gridwalk and Schallert Cylinder Test. We also measured several kinematic parameters in a skilled reaching task.Results showed that the combined therapy promoted recovery of forelimb functions and that this motor improvement persisted beyond the treatment period. We next tested whether the recovery was associated to disinhibition of perilesional areas; to this aim, we measured GABAergic inhibition in the peri-infarct cortex. We found a reduction in somatostatin+ and parvalbumin+ interneurons as well as GABAergic terminals impinging on the soma of pyramidal neurons. These data supported the clinical evidence that a reduction in GABAergic inhibition promotes functional recovery in stroke patients.In conclusion, our study demonstrated that combining robotic rehabilitation with activation of the serotonergic system has a synergic effect and is beneficial for post stroke recovery.

Title: RNA sequencing analysis revealed a distinct motor cortex transcriptome in spontaneously-recovered mice after stroke

Authors: *M. Y. CHENG[1], M. ITO[6], M. ASWENDT[7], A. G. LEE[2], S. ISHIZAKA[3], Z. CAO[1], E. WANG[4], S. LEVY[1], D. L. SMERIN[3], J. A. MCNAB[8], M. M. ZEINEH[5], C. LEUZE[9], M. GOUBRAN[3], G. K. STEINBERG[3]

Abstract: Background: Many restorative therapies have shown to promote recovery after stroke. These therapeutic-induced changes have revealed important insights on brain repair and recovery mechanisms, however, the intrinsic changes that occur in spontaneous recovery after stroke is less clear. In this study we used RNA sequencing to elucidate the intrinsic changes in spontaneous recovery after stroke, by directly investigating the transcriptome of primary motor cortex in mice that naturally recovered after stroke. Methods: Ischemic stroke was induced in C57BL/6J adult male mice by transient MCAO for 30 min. Neurological score, vertical pole, rotating horizontal beam test and body weight monitoring were performed at baseline and post-stroke days 4, 8, and 14 to evaluate their recovery. All mice were sacrificed at post-stroke day 15, and a subset of these mice was processed for immunostaining with antibodies for inflammatory mediators such as astroglial (GFAP) and microglial activation (CD68). Infarct size and locations were evaluated either using T2-weghted MRI or histology. Ipsilesional and contralesional primary motor cortices (iM1 and cM1) were dissected and processed for RNA sequencing (RNA-seq) transcriptome analysis. Results: Cluster analysis of the stroke mice behavior performance revealed two distinct recovery groups: a spontaneously-recovered and a non-recovered group. This cluster separation corresponded well to their rotating beam performance, as spontaneously-recovered mice showed good performance at post-stroke day14, whereas non-recovered group exhibited poor performance. Lesion mapping analysis showed that there was no difference in the lesion size and locations between the groups. RNA-seq transcriptome analysis revealed distinct biological pathways in the spontaneously-recovered stroke mice, in both iM1 and cM1. Correlation analysis revealed that 38 genes in the iM1 were significantly correlated with improved recovery, while 74 genes were correlated in the cM1. In

particular, ingenuity pathway analysis highlighted the cyclic adenosine monophosphate (cAMP) signaling in the cM1. Conclusions: Our RNA-seq data revealed a panel of recovery-related genes in the motor cortex of spontaneously-recovered stroke mice and highlighted the involvement of contralesional cortex in spontaneous recovery. Current studies include validation of key molecular candidates in the cAMP pathway and their role in recovery. Developing drugs targeting the cAMP pathway after stroke may provide beneficial recovery outcome.

Title: Targeting antibodies to the CNS: A comparative study of intrathecal, intravenous and subcutaneous antibody treatment after stroke

Authors: *D. CORREA, A. S. WAHL, S. IMOBERSTEG, M. MAURER, M. E. SCHWAB
Univ. of Zurich, and Dept. Hlth. Sci. and Technology, ETH Zurich, Brain Res. Inst., Zuerich, Switzerland

Abstract: With more and more antibody-based potential therapeutics emerging as promising treatments for central nervous system (CNS) disorders, the question of how to bring these high molecular compounds into the CNS parenchyma is of utmost importance. Here, we provide a comparison of antibody distribution in the CNS tissue, the cerebrospinal fluid and the serum following three routes of administration: intravenous (i.v), intrathecal (i.t), and subcutaneous (s.c) in intact rats or after stroke. For the stroke experiments, rats were subjected to a photothrombotic stroke destroying >95% of the sensorimotor cortex unilaterally. We infused full length IgG antibodies against the neurite growth inhibitory CNS membrane protein Nogo A by lumbar intrathecal pumps (for 2 weeks after stroke). Alternatively, intravenous antibodies dosed 10 times higher than the total amount given i.t. were injected twice, within the first week after stroke. Subcutaneous antibodies were injected at total amounts of 15 times higher than the total amount given via intrathecal pump in the first 3 days post insult followed by booster doses once

every day, over the next 7 days. We measured the plasma pharmacokinetics (PK), tissue concentrations in the brain, functional readouts including detailed characteristics of grasping behaviour during stroke recovery, and analysis of neuronal, corticospinal rewiring in the spinal cord. We find that the intrathecal application of anti-Nogo antibodies results in the highest recovery levels after stroke. Functional recovery and anatomical rewiring were much lower in the groups with intravenous or subcutaneous antibody application, in spite of the high plasma levels of the antibodies. Serum concentration of antibodies was higher within the first 7 days in the intravenous than the subcutaneous condition. This study shows that intrathecal lumbar infusion of anti-Nogo-A antibody achieves excellent CNS targeting, leading to a high level of functional recovery and enhanced anatomical plasticity, whereas even large amounts of peripherally administered antibodies failed to reach functionally effective levels in the CNS.

Title: The neuroprotective effects of non-competitive ampa receptor antagonist (perampanel) and a2a receptor antagonist (istradefylline) in a small vessel stroke model

Authors: *M. ZAKI[1,2], F. S. CAYABYAB[3]
[1]Col. of Med. Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]Dept. of Pharmacol. and Toxicology, Fac. of Pharm., Kafrelsheikh, Egypt; [3]Dept. of Surgery, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Extracellular brain adenosine concentrations increase more than 100-fold after pathological trauma such as head injury, hypoxia and ischemia. The neuroprotective effect of adenosine through A1R is short lived as A1R desensitization occurs after 12-24 hour of chronic A1R stimulation. Therefore, ischemic stroke is associated with low expression of the neuroprotective inhibitory A1R and high expression of A2AR, which enhances neuronal excitability and glutamate-induced neurotoxicity. We hypothesize that induced neurodegeneration in our in vivo focal cortical stroke model, is mediated by action of elevated

adenosine and glutamate on the highly expressed A2AR and calcium-permeable AMPAR, respectively. This can be prevented by administration soon after a stroke of a clinically approved drug Perampanel, a non-competitive AMPAR blocker, or Istradefylline a selective A2AR antagonist. Propidium Iodide and Fluoro-Jade C staining showed increased neurodegeneration in hippocampus in PVD group compared to SHAM, Perampanel- and Istradefylline-treated groups. Western blots of SHAM and Perampanel or Istradefylline treated groups have lower expression of both nNOS and iNOS compared to PVD group. Finally, 200 nM Perampanel significantly inhibited the post-hypoxic synaptic potentiation in fEPSP that occurs after hypoxia/reperfusion and returned the potentiated fEPSP back to baseline levels. Moreover, perfusing 75 nM perampanel after 5 min. of hypoxia prevented the post-hypoxic synaptic potentiation in fEPSP during the washout. Taken together, Perampanel and Istradefylline exhibit a neuroprotective effect in PVD model, by inhibiting glutamate excitotoxicity mediated by the upregulated expression of calcium-permeable AMPARs and A2AR after ischemic stroke.

Title: Quercetin prevents the ischemic brain injury-induced decrease of neuronal calcium sensor protein, hippocalcin

Authors: *P.-O. KOH[1], D.-J. PARK[1], M. SHAH[1], M.-O. KIM[2]
[1]Dept. of Anatomy, Col. of Vet. Med., [2]Div. of Life Science, Col. of Natural Sci. and Applied Life Sci., Gyeongsang Natl. Univ., Jinju, Korea, Republic of

Abstract: Intracellular calcium is involved in a variety of biological events such as metabolism, cell proliferation and apoptosis. Hippocalcin is a neuronal calcium buffering protein that regulates intracellular calcium concentration and prevents cells death against apoptotic stimuli. Quercetin has an excellent anti-oxidant property and exerts a neuroprotective effect. The aim of this study was to investigate whether quercetin is capable of modulating hippocalcin expression in cerebral ischemia and glutamate excitotoxicity-induced neuronal cell death. Focal cerebral ischemia was induced by middle cerebral artery occlusion (MCAO). Male Sprague-Dawley (n = 40) rats were treated with vehicle or quercetin (30 mg/kg) 1 h prior to MCAO, and cerebral cortical samples were obtained 24 h after MCAO. Protein and transcription levels of hippocalcin were measured by Western blot and RT-PCR and hippocalcin decreased in vehicle-treated

animals with MCAO, whereas quercetin attenuated the ischemic injury-induced decline of hippocalcin expression. Glutamate exposure induced intracellular calcium overload in cultured mouse hippocampal cells, whereas quercetin remarkably alleviated the intracellular calcium increase induced by glutamate exposure. Glutamate-induced excitotoxicity decreased hippocalcin level, while quercetin treatment prevented the glutamate exposure-induced decrease of hippocalcin. Taken together, these results suggest that quercetin exerts a neuroprotective effect through regulating hippocalcin expression and modulating intracellular calcium levels during cerebral ischemia and glutamate-induced neuronal cell damage.

Cheonan Hosp., Cheonan-Si, Chungcheongnam-Do, Korea, Republic of

Abstract: Ischemic stroke is one of the major diseases in the worldwide. Also, the one of most common causes of death in Korea is stroke and many people suffer from stroke as well. Especially, about 10% of stroke cases lead to epilepsy, and repeated strokes lead to vascular dementia. So, there is increasing interest in clearing the underlying pathological mechanisms and identifying possible treatment strategies. Sildenafil, as known as Viagra is a phosphodiesterase-5 inhibitor and effect the nitric oxide-cyclic guanosine monophosphate pathways, which are deeply involved in the pathogenesis of the neurological diseases by causing intracellular accumulation of cGMP. Thus, it may have a favorable therapeutic effect on the treatment of stroke, neurodegenerative disorders and vascular dementia by enhancing angiogenesis and neurogenesis. Therefore, in this study, we investigated whether its beneficial effects involve to the change of

stroke infarct size and the cognitive functions. The first stage of this study is to confirm the phenotype after mild MCA occlusion (MCAo). The focal cerebral ischemia was induced by 30 min of MCAo in adult rats. After establishing the mild stroke-induced MCAo animal model, we injected Sildenafil in mild stroke model and conducted a behavioral test to identify the cognitive function. In addition, mild stroke animal models were tested by using variety of electrophysiological parameter following MCAo. Moreover, to confirm the infarct volume of brain, histological staining was performed. As a result, we obtained significant results compared with the mild stroke animal model treated with and/or without Sildenafil, which means that improving the cognitive behavioral phenotypes and the potential role for reducing the symptomatic outcomes after mild MCAo. According to these results in this study, therefore, we suggested that it may involve to the novel therapeutic effects for progressing the diverse phenotypes of mild ischemic stroke following MCAo.

Title: Removing the brakes on brain recovery after stroke by metabotropic glutamate receptor 5 negative allosteric modulators

Authors: J. HAKON[1], J. QUATTROMANI[1], F. MASTROIACOVO[2], E. ENGLUND[1], C. SJÖLUND[1], L. DI MENNA[2], K. BEIRUP[1], S. MOYANOVA[2], K. RUSCHER[1], F. NICOLETTI[2,3], A. Q. BAUER[4], *T. W. WIELOCH[1]
[1]Lund Univ., Lund, Sweden; [2]IRCCS Neuromed, Pozilli, Italy; [3]Sapienza Univ., Rome, Italy; [4]Washington Univ., Saint Louis, MO

Abstract: Stroke is a main cause of life-long disability worldwide. Whilst task-specific rehabilitative training is an evidence based stroke treatment, there is no pharmacological therapy that enhances neurological recovery after stroke beyond the therapeutic time window of neuroprotection. In the experimental setting, housing rodents in an enriched environment (EE) accelerates behavioural recovery and enhances brain-wide functional connectivity in cortical regions local and distant from the injury (Hakon et al., NeuroImage: Clinical, 2018). We

investigated how modulation of mGluR5 receptors influences the recovery of neurological function after stroke in rodents. We employed the photothrombosis or endothelin-1 stroke models in rats or mice. Housing in an EE or treatment with mGluR5 modulators typically started 2 days after stroke and continued for 14 days. Neurological function was assessed by paw placement, grid, and grip tests. Resting-state functional connectivity (RS-FC) was assessed using optical intrinsic signal (OIS) imaging. Treatment with 5 structurally different mGluR5 negative allosteric modulator (NAM) molecules provided a robust improvement of neurological function compared to vehicle-treated animals 14 days after stroke. Improvement was attained even when treatment started 7 days after stroke, and the therapeutic effect remained at least 7 days after termination of treatment. In mGluR5 knock-out mice, function improved to the same degree as observed in wild type animals treated with the mGluR5 NAM 3-[(2-methyl-1,3-thiazol-4-yl)ethynyl]pyridine (MTEP). Housing in an EE in combination with MTEP treatment provided a synergistic recovery enhancing effect. Daily pre-treatment with the mGluR5 positive allosteric modulator VU0360172 prevented the recovery enhancing action of MTEP. In addition, the recovery enhancing effect of EE was prevented by concomitant treatment with VU0360172. None of the treatments affected infarct size when assessed at 7 or 14 days of recovery. At the network-level, treatment with MTEP increased intra-hemispheric RS-FC in contralesional sensorimotor areas, and at the cellular level a time-dependent modulation of mGluR5 mediated cell signalling was found. The presence of mGluR5 was confirmed in both brain hemispheres of stroke patients. We conclude that post stroke mGluR5 activation hampers neurological recovery in rodents and that treatment with mGluR5 NAMs provide strong recovery of integrated sensorimotor function associated with contralesional cortical remodelling. Selective mGluR5 NAMs could become a future pharmacological therapy for promoting functional recovery after stroke.

Title: Coadministration of metformin and the dpp-4 inhibitor evogliptin counteracts stroke in diabetic rat brain

Authors: *S.-J. LEE[1], B. YOON[2], J. HONG[3], J. LEE[4]
[1]Ajou Univ. Med. Ctr., Suwon, Korea, Republic of; [2]Ajou Univ. Grad. Sch., Suwon, Korea, Republic of; [3]Sch. of Med., Ajou Univ., Suwon, Korea, Republic of; [4]Ajou Universityu Med. Ctr., Suwon, Korea, Republic of

Abstract: Presenting hyperglycemia and diabetes mellitus (DM) are predictors of a poor outcome in acute ischemic stroke. Beta cell dysfunction and insulin resistance are the two main underlying physiology of DM. The aim of the study was to determine the ant-ischemic effects of counteracting beta cell dysfunction and insulin resistance by pretreatment with evogliptin, a dipeptidyl peptidase (DPP-4) inhibitor, and metformin, respectively, and combined. Type 1 diabetes was induced by intraperitoneal injection of streptozotocin in rats aged 6~8 weeks. The rats were treated with vehicle, evogliptin, metformin, or evogliptin/metformin co-administration for 30 days. Stroke was induced by transient middle cerebral artery occlusion afterwards. Blood DPP-4 activity, GLP-1 levels, glucose, body weight, and food intake were evaluated. Blood levels of fasting insulin and glucose were measured after 30 days of medical treatment for assessment of homeostatic model assessment (HOMA) of insulin resistance and beta cell function in each groups. Ischemic damage was measured by determining infarct volume through T2 weighted magnetic resonance imaging. Immunohistochemistry for GLP-1 receptors in infarct tissue and penumbra were performed. Western blotting of AMPK, Akt/PI3K pathways, and markers of apoptosis were performed in ischemic core and penumbra. The results showed pronounced reduction of infarct volume in the co-administration group. Blood glucose lowering effects were significant in the metformin group and co-administration group, while glycated hemoglobin levels were significantly lower in the co-administration group. Basal insulin levels and HOMA-ß% was significantly higher in the co-administration group, while HOMA-IR did not differ. These results show that combined treatment of metformin and evogliptin strengthen the beta cell protective effects in streptozotocin induced diabetic mice, and this this may offer neuroprotective effects in addition to the direct effects of the antidiabetic drugs. This finding may provide guidance in selection of antidiabetic drugs to reduce neurovascular outcomes in diabetic patients, and give insight into the effects of prediabetic pathophysiology in stroke outcomes.

Title: Hypothermia but not MK801 protects against brain infarction caused by distal middle cerebral arterial occlusion

Authors: *C. LIU[1,2], C. H. TSENG[1], K.-M. HUNG[2], T. W. LAI[1,2]
[1]Sch. of Med., [2]Grad. Inst. of Biomed. Sci., China Med. Univ., Taichung, Taiwan

Abstract: Stroke is a major cause of death and disability in Taiwan, USA, and other developed countries. Yet, there remains no effective neuroprotective treatment for stroke. NMDA receptor blockers like MK801 have been shown to be effective against the most popular animal model of stroke: the suture-insertion model, in which the middle cerebral artery is occluded by a suture inserted from the carotid artery. However, this model causes collateral damage to the hypothalamus, leading to hyperthermia that is widely believed to exacerbate brain damage. As a result, MK801-mediated protection of the hypothalamus, which in turn prevents hyperthermia, can contribute to neuroprotection in this model. To better evaluate whether MK801 is neuroprotective, we investigated the effect of hyper- and hypothermic treatment and MK801 administration in a stroke model that does not damage the hypothalamus nor cause hyperthermia. Specifically, we subjected mice to distal middle cerebral arterial occlusion (dMCAo), and 24 h later measured their infarct area/volume after staining by 2,3,5-triphenyltetrazolium chloride (TTC). As with the suture-insertion model, hypothermia strongly protected against brain infarction caused by dMCAo. Nevertheless, MK801 treatment had no appreciable effect on infarct volume. Our study supports the notion that hypothermia is neuroprotective against focal ischemia regardless of whether the stroke model predisposes animals to hyperthermia. Furthermore, and contrary to the results based on the suture-insertion model, MK801 failed to protect against stroke damage. Title: Identification and characterization of bioactive component which contributes to the beneficial extract of clinacanthus nutans against ischemia-reperfusion injury

Authors: *J.-S. WU, M.-H. KAO, H.-D. TSAI, W.-M. CHEUNG, T.-N. LIN
Neurosci. Division, IBMS Academia Sinica, Taipei, Taiwan

Abstract: BACKGROUND AND OBJECTIVE:
Clinacanthus nutans Lindau (C. nutans), a popular traditional herb in many tropical Asian, is widely used for treating snake and insect bites, viral infections, due largely to its anti-inflammatory, anti-oxidative properties. Recently, we have reported that C. nutans (CN) protected cortical neuron from hypoxia/ischemic insult in experimental stroke study, however, biological active ingredients and the underlying molecular mechanisms remain largely unknown. In this study, we aimed to identified investigate whether this bioactive component protects against ischemic brain injury via C/EBPβ-dependent PPAR-γ signaling pathway.
METHODS:
Analysis of CN extract using HPLC and high resolution tandem MS/MS identified which component contributing to the neuroprotective effects. To investigate the protective effects of biological active ingredients of CN extract against stroke. Primary cortical neurons were subjected to oxygen/glucose deprivation-reoxygenation (H-R) *in vitro* hypoxic model. MTT assay was used to detect cell viability. Flowcytometry was used to monitor apoptosis. Reporter assay and ChIP were used to detect the transcriptional activity of PPAR-γ. For *in vivo* study, rats were subjected to 3-vessel occlusion (MCAO)/reperfusion. Neurological deficit scores and infarct volumes were used to evaluate functional and cellular damage.
RESULTS:
In vitro**:* With bioactivity-guided HPLC fractionation and high resolution tandem MS/MS, we identified Schaftoside, a C-glycosyl flavones, as the major component contributing to the neuroprotective effect of CN. Using pharmacological antagonist, siRNA knockdown, reporter and ChIP analyses, we further unraveled that Schaftoside selectively enhanced C/EBPβ binding to a unique C/EBPβ binding site (-332~-325) on the PPAR-γ promoter to drive its transcription and the subsequent activation of 14-3-3ε→p-Bad anti-apoptotic signaling. ***In vivo: Intraperitoneal injection of Schaftoside, either pre-or post-ischemic, significantly reduced infarct brain volumes and improved functional recovery up to 2 weeks of reperfusion. Notably, these

beneficial effects could still be obtained even Schaftoside administered at 24hr after 30-min MCA occlusion.

CONCLUSIONS:

It is the first report Schaftoside to exert neuroprotective effects through the C/EBPβ-PPAR-γ pathway not only provides novel therapeutic targets but also paves new ways for potential drug candidates for prevention and treatment of ischemic stroke and possibly other neurodegenerative diseases.

Title: Mir363 treatment improves depressive-like behavioral phenotype and rescues retrograde degeneration of meso-striatal projections in middle aged female rats

Authors: *A. PANTA, S. PANDEY, I. DUNCAN, S. DUHAMEL, F. SOHRABJI
Neurosci. and Exptl. Therapeut., Texas A & M Hlth. Sci. Ctr., College Station, TX

Abstract: Introduction: Stroke survivors suffer from long-term physical, cognitive and affective disabilities. These disabilities lower the quality of life, contribute to social isolation and anhedonia, and clinical disorders such as post-stroke depression (PSD), which disproportionately affects women. Behavioral tests measuring sociability, helplessness/hopelessness and anhedonia can be used to assess depressive-like behavior in animal models. **Hypothesis**: Ischemia induced by MCAo leads to depressive-like behavior in middle aged female rats which is improved by mir363-3p treatment. The depressive-like behavior is associated with retrograde degeneration of the meso-striatal pathway in the ischemic hemisphere. **Methods:** Middle-aged Sprague-Dawley female rats (12 months old) were subjected to ischemic stroke using stereotaxic injection of a vasoconstrictor, Endothelin-1, and randomly assigned to two treatment groups: scrambled oligos or mir363-3p mimic. Effort-based Sucrose consumption, Social Interaction and Forced Swim Test were performed over the 100 days to assess depressive-like behavioral phenotype. Thereafter, rats were anesthetized and the retrograde tracer, Fluorogold (Flg), was injected into the left and right striatum. Four days later, animals were overdosed with anesthetic, perfused with saline and formaldehyde and the brain removed for cryosectioning.. In three sections per animal, Flg-labeled cells in the VTA and SNc were counted on both hemispheres, using fluorescent illumination. **Results:** After stroke, there was a 3 fold decrease of high-reward choice

(anhedonia) in the Effort-based Sucrose consumption test in the group that received scrambled oligos, as compared to the group that received mir363-3p by 100 days. Social interaction for scrambled group was 3 times lower as compared to the mir363-3p group in 100 days post stroke. The swim test showed significant increase in helplessness for scrambled group (by 32.7%)as compared to mir363-3p (by 6.4%) in 100 days. Flg labeled neurons in the VTA and SNc were significantly reduced in the ischemic hemisphere as compared to the non-ischemic hemisphere (p&IT0.05) by 100 days.Conclusions: Our previous work shows that mir363-3p treatment given 4h after stroke reduces infarct volume in the acute phase (5days). The current studies show that post-stroke mir363-3p treatment improves long-term stroke disability by improving depressive-like behavior. Mir363-3p also preserves striatal-projecting VTA and SNc neurons in the ischemic hemisphere, a pathway that is involved in reward behaviors.

Title: Identifying the cellular basis for early and delayed metformin-induced recovery in a model of neonatal stroke

Authors: *J. LIVINGSTON-THOMAS, J. ANUPOL, T. SAYED, R. RUDDY, C. MORSHEAD
Univ. of Toronto, Toronto, ON, Canada

Abstract: Neonatal hypoxia-ischemia (H/I) is one of the leading causes of childhood brain injury, resulting in profound physical and cognitive deficits. Currently there are no established treatment options to improve deficits following H/I, and current rehabilitation strategies award only modest recovery. We have previously shown that administration of an anti-diabetic drug, metformin (Met) beginning 24 hours after H/I injury on post-natal day (P8) leads to attenuation of motor deficits at P22 and activation of endogenous neural precursor cells (NPCs) including both expansion of the NPC pool and increased migration and differentiation. More recently, we demonstrated that Met treatment also promotes recovery of cognitive dysfunction. Interestingly,

there exists a population of NG2 expressing oligodendrocyte precursor cells (OPCs) that comprise up to 5% of brain parenchymal cells. Given the demonstrated correlation between oligogenesis and functional recovery, we hypothesized that endogenous OPCs may play an important role in Met-induced functional recovery. Using a transgenic approach, we used NG2CreERT2 x TdTomato mice to perform lineage tracing on this population of OPCs following early Met treatment. Moreover, we proposed that delaying Met treatment for 1 week (a clinically relevant paradigm) would be equally effective at improving short- and long-term recovery. Male and female C57/BL6 mice were subjected to H/I (or a sham procedure) at P8, then received either early or delayed Met treatment. Motor and cognitive functions were assessed across time using various behavioural tests (cylinder, foot fault, puzzle box, water maze). Tissue was collected at P28 (short-term) or 63 (chronic) and analyzed for the presence of proliferative cells, immature neurons, and oligodendrocytes. Our findings to date reveal differential effects of treatment on functional recovery in males and females. We found no significant differences in the number of immature neurons in the subventricular zone (SVZ), dentate gyrus (DG), or motor cortex between groups, nor the number of proliferating cells in the SVZ or DG. However, we did observe a significant increase in the number of proliferating cells in the motor cortex of H/I mice that received delayed Met treatment. These results suggest that a clinically relevant Met treatment paradigm is able to rescue functional deficits and lead to neural repair in certain patient populations.

Title: Gpr37 regulates proliferation of reactive astrocytes in peri-infarct region after ischemic stroke in adult mice

Authors: *C. QU[1,3], S. S. ZOU[1], S. OWINO[2], X. H. GU[1], Z. Z. WEI[1], L. WEI[1], R. A. HALL[2], S. P. YU[1]

Abstract: GPR37 belongs to the superfamily of G protein-coupled receptors (GPCRs). In both human and rodents, GPR37 is enriched in the brain; it plays an important role in the pathogenesis

of Parkinson's disease and possibly in autism spectrum disorder. Previous investigations including ours demonstrated that GPR37 is cytoprotective after brain injuries including ischemic stroke. Our recent data reveals that the expression of GPR37 regulates astrocyte activation and gliogenesis in the peri-infarct region after stroke. The present investigation explored the possibility that GPR37 may play a regulatory role in promoting proliferation of reactive astrocytes. GPR37 knockout (KO) mice were subjected to focal ischemic stroke targeting the sensorimotor cortex. Immunohistochemical staining in brain sections compared the number of BrdU+/GFAP+ and Nestin/GFAP+ cells in the cortical peri-infarct area of wild type (WT) and GPR37 KO mice. Three days after stroke, the number of proliferating astrocytes was significantly decreased in GPR37 KO stroke brain. Meanwhile, Sox2+/GFAP+ cells in the subventricular zone (SVZ) were significantly less in GPR37 KO mice compared to WT mice. Interestingly, fewer Nestin/GFAP double positive cells were seen in the peri-infarct region of the KO brain, implying that GPR37 might affect neural progenitors in the post-stroke brain. Long-term study of functional assessments showed that GPR37 KO mice are more likely to exhibit behavioral deficits 21 days after stroke. The available data suggest that GPR37 may play an important regulatory role in astrocyte activation and proliferation. Moreover, the possibility that GPR37 might regulate SVZ neurogenesis and astrogliogenesis should be further investigated.

Title: Role of DNA repair gene in estrogen receptor alpha expression following neonatal hypoxic ischemic encephalopathy

Authors: V. CHANANA[1], D. ZAFER[1], D. HANALIOGLU[1], M. SEREBIN[1], K. M. AMBORN[1], M. FROBER[1], M. B. HACKETT[1], P. FERRAZZANO[2], A. P. AUGER[3], J. E. LEVINE[4], *P. CENGIZ[2]

Abstract: Objective: Neonatal hypoxia ischemia (HI) related encephalopathy is one of the major causes of learning disabilities and memory deficits in children. Male neonatal brains are

two times more vulnerable to the effects of HI. We recently reported that HI increases hippocampal estrogen receptor α (ERα) expression leading to neuroprotection only in the female mice hippocampi through crosstalk with the neurotrophin receptor, tyrosine kinase B (TrkB). Phosphorylation of the TrkB via its agonist, 7,8-dihydroxyflavone (7,8-DHF) improves long-term neurological outcome only in female mice. In order to understand the underlying mechanisms of this upregulation, we investigated the panel of methylating and demethylating genes, and found that gadd45b is sexually upregulated in female hippocampi compared to males one day post-HI. We hypothesized that gadd45b upregulation is required for ERα upregulation and TrkB mediated neuroprotection in female hippocampi following neonatal HIE.
Methods: HI was induced in P9 B6/C57 male and female wild type (WT) and gadd45 knock out (KO) mice by using Vannucci's HI model. Hippocampi were extracted at 1 day and 3 days after HI for gadd45b and ERα mRNA expressions using qPCR, respectively.Recognition and object location memories were assessed at P60+ by novel object recognition (NOR) and location (NOL) tests in WT and gadd45b KO mice with and without 7,8-DHF(5mg/kg, i.p.) therapy following neonatal HI. The time spent exploring each object was recorded. Then the discrimination ratio (DR) (time spent with novel object divided by total time spent with both objects) was calculated for 5 min exploration time. ANOVA was used for analysis (mean ± SEM).
Results: The demethylating DNA repair enzyme, gadd45b, was significantly upregulated in the ipsilateral female hippocampi compared to male following in HI on day 1 ($p<0.05$)**.** Increased ERα expression in female hippocampi was ablated in gadd45b KO female mice ($p<0.05$) 3 days post-HI. HI decreased the DRs for both NOR and NOL tests in ERα WT male (% 28 ± 2 and %23 ± 3) and female (% 28 ± 9 and % 28 ± 4) mice compared to sham WT male (% 72 ± 5 and % 55 ± 6) and female (% 68 ± 4 and % 71 ± 12) mice ($p < 0.001$), respectively. HI induced decline in recognition and location memories were recovered by 7,8-DHF therapy only in ERα WT females for both NOR and NOL tests, respectively [% 64 ± 6 and % 67 ± 4, ($p < 0.001$)].
Conclusion: Our preliminary studies suggest that gadd45b is upregulated in female neonatal mice hippocampi and sexually differences seen in ERα mRNA expression is ablated in gadd45b KO female mice hippocampi. NOR and NOL tests in gadd45b KO mice are underway to explore the role of gadd45b in ERα dependent TrkB mediated neuroprotection.

Title: Advanced theranostic nanocarrier-mediated delivery of NGF in a combination therapy stimulates recovery after stroke

Authors: *S. ANSAR[1], K. ARKELIUS[1], T. FECZKO[2], F. BLIXT[1], M. WACKER[3]
[1]Lund University, Dept. of Clin. Sci., Lund, Sweden; [2]Univ. Hosp. Frankfurt, Frankfurt, Germany; [3]Frauenhofer, Frankfurt, Germany

Abstract: ***Background:*** The majority of people who survive the acute phase of stroke remain permanently disabled. So far no treatment to improve function exist, nerve growth factor (NGF) has emerged as excellent candidate to boost recovery processes. However, the approach to effective deliver NGF has not been possible since it does not pass the blood brain barrier. We have previously shown that mitogen activated protein kinase (MEK)1/2 inhibition promotes recovery after stroke.
Aim: The aim of this study was to use an advanced theranostic nanocarrier-mediated delivery of NGF to evaluate if combination therapy (U0126 in acute phase together with NGF in subacute phase) have more beneficial outcome after stroke compared to single treatment by U0126.
Method: Transient middle cerebral artery occlusion was induced in male rats for two hours followed by reperfusion. The specific MEK1/2 inhibitor U0126 was administered i.p at 6 and 24 hours and the NGF was given i.v at day 3 post-reperfusion Neurological functions were evaluated by 28-point tests and 9.4 T magnetic resonance imaging was used to monitor morphological infarct changes.
Results: The combination therapy with NGF and U0126 significantly improved neurological function and reduced infarct compared to vehicle and U0126 treatment alone, 4 weeks after treatment.
Conclusion: NGF delivered by advanced theranostic nanocarrier promotes recovery processes after stroke and most importantly our delivery approach has demonstrated to be successful. This will be the first step that will lead to novel treatment strategies for neurological disorders.

Title: Age- and sex-dependent effects of metformin on neural precursor cell activation and cognitive recovery in a model of neonatal stroke

Authors: *R. M. RUDDY[1], K. ADAMS[1], B. DONVILLE[2], C. M. MORSHEAD[3]
[1]Inst. of Med. Sci., [3]Div. of Anat., [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Resident neural stem and progenitor cells, collectively known as neural precursor cells (NPCs) contribute to ongoing neurogenesis in the adult mammalian brain throughout life. Recruiting these cells as a source for endogenous repair presents a promising opportunity to improve recovery following brain injury. NPCs in the subventricular zone lining the lateral ventricles reside in a well-characterized niche and factors such as age and sex lead to changes in the niche that can alter the behaviour of NPCs. Clinically, these factors play a decisive role in how patients respond to an injury as well as subsequent treatment. Therefore, it is important to investigate the effect of age and sex when examining potential therapeutics for brain injury. The commonly used anti-diabetes drug, metformin, has been shown to activate NPCs in the early postnatal brain, as well as enhance neuro- and oligogenesis. Most importantly, administration of metformin reverses motor impairments in a model of neonatal stroke. In this study, we investigated the age- and sex-dependent effects of metformin on the NPC population from the SVZ of both males and females, at different ages. In addition, we examined whether these age- and sex-dependent effects play a role in cognitive recovery following metformin treatment in a neonatal stroke model. Using the neurosphere assay, we determined that while metformin activates NPCs in the SVZ of both male and female early postnatal mice, the neural stem cell pool is unresponsive to metformin in juvenile mice. Interestingly, metformin activates the neural stem cell pool in adult females, but not males. We determined that the observed sex-differences are due to hormone-mediated effects on the niche as ovariectomized females lost their responsiveness to metformin, suggesting a potential permissive effect of the female niche. Furthermore, when we administered estradiol to previously unresponsive females, we were able to rescue the effect of metformin on NPCs. Finally, we administered metformin to male and female mice following a neonatal stroke injury and assessed cognition using the puzzle box task. Both male and female mice demonstrated impairments in the acquisition of a new task post-stroke; however, the deficit was only rescued by metformin in female mice, coincident with our finding that only female NPCs are responsive to metformin. This study demonstrates the importance of investigating the effects of age and sex when considering a new potential therapeutic for brain repair.

Title: Edonerpic maleate enhances motor function recovery from the internal capsule hemorrhage in primates

Authors: *W. NAKAJIMA[1], H. ABE[1], Y. MURATA[3], N. HIGO[4], T. OKUDA[5], T. TAKAHASHI[2]
[1]Yokohama City Univ., Yokohama city/ Kanagawa, Japan; [2]Physiol., Yokohama City Univ., Yokohama, Japan; [3]Hum. Technol. Res. Inst., AIST, Tsukuba-Shi, Ibaraki, Japan; [4]Human Informatics Res. Inst, AIST, Tsukuba, Japan; [5]Toyama Chem. Co., Ltd., Toyama-Shi, Japan

Abstract: The central nervous system injury such as stroke can severely limit the motor function. Despite the recent advances in the approach of the rehabilitative training, many patients still face the restrictions in their daily living after rehabilitation. Thereby, a small molecule compound with strong potential to accelerate motor function recovery with rehabilitation is an unmet medical needs. Here, we found a novel small molecule compound, edonerpic maleate, dramatically accelerated motor function recovery after brain damage in rodents and as a next step for clinical evaluation we established stroke model using macaque monkeys. The followings were conducted to evaluate the effects of edonerpic maleate in monkey stroke model: a focal hemorrhage of the internal capsule was induced by collagenase <typeIV> injection. This lesion initially caused flaccid paralysis in the contralateral hand and after initial reaching of affected hand, we started evaluation, drug administration and rehabilitative training for about 2 months. We evaluated two tasks, the simple reach-to-grasp task and the vertical-slit task, for assessment of forelimb function. In the simple reach-to-grasp task, we measured the time to retrieval of pellets. The rate of recovery in the edonerpic maleate-injected monkeys was significantly faster than that in the vehicle-injected monkeys. In the vertical-slit task, we measured the success rate (successful trial/total number of trials). The success rate in the edonerpic maleate-injected

monkeys was significantly improved than that in the vehicle-injected monkeys. These indicated that edonerpic maleate enhanced the upper limb function recovery of macaque monkeys with the internal capsule hemorrhage. Thus, edonerpic maleate is an effective accelerator of functional recovery after brain damage in primates as well as in rodents.

Title: Non-invasive treatment of spasticity in patients with chronic stroke using trans-spinal direct current stimulation with peripheral nerve stimulation

Authors: A. PAGET-BLANC[1], J. CHANG[1], M. SAUL[1], R. LIN[1], N. YAGHOUBI[2], Z. AHMED[3], *B. T. VOLPE[1]

[1]Feinstein Inst. For Med. Res., Manhasset, NY; [2]Pathmaker Neurosystems Inc., Boston, MA; [3]Col. of Staten Island, Staten Island, NY

Abstract: Post-stroke spasticity is a velocity-dependent increase in muscle tone that impedes motor performance and causes pain and discomfort. Preclinical studies have demonstrated that trans-spinal direct current stimulation (tsDCS) paired with peripheral direct current stimulation acts in a polarity-dependent manner to modulate muscle tone, so that anodal tsDCS decreases, and cathodal tsDCS increases muscle tone. In this clinical trial we tested whether DoubleStim™ treatment (non-invasive direct current stimulation via surface electrode at C6 (4mA), paired with simultaneous direct current stimulation of the median nerve (1mA)) delivered by a MyoRegulator™ device (PathMaker Neurosystems) would alter spasticity of the flexor carpi radialis (FCR) in patients with chronic stroke (>6months from ictus). A preliminary safety trial demonstrated that a single 20 minute session of DoubleStim™ caused no untoward effects in 17 patients and controls. Here, we examined whether 5 consecutive 20 minute sessions of anodal DoubleStim™ altered post-stroke spasticity of FCR, as measured by clinical and objective measures of muscle resistance. A single-blind, within-subject crossover design study of 14 patients used clinical assessments: Modified Tardieu Scale (MTS) 11 joints of the upper extremity; Fugl-Meyer Upper Extremity Scale (UE-FM), Wolf Motor Function Test (WMFT)) and objective force measures of passive muscle resistance collected with a calibrated torque sensor at three velocities that permitted analysis of the slope of muscle resistance. Clinical and objective measures were collected before treatment, immediately following Day 5 of treatment, and again weekly for 5 subsequent follow ups (FU) Results, expressed as a ratio (discharge-admission/admission), showed that after DoubleStim™ treatment, there was reduced MTS: FU2 ($p<.05$) and FU3 ($p<.05$), and significant improvements in UE-FM ($p<.05$) and WMFT ($p<.05$) observed immediately after DoubleStim™ treatment were maintained through the last FU. Objective measurements revealed significant reduction of muscle resistance that peaked at FU2 ($p<.05$). Overall, the results indicated that spasticity reduction in upper distal affected limb occurred after 5 consecutive sessions of anodal DoubleStim™ with optimal results observed 2 to 3 weeks after this regimen. Changes in objective measures were consistent with clinical measures, and the improvement in motor function as measured by UE-FM and WMFT suggest that the future details of the timing and dose of DoubleStim™ treatment may have important and enduring clinical effects on motor recovery after stroke.

Title: Time and use dependent effects of constraint induced movement therapy (CIMT) on functional recovery and neural network remodeling after severe stroke in rats

Authors: *N. OKABE, N. HIMI, E. NAKUMURA-MARUYAMA, N. HAYASHI, I. SAKAMOTO, O. MIYAMOTO
Kawasaki Med. Univ., Kurashiki, Japan

Abstract: Constraint induced movement therapy (CIMT) is a rehabilitative therapy which has been demonstrated to improve functional recovery after stroke in both animal models and stroke patients. Because the effect of rehabilitative training is influenced by training modification such as initiation time, duration and intensity of training, optimization of training is critical issue for post-stroke recovery. However, guideline for optimization of rehabilitation protocol has not been established due to lack of sufficient information about training modification. The present study investigated how the initiation time (Time-dependency) and intensity of affected forelimb use (Use-dependency) impact the effects of CIMT on the functional recovery. Time-dependency of CIMT was investigated by the comparison of rats treated with CIMT beginning immediately, 1day (acute) and 4days (subacute) after stroke. Use dependency of CIMT was investigated by the comparison of rats with affected forelimb restriction [CIMT (Non-use)], unaffected forelimb restriction [CIMT (Use)] and combination of CIMT (Use) and skilled forelimb training (SFT). Axonal remodeling in the corticospinal projections was assessed by double labelling of total corticospinal neurons (CSN) and forelimb CSN with two types of retrograde tracers (Fastblue and Retrobeads). In the time-dependency analysis, acute and subacute CIMT induced functional improvement in skilled forelimb reaching task although immediate CIMT did not. Furthermore, movement element analysis revealed that only subacute CIMT normalized compensative movement. In the use-dependency analysis, CIMT (Use) and CIMT (Use) + SFT induced functional improvement in skilled forelimb reaching task, whereas CIMT (Non-use) caused transient impairment of restrained forelimb use. In addition to skilled forelimb reaching task, CIMT (Use) + SFT also improved motor performance in staircase test. In the histological analysis, only CIMT (Use) + SFT increased the number of forelimb CSN without significant changes in the total CSN. These results indicate that additional skilled training is critical to enhance functional recovery induced by CIMT while too early initiation time may decrease the beneficial effects.

[1]Central Inst. of Mental Hlth., Univ. of Heidelberg, Mannheim, Germany; [2]Brain Res. Inst., Univ. and ETH Zurich, Zurich, Switzerland; [3]Inst. for Biomed. Engin., ETH Zurich, Zurich, Switzerland; [4]Brain Res. Inst., Univ. of Zurich, Zurich, Switzerland

Abstract: Once a stroke occurs victims suffer from lifelong disabilities including the impairment of speech, vision and motor control. No pharmacological therapy is currently available to stimulate the restoration of function. However, even without a therapeutic intervention a form of spontaneous recovery exists while the underlying principles of increased plasticity promoting map-shifts and rewiring of neuronal circuitry are not well understood. The brain region adjacent to stroke damage - the penumbra zone - has been shown to be critical for stroke rehabilitation. Thus, understanding the reorganization of the peri-infarct tissue around small cortical strokes and its contribution to functional recovery may inaugurate the development of new treatments and improve rehabilitative strategies. Here we used Thy1-ChR2-YFP transgenic mice to initiate a small photothrombic stroke through a chronically implanted cranial window targeting the forelimb motor cortex. Optical mapping was performed to study the reorganization of the peri-infarct sensorimotor cortex in accordance with the level of regained forelimb function using detailed kinematic analysis. Animals showed constant improvement and complete recovery during 4 weeks after stroke in two grasping tasks, while optical mapping revealed a shift for the center of forelimb function towards the cortical area representing the hindlimb. Temporarily and reversibly shutting-off neurons in the peri-infarct area using a virus-based pharmacogenetic approach resulted in a decline of regained motor performance and the re-emergence of motor errors observed initially after stroke onset, indicating the functional relevance of the penumbra for the recovery and re-establishment of motor engrams involved in skilled forelimb function.

Title: Can reaching training alter cortical connectivity from the affected and unaffected hemisphere early after stroke?

Authors: *U. HAMMERBECK[1], P. SAMRAJ[1,2], K. L. HOLLANDS[3], S. TYSON[1], J. C. ROTHWELL[4]
[1]Fac. of Med. and Human Sci., Univ. of Manchester, Salford, United Kingdom; [2]Salford Royal NHS Fndn. Trust, Salford, United Kingdom; [3]Univ. of Salford, Salford, United Kingdom; [4]Inst. Neurol, London, United Kingdom

Abstract: Backgrounds: Chronic stroke survivors present with greater ipsilateral connections from the unaffected hemisphere to proximal shoulder muscles. However, these connections are not correlated to function. We hypothesize that ipsilateral connections are strengthened early after stroke but don't become functionally relevant because of limited arm therapy in this period. We therefore investigated whether reaching training alters the prevalence and functional relevance of these connections.
Methods: 38 sub-acute (23.5 days post stroke) stroke survivors (mean age= 61.2, 14.9 SD) with significant arm weakness attended to measure presence, onset latency and size of contralateral and ipsilateral motor evoked potentials (cMEP & iMEP) at 3 and 6/52 after stroke. 20 TMS stimulations up to 100% stimulator output (cMEP mean 74.3 SD 21.6, iMEP mean 94.0 SD 8.9) were delivered over the affected and unaffected hemisphere and responses measured in the preactivated affected triceps muscle. A blinded assessor established clinical characteristics including Fugl-Meyer upper limb score (mean=30.5, SD=16.4). Individuals were randomized to reaching training attending 6 times, performing up to 420 (mean 371 reps SD 71.5) supported, 20cm reaching movements per session, or a control group. Chi-square test established connection, and repeated measures ANOVA, MEP latency and amplitude change. Spearman correlations assessed correlations of Fugl-Meyer scores with MEP measures on a subject-by-subject basis.
Results: At baseline cMEPs were evoked in 22 individuals. 10 of these individuals also showed iMEPs. iMEPs only occurred in isolation in one participant. 15 individuals did not demonstrate either connectivity. At follow-up this presentation did not change nor was their evidence of a difference between groups. The amplitude of cMEP and iMEP did not change but the onset latency for cMEPs became shorter (Time $F(1,18)=10.41$, $p=0.031$) without evidence of a

difference due to training. Fugl-Meyer scores increased over time (F(1,30)=31.84, p<=0.001) without evidence that training altered this. At baseline a correlation for cMEPs size and Fugl-Meyer score (rho=.491.p=0.028) was evident, not observed for iMEPs, without evidence that time or training altered this relationship.
Conclusion: We did not find evidence that reaching training early after stroke altered the presence or functional relevance of connections. For all participants latency of cMEPs reduced and the presence of cMEPs was associated with less impairment. We further observed that ipsilateral responses from the unaffected hemisphere were more common after stroke but were not correlated with function.

Title: Exploring the mechanisms of motor rehabilitation-induced recovery after white matter stroke

Authors: *T. G. MENGISTU[1], M. A. MARIN[2], T. S. CARMICHAEL[2]
[1]Neurol., Univ. of California, Los Angeles, Los Angeles, CA; [2]Neurol., UCLA, Los Angeles, CA

Abstract: Subcortical white matter stroke (WMS) accounts for 25% all stroke subtypes. White matter is composed of axons that relay brain signals and oligodendrocytes, which produce myelin. Myelin is a multi-lamellar extension of oligodendrocyte membrane that wraps around the axon and provides it with both electrical insulation and metabolic support. WMS is characterized by the formation of white matter lesions, which results in oligodendrocyte death and myelin degeneration. Loss of myelin results in axon degeneration and functional impairment. Previous work in the Carmichael lab demonstrates that after WMS, there is a significant increase in proliferation of oligodendrocyte precursor cells (OPCs), a resident stem cell that functions in part to differentiate into mature oligodendrocytes during development and in adulthood. However, despite proliferation, these OPCs fail to mature into oligodendrocytes following WMS. Recent work in our lab suggests that subjecting mice to motor rehabilitation, such as skilled reach, enhances recovery by promoting both OPC proliferation and their mature into myelinating oligodendrocytes. The goal of this project is to build upon these initial findings by identifying molecular markers of myelin and oligodendrocyte recovery following motor rehabilitation.

Understanding the mechanisms that drive recovery and re-myelination in mice after WMS will enable us to better understand the pathology of WMS and develop novel therapeutic strategies for recovery.

Title: Three-dimensional kinematic evaluation of motor deficit in a rat model of photochemically induced focal stroke

Authors: *A. YOSHIKAWA[1], S. MORISHITA[2,3], K. HOKAMURA[4], K. UMEMURA[2], M. IZUMIZAKI[1], T. KUMADA[5]
[1]Dept. of Physiol., Showa University, Sch. of Med., Tokyo, Japan; [2]Dept. Pharmacol., Hamamatsu Univ. Sch. Med., Hamamatsu, Japan; [3]Fac. Health. Promo. Sci., Tokoha Univ., Hamamatsu, Japan; [4]Dept. Med. Edu., Hamamatsu Univ. Sch. Med., Hamamatsu, Japan; [5]Fac. Health. Med. Sci., Tokoha Univ., Hamamatsu, Japan

Abstract: Rehabilitation such as exercise therapy is known to contribute for recovering the motor function in patients suffering from cerebral stroke. However, its mechanism remains unclear. Thus, we developed a rat model of focal motor cortex infarction by photochemically induced thrombosis (PIT) method and have investigated the role of neuronal reorganization with regard to motor functional recovery. After PIT operation, the rats with the left side of cortical infarction exhibited paralysis-like behavior in the right side of hindlimb. In addition, beam-walking test revealed that these rats significantly increased the slipping errors in the hindlimb compared with sham-operated rats. Therefore, we hypothesized that the rats with focal motor cortex infarction might have some considerable difficulties even in gaiting and these difficulties should be more unmasked by the quantitative evaluation methods with kinematical analysis. Thus we utilized three-dimensional motor analysis (Kinema Tracer, KISSEI COMTEC Co.,Ltd.) with some modifications to evaluate the gaiting movements of PIT operated stroke rats. Here, we analyzed and compared the rat's hindlimb movement between pre- and post 1 day PIT operation. There were no significant differences in gait parameters (gait cycle, stance phase, swing phase, step length and step width) between pre- and post-operated rats, which was similar to the results

of foot-printing tests. On the other hands, the kinematical motions of the ankle, knee and hip joint on each x, y and z plane revealed significant differences in some parameters in the PIT operated rats. Our results suggest that more precise evaluation of the motor behavior by three-dimensional motor analysis should unmask the motor deficits in the model animals of neurologic disorder with seemingly subtle impairments.

Title: Non-paretic forelimb training does not interfere with recovery of paretic forelimb strength after experimental middle cerebral artery occlusion

Authors: *K. S. VALENZUELA, M. BLAKER, N. COHEN, B. COOK, D. BHANDARI, T. A. JONES, T. SCHALLERT
Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Humans often compensate with their unimpaired (non-paretic) limb after surviving a stroke. Research in rats shows that this can be maladaptive after focal motor cortical strokes. The middle cerebral artery is the vessel most commonly affected by cerebrovascular incident. This type of stroke often causes large strokes that affect both cortical and subcortical regions of the brain. It is unclear if behavioral experience with the non-paretic limb differentially affects paretic limb recovery depending on lesion locus. Long Evan rats were preoperatively trained with their preferred limb on the Isometric Pull Task (Vulintus), a skilled reaching task that sensitively assays forelimb weakness. Previous data from our lab suggests that rehabilitative training (RT) improves paretic limb function on the Isometric Pull Task after middle cerebral artery occlusion (MCAo). Transient focal ischemia (60 min) was induced in the hemisphere contralateral to the preferred limb by an intraluminal middle cerebral artery occlusion suture method. Rats received either non-paretic limb training (NPT) on the Isometric Pull Task or non-training control procedures for 14 days. All rats then received six weeks of RT with the paretic limb. Average paretic forelimb strength, as measured in grams, and the number of attempted trials per session were assessed weekly in all rats. At the completion of the behavioral study, the anterograde tract tracer biotinylated dextran amine (BDA) was pressure injected into the lesioned hemisphere. Brains were harvested 21 days later to examine axon sprouting induced by the behavioral

manipulations. NPT did not reduce paretic forelimb strength or trials per session during RT when compared with the control group. In fact, after six weeks of RT, NPT rats (150±12.4) had less forelimb weakness than control rats (115±29.5) when measuring grams of force. NPT rats (107±16.8) also completed more trials per session when compared with control rats (87±23.9). Data are mean±SEM. NPT on the Isometric Pull Task did not interfere with paretic limb recovery, suggesting that compensatory use of the non-paretic limb after strokes caused by occlusion of the middle cerebral artery may not be maladaptive. Understanding behavioral recovery after different types of strokes could influence clinical management of patients. Work to examine the influence of NPT on interhemispheric reinnervation patterns is ongoing.

Title: Interaction between cortico-rubral tract and cortico-reticular tract in rehabilitation-induced functional recovery after capsular hemorrhage

Authors: *A. ISHIDA[1], K. KOBAYASHI[2], T. ISA[3], H. HIDA[1]
[1]Nagoya City Univ. Grad. Sch. of Med. Sci., Nagoya, Aichi, Japan; [2]Natl. Inst. For Physiological Sci., Okazaki, Japan; [3]Dept. of Neuroscience, Grad. Sch. of Med. & Fac. of Med., Kyoto Univ., Kyoto, Japan

Abstract: Stroke often disrupts cortico-spinal tract and causes severe sensorimotor deficit. Cortico-brainstem-spinal pathways can be the compensatory bypass. However, detailed role and interactions of these tracts in rehabilitation-induced functional recovery is still unclear. In this study, we investigated the rehabilitation-induced reorganization of the cortico-rubral tract (CRT) and the cortico-reticular tract (CReT) and its contribution to functional outcome. Intracerebral hemorrhage (ICH) model was made by collagenase injection into the internal capsule, and the rats were forced to use their impaired forelimb by fitting the one-sleeve cast for days 1-8 (D1-8) after ICH (forced-limb use: FLU). Skilled reaching task revealed that FLU promoted substantial recovery of forelimb function in ICH model at D12 and D28. Biotin dextran amine (BDA) injection into the ipsilesional motor cortex revealed the increase of abundant BDA-positive fibers in the ipsilateral red nucleus in ICH-FLU group at D12 and D51 although there were few

positive fibers in the reticular formation. To block the CRT and/or the CReT selectively, we used Tet-on system by injection of NeuRet-TRE-EGFP.eTeNT into the red nucleus and AAVdj-CaMKII-rtTAV16 into the motor cortex and DREADD system by injection of NeuRet-MSCV-Cre into the reticular formation and AAVdj-Flex-DIO-hM4D- mcherry into the motor cortex. Selective CRT blockade by doxycycline after FLU at D13-20 caused apparent impairment of the recovered forelimb function in ICH-FLU group. However, this selective CRT blockage was gradually disappearing in the later phase. Interestingly, additional CReT blockade by clozapine N-oxide administration at D21-28 under CRT blockade caused severe impairment of the forelimb function again. In contrast, only CReT blockade at D13-20 did not affect the FLU-induced recovery. These data suggest that CRT has causal link to FLU-induced recovery of forelimb function after ICH, indicating more dominant role in FLU-induced reorganization and recovery compared to CReT that is a potential compensational pathway in case of the CRT blockade in FLU after ICH.

Title: Elucidating the mechanisms of activity dependent remyelination after stroke

Authors: *M. A. MARIN[1,1], K. NG[2], R. KAWAGUCHI[1], G. COPPOLA[1], S. T. CARMICHAEL[1]

Abstract: Subcortical white matter stroke (WMS) damages neural connections via the formation of lesions along tracts of myelinated axons. These strokes kill oligodendroctyes resulting in demyelination of axons, and behavioral impairments, dementia, and death. Following WMS, there is a significant increase in oligodendrocyte precursor cell (OPC) proliferation, which if driven to maturity would repair the lesion as they do in the early stages of multiple sclerosis (MS). However, OPCs fail to mature into oligodendrocytes after WMS, the mechanisms of which are poorly understood. Here we demonstrate that motor activity releases this developmental block by driving the maturation of OPCs into myelinating oligodendrocytes and enhancing recovery after WMS. Furthermore, we have developed a transcriptional profile of OPCs using Ribotag mRNA precipitation after WMS and motor rehabilitation. Our findings will

be used to develop molecular strategies to target candidate genes and test their effect on repair and recovery after WMS (in the absence of motor rehabilitation) and identify the molecular systems that underlie remyelination.

Title: Mental imagery as a tool to change muscle coordination patterns in chronic stroke survivors

Authors: *S. JAYASINGHE, R. RANGANATHAN
Kinesiology, Michigan State university, East Lansing, MI

Abstract: Mental imagery and visual feedback are widely used in real-world skill learning, and their utility in stroke rehabilitation has also received some attention. However, research on the use of mental imagery in stroke rehabilitation has not explored its effects on muscle coordination. This is a critical area of research since chronic stroke survivors exhibit incorrect muscle coordination patterns. This study focused on the effects of mental imagery and supplementary visual feedback on muscle coordination in healthy participants, with the goal of extending the approach to chronic stroke survivors.
We designed an isometric virtual reaching task where the electrical activity of six arm muscles was mapped on to the two-dimensional position of a cursor on the computer screen. Participants were asked to move this cursor into a target presented at six pseudorandom locations equidistant from the central start position. The muscle map was designed to be non-intuitive. We recruited 30 healthy college-aged students, and placed them in one of 3 groups: control i.e. no intervention, mental imagery intervention, and supplementary visual feedback intervention. Participants in the mental imagery group were given a specific kinesthetic imagery scenario to practice on. The supplementary visual feedback group was shown how the activity of each muscle individually contributed to the motion of the cursor on the screen by setting the gains for the other muscles to 0. This intervention was done to check for whether mental imagery was truly beneficial, or whether simply providing additional visual feedback would have been enough. Each intervention lasted approximately 2 minutes, and all participants completed 180 trials.
Results showed that both mental imagery and supplementary visual feedback reduce movement time at a faster rate than the control group. We also found that the mental imagery group was

able to reduce both task and null space variability more than both the other groups, with this reduction being significantly greater ($P < 0.05$) than the control group. These preliminary results suggest that mental imagery may be a potential tool for use in the clinical setting after testing for efficacy in stroke survivors.

Title: Heterozygous deletion of ephrinA5 does not affect functional motor performance after experimental stroke in mice

Authors: A. DE BOER[1,2], A. STORM[1,2], L. RUÉ[1,2], W. ROBBERECHT[3,2], *R. LEMMENS[3,2]
[1]KU Leuven, Leuven, Belgium; [2]VIB, Ctr. for Brain & Dis. Res., Leuven, Belgium; [3]KU Leuven - UZ Leuven, Leuven, Belgium

Abstract: Stroke is the main cause of adult disability, affecting about 15 million people each year worldwide. During an ischemic insult, different molecular mechanisms lead to neuronal and glial cell death causing impaired neurological functioning. Although stroke damage can be devastating, most patients survive the initial insult, resulting in large numbers of stroke survivors in long-term care facilities. After stroke, the brain is capable of some spontaneous recovery. However, this process is limited by inhibitory molecules, including various developmental guidance cues like members of the ephrin system.
The ephrin system is mainly known for its role in central nervous system (CNS) development but the majority of Eph receptors and ephrin ligands are still expressed during adult life. It has become clear that this system is important for neural repair during adulthood, as shown in various CNS injury models. After experimental stroke, ephrinA5 was shown to be upregulated in reactive astrocytes in the peri-infarct area and blocking ephrinA signaling improved remapping and behavioral outcome. In the present study, we aim to validate the role of ephrinA5 in stroke recovery using ephrinA5 heterozygous mice which are functionally assessed after experimental stroke introduced by the photothrombotic lesion model (PTL). Additionally, the effect of ephrinA5 reduction on astrocyte reactivity, glial scar formation and neural plasticity is determined.
Adult male mice were subjected to PTL and functionally tested to assess stroke recovery until four weeks post stroke. After 24 hours, a subset of mice was sacrificed to determine infarct size

and brain swelling and cortical brain tissue was collected at day 7 to identity the expression level of various astrocytic, glial scar and plasticity markers. Results show that heterozygous deletion of ephrinA5 did not affect infarct size and brain swelling after PTL. Using the single pellet reaching task and horizontal ladder task, no differences were observed in functional recovery between ephrinA5+/- and control mice. In accordance to this, ephrinA5 reduction did not affect astrocyte reactivity as assessed by GFAP and vimentin protein levels. In addition, the expression of various glial scar components were not affected in ephrinA5+/- mice. We determined NF200 levels as an indication of neurodegeneration/regeneration, however no differences were found between ephrinA5+/- and control animals.
In future experiments, we will determine the cell-type specific expression of ephrinA5 using in situ hybridization as well as the effect of ephrinA5 reduction on axonal sprouting into the denervated cervical spinal cord using BDA tracing.

Title: Exploring the temporal profile of myelination changes after stroke in relation to function remapping

Authors: *E. WENDLANDT[1,2], I. R. WINSHIP[3]
[2]Dept. of Psychiatry, [1]Univ. of Alberta, Edmonton, AB, Canada; [3]Neurosci. and Mental Hlth. Inst., Univ. Alberta, Edmonton, AB, Canada

Abstract: Functional recovery after stroke is driven by mechanisms of central nervous system plasticity - including the structural reorganization of surviving neuronal networks and, crucially, the re-establishment of a functional pattern of myelination across these newly created circuits. The time-course and extent of this type of re-patterning, however, are not well understood and their relation to cortical network impairment and recovery is not defined. Immediately after stroke, peri-infarct areas seem to undergo a period of severe de- and dysmyelination, followed by partial remyelination which appears to be temporally staggered depending on the region's distance from the stroke core. In this project, we longitudinally tracked and quantified in vivo

myelination changes in the peri-infarct cortex of mice for up to four weeks following targeted photothrombosis of the forelimb somatosensory cortex using Spectral COnfocal Reflectance microscopy - a label-free imaging technique that utilizes the high reflectivity of lipid-rich myelin and is able to resolve single cortical myelinated fibres. Functional changes were concurrently monitored via Optical Signal Imaging of the remapping responses in the fore- and hindlimb somatosensory representations and the time-course and spatial extent of the two measures compared to probe their putative relationship. We observed partial and prolonged demyelination of the peri-infarct cortex for up to 14-21 days post-stroke and a simultaneous loss of the forelimb representation. Eventual remyelination occurred in close temporal correlation to the re-emergence of the forelimb map. In our final experiment, we manipulated the time-course of the post-stroke myelin changes using an experimental compound called fluorosamine - a CSPG biosynthesis inhibitor previously demonstrated to enhance remyelination in a mouse model of Multiple Sclerosis - and found this resulted in a corresponding temporal shift in the cortical remapping response. These results help underscore the importance of myelination as a key post-stroke plasticity mechanism.

Title: Characterizing blood-brain barrier disruption in degenerative thalamus after cortical ischemic stroke

Authors: *S. HARVEY, Z. CAO, M. Y. CHENG, G. K. STEINBERG
Neurosurg., Stanford Univ., Stanford, CA

Abstract: Background: After an ischemic cortical stroke, a delayed secondary degenerative injury occurs in the ipsilesional thalamus. Anterograde and retrograde degeneration between thalamocortical circuits exacerbate neuronal cell death and hinder stroke recovery. Inflammatory responses from both resident glial cells and infiltrating monocytes are a hallmark of secondary thalamic injury. Blood-brain barrier (BBB) disruption and permeability in the thalamus may exacerbate this inflammatory response, thus worsening thalamic injury and stroke outcomes. We aim to investigate how BBB disruption contributes to secondary thalamic injury after stroke. **Material and Methods:** Cortical ischemic stroke was generated by permanent occlusion of left middle cerebral artery in male C57BL6 mice (12-15 weeks). Time course analysis of BBB permeability was assessed by immunostaining in brain sections collected on post-stroke day (PD) 3, 7, 14, 21 and 28. To assess BBB permeability, Alexa 488 dextran was injected via femoral

vein 90 minutes prior to sacrifice. BBB permeability was also assessed via immunostaining with antibodies specific for IgG and the blood vessel marker Isolectin-B4. Inflammatory cells were visualized with antibodies targeting microglia (Iba1) and astrocytes (GFAP). **Results:** After cortical ischemic stroke, Alexa 488 dextran showed strong signal in the ipsilesional somatosensory cortex (iS1) and persisted through day 28. Dextran signal in the ipsilesional thalamus (iTH) was delayed, detectable starting at PD7 and increasing through PD28. IgG immunostaining showed similar trend. The expression profile of inflammatory markers (GFAP and Iba1) mirrored the timeline of BBB permeability; iS1 showed robust astroglial and microglial activation beginning at PD3, and persisting through PD28. Inflammatory cell activation was delayed in iTH; microglia and astrocytes began exhibiting an activated morphology at PD7 and gradually increased through PD28. **Conclusion:** Our study suggests that BBB disruption in the thalamus contributes to neuroinflammation and secondary thalamic injury after ischemic stroke. This BBB permeability begins in the acute phases and persists through at least one month after stroke. Current studies investigate the cellular and molecular mechanism of BBB disruption after stroke. Identifying specific BBB-related proteins in endothelial, astrocyte, and pericyte populations may provide insight into how the BBB is maintained in the healthy brain, and reveal potential targets to alleviate secondary thalamic injury after stroke.

Title: Detection of altered network function after stroke is task-dependent

Authors: *S. M. SCHINDLER-IVENS[1], B. D. SCHMIT[2], K. VINEHOUT[3]
[1]Physical Therapy, Marquette Univ., Milwaukee, WI; [2]Dept. of Biomed. Engin., Marquette Univ. Dept. of Biomed. Engin., Milwaukee, WI; [3]Marqutte Univ., Milwaukee, WI

Abstract: Recently, our group used fMRI to examine brain activation during pedaling and tapping in people with and without stroke (Promjunyakul et al., 2015). Brain activation volume in the stroke group tended to be higher than controls during paretic foot tapping and lower than controls during pedaling. These observations led us to consider that tapping and pedaling may be differentially sensitive to stroke-related changes in local and global network function of the brain. The work presented here sought to examine this issue by quantifying task-based functional connectivity during pedaling and tapping. We hypothesized that global network connectivity would be reduced and local network connectivity would be elevated in people with stroke, as compared to controls. We also predicted that the ability to detect these effects would be task

dependent. Pedaling would reveal between-group differences in global connectivity; tapping would reveal differences in local connectivity. 15 people with stroke and 8 controls performed pedaling and foot tapping during fMRI. ROIs were identified with independent component analysis. Correlations were computed among ROIs; values were used to quantify global connectivity. Correlations were also computed for all pairwise combinations of time series within each ROI; the mean of these values defined local connectivity. During pedaling, global connectivity among all ROIs was lower in the stroke than the control group ($p<0.001$). The largest effect was for connections to S2 on the lesioned side of the brain. During paretic tapping, global connectivity was not different between groups for any ROI ($p>0.057$). People with stroke displayed greater local connectivity than controls during paretic foot tapping ($p=0.002$). However, during pedaling, they displayed lower local connectivity than controls ($p=0.02$). Our data indicate that local and global networks of the brain are affected by stroke. The ability to detect these changes is affected by task. Pedaling is more sensitive to global changes; tapping is more likely to reveal changes in local network function. It may be important to examine functional connectivity of the brain across tasks to gain a full appreciation of the nature and extent of altered brain function post-stroke.

Title: The effect of physical exercise participation on Brain-Derived neurotrophic factor among people with SCI

Authors: *A. A. ALGHAMDI[1,2], A. M. WILLIAMS[1,2], M.-S. POORMASJEDI-MEIBOD[1], G. EGINYAN[1,2], T. LAM[1,2]
[1]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada; [2]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Background**:** Beyond the benefits of physical activity on overall health, there has been increasing recognition of the positive effects of exercise on brain function (e.g. memory and learning). It is thought that the mechanisms behind this effect are related to increased blood flow to the brain and release of neurotrophins, especially brain-derived neurotrophic factor (BDNF). Participation in long-term physical activity programs has been associated with elevated levels of basal BDNF. In the spinal cord injury (SCI) literature, elite athletes with SCI showed a high basal BDNF concentration, even compared to the general able-bodied population. However, it is unknown whether the general SCI population similarly experiences an increase in basal BDNF

from regular physical activity participation. The aim of this study was to 1) compare basal BDNF levels in active vs. inactive persons and 2) characterize the effect of high vs. low levels of physical activity participation on other measures of health and fitness (e.g. VO2 peak, depression, fatigue, pain) among people with SCI.
Methods: Individuals with chronic SCI were enrolled in this study. A blood sample was taken after fasting for serum BDNF analysis. Participants also completed the Physical Activity Scale for Person with Physical Disability, Beck's Depression Inventory, Perceived Stress Scale, Fatigue Severity Scale, and Multidimensional Pain Inventory. Body composition was measured by whole-body Dual-energy X-Ray Absorptiometry. VO2 peak was tested by an incremental arm ergometer test.
Results**:** The majority of participants were males and more than half of them with incomplete SCI (iSCI). There were no significant differences in BDNF concentration, other physical outcomes, or questionnaire results between iSCI and cSCI participants. Active subjects had significantly lower scores in depression and stress, and higher VO2 peak ($p < 0.05$) when compared to inactive subjects. In addition, active participants tended to have higher lean body mass and basal BDNF concentration compared to inactive, but the difference was not significant.
Conclusion**:** Individuals with SCI classified as physically active exhibited expected benefits of exercise on health measures (e.g. depression and stress levels) and fitness (VO2 peak) compared to physically inactive individuals. However, the purported effect of physical activity participation on basal levels of circulating BDNF was not as apparent.

Title: Exploring pelvic floor muscle sparing in spinal cord injured individuals using transcranial magnetic stimulation, targeted exercises, and exoskeleton walking

Authors: *A. M. M. WILLIAMS[1,2], G. EGINYAN[1,2], A. E. CHISHOLM[1,2], T. LAM[1,2]
[1]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada

Abstract: Background: The pelvic floor muscles (PFM) are important for maintaining urinary continence. In able-bodied individuals, exercise programs intended to strengthen the core and PFM are commonly used to treat incontinence. However, limited research has explored applying these exercises to the spinal cord injury (SCI) population where 80% of individuals experience neurogenic bladder dysfunction. PFM training programs may not have been attempted in people with SCI because of a lack of understanding about how the PFM functions post-injury. Further, for those with high-thoracic motor-complete SCI (mc-SCI), it is often incorrectly assumed that they cannot engage core muscles based on standard neurological assessment. Previous work has shown that sparing in abdominal muscles can be detected using manual palpation, electromyography (EMG), and transcranial magnetic stimulation (TMS). Since the abdominal and PFM are part of the core, this raises questions as to the extent that PFM muscles may be similarly spared in this population. The purpose of this project was to a) evaluate corticospinal excitability to the PFM via TMS and b) characterize and compare activation patterns of the PFM and other core muscles during validated PFM training exercises and exoskeleton walking in individuals with mc-SCI. **Methods**: This study used a two-part cross-sectional design. EMG signals were recorded bilaterally from rectus abdominis, external oblique, erector spinae, levator ani, and gluteus maximus. In Part 1, TMS was delivered over the PFM region of the primary motor cortex in both supine and supported standing conditions. In Part 2, EMG signals were recorded while participants attempted validated PFM exercises (e.g. kegels) and performed overground walking using the Ekso robotic exoskeleton. **Results**: Motor-evoked potentials in the levator ani were elicited in response to TMS in able-bodied participants, but not as readily in individuals with mc-SCI. Participants with mc-SCI also had difficulty recruiting the PFM using the validated PFM exercises, however, activation could be elicited during Ekso-assisted walking. **Conclusion**: Our preliminary results suggest that PFM activity can be elicited in mc-SCI participants during Ekso-assisted walking, but conventional exercises may not be effective for this population. Furthermore, it is unclear if there is sparing in descending pathways to the PFM, similar to what we have previously observed in the abdominal muscles. However, the possibility of recruiting PFM activation by exoskeleton-assisted walking could lead to new training strategies to strengthen the PFM, potentially improving bladder function in individuals with SCI.

Title: Gains in overground walking performance following low oxygen therapy are not accompanied by reductions in intralimb kinematic variability in persons with iSCI

Authors: *A. Q. TAN[1,2], W. SOHN[3], L. WAN[1,2], R. TRUMBOWER[1,2]
[1]Physical Med. and Rehabil., Harvard Med. Sch., Boston, MA; [2]Spaulding Rehabil. Hosp., Boston, MA; [3]Northeastern Univ., Boston, MA

Abstract: Mild breathing bouts of low oxygen (intermittent low oxygen therapy, iLOT) is a promising intervention that induces spinal plasticity, leading to improvements in both breathing and locomotion in rats with spinal cord injury (SCI). More recent work supports that iLOT induces profound motor recovery in persons with SCI, augmenting ankle strength and clinical measures of walking performance. Despite growing evidence of the translational potential of iLOT, it is unclear if gains in walking function are associated with shifts in neuromotor strategies. Recently, we found that excessive kinematic variability during overground walking post SCI predicts walking performance, suggesting that variability reliably reflects underlying motor control impairments. Characterizing changes in kinematic variability may therefore yield insight into the range and stability of motor patterns that accompany iLOT induced functional gains.

The purpose of this study is to characterize the effect of iLOT on the variability of endpoint foot trajectory (EPVAR) and hip-knee coordination (ACC) during overground walking. We hypothesize that improvements in walking performance following iLOT would be concurrent with reductions in both parameters of kinematic variability. To test our hypotheses, persons with chronic iSCI walked overground at cadence-matched self-selected speed before and after exposure to iLOT (15, 1.5 min episodes at 9% FiO_2 with 1 min intervals at 21% FiO_2 for 5 consecutive days). Kinematic walking features were captured using a motion analysis system at day 5 (T5), 1 week (F1), and 2 weeks (F2) following iLOT. EPVAR was computed from the spatial density profiles of 5^{th} MTP marker in the sagittal plane during the swing phase of gait. ACC was quantified from each gait cycles cyclogram.

Consistent with previous studies, we observed a significant reduction in 10-meter walk test time relative to baseline at T5 (-2.23s), F1 (-1.8s) and F2(-2.34s). Similarly, participants increased the distance walked in 6 min at T5 (+42.3m), F1(+38.2m), and F2 (+28.4m) relative to baseline. In contrast with our hypothesis, neither reductions in foot path variability (EPVAR: BL =2.84±0.68, F1=2.69±0.38, F2 =2.39±0.28) nor improvements in hip-knee coordination (ACC: BL = 0.83±0.03, F1 =0.84±0.02, F2 =0.83±0.03) accompanied increases in walking performance. These results suggest that the reversion of neuromotor strategies to able bodied patterns following iLOT do not sufficiently explain walking improvements. In addition to compensatory strategies, gains in interlimb performance must be considered when evaluating specific aspects of iLOT induced motor recovery.

Title: Dose-dependent effects of whole body vibration on spasticity in individuals with spinal cord injury

Authors: *J. HOPE[1,2], S. P. ESTES[2], J. A. IDDINGS[2], N. J. KIRK-SANCHEZ[3], E. C. FIELD-FOTE[2,4]
[1]Neurosci. Program, Emory Laney Grad. Sch., Atlanta, GA; [2]Shepherd Ctr. - Crawford Res. Inst., Atlanta, GA; [3]Physical Therapy, Univ. of Miami-Miller Sch. of Med., Coral Gables, FL; [4]Emory University-School of Medicine, Div. of Physical Therapy, Atlanta, GA

Abstract: Background & Purpose: While muscle paralysis is the most obvious consequence of spinal cord injury (SCI), approximately 65% of individuals with SCI experience uncontrolled muscle contractions, stiffness, and decreased motor control associated with spasticity. Spasticity is a consequence of decreased presynaptic inhibition in the spinal reflex circuit caused by the disruption of descending signals from the brain to the spinal cord. While there is early evidence for the use of whole body vibration (WBV) as an anti-spasmodic treatment in people with SCI, there is limited understanding of the optimal dose to reduce spasticity. The purpose of this study was to compare the single-session effects of four different WBV frequency/duration dose conditions on spasticity. We also measured walking speed as a secondary outcome.
Methods: Thirty-five individuals with motor-incomplete SCI received 4 different dose conditions of WBV: high frequency (50Hz)/short duration (180 seconds), high frequency/long duration (360 seconds), low frequency (30Hz)/short duration, and low frequency/long duration, plus a sham-control condition. Quadriceps spasticity was measured using the pendulum test at 4 timepoints during each session: before and 3 timepoints after WBV. Walking speed was quantified using the 10-meter walk test at 3 timepoints during each session: before and 2 timepoints after WBV. The condition order was randomized across participants and sessions were separated by at least 1 week to minimize the potential for carry-over effects.
Results: In participants with more severe spasticity, the high frequency/long duration WBV condition was associated with a greater reduction in spasticity. The sham-control condition was also associated with reduced spasticity. There were no changes in walking speed from baseline to post-intervention in any of the WBV dose conditions compared to the sham-control.
Discussion & Conclusions: Our study suggests that inhibitory mechanisms are evoked in a frequency-dependent manner. Longer exposures to vibration resulted in greater reduction in

spasticity suggesting that duration is an important component of WBV dose. Finally, in our prior studies we have found that the immobility associated with extended sitting had a negative effect on spasticity. Conversely, in the current study the sham condition involved repetitions of sitting and standing, and this repeated activity appeared to have a beneficial influence on spasticity. WBV and other non-pharmacological approaches to management of spasticity warrant further study.

Title: Pediatric constraint induced movement therapy for children with brachial plexus palsy: Using the Shriners Hospital upper extremity evaluation tool to assess performance

Authors: *T. KARAKOSTAS[1], S. HSIANG[2], E. C. KING[3,4]
[1]Motion Analysis Ctr., Rehabil. Inst. of Chicago, Chicago, IL; [2]Systems Engin. & Engin. Mgmt., Univ. of North Carolina, Charlotte, NC; [3]Surgery, Lurie Childrens Hosp. of Chicago, Chicago, IL; [4]Surgery, Northwestern Univ., Chicago, IL

Abstract: In the past we reported upper and lower extremity function changes following a pediatric constraint induced therapy (pCI) camp for children with hemiplegia. We wondered if pCI can be used for other pediatric populations with upper extremity (UE) deficits. The objectives of this study were to a) assess if pCI can be used to treat children with brachial plexus (BP), b) determine the fesibility of using the Shriners Hospital Upper Extremity Evaluation (SHUEE) to assess functional changes due to treatment.
This is a randomized control study including 17 children with BP, 3-7 years of age, 9 of them randomly assigned in the experimental group (EG). No participant had history of other neuromusculoskeletal injury or pCI exposure. All subjects could use the affected arm as gross assist during play and self care tasks. Cognitively, they could follow two step commands. Treatment took place at a Children's Hospital.
We delivered 30 hours of treatment (3 hours of treatment specific training over 10 days). Activities focused on gross, fine motor and self feeding skills. Control group (CG) participants had traditional occupational therapy (OT). Outcomes were measured using the SHUEE. Participants in EG were tested pre post and six months post pCI. Participants in CG were tested

pre and post 30 hours of treatment (6 months). Discriminant analysis was used to determine if the SHUEE is appropriate for assessing UE function for BP and then results were explored for simplicity and reporting with t-tests ($a<0.05$).
Table 1 presents selected results based on the SHUEE. The discriminant analysis showed perfect discrimination between pre and post pCI, low correlations among the SHUEE components and different Eigen values.
Table 1. Means, standard deviations and p values for selected output.

Parameter	Pre-EG Mean*(SD)*	Post-EG Mean*(SD)*	p	6Post-EG Mean*(SD)*	p	Pre-CG Mean*(SD)*	Post-CG Mean*(SD)*	p
Spontaneous Functional Analysis	*71.6(9.9)*	*86.5(10.3)*	.00	73.4*(13.8)*	.07	68.5*(12.6)*	73.4*(16.7)*	.36
Dynamic Positional Analysis	*62.9(12)*	79.7*(9.1)*	.00	76.2*(8.6)*	.25	69.6*(9.3)*	74.2*(11.1)*	.15

This is, to our knowledge, the first randomized control study investigating the effects of pCI on UE function of children with BP. It is also the first study investigating the feasibility of the SHUEE to assess UE deficits of BP. The results demonstrate clear improvements and retention in UE function. They also suggest superiority of pCI over the traditional OT approach when treating the UE of children with BP. Furthermore, the SHUEE appears to be an appropriate tool for assessing UE function of children with BP.

Abstract: We report preliminary results on the long-term effects of rehabilitation enabled by spatiotemporal neuromodulation of the lumbar spinal cord and a multidirectional gravity-assist on functional recovery in individuals with incomplete spinal cord injury. After surgical implantation of a spinal cord stimulator and personalization of the neuromodulation strategy, individuals followed a 5-month rehabilitation period. Functional improvements were tested using a range of advanced neurobiomechanical recordings, well-established electrophysiological measurements, and standard clinical tests that were repeated monthly. In all participants, gait training led to improvement of motor functions, even in the absence of stimulation. These improvements included improved kinematics and muscle activity during locomotion as well as increases in maximal and finely controlled forces, ASIA motor scores, Walking Index of Spinal Cord Injury and 6 Minute Walk Test. These preliminary results provide encouraging insights into the potential of this combined intervention to augment neural plasticity and functional recovery after SCI.

Abstract: We report the immediate effects of spatiotemporal neuromodulation of the lumbar spinal cord on leg motor control in individuals with incomplete spinal cord injury. This spatiotemporal neuromodulation aims at activating or reinforcing the activity of muscle groups underlying lower limb movements during locomotion. Non-ambulatory Individuals with severe spinal cord injury were surgically implanted with an epidural electrode array. After recovery from the surgery, we personalized the spatial location, temporal structure and stimulation parameters of the electrical spinal cord stimulation strategy. First, we identified electrode configurations able to target specific regions of the spinal cord using personalized computational models and electrophysiological recordings. Second, we identified the optimal temporal structure to activate these spatially selective electrode configurations in order to reproduce the spatiotemporal maps of motoneuron activation underlying locomotion of healthy individuals. Application of these personalized spatiotemporal neuromodulation strategies during overground locomotion with robotic assistance immediately enabled overground walking in completely or partially paralyzed individuals who had suffered a spinal cord injury more than four years ago. These results establish the conceptual and engineering framework to develop neuroprosthetic systems that facilitate walking during activities of daily livingvin paraplegic individuals.

Title: Locomotor training combined with transspinal and transcortical paired associative stimulation reorganizes spinal neural function after spinal cord injury

Authors: *T. S. PULVERENTI[1], M. A. ISLAM[1], L. M. MURRAY[1], M. KNIKOU[2]
[1]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY; [2]The Grad. Ctr., City Univ. of New York, Staten Island, NY

Abstract: Spinal cord injury (SCI) disrupts descending supraspinal input to lower limb muscles and results in substantial pathological reorganization of spinal neuronal circuits affecting locomotor performance. It is well known that locomotor training normalizes the function of spinal neuronal circuits after SCI, and that paired associative stimulation (PAS), particularly transspinal-transcortical PAS, can enhance corticospinal excitability in non-injured individuals. However, the effectiveness of augmenting activity-based therapies with non-invasive transspinal-transcortical PAS on the recovery of sensorimotor function after SCI remains largely unexplored. In this study, we delivered paired transspinal and transcortical stimuli at an interstimulus interval in which TMS was delivered after transspinal stimulation in two people, one with chronic motor incomplete SCI (AIS D)and the other with complete SCI (AIS B) during Lokomat robotic gait training. Paired stimuli were delivered during the stance phase of the step cycle, triggered based on foot switches, throughout at least 20 sessions (1h/day, 5 days/week) of locomotor training. For transspinal stimulation, the cathode electrode was placed over T10-L1, and two anode electrodes were placed bilaterally on the abdominal muscles, while for transcortical stimulation a double cone coil was placed over M1. Both stimuli were delivered at intensities that evoked cortical or spinal motor responses in the soleus muscle. Soleus H-reflex excitability during Lokomat walking were assessed before and after intervention. Transspinal-transcortical paired stimulation and locomotor training produced a significant depression of the soleus H-reflex during the stance phase, and promoted soleus H-reflex inhibition during the swing phase of the step cycle. Despite being an ongoing project, the current findings clearly indicate that this novel intervention contributes to normalization of soleus H-reflex phase-dependent modulation in

people with motor incomplete and complete SCI. These findings provide evidence towards a novel rehabilitation paradigm to promote recovery of motor function after SCI.

Service, [7]Urology, Fiona Stanley Hosp., Murdoch, Australia; [8]Perth Urology Clin., Murdoch, Australia

Abstract: Introduction: Following traumatic spinal cord injury (SCI), urinary tract infection (UTI) results in high morbidity and is a major cause of re-hospitalisation. Bladder management differs at spinal units around Australia and the relationship between early management and subsequent UTI rates is largely unknown.
Methods: We undertook a retrospective audit of all new cases (n=70) of adult traumatic SCI managed at Royal Perth and Fiona Stanley Hospitals, Jan 2015-Feb 2017. Bladder management practices and UTI incidence were mapped using data from hospital electronic databases, medical records and nursing fluid balance charts. Modelling of infection rates and UTI during nursing-administered intermittent catheterisation (staff-IC) involved generalised linear models.
Results: Protocols for 6-hourly staff-IC were adhered to closely (85.7% of staff-ICs were performed within 6.5 hours, 96.1% within 8 hours; only 3.5% of bladder volumes were >800mL). The rate of symptomatic UTI was 1.1 starts/100 days and symptomatic UTI by multi-resistant organisms 0.1/100 days. Modelling of potential drivers of UTI showed longer duration of urethral indwelling catheterisation (IDC) was associated with shorter time to first infection (p-value 0.044), which in turn predicted a higher UTI rate during inpatient stay (p-value 0.039). During staff-IC periods, high volumes and interruptions requiring IDC led to an increased UTI rate in the following week (odds ratios (ORs)=1.59, 95% CI 1.12-2.27, p-value 0.009 and 2.93,

95% CI 2.58-5.92, p-value <0.001 respectively). Delays between staff-ICs (>8 hours) did not change the UTI rate. Subsequent analysis identified drivers of odds of UTI including: being female (OR=8.7, 95% CI 1.45-52.5, p-value 0.006) and complete injury (OR=12.3, 95% CI 1.28-117.4, p-value 0.008). Hospital stay was longer for those with complete compared to incomplete injuries (rate ratio (RR)=1.31, 95% CI 1.07-1.61, p-value 0.007) and longer for those with UTIs than those without (RR=1.39, 95% CI 1.16-1.69, p-value <0.001). Longer hospital stays were also associated with increased IDC days (p-value <0.001) and pre-existing neurological disorders (p-value 0.011).
Conclusions: Reducing initial IDC duration, preventing early UTIs, minimising high bladder volumes and IC interruptions and targeting specific patient sub-groups may optimise bladder management, reduce UTI rate and reduce hospital length of stay following SCI.

Lausanne (CHUV), Lausanne, Switzerland

Abstract: Epidural Electrical Stimulation (EES) applied over the lumbosacral spinal cord restored voluntary leg movements in animal models and humans with spinal cord injury (SCI). These studies have shown the importance of targeting the proprioceptive afferent fibers located in the individual dorsal roots in order to maximize the efficacy of the stimulation. Humans exhibit a broad range of anatomical features, emphasizing the importance of developing targeted surgical procedures and personalized stimulation protocols to deliver EES therapies in patients

with SCI. To this aim, we developed a computational platform supporting the semi-automatized creation of hybrid computational models of epidural electrical stimulation applied to the human spinal cord using the Sim4Life computational life sciences platform. These models combine personalized, geometrically realistic 3D finite element models of the lumbar and sacral spinal cord of individual patients with realistic neural dynamics models of proprioceptive feedback circuits. For this, we developed ad-hoc high-resolution MRI sequences of the spinal cord, which are reproducible across vendors, that allow the semi-automatic extraction of patient-specific anatomical features, including the 3D trajectories of the dorsal and ventral spinal roots. We established a computational pipeline to obtain (anisotropic) tissue properties maps, discretize the model, perform simulations using an electro-quasistatic solver, couple these simulations with NEURON-based electrophysiology models, determine stimulation selectivity for given electrode configurations, and map these configurations to task-specific motoneuron pool activation profiles. This platform enables the optimal surgical placement of electrode arrays, the personalization of stimulation protocols and even the tailoring of electrode arrays to the specific anatomical features of each patient. We validated this approach in three paraplegic patients with SCI.

Title: A novel task to measure lower limb coordination after spinal cord injury and its relation to proprioceptive sense

Authors: *R. N. MALIK[1,2], M. CHOW[1,2], G. EGINYAN[1,2], T. LAM[1,2]
[1]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada; [2]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Following motor-incomplete spinal cord injury (m-iSCI) community ambulation becomes limited, partly due to the difficulties of skilled walking in our everyday lives. During skilled walking tasks, appropriate modification of the gait pattern requires precise coordination between the joints of the lower limb (i.e. inter-joint coordination). Following SCI, inter-joint coordination can be impaired not only due to motor impairments, but also proprioceptive deficits. In this project, we developed a new task for examining inter-joint coordination in the legs with the aim of understanding the effect of proprioceptive impairments in people with SCI on lower limb coordination.
Both able-bodied individuals and individuals with SCI were recruited. Lower limb proprioceptive sense and clinical measures of skilled walking were determined in the subjects with SCI. All subjects then completed a lower limb pointing task where they aimed their toe from a "home position" to one of three possible targets. Each target required varying degrees of inter-joint coordination and the excursion of the leg to each target was normalized to every individual's active range of motion. The pointing task was completed under two visual conditions, full and obstructed vision. In the full vision condition, vision of the lower limbs was unobstructed, and participants received knowledge of performance after every trial. In the obstructed vision condition, vision of the lower limbs was blocked, and subjects did not receive knowledge of performance. Motion capture markers were used to determine foot trajectory, as well as hip, knee and ankle angles. From the kinematic data, end-point (toe) accuracy and inter-joint coordination, quantified by joint angle-angle plots, were extracted.
Individuals with SCI had deficits in lower limb proprioceptive sense and displayed poor end-point accuracy when pointing to the different targets, which was particularly exacerbated in the obstructed vision condition. Lower limb proprioceptive sense was related to lower limb coordination such that greater proprioceptive deficits was related to poor coordination. Able-bodied individuals on the other hand were able to accurately point towards all targets while displaying appropriate coordination patterns. There results show that our new task is well suited for measuring lower limb coordination and provides a new approach for future studies to examine how lower limb coordination affects community ambulation.

Title: Improvements in lower limb coordination following locomotor resistance training is related to improvements in skilled walking function, but not walking speed

Authors: *G. EGINYAN[1,2], R. N. MALIK[1,2], A. K. LYNN[1,2], T. LAM[1,2]
[1]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada; [2]Sch. of Kinesiology, Univ. of British Columbia (UBC), Vancouver, BC, Canada

Abstract: Introduction: Following motor-incomplete spinal cord injury (m-iSCI), functional ambulation is reduced partly due to the skilled walking requirements of everyday life. Our laboratory previously showed that body weight supported treadmill training (BWSTT) with Lokomat-applied resistance (Loko-R) led to greater improvements in skilled walking capacity compared to conventional Lokomat assisted (Loko-A) BWSTT. Following SCI, coordination can be impaired, which may contribute to the reduced ambulatory capacity among these individuals. The aim of this project was 1) to determine whether there were improvements in intra-limb coordination following Lokomat training, and 2) whether these improvements corresponded with improved functional walking capacity in individuals with m-iSCI. **Methods:** Nine individuals with chronic m-iSCI were randomly assigned to BWSTT with Loko-R (n=6) or Loko-A (n=3) groups and underwent a 3-month training intervention. Clinical measures of skilled walking and walking speed were conducted before and after training. Lower limb joint kinematics during treadmill walking with BWS was recorded at baseline and post-training. Motion capture markers were used to determine, hip, knee and ankle angles. Joint angle-angle plots were then created to quantify intra-limb coordination. Changes in intra-limb coordination before and after training for each subject was determined by comparing joint angle-angle plots against normative able-bodied data that was matched for speed and percentage of body weight supported.
Results and conclusion: Following training, both groups showed improvements in walking speed, but only individuals in the Loko-R group showed improvements in skilled walking. After Loko-R training most individuals showed improvements in intra-limb coordination which was related to skilled walking function, but not walking speed. We found that individuals with SCI whose coordination patterns became more similar to able-bodied controls after training had greater improvements in skilled walking function. A larger scale study needs to be conducted to further illustrate the differential effects of Loko-R and Loko-A training, and to determine the

effectiveness of Loko-R training to improve lower limb coordination and community ambulation following SCI.

Title: Corticospinal and reticulospinal contributions to spasticity after human spinal cord injury

Authors: *S. SANGARI[1,2], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: Animal models of spinal cord injury (SCI) suggest that the corticospinal and reticulospinal tract contribute to the development of spasticity. The extent to which these descending motor pathways are involved in spasticity in humans with SCI remains poorly understood. We examined the contribution of the corticospinal pathway by measuring input-output motor evoked potential (MEP) recruitment curves in the rectus femoris muscle elicited by transcranial magnetic stimulation over the leg motor cortex. The contribution of the reticulospinal tract was explored by using the StartReact response measuring reaction time from the rectus femoris electromyographic activity during isometric knee extension in the presence of a startle acoustic stimuli. Experiments were performed in adults with chronic incomplete SCI with different degrees of spasticity and aged-matched controls. We found that SCI participants with severe spasticity exhibited smaller MEP-max and shorter reaction time during a startle stimuli compared with those with lesser spasticity and uninjured controls. SCI participants with severe spasticity also showed smaller maximal voluntary contractions compared with those with lesser spasticity and control subjects. Our results indicate balanced contributions of both corticospinal and reticulospinal pathways in incomplete SCI participants with spasticity. Thus, interactions between these residual supraspinal motor pathways might be critical for understanding the mechanisms of spasticity.

Title: Identifying cellular dynamics in mouse sympathetic neurons: A computational modeling approach

Authors: *K. TIAN[1], M. L. MCKINNON[2], S. HOCHMAN[2], A. A. PRINZ[3]
[2]Physiol., [3]Biol., [1]Emory Univ., Atlanta, GA

Abstract: Sympathetic postganglionic neurons (SPNs), located in the sympathetic ganglion chain, pass converged motor commands from the spinal cord to the downstream muscles and visceral organs. SPNs in the thoracic region of the sympathetic nervous system (tSPNs) regulate vasoculature and dysfunction of tSPNs is implicated in various autonomic disorders such as autonomic dysreflexia, yet because of experimental difficulties, little is known about the cellular mechanisms that control the excitability of tSPNs. By combining eletrophysiological data with computational modeling, we built the first physiologically-realistic single neuron model of tSPNs in mice, and elucidated several cellular mechanisms that govern tSPN dynamics. This model reproduced all the essential features of tSPNs *ex vivo* with eight types of ionic currents, which are a fast sodium current (I_{Na}), a delay-rectified potassium current (I_{Kd}), a slow and non-inactivating potassium current (I_M), a calcium-dependent potassium current (I_{KCa}), a fast transient potassium current (I_A), a persistent calcium current (I_{CaL}), a hyperpolarization-activated inward current (I_h), and a leak current (I_L). Among other results, we found that the post-inhibitory rebound that has been observed in tSPNs *ex vivo* was induced by I_{Na} and I_{Kd} rather than the T-type calcium current. We also found that both I_M and I_{KCa} were necessary and sufficient to replicate tSPN spike rate adaptation. To conduct a more comprehensive and rigorous examination of the range of tSPN cellular dynamics and responses to various synaptic inputs, we employed an ensemble modeling approach [1-2] to build a database of physiologically-realistic tSPN models. We further analyzed the pairwise correlations between ionic currents using both Pearson's correlation and mutual information. Simulation and analysis were written in Python 2.7.10 and executed on the Neuroscience Gateway Portal [3]. The database was parallelized with the SCOOP module. Overall, we built the first physiologcally-realistic single neuron model and database of tSPNs, which lays the foundation to examine both the recruitment principles of synaptic inputs at tSPNs and the role tSPNs play in autonomic disorders in the future.

Title: Raising the threshold: A perturbation protocol to improve non-stepping responses to rapid surface translations

Authors: *J. H. BARNES[1,2], A. EFTEKHAR[1], T. T. FAKE[1], C. S. CARMACK[1], J. R. CRENSHAW[2], J. R. WOLPAW[1,3]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Univ. of Delaware, Newark, DE; [3]Stratton VA Med. Ctr., Albany, NY

Abstract: The ability to maintain upright stance despite disturbances is a motor skill and as such should improve with practice. While training protocols that perturb standing balance by rapidly translating the support surface have been used to reduce the likelihood of falls in at-risk populations (e.g., older adults), their underlying mechanisms are not fully understood. By investigating motor learning in younger, unimpaired, individuals we can remove potential confounds of age and morbidity, however the degree to which this type of balance reaction is modifiable in high-functioning groups is unknown. To test this we developed a protocol that challenges younger healthy individuals to produce non-stepping responses to progressively larger disturbances. Each participant stands on a Bertec split-belt treadmill while perturbations (rapid surface translations) are triggered at random times by custom software. Each perturbation lasts ~600-700 ms and has a trapezoid-shaped velocity profile. Acceleration and deceleration phases are 200 ms each. Difficulty levels are defined by acceleration and deceleration rates that are equal in absolute value and increase in increments of 0.25 m/s^2. A tachometer is used to ensure perturbations reach target peak velocity. Limitations in treadmill instrumentation produce variability in time at peak velocity; this causes perturbation displacements to overlap across levels and challenges participants to respond to disturbances that vary differentially (i.e., those equal in acceleration may vary in displacement and vice versa). A successful response is defined as maintaining balance without stepping. Participants begin at a low level and move up one level

at a time until stepping occurs in 3 consecutive trials. This is defined as their stepping threshold. Then, over the course of 6 training sessions, each comprising 50-75 perturbations, participants are challenged to raise their threshold. They start one level below it, progress to the next higher level after 3 successful responses, and transition down a level after an observed step. A motion-capture system records the perturbation and the kinematics of the participant's response; and electromyography (EMG) is recorded from ankle flexor and extensor muscles bilaterally. Further, at the beginning of each session, right and left soleus H-reflexes are recorded during standing. Initial data suggest that healthy individuals can learn to respond to faster and larger perturbations without stepping. Ongoing studies seek to confirm this preliminary result, to define the associated kinematic and EMG changes, and to explore the possibility that reflex function is affected.

Title: Bilateral asymmetries in spasticity following spinal cord injury

Authors: *B. CHEN[1,2], J. LORENTZEN[3], J. B. NIELSEN[3], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL; [3]Inst. of Neuroscience, Inst. of Nutr. and Exercise and Elsass Inst., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Spasticity is one of the most common symptoms present in humans with spinal cord injury (SCI). Although SCI mostly result in bilateral damage of neuronal pathways, the extent to which spasticity is affected on both sides of the body remains unknown. The aim of our study was to assess ankle plantar flexor stiffness in adults with and without chronic SCI bilaterally. We performed slow and fast dorsiflexion stretches of the ankle joint to measure the range of motion (ROM), passive stiffness, and reflex mediated stiffness bilaterally using a dynamometer. We found that passive ROM was reduced in both sides of SCI participants compared with control subjects. Passive stiffness between 30 to 50% of the dorsiflexion ROM was increased in one side

more than the other in SCI participants and remained similar in controls. The joint angle at which the stretch reflex was elicited was larger in controls compared with SCI participants. In addition, the total torque and reflex induced torque was larger in one side in SCI participants and remained similar in controls. Our results indicate that symptoms of spasticity in ankle plantarflexor muscles are asymmetrically present in humans with chronic SCI.

Title: Corticospinal excitation and inhibition for the ankle dorsiflexor tibialis anterior: A mapping study

Authors: *R. COTE[1], A. K. THOMPSON[2]
[1]Col. of Hlth. Professions, [2]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: The corticospinal tract (CST) is important in motor control, motor skill learning, and re-learning after CNS injury. While it has become increasingly common to measure motor evoked potential (MEP) to transcranial magnetic stimulation (TMS) as a measure of corticospinal excitability and plasticity, its relation to the silent period (SP; suppression of ongoing EMG, reflecting corticospinal inhibition) after MEP or cortical map representation of the SP are less known. Thus, to better understand the corticospinal excitation and inhibition, we are currently examining cortical maps and recruitment curves of MEP and SP for the tibialis anterior (TA), using two different coils.
All TMS trials occur while the subject is seated in a chair with a leg fixed in a custom-made apparatus with ankle, knee, and hip joint angles fixed at ≈100, ≈120, and ≈110°, respectively. TMS is performed using Magstim 200^{-2} and a 110 mm double-cone coil or a custom-made bat-wing coil with radii of 9 cm, held over the scalp such that the induced current flows in the posterior–anterior direction in the brain. When the absolute TA EMG level is maintained at ≈15% MVC, an MEP is elicited at an interval of 5-6 seconds between stimuli. To determine the stimulus intensity to be used for mapping, an MEP recruitment curve is measured at a tentative optimum location typically identified near the vertex. Then, using the TMS intensity that

produces a half-maximal response at this tentative location, MEP mapping is performed over -3-to-+3 cm anterior and -1-to-+4 cm contralateral to the vertex. Four stimuli are applied at each location. After mapping, an MEP recruitment curve is obtained at the optimum location. For each stimulus location and intensity, the end of SP is determined as the recovery of background EMG activity in 50% of the responses.
Our initial results suggest that the double-cone coil and batwing coil do not produce the same MEP or SP maps. While the MEP hotspot for TA can be identified using either coil, the location differs between the coils by ≈1.69±0.78 cm. With the batwing coil the SP duration differs across stimulus locations and the SP hotspot is identifiable. In contrast, with the double-cone coil, the map distribution of SP duration is diffused, indicating a broader recruitment of inhibitory interneurons. Although the MEP and SP maps are not identical, there is a positive correlation between the MEP size and the SP duration across the map locations. This supports a possibility that inhibitory neurons responsible for producing the SP may be closely located to CST neurons for a given muscle in the cortex. To further understand the MEP- SP relation, additional analyses are currently underway.

Title: Chronic stability of soleus stretch reflexes during standing in neurologically normal adults

Authors: *A. OLIVIER[1], A. LUNDGAARD[5], K. ORITA[2], B. A. POULIOT[3], J. B. ANDERSEN[5], A. K. THOMPSON[4]
[2]Col. of Hlth. Professions, [3]Hlth. Sci. and Res., [4]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, [1]Med. Univ. of South Carolina, Charleston, SC; [5]Ctr. for Sensory-Motor Interaction, Aalborg Univ., Aalborg, Denmark

Abstract: People can learn to change spinal reflexes through operant conditioning. Previous work shows that successful reflex operant conditioning changes not only the reflex pathway that is conditioned but also the activity of other spinal and supraspinal pathways. In order to further understand the mechanisms of this plasticity, we are currently investigating the chronic stability

of the stretch reflexes in the soleus during standing, as well as the tolerability of repeated ankle joint rotation. Stretch reflexes are affected by fusimotor control of muscle spindle sensitivity. Unlike electrical nerve stimulation that elicits the H-reflex, excitation of spindle afferents by muscle stretch is temporally dispersed and may result in activating motoneurons via several different spinal and supraspinal pathways. In humans, the soleus stretch reflexes usually appear in a series of three components: spinal short-latency "M1" (mainly Ia afferent origin), spinal long-latency "M2" (presumably mainly II afferent mediated), and the long latency "M3" (suggested to be transcortical or subcortical).
Healthy adults with no known neurological conditions are exposed to 30 stretch reflex sessions over 10 weeks (3/week). In each session, the subject completes an H-reflex/M-wave recruitment curve measurement, 1 block of 20 submaximal H-reflex trials, and 3 blocks of 75 stretch reflex trials while s/he stands on the custom ankle joint-rotation device (JAKraft, Aalborg University, Denmark). A reflex trial occurs when the subject has maintained a preset level (i.e., natural standing level) of background soleus EMG activity for at least 2 s and at least 5 s has passed since the last trial. To elicit stretch reflexes, a fixed amount (6 or 12°) of dorsiflexion rotation is applied at a fixed initial speed (125°/s or 170°/s). For a given subject, these stretch parameters are maintained throughout the study.
To date, four subjects have completed the 30 reflex sessions. In these subjects, amplitudes of the soleus maximum M-wave and H-reflex, submaximal H-reflex, soleus and tibialis anterior background EMG, M1 and M2 reflexes did not change systematically across sessions ($p>0.05$ for all, by repeated measures ANOVA), indicating the stability of the H- and stretch reflexes over an extended period of time (i.e., 10 weeks). All subjects have well tolerated either amount or speed of joint rotation, and preferred mechanical perturbation (stretch reflex elicitation) over electrical stimulation (H-reflex elicitation). These initial results support the feasibility of operantly conditioning the soleus stretch reflex during standing in people with and without neurological disorders.

Title: Plasticity of thoracic sympathetic post-ganglionic neuron after spinal cord injury

Authors: *Y. LI, M. L. MCKINNON, M. HALDER, S. HOCHMAN
Emory Univ., Atlanta, GA

Abstract: Autonomic dysreflexia (AD) is a hypertensive crisis seen in high-thoracic spinal cord injured (SCI) patients normally triggered by noxious stimuli below injury. Previous animal research on mechanisms underlying AD have mostly focused on neural plasticity within the injured spinal cord. No studies have assessed whether there is also plasticity in the sympathetic post-ganglionic neurons - the final neural element responsible for vasoconstriction.
Thoracic sympathetic post-ganglionic neurons (tSPNs) are located in thoracic paravertebral ganglia that provides dominant sympathetic control of vasculature. Their cellular properties are understudied due to their anatomical difficulty. The few previous *ex vivo* studies all used sharp electrodes that likely leads to significant impalement injury-induced changes. Here, we undertook whole-cell patch clamp recordings in an adult mouse tSPN *ex vivo* preparation, in which the thoracic sympathetic post-ganglionic chain was isolated and perfused in artificial CSF at room temperature. Compared to earlier reports, we observed order of magnitude greater values for passive membrane properties (cell resistance and membrane time constant) and repetitive rather than phasic firing properties (n=39, 100% of recorded tSPNs). These observations support greater ability for synaptic integrative actions and stronger output than previously assumed.
Using the same methodology, we then studied whether these neurons undergo plastic changes after high-thoracic (T2) spinal cord transaction in the young adult mouse as a model of AD. Recordings were obtained from T3-T9 ganglia at different time points after SCI. Five days after SCI, resting membrane potential (RMP) was 10mV more hyperpolarized (n=6). Interestingly, in response to depolarizing current injection, 3/6 tSPNs were inexcitable, 2/6 fired phasically, with only one neuron capable of repetitive firing. At both 3 weeks (n=5) and 6 weeks (n=13) post-SCI, mean tSPN RMP and capacity for repetitive firing returned to that in naïve animals. Notably, at 3 weeks one tSPN showed spontaneously period of single channel activities and maintained bouts of spontaneous synaptic activity that lead to large shifts in membrane potential. By 6 weeks, these bouts of spontaneous activity and associated membrane potential shifts were seen 6/13 neurons. Together, these results highlight the temporal changes in tSPN properties that emerge after SCI.

Title: Towards operant conditioning of the flexor carpi radialis: Methods and initial results

Authors: *J. NORTON, A. EFTEKHAR[1], S. HECKMAN[1], J. H. BARNES[1], L. MCCANE[1], J. R. WOLPAW[1,2]

Abstract: Operant conditioning of the H-reflex (electrical analog of the spinal-stretch reflex) is a promising new therapeutic intervention for those with motor dysfunction following stroke or spinal cord injury (e.g., Thompson et al. J Nsci, 2013). To extend H-reflex operant conditioning to the upper extremity, we are developing a methodology for operant conditioning of the H-reflex of the forearm muscle flexor carpi radialis (FCR). Because the conditioning protocol comprises 30 1-hr sessions over 10 weeks, signal quality (amplitude and signal-to-noise ratio [SNR]) and signal stability are critical. Here we compare the quality and stability of H-reflexes and M-waves (direct muscle responses) obtained with alternative forearm positions and electrode locations over multiple study sessions.
Data were recorded during 5 sessions over two weeks from 7 total participants. The participant sat in a comfortable chair with their right forearm supported on a table. We collected data with two different arm positions and two different reference electrode locations: condition one (CND1) (forearm fully supinated; an EMG electrode pair (3cm separation) over the muscle belly); and condition two (CND2) (forearm at neutral position with some external rotation of the upper arm; one EMG electrode over the muscle belly and the other over the tendon). FCR H-reflexes were elicited by digitally controlled 0.5-ms biphasic median-nerve stimulation (Digitimer DS5) while the participant maintained a defined level of FCR muscle activation (5-10% of M-wave$_{max}$) guided by feedback on a video screen. In the first session, stimulation and recording electrode locations were determined for each participant. During subsequent sessions, the same stimulation and recording sites were used to elicit and measure M-wave and H-reflex recruitment curves.
Across participants and sessions, H-reflex (~1100%) and M-wave (~375%) amplitudes were larger in CND2. The H-reflex SNR also appears (~260%) larger in CND2, while the coefficients of variation appear smaller (CND1 - 0.15 M-wave, 0.33 H-reflex; CND2 - 0.08 M-wave, 0.19 H-reflex).
Based on these results, we are now proceeding with FCR operant conditioning using the positioning and electrode locations of CND2. We expect that CND2 will provide H-reflex conditioning equal to, and perhaps better than, that previously obtained with CND1. If the new protocol is validated, we plan to assess the ability of FCR H-reflex conditioning to enhance recovery of hand/arm function after stroke.

Title: Molecular basis of H-reflex operant conditioning: Methods development

Authors: *B. HERRON[1], J. S. W. CARP, 12208-3423[1], Y. WANG[1], X. Y. CHEN[1], J. R. WOLPAW[1,2]

[2]Stratton VA Med. Ctr., Albany, NY

Abstract: The spinal stretch reflex (or its electrical analog, the H-reflex) represents one of the simplest mammalian behaviors. When appropriately rewarded, animals and people can produce long-lasting increase or decrease in H-reflex size. Thus, operant conditioning of the H-reflex constitutes a novel model for studying the mechanisms of neuronal plasticity involved in the acquisition of a new motor skill. Previous studies from our laboratory have shown that plasticity involved in H-reflex conditioning requires hierarchical control at multiple levels in the brain and spinal cord that mediate learning of a new behavior while maintaining previously acquired skills. This work has implicated cortically controlled spinal GABAergic interneurons and their receptors on motoneurons in the induction and maintenance of H-reflex change after operant conditioning. However, the molecular mechanisms that mediate H-reflex conditioning remain largely uncharacterized. Recent advances in next-generation genomic technologies make novel approaches possible to determine the molecular factors that mediate adaptive plasticity associated with H-reflex conditioning. This study describes the development of RNA-Seq methods that will be used to determine genome-wide transcriptional changes due to H-reflex conditioning. This preliminary work has focused on laser-captured motoneurons and the surrounding grey matter in control animals to establish sample variance and best practices for tissue collection and signal amplification. We were successful in isolating highly purified motor neuron pools from soleus muscle that, when compared to distinct tissue sources such as white matter from the same spinal cord, show minimal expression of glial cell markers (e.g. GFAP) and enrichment for neuronal genes (e.g. FoxP1). Within-sample variance is currently being optimized to increase the sensitivity and overall reproducibility of this system. Our goal is to determine cell-level effects before, during, and after H-reflex conditioning using a combination of gene-set enrichment approaches and correlations with phenotype outcomes (e.g., H-reflex increase/decrease, successful conditioning). These data will provide the molecular basis for this

simple learning paradigm and generate new hypotheses to ultimately utilize this approach in clinical therapy.

Title: Multi-electrode arrays for automatic selection of recording and stimulation sites in spinal reflex operant conditioning protocols

Authors: *A. EFTEKHAR[1], J. J. S. NORTON[1], S. M. HECKMAN[1], A. K. THOMPSON[2], J. R. WOLPAW[1,3]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [3]Dept. of Neurol., VA Med. Ctr., Albany, NY

Abstract: Operant conditioning protocols that target beneficial plasticity to spinal reflex pathways can improve walking in rats and people with incomplete spinal cord injury (SCI) (PMC38620 & PMC3579496). Clinical translation of these protocols requires that the current complex lab system for operant conditioning be converted into a simple robust system for clinical therapists. One of the most demanding aspects of the current system is selection of nerve stimulation and EMG recording sites that provide EMG from the targeted muscle and an M-wave/H-reflex recruitment curve that enables stimulation that elicits a small M-wave and an H-reflex on the rising phase of H-reflex recruitment. Furthermore, these sites must be reliably re-located in subsequent treatment sessions. At present, these tasks require a highly trained person and substantial time. We explored the use of a multi-electrode array and automatic site selection algorithms to reduce the training and time requirements. H-reflex/M-wave recruitment curves for flexor carpi radialis (FCR) (median nerve (cubital fossa) stim) and soleus (posterior tibial nerve stim) were elicited and recorded with electrode arrays (OT Bioelettronica). FCR participants sat with right arm supinated and supported at a 90̊ angle in the sagittal plane; soleus participants were tested in a natural standing posture. EPOCS, a BCI2000-based operant conditioning program (PMID: 15188875), and a Digitimer D188 multiplexer connected to a DS5 stimulator

automatically cycled through stim sites. One-ms (soleus) and 0.5-ms (FCR) bi-phasic square pulses occurred at ≥5-s intervals while the person maintained a given EMG level (~5-10% maximum voluntary contraction). Recruitment curves were constructed by averaging 4 pulses for each stim levels from below H-reflex threshold to Mmax (~5-30 mA). EMG was digitized at 3200 Hz (bandpass 1-1000 Hz). EMG data were automatically analyzed to find the stim site that gave a maximum H-reflex response with the least current. Initial results from 3 people were very similar to those obtained with the lab system by expert operators. Multi-electrode array data were also useful for identifying and reducing artifacts and for separating overlapping artifact, M-wave, and H-reflex responses. Multi-electrode arrays with automated algorithms should reduce the expertise and time needed to locate and re-locate electrode sites and build recruitment curves. These arrays and algorithms are an important step toward the robust clinical system essential for widespread dissemination of spinal reflex operant conditioning as a new therapy that can enhance functional recovery for people with SCI and other disorders.

Title: Soleus H-reflex up-conditioning promotes H-reflex recovery and improves locomotor kinematics in rats during or after regeneration of a transected sciatic nerve

Authors: *L. CHEN[1], Y. CHEN[1], X. YANG[1], Y. WANG[1], J. R. WOLPAW[1,2], X. Y. CHEN[1]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYSDOH, Albany, NY; [2]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the spinal stretch reflex or its electrical analog, the H-reflex (HR), changes the brain and spinal cord (Curr Opin Behav Sci 20:138-144, 2018 for review). In rats and humans with incomplete spinal cord injury, appropriate reflex conditioning improves locomotion (J Neurosci 26:12537-12543, 2006 & 33:2365-2375, 2013). Reflex conditioning can

help restore spinal reflexes after nerve injury and regeneration (J Neurosci 30:16128-16136, 2010). This study explores in rats with sciatic transection the impact of soleus H-reflex conditioning during or after sciatic regeneration on HR and locomotion.
Sprague-Dawley rats are implanted with EMG electrodes in the right soleus and a stimulating cuff on the right posterior tibial nerve. After control data collection, the right sciatic nerve is transected (TX) and repaired. Data collection continues for 20 (TC_{120}, TU_{120}, TD_{120} rats) or 120 (TC_{220}, TU_{220} rats) more days. The rat is then exposed for 100 days to: continued control data collection (TC_{120}, TC_{220}); soleus HR up-conditioning (TU_{120}, TU_{220}) or down-conditioning (TD_{120}). Locomotor EMG, HR, and kinematics are assessed before transection, and 120 (TU_{120},TC_{120},TD_{120}) or 220 (TC_{220},TU_{220}) days after transection.
In 6 TU_{120}, 6 TD_{120}, and 7 TC_{120} rats, the final soleus protocol HR (HR during conditioning) averaged 47(10 SEM)%, 24(7)%, 17(3)%, respectively, of pre-transection value (p=0.01, 0.06, 0.78: TU vs TC, TU vs TD, TD vs TC by ANOVA & Tukey Test). In 6 TU_{220} and 7 TC_{220} rats, final HR averaged 47(11)% and 9(3)% (p=0.0040).
In 6 TU_{120} rats, step symmetry (normal 100) before TX (preTX), and 20 days (TX20) and 120 days (TX120) after TX, averaged 100.9(1.1SEM), 69.1(2.9), 95.2(6.7), respectively, ($p<0.001$, =0.61, =0.002: PreTX vs TX20, PreTX vs TX120, TX120 vs TX20); in 6 TD_{120} rats, it averaged 100.4(±1.0), 72.4 (2.0), 86.3(5.3) ($p<0.001$, =0.02, =0.03: PreTX vs TX20, PreTX vs TX120, TX120 vs TX20); in 7 TC_{120} rats, it averaged 99.8(0.4), 70.5 (6.4), 76.2(6.6) (p=0.003, 0.02, 0.74: PreTX vs TX20, PreTX vs TX120, TX120 vs TX20). In 7 TU_{220} rats, preTX, TX120, and TX220, it averaged 99.8(0.4), 76.2 (6.6), 84.0(5.0) (p=0.007, 0.08, 0.50: PreTX vs. TX120, PreTX vs TX220, and TX220 vs TX120); in 7 TC_{220} rats, it averaged 100.5(0.5), 91.5 (1.1), 89.4 (1.7) ($p<0.001$, <0.001, =0.44; PreTX vs TX120, PreTX vs TX220, TX220 vs TX120).
HR up-conditioning during or after sciatic regeneration improves HR recovery and locomotor symmetry. HR conditioning is a novel therapy that might complement standard rehabilitation methods and enhance functional recovery after peripheral nerve injury and regeneration.

Title: Combining H-reflex conditioning and locomotor training appears to enhance locomotor recovery in rats with incomplete spinal cord injury: Initial results

Authors: *X. Y. CHEN[1], L. CHEN[1], X. YANG[1], Y. WANG[1], Y. CHEN[1], J. R. WOLPAW[1,2]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYSDOH, Albany, NY;

Abstract: Operant conditioning of the spinal stretch reflex or its electrical analog, the H-reflex (HR), changes the brain and spinal cord (Curr Opin Behav Sci 20:138-144, 2018 for review). In rats and humans with incomplete spinal cord injury, appropriate reflex conditioning improves locomotion (J Neurosci 26:12537-12543, 2006 & 33:2365-2375, 2013). We are exploring the impact of combining H-reflex conditioning with locomotor training (an established therapy) in rats after spinal cord injury.

Under anesthesia, female Sprague-Dawley rats are implanted with EMG recording and nerve stimulating electrodes and receive a right spinal cord lateral column (LC) transection at T9. Twenty days later, each rat is exposed to a 60-day intervention of either right soleus H-reflex (HR) up-conditioning combined with 5 days/wk locomotor training (CB rats) or locomotor training alone (LT rats). Locomotor EMG, HR, and kinematics are assessed (during treadmill walking and horizontal ladder crossing) before and after LC transection, and at the end of the 60-day treatment.

To date, we have completed studies in 3 CB and 3 LT rats. Final soleus protocol H-reflex, locomotor H-reflex, and locomotor burst area after treatment in the CB rats averaged 203(±39 SEM)%, 220(±90SE)%, and 128(±10SE)%, respectively, of their pre-exposure values; in the LT rats, they averaged 101(±8)%, 105(±7)%, and 129(±17)%, respectively. Before LC transection, step symmetry (normal 100) averaged 101.9(±0.78SE) in CB rats and 99.6(±0.26) in LT rats ($p=0.83$ by ANOVA followed by Tukey test); after LC transection and before treatment, it averaged 90.8(±2.6) in CB rats and 88.4(±1.1) in LT rats ($p=0.81$); After treatment, it averaged 99.1(±1.6) in CB rats and 91.1(±0.54) in LT rats ($p=0.018$). Before LC transection, footfalls during horizontal ladder crossing averaged 0.33(±0.19SE)/crossing in both CB and LT rats; after LC transection and before treatment, it averaged 8.44(±0.19)/crossing for CB rats and 6.00(±1.33)/crossing for LT rats ($p=0.36$ by t-test); after treatment, it averaged 3.67(±0.19)/crossing in CB rats and 6.50(±0.09)/crossing in LT rats ($p=0.014$ by t-test).

In addition, in CB rats, up-conditioning increased the H-reflex more quickly and more than it did in 77 uninjured normal rats and 16 rats with spinal cord LC injury up-conditioned in all previous studies to date.

These initial results suggest that, in rats with unilateral LC transection, the combination of H-reflex up-conditioning and locomotor training is more effective than locomotor training alone (and may be more efficient that H-reflex conditioning alone). The additional studies needed to confirm these early results are underway.

Title: Operant conditioning of the soleus H-reflex in people with and without chronic CNS injury

Authors: *C. R. GILL[1], Y. MAKIHARA[4], W. HAUG[5], R. L. SEGAL[2], J. R. WOLPAW[6,7], A. K. THOMPSON[3]
[1]Dept. of Hlth. Sci. and Res., [2]Dept of Hlth. Professions, [3]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [4]Sch. of Hlth. Sci. at Narita, Dept. of Physical Therapy, Intl. Univesity of Hlth. and Welfare, Chiba, Japan; [5]Sch. of Sport, Exercise and Hlth. Sci., Loughborough Univ., Loughborough, United Kingdom; [6]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [7]Neurol., VA Med. Ctr., Albany, NY

Abstract: People with chronic CNS injuries often suffer disabilities associated with spasticity and weak voluntary muscle contraction, even after conventional therapy. Abnormal spinal reflexes commonly contributes to these problems. In rats and people, an operant conditioning protocol can restore more normal reflexes and can thereby trigger wider plasticity that improves locomotion; benefits persist after conditioning ends (Neuroscientist 2014:21:203-215). To further understand the conditioning-induced plasticity, we are comparing the time courses of H-reflex change among people with no CNS injury, with chronic incomplete spinal cord injury (SCI), and with stroke.
The conditioning protocol comprises 6 baseline and 24 (in people without CNS injury) or 30 (in people with SCI or stroke) conditioning sessions (3/wk). In each baseline session, 225 control H-reflexes are elicited without any feedback on H-reflex size. In each conditioning session, 20 within-session control H-reflexes are elicited first, and then 225 conditioned H-reflexes are elicited while the subject is encouraged to change H-reflex size guided by immediate visual feedback. Background EMG activity and M-wave size are kept stable throughout data collection. Conditioning was successful for 29/39 (74%) people without CNS injury, 6/9 (67%) people with SCI, and 6/12 (50%) people with stroke. (Subsequent data are those of the successful

individuals.) For people without injury who were down-conditioned (N=18), final H-reflex size was 69±6(SE)% of baseline (-17% within-session task-dependent adaptation (TDA); -14% across-session long-term (control reflex) change (LTC)). For people without injury who were up-conditioned (N=11), final H-reflex size was 144±9% (+16% TDA; +28% LTC). For people with SCI who were down-conditioned (N=6), final H-reflex size was 69±11% (-7% TDA; -24% LTC). For people with stroke who were down-conditioned (N=6), final H-reflex size was 69±9% (-15% TDA; -16% LTC).
While final reflex sizes after down-conditioning were identical for the groups, they differed in the relative magnitudes of TDA and LTC, and in the time of onset of LTC (≈6 sessions later in people with SCI and ≈12 sessions later in people with stroke than in people without CNS injury). These differences are likely to reflect: inter-group differences in the characteristics and capabilities of the descending influence that is thought to be directly responsible for TDA and to eventually produce LTC; and inter-group differences in the functional impact of TDA vs. LTC (explicable in terms of the negotiated equilibrium model of spinal cord function (J Physiol in press)).

Title: Soleus H-reflex modulation during a double-legged drop landing task

Authors: *M. A. LYLE[1], M. MCLEOD[2], B. A. POULIOT[3], A. K. THOMPSON[4]
[1]Div. of Physical Therapy, Emory Univ., Atlanta, GA; [2]Hlth. & Human Performance, Col. of Charleston, Charleston, SC; [3]Hlth. Sci. and Res., [4]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: Sensory feedback from muscle spindles is known to influence muscle activity during locomotor activities such as walking and running. Potential functional role of muscle spindle feedback may be reflected in the H-reflex amplitude during dynamic motion. For example, during walking the soleus H-reflex peaks during mid to late stance when muscle spindle feedback can reinforce and assist ankle extensor activation and is low during the swing phase

when feedback could interfere with ankle dorsiflexion. Tasks such as landing from a jump involve rapid joint flexion and thus muscle spindle feedback could have an important role in controlling muscle and joint stiffnesses. Several studies have evaluated soleus H-reflex amplitudes during landing, but a thorough understanding of H-reflex modulation is lacking and whether H-reflex magnitude is related to landing mechanics is unknown.
Here, we evaluate soleus H-reflex modulation and landing mechanics in healthy adults without a history of neurological injury. After collecting a standing H/M recruitment curve, each participant performed 100-120 double-legged drop landing trials from a 30.5 cm platform, with ≈10 s between trials. For ≈80% of landing trials, the soleus H-reflex is elicited unilaterally by tibial nerve stimulation just above M-wave threshold before, at, and after ground contact (-150, -100, -75, -50, -25, 0= ground contact, +25-50 ms). The test leg is randomly assigned. Bilateral surface EMG (soleus, medial gastrocnemius, tibialis anterior, vastus lateralis), vertical ground reaction force (GRF), and knee and ankle joint motion are measured. For comparison across different phases of landing, H-reflexes with the M-wave amplitude of ≈2-10% Mmax are included for analysis.
In the initial group of participants, knee and ankle joint angles at ground contact (10-18° and 30-35°) and the maximum GRF on the test leg (150-250% full body weight) remained relatively constant between stimulated landing (of various stimulus timings) and unstimulated landing within each participant. Thus, any systematic changes in H-reflex amplitude across different phases of landing would likely reflect phase-dependent modulation. H-reflex amplitude (expressed as %Mmax) steadily decreased during the flight phase from 58±13 (mean±SD) %Mmax at -150 ms to 9±7% at 0 ms, to 10±9 at +25-50 ms post ground contact. Our preliminary findings suggest the H-reflex modulation during drop landing differs from that observed for walking, running and drop jump. To elucidate the functional role of muscle spindle feedback during landing, further analysis to evaluate relations between H-reflex amplitude and landing mechanics is currently underway.

Title: Lower leg EMG and H-reflex modulation during two-leg hopping

Authors: W. HAUG[1], *A. K. THOMPSON[2]
[1]Sch. of Sport, Exercise and Hlth. Sci., Loughborough Univ., Loughborough, United Kingdom; [2]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: Hopping is a series of jumps in which landing from a jump seamlessly transitions to the subsequent jump. While it is a common form of jump, motor control during generation of two-leg hopping is not well understood. The aim of this study was to examine generation and modulation of the lower leg EMG and H-reflex activity during two-leg hopping, in relation to jump height and joint kinematics. We also compared the EMG and H-reflex activity during maximal height hopping and landing after the last maximal height hop.
Healthy adults with various athletic backgrounds participated in this study. Each subject performed 14-20 sets of 2 build up hops + 4 maximal hops + 1 landing, with a 90 s interval. Surface EMG from the soleus, medial (MG) and lateral gastrocnemius (LG), and tibialis anterior, vertical ground reaction force, and knee and ankle joint motion were measured. Triceps surae H-reflexes were elicited across different phases of hopping cycle.
In 19 (10 men and 9 women) subjects studied, the flight time (reflecting jump height) increased from the lower buildup (349±47(SD)ms) to the higher buildup (420±44ms) to the maximal height hop (497±53ms), and the flight time was positively correlated with triceps surae EMG amplitudes for -100 to 0 ms and 0 to 100 ms after ground contact (GC) ($r > 0.57$ for all). Correspondingly, the rate of ankle planterflexion and knee extension increased with increasing flight time: from -525 to -586 to -673 °/s for the ankle and -297 to -367 to -484 °/s for the knee. H-reflex size in -100 to 100 ms post GC also increased from the lower buildup to the maximal height hop. During maximal height hopping, the soleus H-reflex was phase-dependently modulated in each individual (i.e., modulation index: 79±16%), with no consistent pattern across subjects. The MG H-reflex was phase-dependently modulated individually (modulation index: 77±16%) and systematically across subjects ($p=0.02$, ANOVA), with the largest H-reflex elicited from -100 to 200 ms post GC.
During landing, the triceps surae EMG became suppressed immediately after GC, and the H-reflexes were almost completely suppressed from 50 to 200 ms post GC, in clear contrast to hopping.
Our study shows that (1) the triceps surae muscle activity likely contributes to two-leg hopping performance (i.e., higher jumps), (2) H-reflex is phase-dependently modulated, but the modulation patterns may differ across subjects and muscles, and (3) from hopping to landing, the muscle activity and H-reflex are rapidly and dynamically modulated. These findings suggest that the maximal height two-leg hopping involves dynamic neural control of knee and ankle joint motion within the constraints of rapid motion.

Title: Soleus H-reflex down-conditioning affects the motoneuron axon initial segment (AIS)

Authors: *Y. CHEN[1], Y. WANG[1], L. CHEN[1], J. R. WOLPAW[1,2], X. Y. CHEN[1]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYSDOH, Albany, NY;
[2]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the spinal stretch reflex or its electrical analog, the H-reflex (HR), changes brain and spinal cord (Curr Opin Behav Sci 20:138-144, 2018 for review). Soleus (SOL) HR up-conditioning increases SOL motoneuron (MN) axon initial segment (AIS) length; the increase correlates with the HR increase (Chen et al. SFN Abs 780.07, 2017). We assessed the impact of SOL HR down-conditioning on the AIS.
Twelve successfully down-conditioned (DS, HR decrease ≥20%) rats, 8 down-conditioning failed (DF, HR change <20%) rats, and 13 naive control (NC) rats were studied. Each was injected in SOL with CTB-Fluor488 and perfused 3 days later. Serial 25-μm lumbar spinal cord coronal sections were immunohistochemically processed for CTB-Fluor488 (identifying SOL MNs) and anti-ankyrin G (labeling the AIS). SOL AIS length, proximal and middle widths, and location (distance from soma)), and ANK3-IF and Nav-IF on SOL MN soma and/or AIS, were measured in a blinded manner. ANK3-IF and Nav-IF were expressed in % of average NC rat values. Statistical analysis was by nested ANOVA followed by least mean contrast test.
A total of 433 SOL AIS (106 DS, 98 DF, 229 NC) were studied. SOL AIS lengths in DS, DF, and NC rats averaged 26.1±0.3SE μm, 25.1±0.4 μm, and 26.0±0.3 μm, respectively. The groups did not differ ($p>0.05$). SOL AIS locations in DS, DF, and NC rats averaged 7.49±0.41 μm, 8.48±0.45 μm, and 7.0±0.39 μm, respectively. AIS location was significantly increased in DF rats ($p<0.01$ vs. NC). AIS proximal width in DS, DF, and NC rats averaged 5.24±0.10 μm, 5.13±0.11 μm, and 5.44±0.08 μm, respectively; it was narrower in DF rats than in NC rats ($p<0.05$). AIS middle width in DS, DF, and NC rats averaged 3.45±0.06 μm, 3.44±0.06 μm, and 3.50±0.05 μm, respectively. The groups did not differ ($p>0.05$). Nav-IF on SOL MN soma in DS

and DF rats averaged 87(±3)% and 91(±3)% respectively, weaker than that in NC rats ($p<0.001$ and $p<0.05$, DS and DF vs. NC). Nav-IF on SOL AIS in DS and DF rats averaged 88(±3)% and 91(±3)%, respectively, weaker than in NC rats ($p<0.001$ and $p<0.01$, DS and DF vs. NC). ANK3-IF on SOL AIS_{MN} averaged 87(±2)% and 96(±2)%, respectively, in DS and DF rats; it was weaker in DS rats ($p<0.001$ DS vs. NC; $p>0.05$ DF vs. NC).
Successful HR down-conditioning is associated with decrease in AIS Nav-IF and ANK3-IF. This seems consistent with studies showing that down-conditioning is due to a positive shift in MN firing threshold (J Neurophysiol 72:431-442, 1994, 74:867-871, 1995). Together with the finding that successful up-conditioning is associated with increased AIS length, these results suggest that AIS plasticity, previously reported to occur during development, may also contribute to motor learning.

Title: Soleus H-reflex up-conditioning increases soleus motoneuron ionotropic glutamate 1 (GluR1) receptor labeling

Authors: *Y. WANG[1], L. CHEN[1], Y. CHEN[1], J. R. WOLPAW[1,2], X. Y. CHEN[1]
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYSDOH, Albany, NY; [2]Stratton VA Med. Ctr., Albany, NY

Abstract: Successful up-conditioning of soleus (SOL) H-reflex (HR) in rats increases SOL motoneuron (MN) group-1 metabotropic glutamate receptor 1 immunoreactivity (mGluR1-IR) and the length of the SOL MN axon initial segment (AIS) (Wang et al., SFN Abs 917.11, 2011; Chen et al., SFN Abs 780.07, 2017). Furthermore, both increases correlate with the magnitude of HR increase produced by up-conditioning. To further explore the mechanisms of HR up-conditioning, we studied the effect of SOL HR up-conditioning on SOL MN surface ionotropic

glutamate 1 receptor (GluR1), phosphorylated GluR1 (pGluR1), and phosphrylated extracellular signal-regulated kinase (pERK).
Rats were implanted with EMG electrodes in the right SOL and a stimulating cuff on the posterior tibial nerve. Electrodes connected to a head-mounted tether. When EMG activity remained in a specified range for 2.3-2.7 s, nerve stimulation just above the M-response threshold elicited the HR. In the control mode (first 10-20 days), no reward occurred. In the HR up-conditioning mode (next 50 days), reward occurred when the HR size was greater than a criterion.
Seven SOL HR up-conditioning successful (i.e., HR increase ≥20%, US rats), 4 SOL HR up-conditioning failed (HR change <20%, UF rats), and 8 body-weight-matched naïve control (NC) rats were injected in the right SOL with CTB-Fluor 647 (to identify SOL MNs), and perfused 3 days later. The lumbar 4-5 spinal cord was blocked and cut coronally at 16 μm. One of every 3 consecutive sections was processed for anti-GluR1, anti-pGluR1 (Ser831), or anti-pERK (Thr202/Tyr204) immunofluorescent (IF) labeling of SOL MNs. Three-D image stacks were photographed, coded, and quantified with the Fiji-image J program in a blinded manner. Data were expressed in % of the average NC rat values, and analyzed with one-way ANOVA and tested by least mean contrast.
In the 7 US rats, SOL MN GluR1-IF, pGluR1-IF, and pERK-IF averaged 116(±3SE)%, 133(±4)%, and112(±2)%, respectively, of that in NC rats ($p=0.0004$, $p<0.0001$, and $p<0.001$ vs. NC, respectively). In the 4 UF rats, GluR1-IF, pGluR1-IF, and pERK-IF averaged 109(±4)%, 102(±6)%, and 108(±3)%, respectively, of that in NC rats ($p=0.11$, $p=0.76$, and $p=0.032$, vs. NC rats, respectively). These initial results suggest that increases in SOL MN GluR1 and phosph-GluR1 (which appeared to occur only in US rats) may contribute to operantly conditioned HR increase, while increase in pERK (which appeared to occur in both US and UF rats) may not.

Title: Piezo2 channel-Merkel cell signaling modulates the conversion of touch to itch

Authors: *J. FENG[1], J. LUO[1], P. YANG[1], J. DU[2], B. S. KIM[1], H. HU[1]

Abstract: The somatosensory system relays many signals ranging from light touch to pain and itch. Touch is critical to spatial awareness and communication. However, in disease states, innocuous mechanical stimuli can provoke pathologic sensations such as mechanical itch (alloknesis). The molecular and cellular mechanisms that govern this conversion remain unknown. We found that alloknesis in the setting of aging and dry skin is associated with a loss of Merkel cells, the touch receptors in the skin. Targeted genetic deletion of Merkel cells and associated mechanosensitive Piezo2 channels in the skin was sufficient to produce alloknesis. Chemogenetic activation of Merkel cells protected against alloknesis in dry skin. This study reveals an unknown function of the cutaneous touch receptors and may provide insight into the development of alloknesis.

Title: Local input connections to GRPR expressing dorsal horn interneurons

Authors: *F. B. FREITAG, A. AHEMAITI, J. JAKOBSSON, M. LAGERSTRÖM
Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Somatosensory information from different modalities are detected by specific receptors in the peripheral primary afferent terminals but sensations as pain and itch can share common pathways, bringing this information to the dorsal horn. Early evidences suggested a dedicated circuit to process itch-related information through the use of the peptide Gastrin releasing peptide (GRP) and its receptor GRPR. Furthermore, itch sensation has also been shown to be negatively modulated by an inhibitory tone in the dorsal horn as an increase in scratch behavior could be induced by disinhibition. In order to investigate the GRP/GRPR system and its local connectivity, the calcium indicator GCaMP6 was delivered through viral injection in the spinal cord of Grpr-Cre animals. To retrogradely trace dorsal horn GRPR neurons and

characterize its local inputs, rabies virus was injected in the spinal cord of Grpr-Cre mice. Finally, whole cell patch clamp recordings were performed to confirm the prevalence of spontaneous inhibitory/excitatory input to this subpopulation of local dorsal horn interneurons. The results from these experiments bring important conclusions about local connectivity of GRPR dorsal horn interneurons and contributes to our increasing knowledge of how itch is processed and regulated in the spinal cord level.

Title: Characteristics of primary afferent nerve fibers elongated into the epidermis in dry skin with itch

Authors: *T. ANDOH, Y. ASAKAWA, Y. KURAISHI
Univ. Toyama, Toyama, Japan

Abstract: Itch/pruritus is the most common symptom of cutaneous diseases (e.g. atopic dermatitis and xerosis) characterized by dry skin. Pathohistological analyses of chronic skin diseases with severe itch and dry skin have shown that the density of peripheral nerve fibers is increased in the epidermis. However, the characteristics of the elongated nerve fibers remain unclear. Therefore, we investigated the characteristics of the elongated nerve fibers using a dry skin mouse model with itch. In this study, we used male ICR mice. The dry skin mouse model was prepared via repetitive treatments with an acetone/ether mixture and water for 5 days. In this mouse model, the stratum corneum water content was decreased, whereas spontaneous scratching and epidermal hyperplasia were increased. In the epidermis of the dry skin, PGP9.5-immunoreactive nerve fibers were increased. In addition, the number of substance P (SP)- and calcitonin gene-related peptide (CGRP)-immunoreactive nerve fibers (C-fibers) was also increased in the epidermis of treated mice compared to that in non-treated control mice. However, neurofilament 200-immunoreactive nerve fibers (A-fibers) were not detected in the epidermis of treated mice. These results suggest that the elongated epidermal peripheral nerve fibers comprise SP/CGRP-containing C-fibers but not A-fibers. Thus, these fibers may be involved in the induction of dry skin pruritus.

Title: Proenkephalin-derivged pruritogen, BAM8-22, and increased activity of MRGPRX1 are responsible for pruritus in cholestasis

Authors: *B. SANJEL, H.-J. MAENG, W.-S. SHIM
Col. of Pharm., Gachon Univ., Incheon, Korea, Republic of

Abstract: Pruritus is an unexpected symptom observed in various liver diseases, which is caused by impaired bile flow or cholestasis. However, the mechanism via which cholestasis induces the intractable itch is still unclear. Here, we show that bovine adrenal medulla (BAM) 8-22, an endogenous itch-inducing peptide, could be involved in cholestatic pruritus. In this study, mice with bile duct ligation (BDL) were used as an obstructive cholestasis model to investigate cholestatic pruritus. We observed that BDL mice showed increased spontaneous scratching behavior than sham-operated mice. Importantly, the mRNA level of proenkephalin, a precursor polypeptide of BAM8-22, was significantly increased in the skin of BDL mice. Moreover, there was a significant increase in the mRNA level of *Mrgprx1*, which encodes a receptor for BAM8-22, in the dorsal root ganglia (DRG) of BDL mice. This was confirmed by calcium imaging, which showed that the primary culture of DRG neurons exhibited higher calcium influx upon BAM8-22 treatment than those observed in sham-operated mice. In addition, BDL mice showed more potentiated scratching behavior when BAM8-22 was injected, indicating increased activity of MRGPRX1. Finally, among the various bile acids, chenodeoxycholic acid significantly increased proenkephalin transcription in a human keratinocyte cell line (HaCaT). In conclusion, the intractable itch associated with cholestasis could be attributed to enhanced production of BAM8-22 and its receptor MRGPRX1 in sensory neurons.

Title: Cortical representation of itch sensation

Authors: *X. CHEN, Y. SUN
Inst. of Neuroscience, Chinese Acad. of Scie, Shanghai City, China

Abstract: Human functional imaging studies have shown that primary somatosensory cortex (S1) is activated by itch stimuli or itch-associated scratching. However, whether S1 receives peripheral itch information, and how S1 neurons encode itch information remain poorly understood. Here, we report that S1 pyramidal neurons exhibited itch-related response. We manipulated the spinal itch circuit by introducing ChR2 into the spinal neurons expressing gastrin-releasing peptide receptors (GRPR). By *in vivo* two-photon calcium imaging, we found that a large proportion of S1 pyramidal neurons were activated by optogenetic activation of spinal $GRPR^+$ neurons. Importantly, some of the S1 neurons responding to $GRPR^+$ neuron activation were activated by intradermal injection of pruritogens. Furthermore, a subset of S1 neurons displayed differential responses to spinal $GRPR^+$ neuron stimulation at different intensity, thus were capable of encoding itch intensity. Pharmacological inactivation experiments confirmed that contralateral S1 activity was necessary for pruritogen induced scratching behavior. Our results provide a comprehensive examination of the itch signal processing in the somatosensory cortex, and suggest that S1 plays a key role in encoding itch sensation.

Title: Serotonin receptor subtypes involved in scratching behavior in the rat

Authors: *D. T. DOMOCOS[1], T. SELESCU[1], E. E. CARSTENS[2], M. IODI CARSTENS[2], A. BABES[1]
[1]Fac. of Biology, Univ. of Bucharest, Bucharest, Romania; [2]Neurobiology, Physiol. & Behavior, Univ. of California Davis, Davis, CA

Abstract: Serotonin (5-HT) is an important neuromodulator of both pain and itch. 5-HT elicited 3 types of calcium responses in rat dorsal root ganglion (DRG) cells: transient, sustained, and spiky. The transient responses were elicited by agonists and blocked by antagonists of 5-HT3, while sustained and spiky responses were elicited by agonists and blocked by an antagonist of the 5-HT1a receptor. We presently investigated roles for the 5-HT3 and 5-HT1a receptors in itch and pain in Wistar rats.
Male and female Wistar rats were used. Vehicle, or the 5-HT1a antagonist WAY100,635 (10 mM/ 10 μL) or the 5-HT3 antagonist granisetron (10 μg/ 10 μL) was injected id in the cheek, followed 30 min later by injection of 5-HT (1%; 10 μL) at the same site. The animal was videotaped, and hindlimb scratch bouts (indicative of itch) and forelimb wipes (indicative of pain) directed to the injection site were scored offline. The 5-HT1a agonists 5-CT (50 mM/ 10 μL) and DPAT (10 mM/ 10 μL), and the 5-HT3 agonist SR57227 (1 mM/ 10 μL), were injected id in the cheek as above.
5-HT elicited robust hindlimb scratching and little forelimb wiping. Males scratched more than females but the difference was not significant. Preinjection of WAY100,635 significantly attenuated 5-HT-evoked scratching behavior in males (54%), and non-significantly reduced scratching in females (28%). Granisetron did not reduce 5-HT-evoked scratching in males or females. In females the combination of WAY100,635 and granisetron significantly attenuated 5-HT-evoked scratching (63%).
Both the 5-HT1a and 5-HT3 antagonists significantly attenuated 5-HT-evoked wiping behavior in males and females. 5-CT elicited a significant increase in hindlimb scratching above control levels, although less that that elicited by 5-HT. DPAT and SR57227 did not elicit any significant increase in scratching or wiping.
The results support a role for the 5-HT1a receptor in 5-HT-evoked scratching behavior, at least in males. Wiping was also reduced, suggesting that 5-HT1a may have a role in pain as well as itch. Sustained and spiky 5-HT-evoked responses of DRG cells were reduced by 5-HT1a antagonists, and evoked by 5-HT1a agonists, suggesting that they reflect pruritic and possibly also algogenic input. Our results do not strongly support a role for the 5-HT3 receptor subtype in 5-HT-evoked itch. However, wiping and transient responses of DRG cells were suppressed by the 5-HT3 antagonist, suggesting that the transient response of sensory neurons may contribute to 5-HT-evoked pain. 5-HT-evoked scratching in females was attenuated by a combination of 5-HT1a and 5-HT3 antagonists, suggesting a role for both receptor subtypes in itch in females.

Title: Effects of tofacitinib on psoriatic itch in mice

Authors: *K. M. SANDERS, T. HASHIMOTO, K. SAKAI, G. YOSIPOVITCH, T. AKIYAMA
Dept. of Dermatol. & Cutaneous Surgery, Univ. of Miami, Miami, FL

Abstract: The Janus kinase 1/3 inhibitor tofacitinib has demonstrated a significant anti-pruritic effect in two phase III studies of patients with moderate to severe plaque psoriasis. However, the mechanisms behind this antipruritic effect are still largely unknown. We presently investigated whether tofacitinib affects spontaneous itch as well as expression of itch-related cytokines and epidermal nerve fiber density (ENFD) in the imiquimod-induced mouse model of psoriasis. Psoriasis-like skin lesions were produced by daily topical application of imiquimod to the back skin of adult male C57BL/6 mice (n = 8 per group). Alzet osmotic mini-pumps were subcutaneously implanted in the mice to deliver either tofacitinib or vehicle control (50% DMSO, 10% PEG 300, and 40% distilled water) at 15 mg/kg/day. On Day 7, animals were videotaped to assess spontaneous scratching. Following behavior testing, mice were perfused, and skin was collected. RT-PCR was used to quantify mRNA expression of itch-related cytokines. To investigate ENFD, skin was immunostained with antibodies against CGRP, a marker for peptidergic nerves, or P2X3, a marker for nonpeptidergic nerves.Imiquimod treatment resulted in increased spontaneous scratching, which was significantly inhibited by tofacitinib treatment. Imiquimod treatment significantly increased mRNA expression of IL-22, IL-23, and IL-31 compared to naive mice. Tofacitinib significantly decreased the expression of these cytokines. Finally, imiquimod treatment significantly reduced peptidergic ENFD and increased nonpeptidergic ENFD compared to naive mice. Tofacitinib significantly increased peptidergic ENFD, recovering it to naive skin levels, and further increased nonpeptidergic ENFD. These results indicate that tofacitinib may inhibit psoriatic itch through inhibition of cytokine expressions as well as modulation of epidermal innervation.

Title: Vesicular glutamate transporter 2-independent itch transmission from primary afferent neurons to spinal cord

Authors: *L. CUI[1], W. OLSON[1], M. MA[1], Q. LIU[2], W. LUO[1]
[1]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol., The Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Itch is detected by pruriceptors in dorsal root ganglion (DRG) or trigeminal ganglion (TG), and transmitted to spinal cord. Interestingly, vesicular glutamate transporter (vglut2) knock out in primary afferent neurons in mouse showed deficit in pain response, but increased itch behavior. It is remains unclear what is the itch transmitter from vglut2 knock primary afferent neurons to spinal cord. Here, we used itch-specific Mas-related G-protein coupled receptor A3 (MrgprA3) Cre mice to knockout vglut2 from MrgprA3 DRG neurons and express ChR2. We found that Vglut2 null MrgprA3 afferents still release glutamate and display no deficit in itch behavior. Since no obvious expression of vglut1/3 is detected in these neurons, our results suggest that there is novel vglut2-independent glutamate release from A3+ primary afferent neurons to spinal cord for itch transmission.

Title: Loss of TRESK enhances acute and chronic itch in mice

Authors: *A. ANDRES-BILBE[1,2,3], A. CASTELLANOS[1,2,3], L. CUENCA[1], A. PUJOL[1], N. COMES[1,2,3], D. SOTO[1,2,3], X. GASULL[1,2,3]

Abstract: TRESK (K2P18.1) is a background K^+ channel expressed in sensory neurons, where it modulates the resting membrane potential, action potential firing and neuronal excitability. A subset of these sensory neurons, which express specific TRPs and Mas-related G protein-coupled receptors (Mrgprs), are activated by pruritogens and mediate itch sensations. Because TRESK is involved in somatosensitivity and pain perception, we evaluated the contribution of this channel to pruritic sensitivity and its potential as a target for the treatment of chronic itch pathologies including renal or liver failure, Hodgkin's lymphoma and different types of dermatitis. By combining calcium imaging experiments and behavioral approaches, we found that TRESK is involved in the modulation of non-histaminergic itch. Different populations of primary cultured sensory neurons from both wild-type and TRESK knockout mice were activated by chloroquine, β-alanine, BAM8-22 or histamine in calcium imaging experiments. At the behavioral level, subcutaneous injection of chloroquine in the cheek model produced an acute scratching response, which was significantly enhanced in mice lacking TRESK. Interestingly, TRESK ko mice also showed alterations in mice models of chronic itch. Induction of Allergic Contact Dermatitis showed a significantly higher scratching response in mice lacking TRESK compared to their wild-type counterparts. In the mouse model of imiquimod-induced psoriatic itch, the absence of TRESK produced a significantly enhanced scratching behavior, which developed earlier and was more robust. In summary, our data indicate that TRESK is involved in regulating the excitability of a subset of sensory neurons that mediate histaminergic-independent itch. Given the prominent role of this neuronal subpopulation in chronic itch diseases, TRESK appears as a new potential candidate for therapeutic intervention.

Title: Glucosylsphingosine activates a member of TRP ion channel

Authors: *B. KIM, W.-J. LEE, W.-S. SHIM
Col. of Pharm., Gachon Univ., Incheon, Korea, Republic of

Abstract: Glucosylsphingosine (GS) is generally recognized as an accumulated by-product resulted from deficiency of glucocerebrosidases, mostly found in Gaucher disease. However, recent reports claimed that GS is also highly accumulated and specifically evokes itch-scratch responses in the skins of atopic dermatitis patients and in mice. Previously, we have reported that GS is able to activate mouse serotonin receptor 2a (Htr2a) and 2b (Htr2b), but not 2c. The GS-induced intracellular calcium increase was dose-dependent, and antagonists such as ketanserin (Htr2a antagonist) and RS-127445 (Htr2b antagonist) significantly blocked the GS-induced responses.Meanwhile, another recent study has revealed that scratching behavior was diminished in KO mice of a certain member of transient receptor potential (TRP) ion channel (TRPV4 hereafter), implying that the TRPV4 ion channel could be a downstream molecular entity in GS-induced itch signaling pathway. Along with this finding and our previous results, we hypothesized that GS might also act on TRPV4. To investigate the possibility, Surprisingly, GS was able to activate TRPV4 alone by dose-dependent manner, which was verified by calcium imaging technique. Moreover, mouse scratching behaviors induced by GS subcutaneous injection were significantly decreased when an antagonist of TRPV4 was pre-treated. In addition, a PLC inhibitor U73122 and a Gβγ inhibitor gallein also inhibited the response evoked by GS respectively, indicating that it follows PLC and Gβγ signaling pathway to transmit itch signals.Taken these together, we found for the first time that GS is able to specifically activate TRPV4, a member of TRP ion channel, which in turn may relay itch signals in the sensory neurons.

Title: Electrophysiological and behavioral analysis of a mouse model of atopic dermatitis

Authors: *D. UTA[1], T. ANDOH[2]
[1]Dept. Applied Pharm, Univ. Toyama, Toyama, Japan; [2]Univ. Toyama, Toyama, Japan

Abstract: Atopic dermatitis (AD) is a chronic inflammatory skin disease characterized by severe difficult-to-treat pruritus. Clinically, itch in AD patients is resistant to conventional treatments, and such itch is called intractable itch. The itch induces scratching behavior, resulting in greater damage to the skin barrier. This disruption of skin barrier leads to further itch, causing a vicious cycle called the itch-scratch cycle. During this cycle, even painful stimuli evoke itch in AD patients. This intractable itch lowers the quality of life in AD patients. Determining the fundamental mechanisms underlying intractable itch is therefore important in developing antipruritic treatments. *Nevertheless*, its underlying mechanisms are poorly understood. The present study was designed to analyze pruritic synaptic responses in spinal dorsal horn neurons of a mouse model of AD (NC/Nga mice) by using an in vivo extracellular recording. Spontaneous scratching behavior was AD NC/Nga mice significantly higher than that of healthy. Next we investigated spontaneous neuronal activity of spinal dorsal horn (SDH) was recorded using in vivo electrophysiological techniques. In AD mice, the frequency of spontaneous firing in SDH neurons significantly increased compared with healthy mice. Spontaneous firing was blocked by either AMPA/kainate antagonist CNQX (10 μM) or voltage-gated Na+ channel blocker TTX (1 μM) applied to the surface of the spinal cord. Spontaneous firing neurons in AD mice were located in the superficial layer in SDH. This result consisted with Fos-like immunoreactivity analysis. These observations suggest that a subpopulation of superficial SDH neurons convey pruritic excitatory information to provoke scratching behaviors.

Title: Anxiety-like behavior and Fos expression in amygdala elicited by itch mediators in mice

Authors: *T. AKIYAMA[1], K. M. SANDERS[2]
[1]Dermatol., [2]Dept. of Dermatol. & Cutaneous Surgery, Univ. of Miami, Miami, FL

Abstract: Chronic itch is typically accompanied by negative emotional states. Itch intensity is linked to anxiety, and in turn anxiety and stress can exacerbate itch, leading to a vicious cycle that impacts the quality of life for chronic itch patients. However, the central mechanisms underlying this cycle are poorly understood. We aimed to measure anxiety-related behavior and neuronal activity following acute intradermal injection of three pruritogens: histamine, the major inflammatory pruritogen released by mast cells; chloroquine, a nonhistaminergic pruritogen that

induces itch through MrgprA3 receptors; and serotonin, a nonhistaminergic pruritogen that induces itch through multiple 5-HT receptor subtypes. Adult male C57BL/6 mice received an intradermal injection of histamine, chloroquine, serotonin, or phosphate-buffered saline (PBS) vehicle into the rostral back skin and were recorded on the elevated plus maze (EPM) or open field test (OFT) for 10 min. Open arm time on the EPM and the percent of center square entries on the OFT were used as measures of anxiety-like behavior. Mice displayed significantly reduced open arm time on the EPM following histamine, chloroquine, or serotonin injection compared to PBS control. Similarly, mice displayed significantly reduced percent center square entries in the OFT following histamine or chloroquine injection compared to PBS control. Next, we used immunohistochemistry to label c-Fos, a marker of neuronal activity, in several anxiety-related brain regions. Mice received an intradermal injection of histamine, chloroquine, serotonin, or PBS to the rostral back, and after 2 hr, they were perfused and dissected. c-Fos was labeled and quantified in the amygdala, parabrachial nucleus, and midcingulate cortex. Pruritogens evoked significantly a greater number of c-Fos+ neurons in these areas compared to PBS control. These results suggest that the amygdala, parabrachial nucleus, and midcingulate cortex may be part of a brain circuit that processes the affective component of itch and contributes to itch-induced anxiety-like behavior.

Title: Scratching the surface of itch in fish: A cross-species model for selective pruritus via activation of TRPA1

Authors: *K. ESANCY, L. CONDON[1], J. FENG[2], C. KIMBALL[1], A. CURTRIGHT[1], A. DHAKA[1]
[1]Biol. Structure, Univ. of Washington, Seattle, WA; [2]Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Little is known about the capacity of lower vertebrates to experience itch. In mammals, itch is thought to ensue when transient receptor potential (TRP) ion channels on

peripheral somatosensory neurons are activated downstream of G-protein coupled receptors (GPCRs) that bind to pruritic (itch-inducing) stimuli. By contrast, chemically- and thermally-induced pain is elicited when these TRP ion channels are directly activated by algogens. Through a combination of behavioral and neuronal activity assays in the zebrafish, we found that the TRPA1 ion channel can be directly activated to elicit both pain and itch behaviors. Pruritogens evoked robust lip-rubbing behaviors (analogous to scratching in mammals), while algogens elicited nocifensive behaviors such as freezing and reduced swimming velocity. These differential behaviors appear to result from the differential activation of distinct subsets of TRPA1-expressing neurons. One neuronal subpopulation is activated by the same low-intensity stimuli that evoke itch behaviors, such as low concentrations of the TRPA1 agonists imiquimod (IMQ) and allyl isothiocyanate (AITC). Neurons within this subpopulation also respond more robustly to other noxious stimuli, indicating that they likely comprise a more sensitive subset of neurons. Conversely, the remaining TRPA1-expressing neurons are less sensitive to noxious stimuli, and are only activated by high-intensity stimuli (i.e., high concentrations of TRPA1 agonists) associated with nocifensive behaviors. We replicated these findings in the mouse, suggesting that our observations are not unique to fish. Together, these results suggest a conserved model for selective itch via activation of a specialized subpopulation of somatosensory neurons with a heightened sensitivity to noxious stimuli. However, the molecular factors that distinguish these neurons remain unknown. Additional evidence from our studies suggests that multiple subpopulations with intermediate sensitivities exist between the two discrete populations we initially observed, and that this phenomenon may be generalizable to other nociceptive subtypes. We are investigating the factors that underlie the different sensitivities of nociceptors to a common agonist and what role neurons with different thresholds for noxious stimuli play in itch and pain sensation in both acute and pathological conditions.

Title: Skin innervation patterns of itch neurons

Authors: *J. WHEELER, S. K. MISHRA
Mol. Biomed. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Decoding somatosensory information begins at the skin. One sensory input, itch, has only recently begun to be understood. Typically, one of two methods are widely used to study itch: intradermal injection into the nape of the neck and cheek injections. Despite giving the same basic information, the number of scratching bouts for a given compound in cheek assays is usually about one-fifth of the number of scratching bouts from nape injections. Additionally, itch compounds injected into the cheek also cause wiping, which is assumed to be a nocifensive response. In this study, we explored the discrepancy of itch response in the nape of the neck and in the cheek by examining the skin tissues derived from the mice, which express tdTomato in somatostatin (*SST)* neurons. In the dorsal root ganglia, *SST* is a marker for itch sensory neurons. These mice with labeled *SST* neurons were perfused and skin from the cheek and the nape of the neck were sectioned and imaged with confocal microscopy. These images were used to determine the density of *SST* positive neurons (in neurons/μm^2) for the nape and cheek regions. Additionally, it has been reported that female mice injected in the nape of the neck with chloroquine have a higher number of scratching bouts than males injected with chloroquine in the nape of the neck. Therefore, we used these mice to compare the skin innervation density of somatostatin neurons for the cheek and nape between male and female mice. Finally, we compared the changes in innervation patterns of somatostatin neurons by developing an atopic dermatitis mouse-model using compound MC903 (a vitamin D analog). Overall, our findings will help to understand the discrepancy in itch behavior in mice due to distribution of primary afferent innervation in the skin.

Title: Investigation of a mechanism for pruritic priming

Authors: *Z. K. FORD, S. DAVIDSON
Anesthesiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Pain and itch are closely related, and are thought to share central and peripheral neural pathways. A well-established mechanism to explain the transition from acute to chronic pain is hyperalgesic priming. Hyperalgesic priming is characterized by extended hypersensitivity to an inflammatory mediator after recovery from a previous inflammatory injury. It is currently unknown whether a similar mechanism exists for itch, which could lead to chronic pruritus.

We hypothesized that an early pruritic event would cause latent sensitization, resulting in increased hypersensitivity to a pruritic stimulus in the future. To test this, we used the AEW (acetone/ether-water) model to mimic a chronic itchy, dry skin condition in mice. Previously, it was shown that this model increased the number of neurons responsive to chloroquine (CQ); however, no study has tested behavioral responses to pruritogens after AEW treatment. Additionally, while the time to initiate scratching with the AEW model has been well-documented, it has not been determined how long scratching behavior persists once the treatment has ended. In order to gain a greater understanding of the physiological changes taking place in the skin after AEW treatment, we explored whether the previously described hyper-innervation of fibers into the epidermis associated with the AEW model correlates with the timeline of scratching behavior, as well as if these changes were taking place in the CGRP-positive peptidergic or the P2X3-positive non-peptidergic population. We investigated the possibility of cross-modality priming, by using the traditional model of hyperalgesic priming in the cheek (carrageenan followed by PGE2) to determine whether this would elicit painful or pruritic behavior. To ascertain whether a pruritic secondary stimulus could cause hyperknesis after giving a subcutaneous carrageenan injection to the cheek, chloroquine, histamine, or AEW treatment was delivered and scratching behavior measured.
We found that 6 hours after the final AEW treatment scratching behavior increased from 8.12±2.4 bouts/hr at baseline to 36.75±8.12. A full day after AEW, scratching significantly increased to 127.5±37.59 bouts/hr, but then steadily returned to baseline levels (5.62±2.76 bouts/hr) by five days post treatment. Contrary to our hypothesis, mice that received the AEW treatment did not increase scratching following either acute pruritogen (CQ or histamine), nor did wiping behavior, an indicator of pain, change. These results suggest that AEW may not be capable of triggering pruritic priming, or inducing hyperalgesia.

Title: The adhesion-GPCR CIRL promotes mechanosensory signal discrimination

Authors: *R. J. KITTEL, S. DANNHÄUSER, H. HOFMANN, N. EHMANN
Dept. of Animal Physiology, Inst. of Biol., Leipzig Univ., Leipzig, Germany

Abstract: Research on the sense of touch has long been a center stage for receptors that directly convert mechanical force into electrical signals, and the function of such mechanosensing ion channels remains a topical research focus. In contrast, evidence for mechano-metabotropic signal transduction and compelling models of force conversion into an intracellular second messenger response are limited, despite the vital role of metabotropic modulation in all corners of physiology. Adhesion-type G protein-coupled receptors (aGPCRs), a large molecule family with over 30 members in humans, operate in a vast range of physiological processes. Correspondingly, these receptors are associated with diverse human diseases, such as developmental disorders, defects of the nervous system, allergies and cancer. Several aGPCRs have recently been linked to mechanosensitive functions suggesting that processing of mechanical stimuli may be a common feature of this receptor family, not only in classical mechanosensory structures (Langenhan et al., 2016).
Drosophila Latrophilin/CIRL, one of the oldest members of the aGPCR family, modulates mechanosensory signal transduction. In addition to shaping sensory responses to gentle touch and sound (Scholz et al., 2015; 2017), we show here that CIRL also influences mechanical nociception *in vivo*. *Cirl* is expressed in peripheral larval nociceptors where it adjusts nocifensive behaviour under physiological conditions and in a chemical neuropathy model. By combining behavioural analyses with optogenetic manipulation of cyclic AMP levels *in vivo*, we find that CIRL exerts opposing modulatory effects in low-threshold mechanosensory neurons and high-threshold nociceptors. This bipolar action likely facilitates the differentiation of mechanosensory signals carrying different physiological information.

Title: Pre exposure of noxious heat and painful sensation in mice induce antipruritic effect

Authors: *R. KOPPARAJU, C.-C. CHEN
Neurosci., Inst. of Biomed. Sci., Taipei 115, Taiwan

Abstract: Itch is an unpleasant sensation caused by pruritogen transmitted by sensory neurons to the spinal dorsal horn and then to higher brain center, which eventually induces the desire to scratch. The act of scratching and vairable noxious counter stimuli like noxious heat and painful sensations relieve the itch sensation. However, it is not clear whether the noxious stimuli prior to injection of pruritogen could effectively reduce the itch sensation. Here we observed antipruritic effect produced by brief noxious stimuli applied on mouse skin prior to pruritogen. We demonstrated that application of noxious stimuli (e.g., passive scratching) on the nape skin of mild anaesthetized prior to prutrinogen application could significantly reduce itch response. Similarly itch reduction was observed in the nape and cheek skin models, when intradermal injection of capsaicin was given prior to prutinogen. The antipruritic effect produced by brief noxious stimuli lasted for more than 20 minutes. We further demonstrated that passive scratching of mice led to phosphorylation of ERK in cervical DRG neurons and enhanced c-Fos expression in lamina II of cervical spinal dorsal horn. Taken together, noxious stimuli prior to pruritogen challenges are effective to diminish itch responses by neural modulation at the spinal cord level, although possible involvement of supraspinal control cannot be excluded.

Title: An EEG method for measuring spontaneous pain in awake, freely behaving rodents

Authors: *C. Y. SAAB[1], S. KOYAMA[2], J. W. GU[3], S. R. JONES[4], J. LEVITT[5]
[1]Neurosurg. & Neurosci., Brown/RIH, Providence, RI; [2]Brown Univ. / RIH / Asahi Kasei Pharma, Providence, RI; [3]Boston Scientific, Valencia, CA; [4]Dept. of Neurosci., [5]Neurosci. & Neurorusgery, Brown Univ., Providence, RI

Abstract: Pain across evolutionary spectra is measured according to subjective criteria and behavioral observations. We developed an objective method for quantifying pain in rodents based on the fundamental principle that pain is a manifestation of brain activity, which in turn

engenders pain 'biosignatures'. We previously reported that theta (4-8 Hz) power of the resting state electroencephalography (EEG) over primary somatosensory cortex is elevated in rat models of pain (Leblanc et al. *Pain* 2014, 2016a,b). Pain-induced theta is phasic in rats with acute pain and tonic in those with chronic pain. We present new data showing that pain-induced theta is attenuated in rats with chronic neuropathic pain following dose-dependent administration of the effective analgesic EMA 401 (a peripherally-acting angiotensin II receptor inhibitor) and pregabalin (a centrally-acting calcium channel inhibitor), but remains elevated upon administration of minocycline (a glial inhibitor). Hence, EEG theta power detected false positive and false negative outcomes of the commonly-used thermal hyperalgesia test. Pharmacokinetic studies were performed to determine optimal doses for each drug. Moreover, neuromodulation by spinal cord stimulation at sub-paresthesia current intensity, which leads to modest analgesic effects in humans, attenuated EEG power in the 3-4 Hz range adjacent to the theta band (Koyama et al. *Sci Rep* 2018). Related to our EEG method, we developed a support vector machine (SVM) algorithm to automatically detect EEG artifacts in awake human, canine and rodent subjects. The levels of SVM accuracy for artifact classification in humans, Sprague Dawley rats and beagle dogs were 94%, 83%, and 85%, respectively with each result being significantly higher than chance. These data fully validate our empirical, real-time and cost effective method for the rapid and automated measurement of spontaneous pain in rodents and potentially other species.

Title: A multi-modal approach to elucidate the spinal circuits mediating tactile allodynia

Authors: *C. BLACK[1], A. ALLAWALA[1], R. THORPE[1], C. Y. SAAB[4], S. R. JONES[2], D. A. BORTON[3]
[2]Dept. of Neurosci., [3]Neuroengineering, [1]Brown Univ., Providence, RI; [4]Neurosurg. & Neurosci., Brown/RIH, Providence, RI

Abstract: Tactile allodynia (TA) is a symptom of neuropathic pain whereby innocuous tactile stimuli cause painful sensations. While TA is attributed in part to spinal disinhibition, a failure of the normal process of spinal inhibition by which dorsal horn interneurons silence feed-forward excitation of pain projection neurons, there is a lack of understanding regarding the emergence of such maladaptive plasticity. In an on-going multi-modal effort to dissect neural circuits mediating pain, we have implemented acute spinal electrophysiology in transgenic mice parallel to biophysically realistic computational modeling of the dorsal horn to elucidate the mechanisms of TA in more detail. Using a transgenic mouse line that co-expresses channelrhodopsin-2 (ChR2) with transient receptor potential vanilloid 1 (TRPV1) neurons, we selectively activate Aδ and C-fiber afferents through non-invasive optogenetic stimulation of the skin. Thus, differential activation of primary afferents has allowed us to isolate nociceptive responses in local field potentials (LFP) and single/multi-unit activity in the superficial dorsal horn from tactile responses during acute *in vivo* recordings. We are using this model to test if tactile evoked potentials are enhanced by optogenetic nociceptive stimulation. To better define the cellular circuits mediating the results observed in our acute electrophysiology studies, we have developed a computational model of the dorsal horn that contains peripheral inputs, inhibitory and excitatory interneurons, and pain projection neurons implicated in TA. We show that C-fiber volleys can drive feed-forward inhibition of laminae II-III interneurons to generate a 'window of opportunity' that facilitates the emergence of TA. In total, our results in vivo and in silico suggest that rampant nociceptive activity associated with chronic pain states could be responsible for causing the sustained and irreversible spinal disinhibition that leads to TA.

Abstract: Pain has long been characterized as a qualitative feature providing scale to the level of sensory discomfort. While behavioral states can be identified that indicate a painful percept (e.g. an evasive movement or a patient's descriptive words), interpretable biophysical markers in the central nervous system (CNS) have yet to be established that clearly discriminate between normal sensory perception and the feeling of pain. Additionally, mechanisms of non-invasive treatments such as transcranial direct current stimulation (tDCS) for pain are not well understood. Here, we investigate the circuit level origin of electroencephalography (EEG) measured markers of nociceptive pain using a new software tool whose foundation is a biophysically principled computational neural model that simulates the primary electrical currents underlying EEG: Human Neocortical Neurosolver (HNN, hnn.brown.edu). Specifically, we apply the neural model to interpret circuit mechanisms in primary somatosensory cortex (S1) that underlie differences in event related potentials (ERPs) from nociceptive laser stimulation as compared to non-nociciptive vibrotactile and median nerve stimulation, as identified in Lenoir et al., *J. Neurophysiology* (2017). Furthermore, we explore mechanisms of observed changes in ERP latency and amplitude components correlated with reduced pain perception in the nociceptive laser stimulation case due to tDCS. Initial results suggest involvement of higher-order feedback projections into the distal dendrites of layers 2/3 and 5 of S1 in the early-latency component of the median nerve stimulation evoked response. This work aims to provide a foundation for future quantitative classification of circuit mechanisms underlying pain-perceiving versus non-pain-perceiving signatures of EEG signals.

Title: Nerve injury increases excitability of a subpopulation of Y1R-eGFP expressing dorsal horn neurons that exhibit Kv4.2 channel subunit mediated delayed firing

Authors: *G. P. SINHA[1,2], S. SCHMITT[2], L. ZHANG[2], B. K. TAYLOR[1,2]
[1]Dept. of Anesthesiol., UNIV OF Pittsburgh, Pittsburgh, PA; [2]Dept. of Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Activation of NPY Y1-receptors (Y1R) on excitatory interneurons in the dorsal horn inhibits nociception. To understand the cellular mechanisms underlying Y1R-mediated analgesia, we first characterized the electrical properties of spinal cord lamina II Y1R-eGFP expressing neurons from lumbar L3/L4 segments in naïve, sham-injured, and spared nerve-injured (SNI) mice. Firing patterns of Y1R-eGFP neurons using patch-clamp electrophysiology included delayed firing in both naïve (74%) and SNI mice (90%). Kv4.2-mediated A-type currents underlie delayed firing. We found A-type currents with fast (~30ms) and slow (>100 ms) decay constants in the following populations: Fast - 50% of neurons in naïve animals and 67% from SNI animals; Slow - 24% in naïve and 23% in SNI. From immunohistochemical (IHC) studies we observed that 70% of Y1-eGFP expressing neurons co-localized with Kv4.2 immunoreactivity. 4-aminopyridine (4-AP), a Kv4.2 channel blocker, inhibited both fast and slow A-type currents. These data indicate that delayed-firing Y1R neurons express Kv4.2 - mediate A-type currents. As suggested by Gereau and colleagues phosphorylation and internalization of Kv4.2 channels can lead to a reduction in A-type potassium currents. By using a phospho-Kv4.2 (S616) antibody, we found that the percentage of phosphorylated Kv4.2 expression in Y1R-expressing neurons was increased in SNI-injured mice (67%) as compared to sham-injured (56%) mice. We next compared electrophysiological properties of neurons that express Y1R-eGFP and exhibit delayed firing in slices from SNI and sham mice. We found that compared to naive mice, SNI mice exhibited a resting membrane potential that was depolarized by ~2 mV, a latency to first spike that was shorter, and a decreased amplitude of A-type currents in the sub-type of neurons exhibiting fast A-type currents. This suggests that SNI increases excitability in this sub-population of Y1R-eGFP neurons. We suggest that nerve injury increases phosphorylation and possibly internalization of Kv4.2 subunits; this in turn might decrease fast A-type potassium conductance (reflected as shortened latency to stimulus) in delayed firing neurons. We conclude that: 1. A large population of Y1R expressing neurons exhibit delayed firing due to an enrichment of Kv4.2 channels that mediate fast A-type current; and 2. Peripheral nerve injury reducing the available of Kv4.2 channels, leading to an increase in the excitability of Y1R expressing neurons.

Title: Possible involvement of spinal cannabinoid receptors in trigeminal nerve injury-induced mechanical hypersensitivity of rats

Authors: *K. NAKAI[1], A. NAKAE[2], Y. MINEGISHI[1], R. URABE[1], M. MIYAMAE[1], T. KUBO[3], K. HOSOKAWA[3]

Abstract: Background: Cannabinoids (CBs) produced analgesic effects via CB1 and CB2 receptors. CB1 receptors are distributed on neurons in the dorsal horn of the spinal cord. CB2 receptors are mainly expressed on peripheral immune cells, including macrophages. Recent studies have been shown the up-regulation of the CB2 receptors in the spinal cord following peripheral nerve injury. The contribution of spinal CB receptor subtypes in the trigeminal neuropathic pain remains unclear. Chronic constriction injury to the infraorbital nerve (ION-CCI) has proven to be a useful model for trigeminal neuropathic pain. The present study evaluates the possible role of spinal CB1 and CB2 receptors in ION-CCI rat model. Material and Methods: Male Sprague Dawley rats underwent unilateral CCI to the right ION by two nylon (5-0) ligatures. A series of von Frey filaments were used to determine pain hypersensitivity to mechanical stimulation on day 14 after surgery. A polyethylene (PE-10) catheter was implanted for upper cervical spinal injection of drugs. The time course of an antiallodynic effects of intrathecally administered a CB1 receptor agonist R(+)-Methanandamide, a CB1 receptor antagonist SR141716A, a CB2 receptor agonist HU308, and a CB2 receptor antagonist AM630 were examined. If the CB1 receptor agonist or the CB2 receptor agonist produced antiallodynic effects, an additional experiment was performed to evaluate the antagonizing effect of intrathecally pretreatment with the CB1 receptor antagonist or the CB2 receptor antagonist, on the antiallodynic action of the CB1 receptor agonist or the CB2 receptor agonist. The time course data for the dose-response effects were analyzed by two-way analysis of variance and Tukey-Kramer multiple-comparison test. Results: Intrathecal administration of SR141716A and HU308 significantly increased mechanical thresholds in a dose dependent manner. Intrathecal administration of R(+)-Methanandamide and AM630 did not alter mechanical thresholds. AM630 significantly reduced the antiallodynic effect of HU308. Conclusions: The inhibition of spinal CB1 receptors or activation of spinal CB2 receptors reduced the pain-related behavior. The results indicated that spinal CB1 and CB2 receptors may play an important role in a trigeminal neuropathic pain.

Title: Chiropractic spinal manipulation alters nociceptive processing at spinal and supraspinal levels

Authors: *H. HAAVIK[1], D. LELIC[2], I. NIAZI[1], K. HOLT[1], A. DREWES[2]
[1]NewZealand CollegeChiropractic, Auckland, New Zealand; [2]Mech-Sense, Dept. of Gastroenterology & Hepatology, Aalborg Univ. Hosp., Aalborg, Denmark

Abstract: Objective: This study aimed to investigate how chiropractic spinal manipulation affects spinal and supraspinal nociceptive processing.
Methods: Fifteen volunteers attended two sessions (full-spine chiropractic care and passive movement control) in random order, in a crossover design randomized controlled trial. As a proxy of spinal pain transmission, nociceptive withdrawal reflexes (NWRs) to electrical stimulation on the sole of the foot were recorded at tibialis anterior before and after either intervention. For the supraspinal activity, 61-channel electroencephalogram evoked potentials (EPs) were simultaneously recorded. Areas under the curve of the NWR signals were analyzed. Latencies and amplitudes were computed for the major EP peaks. Brain source analysis of the EPs was performed.
Results: The NWR decreased due to the chiropractic intervention (P=0.01). The EPs had two main peaks at 116±19ms and 258±22ms. The amplitudes at both peaks were decreased due to chiropractic intervention at the frontal electrode (P=0.03). Brain source localization revealed no differences in location of brain activity but the strength of anterior cingulate activity decreased following the chiropractic intervention (P=0.04).
Conclusion: Chiropractic care alters nociceptive processing at spinal and supraspinal levels. This study adds to our understanding of how chiropractic care influences nociceptive processing.

Title: Adenylyl cyclase activation induces substance P release in the rat spinal cord through protein kinase A and Epac

Authors: *J. G. MARVIZON, W. CHEN
Dept. of Med., UCLA / VA GLA HS, Los Angeles, CA

Abstract: Substance P release from nociceptive afferents contributes to chronic pain and is mediated by calcium entry in their presynaptic terminals through NMDA receptors and voltage-gated calcium channels (Cav2). Previous studies found that substance P release is increased by activation of adenylyl cyclase by prostaglandins and decreased by its inhibition by μ-opioid receptors. Our objective was to explore the mechanisms by which cyclic-AMP (cAMP) induces substance P release, measured as neurokinin 1 receptor (NK1R) internalization. We found that the adenylyl cyclase activator forskolin added to rat spinal cord slices induced substance P release with an EC_{50} of 6.6 μM, similar to its K_D for adenylyl cyclase (9.8 μM), and a $t_{1/2}$ of 22 min. The NK1R antagonist L-732,136 decreased forskolin-induced NK1R internalization, showing that it represents substance P release. The adenylyl cyclase inhibitor SQ22536 also decreased the effect of forskolin. The cell-permeant cAMP analog 8-Br-cAMP induced robust substance P release with a biphasic concentration-response curve. We hypothesized that these two components correspond to the activation of protein kinase A (PKA) and guanine nucleotide exchange factors for the G protein Rap (Epac). The PKA inhibitors KT5729 and PKI 14-22 decreased the effects of forskolin and 8-Br-cAMP. The selective PKA activator 6-Bzn-cAMP induced substance P release with high potency (0.85 pM). The selective Epac activator 8-pCPT-2'-O-Me-cAMP (CPTOMe-cAMP) also induced substance P release with a lower potency (5.2 μM) consistent with its EC_{50} for Epac (2.2 μM). We then studied the mechanisms downstream of PKA and Epac. The sodium channel blocker lidocaine did not inhibit substance P release elicited by 6-Bzn-cAMP or CPTOMe-cAMP, showing that the effects of PKA and Epac do not involve firing of action potentials. NMDA receptors are downstream of both PKA and Epac, since the effects of forskolin and the three cAMP analogs were decreased by the NMDA receptor blocker MK-801 and the NR2B-selective antagonist ifenprodil. Antagonists of AMPA and kainate receptors decreased substance P release induced by CPTOMe-cAMP but not by 6-Bzn-cAMP. Cav2 channel opening is also downstream of PKA and Epac, since the Cav2 channel blocker ω-

conotoxin MVIIC and the μ-opioid receptor agonist DAMGO decreased the effect of forskolin and all three cAMP analogs. The TRPV1 antagonist capsazepine did not decrease the effects of 6-Bzn-cAMP or CPTOMe-cAMP, indicating that TRPV1 do not mediate the effects of PKA and Epac. Therefore, activation of PKA and Epac induces substance P release by activating NMDARs and opening Cav2 channels in the central terminals of primary afferents.

Title: The action of norepinephrine on lamina X in the spinal cord

Authors: N. OHASHI[1], M. OHASHI[2], *H. BABA[3]
[1]Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata, Japan; [2]Niigata Univ. Grad. Sch. of Med. and, Niigata City, Japan; [3]Niigata Univ, Sch. Med., Niigata, Japan

Abstract: Backgroud: Lamina X is localized in the spinal cord within the region surrounding the central canal, and the neurons in lamina X receive the descending projection from supraspinal nuclei. Norepinephine (NE) is one of the neurotransmitters in descending pathways emanating from brain stem and it is known that NE-containting fibers terminate in the spinal dorsal cord, particularly the substantia gelatinosa, and are involved in the transmission and modulation of nociception. However, several studies have also indicated that NE-containing fibers from the locus coeruleus terminate densely not only in the superficial layers of the spinal dorsal cord, but also in lamina X. Therefore, it is possible that NE also acts on the lamina X and contributes the modulating nociceptive information. However, there are no previous reports investigating how NE released form descending pathway acts on lamina X and modulate nociceptive information at the cellular level. We therefore hypothesized that NE acts on lamina X in the spinal dorsal horn directly and inhibits nociceptive transmission at the spinal level.
Methods: We used the *in vitro* whole-cell patch-clamp technique to assess the underlying mechanisms of synaptic modulation of NE on miniature excitatory and inhibitory postsynaptic currents (mEPSCs and mIPSCs) at the neurons in lamina X from adult rat spinal cord slices.
Results: Bath-applied NE (20 μM, 2 minutes) to the lamina X did not affect the mean mEPSCs frequency, nor amplitude. However, bath-applied NE (20 μM, 2 minutes) increased the mean mIPSCs frequency (Control, 1.9 ± 0.9 Hz; NE, 5.4 ± 2.5 Hz; 291.1 ± 90.2% of control; n = 7; $P < 0.01$, paired t-test). NE also induced an outward current of mIPSCs in lamina X, and the average peak amplitude of the NE-induced outward current in mIPSCs was 5.7 ± 5.4 pA. In the presence of the α1-receptor antagonist prazosin (0.5 μM), NE-induced increase in mIPSCs

frequency was inhibited, and in the presence of the α2-receptor antagonist yohimbine (1 μM), NE-induced an outward current of mIPSCs was also inhibited. **Conclusion:** These results suggest that NE acts at presynaptic terminals of GABAergic and glycinergic interneurons in lamina X to facilitate inhibitory transmitter release through the activation of α1-receptors, and also depolarizes inhibitory interneurons in lamina X through the activation of α2-receptors. These actions of NE on neurons in lamina X may contribute to inhibition of the nociceptive transmission at the spinal level directly.

Title: Evans blue reduces neuropathic pain behavior by inhibiting spinal ATP release

Authors: *Y. YIN[1,2], J. HONG[3], J. SHIN[1], D. GWON[1], H. KWON[1], N. SHIN[1], H. SHIN[1], S. LEE[2], W.-H. LEE[2], D. KIM[1,3]

Abstract: Evans blue (EB), an azo dye used to assess the permeability of the blood-brain barrier to macromolecules, is also known as a vesicular nucleotide transporter (VNUT) inhibitor. Because VNUT plays an essential role in the vesicular storage of ATP and because the activation of purinergic receptors in the spinal cord by extracellular ATP is essential for neuropathic hypersensitivity, we investigated whether EB could decrease neuropathic pain in a L5 spinal nerve ligation (SNL) rat model. Surprisingly, intrathecal injection of EB efficiently and dose-dependently attenuated pain behavior (mechanical allodynia) for 7 days (5-50 μg). EB co-localized with neurons, but not with astrocytes and microglia, in the dorsal horn. The ATP assay showed decreased ATP concentration in the cerebrospinal fluid (CSF). Additionally, we confirmed EB blocked ATP release from neurons but not from glia *in vitro*. EB injection also decreased microglial activity in the spinal dorsal horn. Moreover, reactive oxygen species (ROS) production and proinflammatory mediators, such as IL-1β and IL-6, were decreased in the EB-treated group. Taken together, these data demonstrate that EB inhibited ATP release from

terminals of primary afferent neurons but not from astrocytes or microglia in a SNL-induced rat model. Eventually, the EB-inhibited release of ATP suppressed the ATP/purinergic receptor signaling involved in the spinal microglial activation associated with the pathophysiology of neuropathic pain. The results show that EB has an analgesic effect on neuropathic pain in the SNL animal model and is a new potential therapeutic for the treatment of chronic pain (NRF-2016M3C7A1905074, 2016R1A2B4009409).

Title: A novel rat model of neuropathic pain established by clamping the sciatic nerve shows mechanical allodynia and microglial hyperplasia in the spinal cord

Authors: *M. KUMAGAI[1], T. MURAKAMI[1], H. OBATA[2], M. YAMAUCHI[1]
[1]Tohoku Univ. Grad. Sch. of Med., Miyagi,Sendai, Japan; [2]Fukushima Med. Univ., Fukushima-Shi, Japan

Abstract: Background: Neuropathic pain is difficult to treat and remains a major public health problem. Current treatments provide only limited therapeutic effect, and regenerative medicine is expected to be a curative therapy. In previous research, traditional animal models were often used. Although these models are useful to elucidate the mechanisms of pharmacological therapies, they are not suitable for the evaluation of recent nerve regeneration therapies because of the presence of residual threads at the injury site. Thus, animal models characterized by prolonged neuropathic pain without residual threads are necessary. Here, a novel rat model of neuropathic pain established by clamping the sciatic nerve was assessed.
Materials and methods:
Eight-week-old male Wister rats were anesthetized, following which their left sciatic nerve was exposed and clamped with surgical clips that applied a force of 60 g. Animals were divided into 1, 5, and 10 minutes clamped and sham-operated groups.
The threshold responses to mechanical and thermal stimuli were tested on both sides of their hind paws with the von Frey filaments and Hargreaves tests. Mechanical and thermal thresholds were assessed weekly until 56 days after injury.
Immunohistochemical assessment was performed at 21 days after injury. The expression of Iba-

1, a microglial marker, in the L5 spinal cord segments and ATF3, a marker of axotomy, in the dorsal root ganglia (DRG) was evaluated with immunofluorescent staining.
Results: Mechanical thresholds decreased significantly in all three experimental groups after sciatic nerve clamp injury from days 4 to 21 compared with the sham group. Thermal thresholds were slightly decreased in clamped groups. Both allodynia and thermal hyperalgesia recovered to the baseline state before 35 days after injury.
In the immunohistochemical experiments, the Iba1-positive areas significantly increased in the experimental groups compared with the contralateral side. Some L5 DRG neurons were positive for ATF3 on the experimental side, with no expression found on the contralateral side.
Conclusions: A novel rat model of neuropathic pain, without any threads, was assessed. The model rats showed statistically significant mechanical allodynia,
microglial hyperplasia in the spinal dorsal horn, and axonopathy. These results confirmed that the model rats indeed exhibited characteristics of neuropathic pain. These symptoms recovered to the baseline state after a certain period. This model is easily producible, does not impede nerve regeneration, and consequently can be used to develop nerve regenerative therapies and further elucidate mechanisms of neuropathic pain.

Abstract: Aim: To investigate whether p38 siRNA-loaded nanoparticles (p38 siRNA NPs) attenuate spinal nerve ligation (SNL)-induced neuropathic pain in rats by suppressing spinal microglia activation via p38 targeting. **Experimental:** After synthesizing p38 siRNA NPs with sonication, physical characteristics were measured for size and zeta potential. p38 siRNA NPs were then administrated intrathecally into SNL rats if they could reduce pain behavior excellently. **Results:** p38 siRNA NPs significantly reduced mechanical allodynia as well as microgliosis in the spinal dorsal horns of SNL rats, consistent with a downregulation of p38-related proinflammatory mediators. **Conclusion:** As p38 in the spinal microglia plays a critical role in neuropathic pain, we expect that p38 siRNA NPs could be a promising tool for the treatment of neuropathic pain (NRF-2016M3C7A1905074, 2016R1A2B4009409).

Abstract: Chronic pain afflicts roughly 44% of Service Members returning from Iraq and Afghanistan, and it is estimated that 100 million Americans suffer from this condition. The underlying molecular mechanisms of chronic pain development have remained elusive. The objective of this study is to identify gene expression changes in key brain regions during the onset and progression of neuropathic pain in a rodent model. We collected tissue from five brain

regions (thalamus, amygdala, cingulate cortex, insular cortex, and somatosensory cortex), from rats (n = 6/group) subjected to the spared nerve injury (SNI) protocol, a model for chronic neuropathic pain. Tissue was collected from the side of the brain contralateral to the SNI hind limb at 1, 3, 7, 14 and 21 days post-injury and RNA was extracted for mRNA sequencing (TruSeq total RNA protocol and Illumina HISCAN-SQ platform). Sequence data was processed through a novel workflow (pipeline) customized to provide the full complement of mRNA data (transcriptome) for this multidimensional data set. We first focused on the assessment of the transcriptome of the thalamus, which is an important center of pain processing in the brain. In rats experiencing chronic pain relative to controls, we observed a decreased expression of several neurotransmitter receptor mRNAs, including cholinergic receptors (CHRM4, CHRNB3, CHRNB4), dopamine receptors (DRD1, DRD2), the cannabinoid receptor (CNR1), adenosine A2a receptor (ADORA2A), bradykinin receptor B2 (BDKRB2); and associated G proteins, such as GPR52, GPR88, GNB3, and GNG7; and neurotransmitters such as TAC1 (substance P). The majority of these changes occurred at day 21, but not sooner. Our data also indicates suppressed signaling through the Extracellular Signal-Regulated Kinase (ERK1/2) pathway, as well as inhibited dopamine signaling, in the day 21 post-injury contralateral thalamus. These findings suggest a global suppression of neural signaling in the thalamus (desensitization), much of which does not commence until after 14 days post injury. This apparent desensitization remains to be confirmed by electrophysiological methods and does not correlate with reduced mechanical allodynia. The gene expression changes in the other brain regions were distinct and the majority non-overlapping. An integrated model for gene expression changes in the different brain regions during the transition from acute to chronic neuropathic pain is presented.

Title: Disrupting interaction of PSD95 with nNOS attenuates hemorrhage induced thalamic pain

Authors: *W. CAI, S. WU, Z. PAN, J. XIAO, Y. TAO
Rutgers Biomed. and Hlth. Sci., Newark, NJ

Abstract: Hemorrhages occurring within the thalamus lead to a pain syndrome. Clinical treatment of thalamic pain is ineffective, at least in part, due to the elusive mechanisms that underlie the induction and maintenance of thalamic pain. The present study investigated the possible contribution of a protein-protein interaction between postsynaptic density protein 95 (PSD-95) and neuronal nitric oxide synthase (nNOS) to thalamic pain in mice. Thalamic hemorrhage was induced by microinjection of type IV collagenase into unilateral ventral posterior medial/lateral nuclei of the thalamus. Pain hypersensitivities, including mechanical allodynia, heat hyperalgesia, and cold allodynia, appeared at day 1 post-microinjection, reached a peak 5-7 days post-microinjection, and persisted for at least 28 days post-microinjection on the contralateral side. Systemic pre-treatment (but not post-treatment) of ZL006, a small molecule that disrupts PSD-95-nNOS interaction, alleviated these pain hypersensitivities. This effect is dose-dependent. Mechanistically, ZL006 blocked hemorrhage-induced increase of binding of PSD-95 with nNOS and membrane translocation of nNOS in thalamic neurons. Our findings suggest that the protein-protein interaction between PSD-95 and nNOS in the thalamus plays a significant role in the induction of thalamic pain. This interaction may be a promising therapeutic target in the clinical management of hemorrhage-induced thalamic pain.

Title: ETA receptors contribute to sickle cell disease-associated pain via the NF-κB-triggered increase in $Na_v1.8$ in primary sensory neurons

Authors: *S. WU[1], B. M. LUTZ[2], A. BEKKER[1], Y.-X. TAO[1]

Abstract: Sickle Cell Disease (SCD) is a hemoglobinopathy that is associated with acute painful episodes and persistent/chronic pain. Our previous study in humanized Townes mouse (HbSS) model of SCD reproted that pharmacological inhibition or neuron-specific knockout of endothelin type A (ETA) receptors in the dorsal root ganglion (DRG) alleviated basal and post-hypoxia-induced pain hypersensitivitities. We also showed that the ETA receptor inhibition blocked an increase in Nav1.8 in the HbSS DRG. The evidence indicates the potential involvement of the increased DRG Nav1.8 in ETA-mediated SCD-associated pain. Here, we further revealed that phosphorylated p65 (an indicator of NF-κB activation) levels in the HbSS DRG were significantly elevated compared to that in the HbAA (control) DRG. Behavioral observation showed that intraperitoneal administration of ammonium pyrrolidinedithiocarbamate (PDTC), a specific inhibitor of NF-κB, alleviated mechanical allodynia in the HbSS mice, without affecting the basal responses in the HbAA mice. Our chromatin immunoprecipitation showed that a fragment within the Scn10a (encoding Nav1.8) promoter (including two adjacent p65 binding motifs) was amplified from a complex immunoprecipitated with an anti-p65 antibody. This binding activity was markedly increased in the HbSS DRG compared to that in the HbAA DRG. The dual luciferase assay using a luciferase reporter vector containing the Scn10a promoter displayed that phorbol 12-myristate 13-acetate (PMA), an PKC activator, increased the activity of the Scn10a gene promoter. This increase was prevented when PDTC or bisindolylmaleimide (a PKC inhibitor) was co-administered. Our findings suggest the participation of NF-κB in ETA receptor-triggered Nav1.8 upregulation in the HbSS DRG neurons, which may provide a novel strategy for the management of SCD pain.

Title: Octamer transcription factor 1 in dorsal root ganglion contributs to neuropathic pain after peripheral nerve injury

Authors: *Y. TAO[1], J. YUAN[2], S. WU[3], A. BEKKER[2]
[1]New Jersey Med. School, Rutgers, Newark, NJ; [2]Anesthesiol., New Jersey Med. School, Rutgers, The State Univ. of New Jersey, Newark, NJ; [3]Anesthesiol., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Neuropathic pain genesis is related to peripheral nerve injury-induced gene alterations in the dorsal root ganglion (DRG). Transcription factors control gene expression. In this study, we investigated whether octamer transcription factor 1 (OCT1), a transcription factor, contributed to neuropathic pain caused by chronic constriction injury (CCI) of the sciatic nerve. CCI produced a time-dependent increase in the level of OCT1 protein in the ipsilateral L4/5 DRG, but not in the spinal cord. Blocking this increase through microinjection of OCT1 siRNA into the ipsilateral L4/5 DRG attenuated the initiation and maintenance of CCI-induced mechanical allodynia, heat hyperalgesia, and cold allodynia and improved morphine analgesia after CCI, without affecting locomotor functions and basal responses to acute mechanical, heat, and cold stimuli. Mimicking this increase through microinjection of recombinant adeno-associated virus 5 expressing full-length OCT1 into the unilateral L4/5 DRG led to significant mechanical allodynia, heat hyperalgesia and cold allodynia in naive rats. Mechanistically, OCT1 participated in CCI-induced increases in *Dnmt3a* mRNA and its protein and DNMT3a-mediated decreases in *Oprm1* and *Kcna2* mRNAs and their proteins in the injured DRG. These findings indicate that OCT1 may participate in neuropathic pain at least in part by transcriptionally activating *Dnmt3a* and subsequently epigenetic silencing of *Oprm1* and *Kcan2* in the DRG. OCT1 may serve as a potential target for therapeutic treatments against neuropathic pain.

Title: Endothelin-type A receptors mediate pain in a mouse model of sickle cell disease

Authors: *J. XIAO[1], B. LUTZ[2], S. WU[3], A. BEKKER[2], Y. TAO[4]
[1]Dept. of Anesthesiol., Rutgers, the State Univ. of New Jersey, Newark, NJ; [2]NJMS, Rutgers, The State Univ. of New Jersey, Newark, NJ; [3]Anesthesiol., Rutgers, The State Univ. of New Jersey, Newark, NJ; [4]New Jersey Med. School, Rutgers, Newark, NJ

Abstract: Sickle cell disease (SCD), resulting from an amino acid substitution in the β globin chain of hemoglobin, is associated with acute painful episodes and chronic intractable pain. Endothelin-1 (ET-1) can induce pain in humans and rodents. Given that its level in the blood

plasma is elevated in the SCD patients and SCD mouse models, ET-1 may play a key role in the SCD-associated pain. Here we reported that the levels of ET-1 and its endothelin type A (ETA) receptor were increased in the dorsal root ganglia from humanized Townes mouse (HbSS) model of SCD. Pharmacologic inhibition or neuron-specific knockdown of ETA receptors in primary sensory neurons of dorsal root ganglion alleviated basal and post-hypoxia evoked pain hypersensitivities in the HBSS mice. Our findings suggest that ETA receptors are the potential targets for the management of SCD-associated pain, although this expectation needs to be further verified in clinic settings.

Title: The mechanistic target of rapamycin (mTOR) pathway in dorsal root ganglion (DRG) neurons and spinal cord microglia differentially contributes to neuropathic pain

Authors: *Y. HU[1], L. CHEN[2]
[1]Zhejiang Univ., Zhejiang, China; [2]Dept. of Orthopedic Surgery, First Affiliated HospitalCollege of Medicine, Zhejiang Univ., HangZhou, China

Abstract: mTOR mediated signaling plays an important role in a wide range of biological processes. Studies have indicated that activation of the mTOR pathway is implicated in the neuropathic pain. However, the cell type in which mTOR activation is involved to regulate pain remains unclear. Identifying the cell type in which mTOR pathway participates in is vital for specific and precise management of neuropathic pain. To identify where mTOR was activated to modulate pain onset and maintenance, we used the spared nerve injury (SNI) model, in combination with DRG and microglia-specific deletion of mTOR, and pharmacological blockade to determine the role of mTOR signaling in different cells for pain genesis. We found that Rapamycin can dramatically alleviated the pain induced by the peripheral nerve injury at early stages (Day 1 to Day3 after the injury). Interestingly, we found mTOR activation in both dorsal horn microglia and DRG neurons. In DRG neurons, mTOR activation peaks at day 1, whereas in the dorsal horn microglia, mTOR activation peaks at day 3 after the nerve injury. Specific deletion of mTOR in microglia substantially reduced microglia proliferation in the dorsal horn; however, no significant changes in the pain behavior, suggesting that

microglia mTOR pathway minimally contribute to the pain. We are carrying out more experiments to determine the role of DRG mTOR in neuropathic pain generation and development.

Title: Nociceptive stimulation produces non random (structured) changes in the timing and direction of the information flowing between the dorsal horn neurons and the brainstem nuclei

Authors: *N. PLAMENOV DONCHEV[1], L. MORENO[1], A. RAMIREZ[1], D. CHAVEZ[1], E. HERNÁNDEZ[1], B. ÁLVAREZ[1], S. GLUSMAN[1,2], P. RUDOMIN[1,3]

Abstract: We have shown that the nociceptive stimulation induced by the intradermal injection of capsaicin produces a non-random increase in correlation between the dorsal horn (DH) neuronal ensembles involved in the generation of the spontaneous L4-L7 cord dorsum potentials (CDPs). These changes underlie the development of inflammatory-neuropathic pain, are supraspinally modulated and transiently reversed by low doses of i.v. lidocaine (Contreras-Hernández et al., J. Physiol 2018). We now studied the effects produced by capsaicin and lidocaine on the functional relationship between the concurrent activity of spinal & supraspinal structures. In 2 anesthetized, paralyzed and artificially ventilated cats, we continuously recorded spontaneous L4-L7 CDPs, L6 DH intraspinal fields as well as ongoing activity in the brainstem Reticular Formation (ReF) and N. Raphe Magnus (NRM). Using the Pearson's coefficient, we found that capsaicin produced a differential increase in the correlation between the spontaneous CDPs and supraspinal potentials during the first 30 min after the onset of nociception. Power Spectrum Density analysis of the ongoing activity further indicated that the main changes occurred within the theta range (3-8 Hz). All these effects were temporarily reduced by i.v. lidocaine. In addition, we used Granger's statistical causality to examine, by means of autoregressive forecastability, the extent to which a particular time series of potentials influenced the activity generated in the other recording sites (Ding and Chen, Handbook of time series analysis, Ch 17, 2006). This allowed appraisal of the changes induced by nociception on the information flowing between the spinal and supraspinal structures. The obtained results appear to

indicate that in control conditions, the information flow between DH and the brainstem was essentially bidirectional. By 10 min after the onset of nociception, there was an initial increase in the ascending information, mostly from the DH to the ReF. Later on, the direction of the information flow reversed and was mainly from the NRM to DH laminae III-V. Following i.v. lidocaine, the descending flow of information was gradually and reversibly reduced. In summary, our data disclose the dynamics of the changes induced by nociceptive stimulation on signal processing of the spinal-supraspinal loop, as well as on the direction of the information flowing between these structures and its reversal by systemic lidocaine. These observations provide a novel approach to examine the development of nociceptive-induced supraspinal control on the functional connectivity between the spinal neurons leading to neuropathic pain.

Abstract: Being aware of and discriminating between different types of cues through the somatosensory system is a critical function for interpreting the internal and external world and for protection from tissue damage. Primary sensory neurons in the dorsal root ganglion (DRG) display distal nerve projections in the skin and deep tissues. Upon activation by a diverse set of chemical, thermal or mechanical stimuli, they relay this information through their central terminations onto neurons located in the dorsal horn of the spinal cord. The dorsal horn of the spinal cord plays a critical role for discriminating different stimuli as well as processing distinct modalities of innocuous and noxious sensation. However, little is known of the neuronal

subtypes involved, hampering efforts to explain principles governing somatic sensation. Here, we used single-cell RNA sequencing to classify sensory neurons in the mouse dorsal horn. We identified 15 inhibitory and 15 excitatory molecular subtypes of neurons, equaling the complexity in cerebral cortex. Validation of our classification scheme *in vivo*, and matching cell types to anatomy of the dorsal horn by spatial transcriptomics reveals laminae enrichment for all cell types. Neuron types, when combined, define a multilayered organization with like neurons layered together. Employing our scheme, we find different sensory stimuli to activate discrete sets of both excitatory and inhibitory neuron types. This work provides a systematic and comprehensive molecular classification of spinal cord sensory neurons enabling functional interrogation of sensory processing.

Title: An optogenetic dissection of parvalbumin^{+} interneuron mediated presynaptic and postsynaptic inhibition in spinal cord sensory circuits

Authors: *M. A. GRADWELL[1], R. J. CALLISTER[1], D. I. HUGHES[2], B. A. GRAHAM[1]

Abstract: The dorsal horn (DH) of the spinal cord is an essential region for the appropriate encoding of sensory signals. The role of inhibitory interneurons in processing sensory inputs at the spinal level is critical to this sensory encoding. Parvalbumin-positive interneurons (PVINs) represent one inhibitory subpopulation known to play an important role in the segregation of tactile and nociceptive signals (Petitjean, 2015 Cell rep 13:1246). The precise circuitry underlying this role, however, remains unclear. To better understand the connectivity underlying the role of PVINs in sensory encoding we have taken an optogenetic approach, using transgenic mice that express Channelrhodopsin-2 in PVINs. Adult mice (30 ± 3 wks, both sexes) were deeply anaesthetized with ketamine (100 mg/kg, i.p.) and decapitated. Parasagittal spinal cord slices were prepared from the lumbar cord. Whole cell patch clamp recordings were made from

unidentified neurons and slices photostimulated using brief whole-field illumination (488nm, 1ms). Synaptic responses were recorded using CsCl- (inhibitory responses), and K-gluc based internals (excitatory responses). During inhibitory recordings, photostimulation evoked short latency mixed GABA/Glycine inhibitory postsynaptic currents (ie, bicuculline and strychnine sensitive) in 79% and 30% of neurons within LIIi-III and LI-IIo, respectively. These recordings showed a broad range of postsynaptic targets, with IPSC amplitude in both putative inhibitory and excitatory interneuron populations. During excitatory recordings photostimulation evoked longer latency bicuculline and temperature sensitive EPSCs in 38% and 49% of neurons within LIIi-III and LI-IIo, respectively. We were also able to demonstrate powerful PVIN mediated inhibition of primary afferent evoked EPSCs (ie presynaptic inhibition). Together these data provide strong evidence for PVIN mediated presynaptic inhibition, which could be mapped using optogenetics. Unlike postsynaptic inhibition, PVINs provided powerful presynaptic inhibition to specific neural circuits, with the strongest connections observed on a population of inhibitory 'deep' islet cells. Together our findings indicate PVINs provide distributed inhibitory control over interneurons within LI-III of the dorsal horn. PVINs also provide powerful, and specific presynaptic inhibition onto myelinated afferent fibers, and our optogenetic approach provides a useful tool for the identification of downstream local interneuron circuits regulated by this form of inhibition.

Title: Interconnectivity between parvalbumin^{+}interneurons in the spinal cord: Implications for dorsal horn oscillations

Authors: *B. A. GRAHAM[1], R. J. CALLISTER[1,2], M. A. GRADWELL[1], D. I. HUGHES[2]
[1]The Univ. of Newcastle, Callaghan, Australia; [2]Univ. of Glasgow, Glasgow, United Kingdom

Abstract: The dorsal horn of the spinal cord is an essential region for the appropriate encoding of sensory signals. A number of studies have established Parvalbumin-positive interneurons (PVINs) as an important inhibitory subpopulation for the segregation of tactile and nociceptive signals within spinal circuits (Hughes, 2012 J Physiol 590:3927; Petitjean, 2015 Cell rep 13:1246). Given PVINs in other brain regions exhibit synaptic and electrical coupling and

generate oscillatory activity, our study has assessed the interconnectivity of spinal PVINs in the dorsal horn. This work was undertaken using an optogenetic approach in transgenic mice that express Channelrhodopsin-2 (ChR2) in PVINs. In addition, pairs of PVINs and other unidentified populations were recorded to directly assess individual connections. Adult mice (30 ± 3 wks, both sexes) were deeply anaesthetized with ketamine (100 mg/kg, i.p.) and decapitated before parasagittal spinal cord slices were prepared from the lumbar cord. Whole cell patch clamp recordings were made from PVINs (identified by ChR2-YFP) and slices photostimulated using brief whole-field illumination (488nm, 1ms). Synaptic responses were recorded using CsCl- (inhibitory responses), and K-gluc based internals (excitatory responses). During inhibitory recordings from PVINs, photostimulation caused an immediate photocurrent in the recorded cell but also caused optically-evoked postsynaptic currents oPSCs in many recordings occurring at short latency (4.9 ± 0.2 ms) and with limited jitter at onset (0.4 ± 0.1 ms). Allowing the time to recruit AP discharge following PVIN photostimulation (1.3 ms, cell attached), these latencies and limited jitter are consistent with direct monosynaptic connections (Lu and Perl 2003). Furthermore, oIPSCs were mixed GABA/Glycine inhibitory postsynaptic currents (ie, bicuculline and strychnine sensitive) and occurred in 61% (67/110) of PVINs. We were also able to demonstrate that photostimulation of PVINs mediated inhibition of primary afferents (ie presynaptic inhibition) and caused oEPSCs in other PVINs (81% - 89/110) that had longer latency (11.5 ± 1.5 ms), higher jitter (5.7 ± 4.1 ms), and were bicuculline sensitive. Together, these findings confirm PVINs are coupled through inhibitory synaptic connections (feed-forward inhibition) and also provide presynaptic inhibition to the same afferent fibers that excite them (feed-back inhibition). Together, these properties are consistent with the connectivity of PVINs in other CNS regions and suggest they are ideally configured to drive oscillations in the sensory circuits of the dorsal horn.

Title: Modulatory effect of psychophysical stress on orofacial nociception at the rostral ventromedial medulla in the rats

Authors: *M. KUROSE[1], M. HASEGAWA[2], Y. NAKATANI[1,3], S. SHIMIZU[1,3], N. FUJII[2], K. YAMAMURA[1], K. OKAMOTO[4]

[1]Dept. of Oral Biol. Sci., Niigata University, Grad. Sch. of Med. and, Niigata, Japan; [2]Gen. Dent. and Clin. Educ. Unit, Med. and Dent. Hospital, Niigata Univ., Niigata, Japan; [3]Div. of Oral and Maxillofacial Surgery, [4]Dept. of Oral Biol. Sci., Niigata University, Grad. Sch. of Med. and Dent. Sci., Niigata, Japan

Abstract: *Introduction* Psychological stress is known to facilitate orofacial nociception. Preclinical studies revealed that psychophysical stress conditionings increased nociceptive neural activities in the medullary dorsal horn (Vc). The basis for increased Vc response could be due to functional changes of descending pain pathways from the rostral ventromedial medulla (RVM): however it remains unclear if psychophysical stress had modulatory effect on neural excitability at the RVM. *Material and Methods* Sprague-Dawley male rats were subjected to repeated forced swim stress (FST, 10 min/day) to induce psychophysical stress. After 3 day FST, we recorded neural activities from the RVM and suprahyoid muscle activity in the presence or absence of noxious heat stimulation to the facial skin. Although three types of neural activity termed as On-, Off- and Neutral-cells were identified, we focused on neural properties of On-cells because evidence revealed that On-cells have roles of pain facilitation. In separate study, we tested the effect of FST on Fos expression in the RVM. Results from FST rats were compared with those of sham rats. *Results* Noxious heat stimulation increased On-cell activities in FST and sham rats: however, quantitative analysis revealed that response magnitude of neural and muscle activities evoked by heat stimulation in FST rats appeared to be greater than that of sham rats. Further, FST rats displayed significant prolonged after-discharges compared with sham rats. The number of Fos positive cells in the RVM was significantly greater in FST rats than in sham rats. These findings indicated facilitatory roles of FST on neural activity in the RVM, although functional relationships between On-cell and Fos positive cells remain unclear. Repeated FST alone had no effects on On-cell activity and Fos expression in the absence of heat stimulation. Further, FST increased muscle activity evoked by heat stimulation compared to sham rats. *Discussion* The functional changes of descending pain controls indicated by increases in On-cell activities and Fos responses in the RVM can explain possible mechanisms for pain exacerbation at the orofacial region under psychophysical stress conditions.

Title: Diverse cell types within the vlPAG exhibit unique adaptations to membrane firing properties after inflammation

Authors: *K. B. MCPHERSON, K. L. SUCHLAND, S. L. INGRAM
Neurolog. Surgery, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The periaqueductal grey (PAG) is an important integration site within the descending pain modulatory pathway that receives diverse inputs from throughout the brain. The ventrolateral region (vlPAG) is a key target for opioid induced analgesia mediated via its projection to the rostroventromedial medulla (RVM). The vlPAG is a highly heterogeneous region with diverse cell types that have yet to be characterized fully in terms of their response to noxious stimuli and opioids. Using whole-cell patch-clamp recordings of vlPAG neurons, we measured intrinsic membrane firing properties in naïve rats and defined 5 distinct cell-types: onset-spiking, fast-spiking, transiently fast-spiking, random-spiking, and dopamine neurons. Complete Freund's Adjuvant (CFA) injections into the hindpaw induced inflammation and hyperexcitability at 2 h post-CFA in a subpopulation of vlPAG neurons, including increased firing frequencies and altered firing patterns. The sensitized characteristics varied between individual cell types suggesting that subsets of neurons are specifically activated by the CFA. To address this variability we are evaluating the use of Fos, a protein marker for strong neuronal activity, as a tool to identify neurons within the vlPAG that are activated by inflammation. Fos expression is robustly increased 2 h after CFA, with a significant reduction 6 d after CFA that remains significantly greater than the naïve animals—suggesting dynamic changes in neuronal activity between early and persistent inflammation. In FosGFP transgenic rats activation of the cFos promoter drives expression of GFP, allowing us to identify and record membrane firing properties from Fos-positive and Fos-negative neurons *in vitro*. Studies will compare inflammation-induced changes at acute (2 and 24 h) and after persistent inflammation (6 d). Additionally, the studies use retrograde fluorescent CTb labeling from the RVM to examine intrinsic properties of vlPAG neurons that project to the RVM. The effects of opioids on the intrinsic membrane properties of these cell types will also be examined.

Title: D2-like receptor agonist inhibits high-voltage activated calcium-current in small IB4 positive dorsal root ganglion neurons and produces specific analgesia in mechanonociceptive test

Authors: *F. MERCADO[1], P. SEGURA-CHAMA[2], B. LEYVA-LÓPEZ[1], F. PELLICER[1], A. ALMANZA-GUTIÉRREZ[1]
[1]Dirección de Investigaciones en Neurociencias, INPRFM, Ciudad de Mexico, Mexico;
[2]Dirección de Investigaciones en Neurociencias, CONACyT - INPRFM, Ciudad de Mexico, Mexico

Abstract: *Background:* The intrathecal (i.t.) administration of quinpirole, a dopamine D2-like receptor agonist, produces significant analgesia during mechanonociceptive stimulus but not with thermonociceptive stimulus in intact rats (Almanza et al., *Pharmacol Biochem Behav*, 2015: 137: 119-125). To find a cellular mechanism for the analgesic specific-effect through D2-like agonist on mechanonociception, we evaluated the effect of quinpirole on high voltage-activated (HVA) Ca^{2+} current (I_{Ca}) and the action potential (AP) discharge of small-diameter neurons of the dorsal root ganglia (DRG) from rats. *Methods:* Rat DRG neurons (P21-P25) were isolated and kept in culture (DMEM + N2 complement) less than 24 h. The I_{Ca} and the AP firing were recorded with the patch-clamp technique. Small-diameter DRG neurons (< 30 µm) were classified in two populations depending on its binding to isolectin B_4 (IB_4+/-), due to non-peptidergic IB_4+ and peptidergic IB_4- have been implicated in mechanonociceptive and thermonociceptive stimulus signaling, respectively. All the experiments in the present work were approved by our Institutional Ethics Committee. *Results:* Quinpirole inhibited significantly the HVA I_{Ca} in 11/21 small IB_4+ neurons, meanwhile, HVA I_{Ca} in peptidergic small IB_4- neurons were almost unaffected, only in 4/34 IB_4- neurons a modest but significant decrease of HVA I_{Ca} was measured. AP from small-IB_4+ and IB_4- neurons were recorded, quinpirole didn't affect DRG's AP firing produced by square or ramp current injection, in neither IB_4+ (n = 24) nor IB_4- (n = 34). *Conclusions:* Activation of D2-like receptors in non-peptidergic small-diameter DRG neurons (IB_4+) inhibits the HVA I_{Ca}, such inhibition could diminish neurotransmitter release at the spinal cord level leaving unaffected the DRG neurons AP-firing. These results could explain, at least in part, the specific analgesia of the D2-like agonist to mechanonociceptive stimuli. *Significance*: We present evidence about D2-like receptors activation modulates mechanonociception at primary afferent level through the inhibition of HVA I_{Ca} in IB_4+ neurons. This finding could convey to rational analgesic therapy for patients with mechanical hyperalgesia or allodynia.

Title: Disinhibition of rostral insular cortex produces pronociceptive activity in brainstem pain-modulating neurons and behavioral hyperalgesia

Authors: *Y. ZHANG[1], M. M. HEINRICHER[1,2]
[1]Neurolog. Surgery, [2]Dept. of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The insula processes information related to pain and bodily state, transmitting that information to higher centers, including amygdala and other cortical areas. However, it also has descending projections to brainstem regions. Activating the rostral agranular insular cortex (RAIC) in rats has shown to produce hyperalgesia, while inhibiting the RAIC has an antinociceptive effect. It has been suggested that the RAIC influences nociceptive processing via a descending pain modulation influence, but the underlying neural circuit remains largely unknown. The rostral ventromedial medulla (RVM) exerts a descending modulatory influence via pain-facilitating "ON-cells" and pain-inhibiting "OFF-cells". The aim of this study was to test the hypothesis that disinhibition of the RAIC produces hyperalgesia via activation of RVM ON-cells and/or suppression of the activity of RVM OFF-cells. We recorded heat-evoked paw withdrawal and activity of identified ON- and OFF-cells in lightly anesthetized Sprague-Dawley rats. Retrograde tracing demonstrated that the densest projection from the insula to the RVM arises in the RAIC. Following a microinjection of the $GABA_A$ receptor antagonist bicuculline (40 pmol/400 nL) in the RAIC, OFF-cell firing decreased and ON-cell firing increased for a prolonged period of time. NEUTRAL-cells, RVM neurons without a known role in pain modulation, were not affected by disinhibition of the RAIC. In addition, the threshold for paw withdrawal to heat decreased after bicuculline injection. These data suggest that the insular cortex exerts it effects on pain at least in part via the pain-modulating neurons in the RVM.

Title: Parabrachial complex relays light-related information to brainstem pain-modulating circuitry

Authors: M. E. MARTENSON[1], E. E. HANSON[2], *M. M. HEINRICHER[3]
[1]Neurolog. Surgery, [2]Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Dept Neurol Surgery, Mail Stop L-472, Oregon Hlth. and Sci. Univ. Dept. of Neurol., Portland, OR

Abstract: Individuals with chronic pain often experience increased sensitivity across multiple sensory modalities. This "multisensory hypersensitivity" is only now starting to be recognized as having an understandable neural basis. We recently showed that some pain-modulating neurons in the rostral ventromedial medulla (RVM) respond to visual light in lightly anesthetized rats, with activation of pain-facilitating ON-cells and suppression of pain-inhibiting OFF-cells. The pathways through which light information gains access to pain-modulating circuitry are thus an important step in understanding the interactions between pain and other sensory modalities. Initial studies showed that non-image forming pathways convey light-related information to the RVM. The goal of the present studies was to identify additional steps in the circuit linking light to pain. ON-cells (known to exert a net facilitating effect on spinal nociceptive processing) and OFF-cells (known to exert a net inhibiting effect on spinal nociceptive processing) were recorded in the rostral ventromedial medulla (RVM). These neurons have historically been defined by changes in activity during noxious somatic stimulation. Approximately half of the pain-facilitating ON-cells sampled, and a similar proportion of pain-inhibiting OFF-cells showed a change in firing with light. We investigated three possible relays through which information about ambient light could reach the RVM: the lateral parabrachial complex, central nucleus of the amygdala, and medial nucleus of the amygdala. Light-evoked changes in ON- and OFF-cell firing were attenuated by inactivation of the lateral parabrachial complex, but not the central or medial amgydala. The parabrachial complex receives interoceptive and exteroceptive sensory information, and is thought to convey threat signals to higher structures such as the amygdala. However, it also transmits information about noxious somatic stimuli to the RVM, where it regulates activity of pain-modulating systems. The present findings thus extend that idea, indicating that the parabrachial complex transmits a range of potentially threatening sensory information to descending control systems as well as to ascending systems

Title: Altered brainstem pain modulation circuit connectivity in chronic pain

Authors: *E. P. MILLS[1], Z. ALSHELH[1], F. DI PIETRO[1], R. AKHTER[2], G. M. MURRAY[2], C. C. PECK[1], L. A. HENDERSON[1]
[2]Fac. of Dent., [1]Univ. of Sydney, Sydney, Australia

Abstract: Background and Aims: Evidence suggests that altered functioning within the brainstem pain modulation network contributes to the maintenance of some chronic pain conditions, for instance painful temporomandibular disorder (TMD), a chronic facial pain condition. TMD patients' abnormal responses to psychophysical paradigms like conditioned pain modulation[1], where "pain inhibits pain", indicate that patients with TMD may not effectively engage pain modulation systems. Despite these psychophysical findings, it is unknown whether the function of the brainstem pain modulation circuitry is altered in TMD subjects. The aim of this investigation is to use resting state functional magnetic resonance imaging (fMRI) to characterize brainstem modulation circuits in individuals with TMD and matched pain-free controls.
Methods: A resting state fMRI scan was performed on subjects with painful TMD (n=15, mean age: 35.3) and pain-free controls (n=45, mean age: 34.1). Using SPM12, fMRI images were realigned, movement and physiological noise removed and the brainstem isolated. The brainstem fMRI images were then spatially normalized to a brainstem-only template using the SUIT toolbox. Two key regions of the brainstem pain modulation network, namely the rostral ventromedial medulla (RVM) and subnucleus reticularis dorsalis (SRD), were selected as "seed" regions. The connectivity of these regions with each brainstem voxel was calculated and compared between TMDs and controls in a voxel-by-voxel analysis ($p<0.05$, small volume correction).
Results: Compared to controls, TMD subjects display enhanced functional connectivity between the RVM and the oralis division of the spinal trigeminal nucleus (SpV: mean ± SEM functional connectivity: *control*: 0.06±0.03, *TMD*: 0.30±0.07) and SRD (*control*: 0.10±0.03, *TMD*: 0.29±0.06). Using the SRD as a second connectivity seed, we found that TMD subjects show negative connectivity with another region important for pain modulation, the midbrain periaqueductal gray matter (*control*: 0.12±0.06, *TMD*: -0.22±0.08). Additionally, TMD subjects

show reduced SRD connectivity with the caudalis division of SpV (*control*: 0.29±0.05, *TMD*: 0.05±0.07).
Conclusions: These results reveal that TMD is associated with alterations in resting functional connectivity within the pain modulation network. The observed alterations primarily involve the pathways involving the SRD, a region critical for the well-described "pain inhibits pain" response. Dysfunction in this network may contribute to the abnormal pain processing reported in TMD subjects and the maintenance of pain in these individuals.

Title: Dopaminergic regulation of the circadian rhythm of pain perception

Authors: C. PIÑA-LEYVA[1], L. RODRIGUEZ-SOSA[2], B. FLORÁN-GARDUÑO[1], *J. A. GONZALEZ-BARRIOS[3]
[1]Fisiología, Biofísica y Neurociencias, CINVESTAV, Ciudad de México, Mexico; [2]Facultad de Medicina, Univ. Nacional Autónoma de México, Ciudad de México, Mexico; [3]Hosp Regional Octubre, ISSSTE, Mexico DF, Mexico

Abstract: Pain is associated to desynchronization of circadian and biological rhythms and some diabetics, multiple sclerosis and arthritics patient refer different intensity of the pain along the day. Nowadays it is well-known that hypothalamic A11 area controls the pain through the dopaminergic receptors present in the dorsal horn of the spinal cord. We investigated: 1) the pain rhythmicity, 2) if the lesion dopaminergic A11 area can alter the diurnal pain behavior and 3) the dopaminergic receptors implicated in the pain rhythmicity regulation. Male Wistar rats were used to evaluate the threshold and rhythms of the pain in a model of mechanical allodynia using the next experimental groups: 1) Control L:D (Light:Dark 12h:12h); 2) D:D (Continuous darkness to 15 days); 3) Injured (Injection of 10 μg/μL of 6-OHDA in the A11 area) and 4) Antagonist (Intrathecal administration of SCH23390, L-741,626, GR-103691 and L-745,870). The results showed a rhythmic activity in the pain perception with 24 h period, 9:35 hours of maxim threshold and 2.67 of amplitude; the hypothalamic lesion A11 changed the maxim threshold to 13:00 h and decreased amplitude to 0.39 h. The administration of the SCH23390, L-

741,626, GR-103691 and L-745,870 dopaminergic antagonists decreased the threshold amplitude to 0.96, 1.84, 0.88 and 0.53, while the acrophase changed to 5:30, 13:83, 13:16 and 4.08 respectively. All together results demonstrate a direct regulation of circadian behaviour in the pain perception by the A11 area through differential activation of all kind of the dopaminergic receptors expressed in the lumbar spinal cord

Title: The effect of transcranial direct current stimulation on conditioned pain modulation in healthy older adults

Authors: *B. WIND[1], A. MEEK[2], M. GODZA[3], Z. A. RILEY[1], K. M. NAUGLE[1]
[1]Kinesiology, [2]Hlth. & Rehabil. Sci., IUPUI, Indianapolis, IN; [3]Physical Therapy, UF, Gainesville, FL

Abstract: Recent evidence suggests aging is associated with reduced endogenous pain inhibitory capacity, placing older adults at risk for developing persistent pain. Transcranial direct current stimulation (tDCS) is a non-invasive brain stimulation technique capable of modulating excitability of cortical and cerebellar neurons. Recent work shows tDCS of the motor cortex (M1) improves pain inhibitory capacity in healthy young adults. The purpose of this study is to examine the effects of anodal tDCS on descending pain inhibition in healthy older adults. This study has enrolled 11 older adults, with enrollment ongoing. Subjects completed three sessions on separate days that include one of the following 15-minute experimental conditions during each session: (1) anodal M1 tDCS, (2) anodal cerebellar tDCS, and (3) sham tDCS. Order of experimental conditions were randomly assigned per session. A dynamic quantitative sensory test called conditioned pain modulation (CPM) was used to assess pain inhibitory capacity pre and post tDCS. A 3 (condition: M1, Cerebellum, Sham) x 2 (time: pre-tdcs, post-tdcs) repeated measures ANOVA was conducted to compare CPM scores. Results showed a main effect of time, p=.016. Regardless of condition, pain inhibition on the CPM test decreased from pre-tdcs (15.3±3.0) to post-tdcs (3.7±2.4). These results indicate both tDCS of M1 and cerebellum are ineffective in enhancing endogenous pain inhibitory capacity on the CPM test in healthy older adults.

Title: Presynaptic inputs to serotonin-containing neurons of the mouse rostral ventromedial medulla

Authors: C. BIAN, R. HU, Y. DU, J. YANG, J. ASGAR, W. GUO, R. DUBNER, K. REN, *F. WEI

Abstract: It has been recognized that 5-HT-containing neurons in the rostral ventromedial medulla (RVM) project to spinal dorsal horn and modulate spinal nociceptive transmission. Recent studies have demonstrated that active 5-HT-dependent descending facilitation after nerve and tissue injury contributes to central mechanisms underlying the development of secondary hyperalgesia and the maintenance of persistent pain and. Although a large number of early studies indicate comparative afferent projections to the RVM in the rat, cat and monkey brain by using conventional tracing approaches, the circuits controlling 5-HT neuronal activity in the RVM remains uncharacterized. To identify local and long-range inputs that strictly target 5-HT neurons in the RVM, we applied a genetically restricted two-viral tracing strategy to target 5-HT neurons of Sert-Cre mice. At 4 w after the first microinjection of helper virus (AAVDJ-EF1a-DIO-HTB) into the RVM, we sterotaxically delivered a genetically modified rabies virus pseudotyped with the avian virus envelope protein (EnvA-ΔG-RV-mCherry) in the same region. To compare afferent inputs to the RVM, we also microinjected the retrograde tracer fluoro-gold into the RVM of wildtype mice. We found that AAV-infected expression of TVA was restricted to the RVM and most of them were 5-HT-immunoreactive. Similar to the local distribution of FG-labeled neurons, we observed a substantial numbers of RV-infected presynaptic neurons within the RVM and medial parts of the pontine reticular nucleus, suggesting local control of 5-HT neurons from other non-5-HT neurons. We also confirmed that there were a large number of presynaptic neurons in the ventrolateral regions of the midbrain periaqueductal gray (PAG) and the dorsomedial nucleus (DMN) of hypothalamus. A small to moderate number of presynaptic neurons were observed in the locus coeruleus and the pontine reticular tegmentum. Different

from FG-labeled neuronal distribution, we found few presynaptic neurons in primary sensory cortex and dorsal raphe. We did not observe presynaptic neurons in the preoptic area, medial prefrontal cortex, anterior cingulate cortex, insular cortex, amygdala, paraventricular nucleus of hypothalamus and parabrachial nuclei. Our results dissect the whole-brain monosynaptic inputs specifically onto 5-HT RVM neurons. The descending 5-HT system mainly receives synaptic inputs and regulation from local neurons in the RVM and higher structures including the ventrolateral PAG and the hypothalamic dorsomedical nucleus linking descending pain modulation and neuroendocrine/autonomic response during stress, respectively.

Title: Analysis of the role of glutamatergic and GABAergic ventrolateral periaqueductal grant (vlPAG) neuronal subpopulations in a mouse model of persistent inflammatory pain

Authors: *J. G. GRAJALES-REYES[1], V. K. SAMINENI[3], B. A. COPITS[2], M. R. BRUCHAS[4], R. W. GEREAU, IV[5]
[2]Pain Center, Dept of Anesthesiol., [1]Washington Univ. Sch. of Med., Saint Louis, MO; [4]Departments of Anesthesiol. and Anatomy-Neurobiology, [3]Washington Univ., Saint Louis, MO; [5]Anesthesiol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: It has been estimated that 100 million adults suffer from chronic pain in the United States, with an annual societal cost of approximately 600 billion dollars. Endogenous analgesic pathways represent an alternative route for the development of new therapies for chronic pain. Pharmacological and electrical stimulation studies have demonstrated the role of the ventrolateral periaqueductal gray (vlPAG) in descending pain modulation. It has been proposed that tonic GABAergic neurotransmission at the level of the vlPAG serves to inhibit efferent excitatory projections that mediate descending analgesia. Disinhibition of vlPAG excitatory neurons is thought to allow subsequent activation of rostromedial ventral medulla (RVM) neurons that project to the spinal cord dorsal horn and inhibit nociception. Nevertheless, the experimental manipulations used in prior studies lack cell-type specificity, preventing unambiguous determination of the role of specific subsets of vlPAG neurons in analgesia. Techniques such as chemo- and opto-genetics now afford us the opportunity to selectively

manipulate identified subclasses of vlPAG neurons allowing for precise identification of circuit components critical for analgesia. With the GABA disinhibition hypothesis as our model, we hypothesized that stimulation of excitatory vlPAG neurons or a reduction of in vlPAG GABAergic tone would result in analgesia. We find chemogenetic stimulation of glutamatergic (Vglut2) or inhibition of GABAergic (Vgat) vlPAG neurons results in an elevation of withdrawal thresholds to noxious stimuli in naïve animals. In the context of persistent inflammatory pain, we find that optogenetic stimulation of Vglut2 or chemogenetic inhibition of Vgat vlPAG neurons results in attenuation of inflammation-induced hyperalgesia. To further characterize the circuitry, anatomical tracing experiments supports the notion that glutamatergic PAGàRVM projections, but not GABAergic projections, are responsible for engaging descending analgesic pathways that result in analgesia in both naïve and inflammatory states. We provide direct experimental evidence for the proposed analgesic role for glutamatergic projections from the PAG to the RVM. In brief, our findings support the GABA disinhibition hypothesis, highlighting the role of local tonic GABAergic neurotransmission at the level of thevlPAGas an analgesic gatekeeper.

Title: Endogenous oxytocin release in periaqueductal gray eased inflammatory pain through long term suppression of pain perception neurons in the spinal cord

Authors: *M. IWASAKI[1,2], A. CHARLET[2]
[1]The Danish Res. Inst. of Translational Neurosci. Building 1171, 128, Aarhus Univ., Aarhus C, Denmark; [2]Inst. of Cell. and Integrative Neurosciences, French Natl. Ctr. for Scientific Res., Strasbourg, France

Abstract: When a pain stimulus is added to healthy animal body, oxytocinergic (OT) neurons in perventricular nucleus (PVN) are activated. OT neurons in PVN project to periaqueductal gray (PAG), and the concentration of OT increases in response to pain input. In view of those, we hypothesize that pain input induces firing of OT neurons in PVN, hence releasing OT locally in PAG. Additionally, previous study reported that the increase of OT concentration in PAG suppressed pain perception. Further, In PAG, administration of OT to PAG resulted in increase of firing of OT receptor (OTR) expressing neurons. Therefore, we can infer that OT achieve

analgesia through facilitation of firing of OTR-expressing neurons in PAG. Based on the background above, my project aims to characterize i) the firing dynamics of neurons in PAG in response to endogenous OT release in PAG, examine if ii) OT release in PAG induces the suppression of pain perception neurons in the spinal cord, and check iii) if inflammatory pain can be eased by it.

Title: KOR activation in the central amygdala increases spinal dorsal horn neuronal activity through an action on amygdala CRF neurons

Authors: *G. JI[1,2], E. NAVRATILOVA[3], F. PORRECA[3], V. NEUGEBAUER[1,2]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Patients with functional pain syndromes (FPS) often experience intermittent episodic pain related to “triggers” including stress. Stress-induced activation of kappa opioid receptors (KORs) has been shown to promote negative affective states, including depression and anxiety. KORs are found in multiple brain regions relevant to pain modulation, including the central nucleus of the amygdala (CeA). The amygdala is a limbic brain area that plays a key role in emotional responses and averse affective states and disorders such as learned fear, anxiety, depression, and pain. We hypothesize that KOR signaling in the amygdala promotes functional pain responses through an action that involves corticotropin releasing factor (CRF) neurons. Our previous work identified the CRF system as a key player in pain-related amygdala plasticity and pain modulation. In this study, systems electrophysiology was used to determine the consequences of KOR activation in the amygdala on spinal dorsal horn neurons in transgenic CRF-Cre rats and the contribution of amygdala CRF neurons. Extracellular single-unit recordings of wide dynamic range (WDR) neurons were performed in the spinal dorsal horn of adult anesthetized (isoflurane, 2%) CRF-Cre rats. Background activity and evoked responses (spikes/s) to brief (15 s) innocuous and noxious mechanical test stimuli applied to the hindpaw were measured before and after stereotaxic administration of a KOR agonist (U-69,593) in the

right CeA (ipsilateral to spinal recording site) by microdialysis. U-69,593 increased the responses of WDR neurons to innocuous and noxious mechanical stimuli and this effect was inhibited by optogenetic silencing of CRF neurons in the CeA in CRF-Cre rats injected with AAV-EF1a-DIO-eNpHR3.0-EYFP into the CeA. Optical silencing was done with yellow light pulses (590 nm) delivered through an optical fiber inserted into the CeA. The data provide direct evidence for facilitatory effects of KOR activation in the amygdala on spinal nociceptive processing through a mechanism that engages amygdala CRF neurons.

Title: Synaptic transmission in different amygdala neuronal cells types under normal condition and in a neuropathic pain model

Authors: *T. KIRITOSHI[1], V. A. YAKHNITSA[1], V. NEUGEBAUER[1,2]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The central nucleus of the amygdala (CeA) is comprised of distinct populations of GABAergic neurons identified by molecular markers such as corticotropin releasing factor (CRF) and somatostatin (SOM), and plays a key role in emotional aspects of pain. The CeA receives polymodal sensory information via the basolateral nucleus (BLA) and purely nociceptive information via parabrachial nucleus (PB). Pain-related changes at these synapses have been shown in different pain models by our group and others but cell-type specific differences in synaptic inputs remain to be determined. In this study, we analyzed synaptic input from PB and BLA to different CeA cell types under normal condition and in a neuropathic pain model. Whole-cell patch clamp recordings were obtained from lateral CeA neurons in brain slices from sham rats and neuropathic rats (4 weeks after L5 spinal nerve ligation, SNL model). Transgenic Crh-Cre rats and posthoc immunohistochemistry of recorded neurons were used to identify neuronal cell-types in the lateral CeA of the right hemisphere. In current clamp mode, action potential firing patterns were measured by injecting depolarizing currents. For selective activation of PB inputs to CeA neurons in amygdala brain slices, a viral vector (AAV) encoding

channelrhodopsin 2 (ChR2) under the control of the CaMKII promoter (AAV5-ChR2-CaMKII-eYFP) was injected stereotaxically into the right PB. BLA inputs were activated by electrical stimulation in the BLA. In voltage clamp mode, amplitudes of excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) and IPSC/EPSC ratio were measured. We found differences of EPSC and IPSC amplitudes and IPSC/EPSC ratio in different cell types. For example, regular spiking (RS) CRF-CeA neurons received stronger excitatory and weaker or no inhibitory input compared to SOM-CeA and non-RS cells. EPSCs of RS-CRF cells increased in slices from SNL whereas non-RS cells showed pronounced IPSCs. These results suggest that cell-type specific differences in synaptic transmission in CeA neurons under normal conditions and differential changes in neuropathic pain.

Title: Group II metabotropic glutamate receptors, particularly mGluR2, in the amygdala regulate sensory and affective responses in a rodent model of arthritis pain

Authors: *M. MAZZITELLI[1], P. CONN[3], V. NEUGEBAUER[1,2]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ., Nashville, TN

Abstract: Pain is a multidimensional experience with an important averse-affective dimension. The amygdala, a limbic brain area, plays a critical role in the emotional-affective aspects of behaviors and pain and in pain modulation. The central nucleus of amygdala (CeA) serves major output functions, and neuroplasticity in the CeA is mechanistically linked to pain-related behaviors in different pain conditions. The activation of Gi/o-coupled group II metabotropic glutamate receptors (mGluRs), which consist of mGluR2 and mGluR3, can decrease neurotransmitter release and regulate synaptic plasticity. Evidence from preclinical studies suggests that mGluR2/3 may be a target for neuropsychiatric disorders and can inhibit pain-related processing and behaviors, but the contribution of mGluR2 and 3 in the amygdala to pain-related behaviors remains to be determined. This knowledge gap was addressed here in a rodent

model of arthritis pain. Audible and ultrasonic vocalizations (averse affective response) and mechanical withdrawal thresholds were measured in adult rats before and 6 h after the induction of a kaolin/carrageenan-mono-arthritis in the left knee joint. Systemic application (intraperitoneally; 30 min before behavioral tests) of a group II mGluR agonist (LY379268 disodium salt) decreased the vocalizations and increased the spinal reflex thresholds of arthritic rats but had no effect under normal conditions. To determine the contribution of mGluRs in the amygdala, a group II mGluR antagonist (LY341495 disodium salt), a positive allosteric modulator for mGluR2 (PAM, LY487379 hydrochloride), or a negative allosteric modulator for mGluR2 (NAM, VU6001966) was applied stereotaxically into the right CeA (contralateral to the arthritic knee) by microdialysis. Stereotaxic administration of the group II antagonist and the mGluR2 NAM in the CeA reversed the effects of the systemically applied group II mGluR agonist. Stereotaxic administration of the mGluR2 PAM alone in CeA was able to mimic the effect of the systemically applied group II mGluR agonist in arthritic rats. These results suggest that group II mGluRs, and particularly mGluR2, in the amygdala can regulate pain-related behaviors and play a major role in the effects of systemic group II agonists.

Title: Sex differences in fear extinction learning ability predicting pain behaviors

Authors: *P. D. PRESTO[1], G. JI[1,2], V. NEUGEBAUER[1,2]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Sex differences in pain and disorders such as depression and anxiety are now being recognized. Pain and fear may share neurobiological mechanisms such as plasticity in emotional networks that include the amygdala. The amygdala plays a key role in fear conditioning and has emerged as an important node of emotional-affective aspects of pain modulation. Impaired fear extinction learning, which involves prefrontal cortical control of amygdala processing, has been linked to conditions such as posttraumatic stress disorder (PTSD). Here we tested the hypothesis that fear extinction learning ability can predict certain aspects of pain-related behaviors of rats

and that these may be different in female and male rats. We correlated fear extinction learning in adult male and female rats with behavioral outcome measures (sensory thresholds, vocalizations, and anxiety-like behaviors) before and >6h after induction of an arthritis pain model (kaolin/carrageenan-induced knee joint arthritis). Auditory fear conditioning, extinction, and extinction retention tests were conducted using two chambers. On Day 1 rats were habituated to context A followed by fear conditioning (2 US-CS pairs). On Day 2, rats were habituated to context B followed by extinction training (30 CSs). On Day 3, rats were habituated to context B followed by extinction retention measurement (5 CSs). There was no difference in fear learning between male and female rats. The majority of rats (78% male, 73% female) showed a quick decline of freezing level during extinction training and retention (FE+) whereas a smaller group of rats (22% male, 27% female) maintained a high freezing level (FE-). Male and female FE- rats had lower open-arm preferences in the elevated plus maze (EPM) or shorter center duration in the open field test (OFT) than FE+ rats, reflecting anxiety-like behavior, but there were no significant differences in sensory thresholds and vocalizations between FE+ and FE- types under normal conditions. In the arthritis pain model, male and female FE- rats developed higher levels of vocalizations and anxiety-like behavior than FE+ rats, but there were no differences in mechanical reflex thresholds. Female FE- rats had stronger vocalizations than FE- males. The data may suggest predictive value of fear extinction ability for emotional-affective pain aspects in male and female rats, and greater vulnerability of female than male rats with lower extinction ability.

Title: KOR activation in the central amygdala enhances pain behaviors through an action on amygdala CRF neurons

Authors: *V. NEUGEBAUER[1,2], P. PRESTO[1], E. NAVRATILOVA[3], F. PORRECA[3], G. JI[1]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: The amygdala plays an important role in emotional responses and affective states and disorders such as anxiety and depression. The amygdala also contributes to emotional-affective aspects of pain and pain modulation. Neuroplastic changes that lead to increased neuronal activity in the amygdala output region (central nucleus, CeA) have been found in different pain models. Corticotropin releasing factor and its CRF1 receptor have been linked to pain-related amygdala changes and behavioral consequences. Mechanisms of pain-related activation of amygdala CRF neurons are still not well understood. The dynorphin/kappa opioid receptor (KOR) system has been linked to stress related conditions such as anxiety and depression, and KOR activation produces dysphoria in humans and aversive behaviors in animals. Evidence points to the amygdala as a major site of action where KOR is expressed. Here we tested the hypothesis that KOR activation in the amygdala under normal conditions promotes pain-related emotional responses and anxiety-like behaviors through activation of amygdala CRF neurons. In adult transgenic CRF-Cre rats, emotional-affective responses were determined by measuring the duration of audible and ultrasonic vocalizations evoked by brief (15 s) innocuous and noxious mechanical test stimuli (compression of the paw). Anxiety-like behavior was assessed in the elevated plus maze (EPM) and open field test (OFT). Stereotaxic administration of a KOR agonist (U-69,593) in the right CeA by microdialysis increased audible and ultrasonic vocalizations and decreased the center duration of OFT. Systemic (intraperitoneal) application of U-69,593 also increased vocalizations and anxiety-like behavior. These effects were inhibited by optogenetic silencing of CRF-CeA neurons in CRF-Cre rats injected with AAV-EF1a-DIO-eNpHR3.0-EYFP. For optical silencing of CRF neurons yellow light pulses (590 nm) were delivered through an optical fiber implanted into CeA and attached to a head stage for wireless stimulation. The data provide direct evidence for facilitatory effects of KOR activation in the amygdala on pain-related emotional responses and anxiety-like behaviors through a mechanism that engages amygdala CRF neurons.

Title: SK-channel function in different amygdala neuronal cell types under normal condition and in a neuropathic pain model

Authors: *V. A. YAKHNITSA[1], T. KIRITOSHI[1], V. NEUGEBAUER[1,2]
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The central nucleus of amygdala (CeA) plays a key role in the regulation of the emotional-affective component of pain. CeA neurons include neurochemically and functionally distinct cell types: GABAergic neurons express corticotropin releasing factor (CRF), somatostatin (SOM) and/or PKCdelta. Activation of CRF neurons and SOM neurons in the CeA contributes to anxiety-like behavior and emotional responses. Work from our group and others showed that increased activation of CeA neurons in acute and chronic pain models drives emotional-effective responses and anxiety-like behaviors. Here we tested the hypothesis that dysfunction of small-conductance calcium-activated potassium (SK) channels contributes to increased excitability of CRF-CeA and/or SOM-CeA neurons in a rat model of chronic neuropathic pain. Whole-cell voltage- and current-clamp recordings were made from latero-capsular CeA neurons in brain slices from behaviorally tested sham rats and neuropathic rats (spinal nerve ligation SNL model) 3-4 weeks after surgery. In transgenic Crh-Cre rats, rAAV5/Ef1a DIO-YFP or mCherry was injected stereotaxically into the CeA to label CRF somata. CRF-CeA neurons and non-CRF-CeA neurons were recorded, filled with biocytin through the patch pipette, and stained immunohistochemically for co-localization with SOM. In slices from sham rats, all neurons showed an apamin-sensitive medium afterhyperpolarization (mAHP). In brain slices from neuropathic rats that had developed mechanical hypersensitivity, increased vocalizations, and anxiety-like behavior, CRF-CeA neurons lacked an mAHP and SOM-CeA had a reduced mAHP, and both showed increased excitability measured as the number of spikes in response to depolarizing current injections (F-I function) compared to neurons from sham rats. The results suggest that SK-channel dysfunction may be more pronounced in CRF than SOM amygdala neurons in a neuropathic pain model.

Abstract: Neuroplastic changes in the central nervous system have been implicated not only in pain conditions associated with an identifiable injury, but also in functional pain syndrome (FPS), in which the pain cannot be attributed to tissue pathology. Mechanisms of FPS remain to be determined, but these conditions are typically triggered by stress, which can advance the pain condition from episodic to chronic. Corticotropin releasing factor and its CRF1 receptor in the amygdala have been linked to emotional-affective behaviors and pain modulation. The amygdala is also a major site of opioid receptors, including $G_{i/o}$-coupled kappa opioid receptors (KOR). KOR activation by its endogenous ligand dynorphin or agonists can have adverse effects. Here we tested the hypothesis that KOR activation disinhibits CRF neurons in the central nucleus (CeA) in uninjured rats. CeA serves major amygdala output functions. Brain slice electrophysiology was used to determine the effects of a KOR agonist (U-69,593) on CRF-CeA neurons. To visualize these neurons, AAV-EF1a-DIO-mCherry was injected into the right CeA of transgenic CRF-Cre rats (4 weeks old). To allow optical activation of glutamatergic afferent input from the lateral parabrachial area (LPB), AAV5-ChR2-CaMKII-eYFP was injected into the LPB. Animals were allowed to recover for four weeks for viral expression. Whole-cell patch-clamp recordings of CRF-CeA neurons were used to measure neuronal excitability (frequency-current F-I relationship), excitatory and inhibitory synaptic currents (EPSCs and IPSCs) evoked by optical activation of LPB terminals in the CeA or by electrical stimulation in the basolateral amygdala, and synaptically-evoked spiking (LPB evoked E-S coupling). U-69,593 decreased glutamate driven IPSCs (feedforward inhibition) and E-S coupling but had no effect on EPSCs and on F-I relationships. The data suggest that KOR activation under normal conditions leads to synaptic disinhibition of CRF-CeA neurons, which could result in increased pain responses and anxiogenic behavior.

Title: Changes in resting-state functional connectivity after cognitive behavioral therapy for chronic pain

Authors: *A. YOSHINO, Y. OKAMOTO, G. OKADA, S. YOKOYAMA, R. JINNIN, M. TAKAMURA, N. ICHIKAWA, S. YAMAWAKI

Abstract: Introduction
The efficacy of cognitive behavioral therapy (CBT) for chronic pain has been demonstrated across clinical trials. However, there are few resting-state functional magnetic resonance imaging (rs-fMRI) studies. We used the intrinsic connectivity network (ICN) analysis to examine changes of neural activities after CBT and to assess whether brain regions predict clinical responses.
Methods
We assessed rs-fMRI data on a group of 29 chronic pain patients and 30 age-matched healthy controls (T1). Patients were enrolled in a weekly 12-session group CBT (T2). We used regions of interest such as the dorsal attention network (DAN) and sensorimotor network (SN) extracted by ICN analysis, exhibited differences in connectivity strength between the patients and controls at T1, and compared T1 and T2. We also examined the correlations between clinical effects and rs-fMRI data. All participants gave their written informed consent before participation, according to a protocol approved by the Hiroshima University ethics committee.
Results
Abnormal ICN connectivity of the orbitofrontal cortex (OFC) and inferior parietal lobule within the DAN and of the paracentral lobule within the SN in patients with chronic pain normalized after CBT. Increased ICN connectivity strength after CBT in the OFC indicated greater improvements in pain intensity. Furthermore, ICN connectivity strength in the dorsal posterior cingulate cortex (dPCC) within the DAN at T1 was negatively correlated with CBT-related clinical improvements.
Conclusions
We consider that the OFC is important for improvements of pain intensity by CBT, and that the dPCC activation at pretreatment also plays a key role in improvement of clinical symptoms via CBT.

Title: Daily caffeine consumption does not modulate acupuncture analgesia and fMRI signal changes evoked by acupuncture stimulation

Authors: *J. CAO[1,3], Y. TU[1], C. LANG[1], J. PARK[1], M. VANGEL[2], J. LIU[1], R. GOLLUB[1], J. KONG[1]
[1]Psychiatry, [2]Dept. of Med., Massachusetts Gen. Hosp., Charlestown, MA; [3]Sch. of Acupuncture Moxibustion and Tuina, Beijing Univ. of Chinese Med., Beijing, China

Abstract: Introduction: Caffeine is a common central nervous system stimulant and is found in coffee, tea, chocolate, energy drinks, and even some medications. Since caffeine is a potent adenosine receptor (A1) antagonist and acupuncture achieves its analgesic effects through the local release of adenosine and activation A1, caffeine consumption may interfere with the efficacy of acupuncture when used to treat pain. In this study, we examined whether individuals' daily intake of caffeine influenced acupuncture analgesia as measured by heat and pressure pain thresholds and fMRI brain responses during acupuncture stimulation. **Methods:** 24 subjects completed this study. We divided the subjects into two groups (high and low consumption groups, n =12 respectively) based on their daily caffeine consumption. Then we investigated baseline pain thresholds before each treatment and compared the difference in analgesia between the real and sham acupuncture in the two groups. fMRI data were collected using a 3.0 T MRI scanner while subjects completed two 9-minute scans during which intermittent intervention was performed. Data analysis was performed using SPM 12 with a threshold of $p < 0.001$ uncorrected and $p < 0.05$ FDR corrected. **Results:** We found that real acupuncture increased subject's pain thresholds compared to sham acupuncture, however, no significant differences between the two caffeine groups before vs. after real and sham acupuncture interventions in pain threshold changes was found.Imaging results indicated that real acupuncture activated the bilateral insula, secondary somatosensory cortex, and right caudate; and deactivated the bilateral anterior cingulate cortex, medial prefrontal cortex, left superior temporal gyrus, and right hippocampus. None of the three caffeine covariates (daily dose, duration of consumption, and their interaction) were statistically significant for any measurement. No significant differences between two caffeine consumption groups in pain thresholds at baseline, pre- to post-intervention threshold changes after real acupuncture treatment, and fMRI signal changes during acupuncture needle stimulation. **Conclusions:** In reality, the invasiveness evoked by acupuncture stimulation in

humans and rodents differ significantly since most acupuncture studies applied in animals have used regular human acupuncture needles. Therefore, the invasiveness and pain produced by acupuncture needles used in animal research are much greater than those experienced by humans. In summary, our results suggest that daily caffeine consumption does not interfere with the analgesic effects associated with acupuncture in healthy populations.

Title: *In vivo* imaging and recording of general anesthesia activated central analgesic neurons

Authors: *B. CHEN, JR, T. HUA, S. ZHAO, B.-X. HAN, P. THOMPSON, L. JIANGXIE, J. LU, F. WANG
Duke Neurobio., Durham, NC

Abstract: One of the key functions of general anesthesia (GA) is analgesia. We hypothesized that the GA-induced analgesic process involves an active process in which endogenous central analgesic neurons are activated by GA. Indeed, our lab has identified neurons in the central amygdala (CeA) that are activated by GA, and these neurons (CeA_{GA}) have profound analgesic functions (See Abstract by Hua et al, SfN 2018). Here, we combine *in vivo* one- and two-photon calcium imaging, photo-tag recording to characterize the in vivo activities of CeA_{GA} neurons. Using the CANE technology developed in our lab, we expressed either GCaMP6m (for in vivo imaging) or ChR2 (for in vivo photo-tagged recording using optotrode arrays) specifically in CeA_{GA} neurons. We found that these neurons are strongly activated by isoflurane GA, and are inhibited by acute noxious mechanical or heat stimuli. To begin to understand how activities of CeA_{GA} neurons are controlled in the neuronal circuit level, we used a CANE-based monosynaptic rabies virus to identify presynaptic inputs to CeA_{GA} neurons. Preliminary studies revealed brain-wide inputs from a diverse source of regions to CeA_{GA} neurons.

Title: Free water as a neural marker of trigeminal neuralgia

Authors: *Q. ZHAO[1], C. SPECTOR[2], I. B. H. SAMUEL[1], J. NEUBERT[3], M. DING[1]
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Orthodontics, [3]Dept. of Neurol., Univ. of Florida, Gainesville, FL

Abstract: Neuroinflammation has been implicated in the pathology of trigeminal neuralgia (TN), a debilitating chronic facial pain disorder, but quantitative analysis of neuroinflammation in human TN patients is still lacking. Recent studies propose that free-water measurement derived from MRI diffusion data provides an index of neuroinflammation. In this study, twenty seven patients (17 females) clinically diagnosed with TN enrolled and underwent diffusion MRI scanning. Among the patients, seventeen had TN1 diagnosis, and twelve (eight TN1 patients) had prior microvascular decompression (MVD) surgery. Selecting the pontine crossing tract (PCT), which links brainstem with the thalamus, as the region of interest, we found that the average fractional volume of the free water in PCT was positively correlated with disease duration, controlling for age ($r=0.50$, $p=0.76\times10^{-2}$). For TN patients without the MVD surgery (n=15), the association between PCT free water and disease duration became stronger ($r=0.89$, $p=7.84\times10^{-6}$), whereas for patients with prior MVD surgery (n=12), the association disappeared ($r=0.20$, $p=0.54$). For patients with TN1 diagnosis and no prior surgery (n=9), PCT free-water and disease-duration association was extremely strong ($r=0.97$, $p=1.10\times10^{-5}$), but for patients with TN1 diagnosis and prior surgery (n=8), the association again disappeared ($r=0.08$, $p=0.84$). These findings suggest that (1) free water in the pontine crossing tract can serve as a neural marker of trigeminal neuralgia especially in patients with TN1 and (2) MVD surgery disrupts the relationship between neuroinflammation and disease duration.

Title: Pain sensation induced by transcranial magnetic stimulation in human

Authors: K. TANI, *S. TANAKA
Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Transcranial magnetic stimulation (TMS) is a non-invasive procedure of cortical stimulation. TMS has been widely used to investigate human cognitive and motor functions. Pain sensation is the most common side-effect of TMS (Rossi et al., 2009). The pain sensation induced by TMS may vary among individuals, and depend on scalp location, intensity and frequency of stimulation. The cutaneous sensation affects behavioral and cognitive performance during experiments and could be a potential confounding factor in TMS studies. However, systematic investigations on the pain sensation induced by TMS have not been reported. In the present study, we examined the difference in the pain thresholds induced by TMS over different scalp locations. Six healthy right handed volunteers (3 females, 3 males) participated in the study after they provided the written informed consent. This study was approved by the ethical committee of Hamamatsu University School of Medicine and performed in accordance with the Helsinki Declaration. The experiment was pre-registered as a clinical trial (UMIN000029783). Single-pulse TMS was applied over the scalp locations just above the left primary motor cortex (M1) or the Broca's area (BA). A magstim 200 square machine and a figure-eight coil were used. The participants were asked to report verbally weather she/he felt the sensation of pain after each TMS. The primary outcome was the pain threshold. The pain threshold was defined as the stimulation intensity that induced the pain sensation five out of ten stimulations. As the result, the mean pain threshold in M1 stimulation was 53.8 % of the maximum machine output, whereas that in BA stimulation was 27.3 %. The difference was statistically significant (paired t-test, $t(5)=9.98$, $p<0.001$). The lower pain threshold in BA stimulation could be due to the trigeminal nerve stimulation. In conclusion, the present study shows that the TMS-induced pain sensation differs in the scalp locations. The present results contribute the further understanding on side-effect of TMS. This work was supported by the Ministry of Internal Affairs and Communications in Japan.

Title: Investigating brain network dynamics of pain perception using MEG measures of dynamic functional coupling

Authors: *J. A. KIM[1,2], R. L. BOSMA[1], K. S. HEMINGTON[1], N. R. OSBORNE[1], A. ROGACHOV[1], J. C. CHENG[1], B. DUNKLEY[3], K. D. DAVIS[1]
[1]Krembil Res. Inst., Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]The Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Introduction: Emerging evidence suggests that brain activity and regional communication is intrinsically dynamic. For example, variability in connectivity within and between nodes of the dynamic pain connectome (salience and default mode networks (SN, DMN) and ascending nociceptive pathway (ANP)), has been linked to variability in pain perception. Here, we leverage the temporal resolution of MEG and introduce a novel metric called dynamic functional coupling (dFCp) to measure brain dynamics. We used this new measure and conventional measures of static FCp within the SN, DMN, and ANP to determine 1) if pain sensitivity is related to dynamic or static FCp, and 2) if there are sex differences in these relationships.
Methods: Healthy participants underwent a 5 minute resting state MEG session and a psychophysiological battery that included measuring heat pain threshold (HPT). Resting state MEG data was processed using Fieldtrip. Atlas-guided beamforming was performed using linearly constrained minimum variance on the data to obtain time series data for regions of interest (ROIs). For FCp analysis, MEG data was divided into 10s epochs and a Hilbert transform was used to calculate instantaneous phase and amplitude in the canonical bands. Phase lag index (PLI) and amplitude coupling was calculated for pairs of beamformed node within and between the SN, DMN and ANP. Static FCp was calculated by averaging the FCp values across all the epochs and dynamic FCp was considered as the standard deviation of FCp values across all the epochs.
Results: In the whole group analysis, HPT was related to dynamic FCp within the SN, cross-network dynamic FCp between the SN and the DMN, as well as the cross-network dynamic FCp between the SN and the ANP. However, a relationship between HPT and cross-network static FCp between the SN and ANP was only present in men, and a relationship between HPT and

static FCp within the SN was only present in women.
Discussion: In this study we applied a new approach to understand the role of brain dynamics in pain sensitivity. We found a link between individual variability in pain sensitivity and dynamic FCp across all participants, whereas sex differences were apparent in measures of static FCp. We propose that dynamic measures of FCp (standard deviation of PLI and amplitude coupling over time) predominantly reflects "state" properties, whereas the static measures of FCp (average PLI and amplitude coupling over time) predominantly reflects "trait" properties. These MEG measures of brain connectivity can provide complementary insight into brain mechanisms of pain perception.

Title: Evaluation of temporal dynamics of pain using electrocorticogram in rat formalin-induced pain model

Authors: Y. TAKAHARA, M. MATSUO, R. TAMONO, T. ASAKI, *K. OGAWA
SHIONOGI & CO., LTD., Toyonaka-Shi, Osaka, Japan

Abstract: Non-clinical pain evaluation method reflecting clinical assessments is of great importance for analgesic drug discovery. The various conventional methods are used for non-clinical pain evaluation, but these have some limitations. For example, the von Frey test assesses the pain thresholds on the basis of withdrawal response to filament stimulus, and the tail flick test does with the response latencies from heat stimulus. These methods can measure the pain thresholds quantitatively at the moment of the test, but it is difficult to assess pain intensity over time, while in human, patients with chronic pain suffer ever-changing ongoing pain without external stimulus. In this study, we aimed to establish the evaluation method for temporal dynamics of pain in rats using electrocorticography (ECoG) in a different way of stimulus-induced responses. We hypothesized that pain sensation affect the cortical neuronal activity and ECoG recording can detect the temporal dynamics of neuronal activity associated with pain. We recorded ECoG from right primary somatosensory cortex (S1) of Wistar rats before and after formalin injection into the plantar of the left hindpaw. The injection of formalin evoked a biphasic pain-like behavior as previously reported. And interestingly, significant increase in gamma band (30-90 Hz) ECoG activity in S1 area was also observed along with the biphasic pain-like behavior. Moreover, the enhancement of gamma band activity was highly correlated

with the amount of pain-like behavior, and lidocaine (local anesthetics) could attenuate the enhancement of formalin-induced gamma band activity. These results indicate that the gamma band activity in S1 area surrogates temporal pain intensity in rats and ECoG recording of gamma power in S1 area is a useful method for evaluating the temporal dynamics of pain in non-clinical study.

Title: Predicting chronic pelvic pain symptom progression based on resting state functional connectivity

Authors: *S. FENSKE[1], J. J. KUTCH[2]
[1]Neurosci. Grad. Program, [2]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: The pathophysiology of Urologic Chronic Pelvic Pain Syndrome (UCPPS) is poorly understood and no generally effective treatment targets have been identified. Studies have demonstrated that brain structure and function are important factors distinguishing UCPPS patients from healthy individuals, and we have recently shown that resting-state functional magnetic resonance imaging (rs-fMRI) at baseline may predict longitudinal progression of UCPPS symptoms. The goal of our current work is to optimize this predictive model of symptom change in UCPPS. In order to predict UCPPS symptom change, we developed a model associating baseline rs-fMRI data and reported symptom progression derived from a pain scale assessed every two weeks up to 1 year collected as part of the Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) Research Network study. The training dataset included 52 UCPPS patients (34 women and 18 men). Each step of our pipeline: brain parcellation, feature reduction, classification, and cross validation, was improved by parameter optimization and investigation into alternative analysis techniques. The dimensionality of the connectivity feature

set was reduced in combination with a machine learning regression and goodness of fit were estimated by leave one out cross validation. Our preliminary results present an optimal model (r^2=0.32 , p=0.031) for 3-month longitudinal symptom change. This model follows a combination of the Power et al. anatomical atlas, univariate feature selection of 100 features, support vector regression, and leave one out cross validation. Top features are associated with connections to regions in the frontal lobe. These results highlight the ability of our model to predict changes in UCPPS symptom behavior as well as identify potential treatment targets. By optimizing and validating our predictive model, we have made a contribution to our understanding of the neural correlates related to UCPPS with potential clinical applications of a wider UCPPS population.

Title: A machine learning approach to establish an EEG-based marker of chronic pain

Authors: S. TA DINH[1], M. M. NICKEL[1], L. TIEMANN[1], E. S. MAY[1], H. HEITMANN[1], V. D. HOHN[1], G. EDENHARTER[2], D. UTPADEL-FISCHLER[1], T. R. TOELLE[1], J. GROSS[3], *M. PLONER[1]
[1]Neurol., [2]Anesthesiol., TU Muenchen, Munich, Germany; [3]Univ. of Münster, Münster, Germany

Abstract: Chronic pain is a pathological condition associated with significant sensory, cognitive and affective abnormalities, has detrimental effects on quality of life and is a leading cause of disability worldwide. Converging lines of evidence from animals and humans indicate that the brain plays an important role in chronic pain. However, the brain mechanisms of chronic pain are not fully clear yet. Further insights into these mechanisms promise to advance the understanding of the neural basis of chronic pain. Moreover, a brain-based marker of chronic pain would be immensely helpful for the diagnosis, classification and treatment of chronic pain. Using electroencephalography (EEG) to establish such a brain-based marker of chronic pain is particularly appealing as it is safe, cheap, broadly available and potentially mobile. Moreover, an EEG-based marker of chronic pain might itself represent a target for novel therapeutic strategies such as neurofeedback or non-invasive brain stimulation techniques.We have recorded EEG during restful wakefulness in 101 chronic pain patients (age 58.2 ± 13.5 years (mean ± standard

deviation), 69 female) and 71 matched healthy controls (age 56.6 ± 14.2 years, 49 female). A previous analysis using well-established measures such as spectral power and graph theoretical network measures did not detect significant differences between patients and healthy controls. However, this lack of differences does not preclude that more complex patterns of EEG data contain predictive information about the chronic pain state. In the present study, we therefore applied a multivariate machine learning approach to differentiate chronic pain patients and healthy controls based on resting state EEG data. In particular, we have tried to classify the two cohorts using a support vector machine (SVM) with a range of features characterizing brain activity and brain connectivity. This includes dominant peak frequency, spectral power, connectivity and connectivity-based graph measures. A systematic and comprehensive exploration of the feature space with a simple linear SVM shows that we can distinguish between pain patients and healthy controls with an accuracy of about 66 percent. The features which are most consistently included by a sequential forward feature selection are the power in the theta and alpha frequency and the total connectivity in the beta frequency band. In a next step, deep learning will be used to autonomously generate meaningful features from our data. We aim to accomplish a better differentiation of the two groups as well as a characterization of the most meaningful features.

Title: Diffuse noxious inhibitory controls and brain networks are modulated in a testosterone-dependent manner in Sprague Dawley rats

Authors: *J. SILVA, Y. ZHANG, J. ASGAR, J. Y. RO, D. SEMINOWICZ
Dept. of Neural and Pain Sci., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Diffuse noxious inhibitory control (DNIC), which involves endogenous pain modulation, has been investigated as a potential mechanism for the differences in pain observed between men and women. We used a capsaicin-induced DNIC behavioral assay and resting state functional magnetic resonance imaging (rsfMRI) to assess the effect of testosterone on pain modulation and related brain circuitry in rats. Male, female, and orchidectomized (GDX) male

rats had a capsaicin injection into the forepaw to induce DNIC and mechanical thresholds were observed on the hindpaw. Rats were scanned using a Bruker 7T MRI and under isoflurane anesthesia ≤ 1.5%. Functional scans (TR = 1500 ms, in plane resolution = 450 μm, slice thickness 1 mm) were acquired during 15.5 minutes. rsfMRI scans were done before and after capsaicin injection to analyze the effects of DNIC on periaqueductal gray (PAG), anterior cingulate cortex (ACC) and nucleus accumbens (NAc) connectivity to the whole brain. The strength of DNIC was higher in males compared to females and GDX males. PAG connectivity with prelimbic cortex (PrL), ACC and insula was stronger in males compared to females and GDX males, whereas females and GDX males had increased connectivity between the right ACC, hippocampus and thalamus. GDX males also showed a stronger connectivity between right ACC and NAc, and right NAc with PrL, ACC, insula and thalamus. Our findings suggest that testosterone plays a key role in reinforcing the endogenous pain inhibitory system, while circuitries related to reward and emotion are more strongly recruited in the absence of testosterone.

Title: Functional ultrasound neuroimaging of the trigeminal ganglion in the context of ocular pain

Authors: *S. PEZET[1], M. THIBAUT[1], L. RAHAL[2], F. JOUBERT[3], A. RÉAUX-LE-GOAZIGO, 75012[3], M. TANTER[4]
[1]Lab. of Brain Plasticity, Paris, France; [2]Wave Physics for Med., Inst. Langevin, Paris, France; [3]INSERM, CNRS, Inst. de la Vision, Sorbonne Univ., Paris, France; [4]Waves for medicine, INSERM, Paris, France

Abstract: Introduction
Ocular pain, in particular corneal pain, is a core symptom of inflammatory or traumatic disorders affecting the anterior segment of the eye. Its increasing prevalence, morbidity, and the resulting

social burden has caused chronic ocular pain to be recognized as a serious public health issue. To date, the management of chronic ocular pain remains a therapeutic challenge in ophthalmology, The absence of therapy imposes a deepening of our fundamental knowledge on the anatomy of the corneal nociceptive system. The cornea is the most densely innervated tissue of the body, as it is innervated by a large number of C and Aδ fibers, the terminal endings of primary sensory neurons (about 150-200) located in the trigeminal ganglion (TG). Preclinical models of corneal injury are characterized by ocular pain and neuronal and microglial activation, both in the TG and the trigeminal sensory complex (Launay et al., 2016). While several preclinical models of corneal injury or dry eye disease have recently been developed, neuroimaging of the TG has never been performed in animal models of ocular pain due to its deep seated location.

The aim of this study was to determine if fUS imaging a novel and highly sensitive neuroimaging modality relying on unequaled spatiotemporal resolution (1 ms, 100µm) could image the functional activations of the TG induced by mechanical or chemical stimulations of healthy cornea in anaesthetized rat.

Results

Our results show that, despite the deep seated location of the TG, fUS is able to image and detect the haemodynamic fluctuations of TG in the rat model. Surprisingly, the TG receives a significant blood supply, which was confirmed using *in toto* vascular staining (using DiI staining). Application of a dynamic mechanical stimulations (5x10 sec) on a healthy cornea induced a rapid and specific activation in the ophthalmic branch of the ipsilateral TG. Such a vascular response was completely prevented by a topical instillation of an anesthetic, oxybuprocain, which blocks the nociceptive corneal nerve fiber activity. In addition, one drop of the potent TRPV1 receptor agonist, Capsaicin (20µM) applied on the cornea induced a rapid and a large phasic haemodynamic response in the ipsilateral TG.

Discussion

This study shows that fUS imaging is feasible and accurate to evaluate neurovascular coupling in the rat TG. This method represents a unique tool for 1) evaluating trigeminal and central neurovascular response in various preclinical model of ocular pain and 2) screening and developing effective therapeutic molecules to alleviate ocular pain.

Title: Imaging of spinal cord functional activation and somatotopy in rats using functional ultrasound (fUS) imaging

Authors: *J. CLARON[1], L. RAHAL[1,2], V. HINGOT[1], M. THIBAUT[2], O. COUTURE[1], M. TANTER[1], S. PEZET[2]
[1]Inst. Langevin, INSERM U979, ESPCI Paris, PSL Res. University,, Paris, France; [2]Lab. of Brain Plasticity, CNRS UMR 8249, ESPCI Paris, PSL Res. Univ., Paris, France

Abstract: Acute pain is a physiological phenomenon characterized by activation of nociceptors in the peripheral nervous system (PNS). Spinal cord plays a major role in nociception as the first synapse of the nociceptive system. This is the site of activation of second order neurons, through glutamatergic neurotransmission (mediated through AMPA and NMDA receptors (NMDAR)), but also of local and descending inhibitory tonus. In the spinal dorsal horn, entry of primary sensory fibers terminals follow particular somatotopy, thereby allowing to separate them by choosing different stimulation areas[1]. Functional Ultrasound (fUS) imaging is a highly resolved technique that can image functional connectivity (FC) in the adult rat brain[2]. Also, using contrast agents, we performed super-resolution in the living rat brain.
This project aimed at studying the spinal functional activation and organization using fUS imaging. In the neuroimaging field, studies using functional magnetic resonance imaging (fMRI) measure blood-oxygen level dependent (BOLD) signal[2]. fUS imaging measures hemodynamic fluctuation corresponding to spinal blood volume (SBV). Therefore, while fUS imaging gives us an *in vivo* spinal vascular organization, due to the neurovascular coupling, it also allows the indirect measurement of neuronal activity.
Our results, obtained or not in combination with micro-bubbles for Ultrasound Localization Microscopy describe in details the vasculature of the rat spinal cord. fUS experiments without contrast agents imaged functional activations induced by either Aβ, Aδ or C fibers and showed that peripheral stimulation of Aδ or C fibers induce a strong increased SBV in the ipsilateral dorsal horn. Pharmacological blockade of NMDAR showed that this is an NMDA-dependent mechanism. Those results are in agreement with other techniques like optical imaging[3], electrophysiology[4] or fMRI but with a much larger field of view and spatiotemporal resolution. Finally, repetitive activation of C-fibers showed spinal hyperexcitability and increased hemodynamic response.
In conclusion, we can image specific activations in ipsilateral dorsal horn. Because fUS is allowing a large field of view, it is possible to follow up high resolution somatotopy. This indicates fUS imaging as a new tool in pain and spinal cord imaging. FC alterations under conditions such as chronic pain will lead to a better fundamental understanding of the spinal cord role.

Title: physical pain modulates reward-related brain activities in medial prefrontal cortex

Authors: *C. WANG, J. GAO, X.-W. DONG
East China Normal Univ., Shanghai City, China

Abstract: Pain modulates motivation and reward-related brain activities. For example, individuals in physical pain are motivated to perform reward-seeking behaviors. However, it is unclear about the mechanism of how pain modulates reward-seeking behavior in humans. By using fMRI technology, the present study investigated the influence of physical pain on reward-related activities of the brain regions in reward/motivation neural circuitry. A total of 50 healthy university students (age = 22.4 ± 2.5) were recruited and were then applied with either Capzasin (pain group) or hand cream (control group). During brain imaging, they were asked to play a card guess game in which they would receive monetary gain by a correct guess or monetary loss by an incorrect guess. Results showed that, the medial prefrontal cortex (MPFC) and bilateral nucleus accumbens (NAcc) were activated when individuals received win feedback in both groups (Fig. a). Interestingly, Results revealed that physical pain increased the reward-related neural activity in the mPFC (Fig. b), but not in the bilateral NAcc. Moreover, the functional connectivity between mPFC and NAcc was decreased in pain condition (Fig. c). Accompanied with the enhanced activation of mPFC responding to monetary reward, participants in pain overestimated their correct choices in the card-guess game (Fig. d) and such positive bias was correlated with subjective rating of pain intensity (Fig. e). These findings demonstrate that the reward-related activity of the mPFC is subject to the modulation of physical pain. We postulate that the modulation of the mPFC activity by pain may result in alterations of both emotional response to and evaluation of reward. The study extends the understanding of the consequences of pain on human cognition and behavior.

Title: Thermal grill model of human pain perception facilitates late but not early somatosensory evoked potentials

Authors: *F. SACADURA[1], T. BROOKES[2], B. BECK[3], F. FARDO[3], P. HAGGARD[3]
[1]Fac. of Life Sci., [2]Div. of Med., [3]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: Aims: The thermal grill illusion (TGI) involves a paradoxical burning heat sensation evoked by alternating non-noxious warm and cold temperatures. The TGI has been proposed as

an experimental model of pain in humans. Reduced intracortical inhibition has been reported in studies of chronic pain patients. We therefore combined TGI conditioning with electrical stimulation of digital nerves of index and middle fingers to investigate whether TGI stimulation affects somatosensory-evoked potentials (SEPs), and measures of intracortical inhibition based on under-additivity of responses to double-digit stimulation. **Methods**: 32 participants received electrical stimulation to the right index, right middle or both fingers simultaneously, during four fingertip thermal stimulation conditions: warm index/cold middle (TGI), warm/neutral, neutral/cold or neutral/neutral. Importantly, thermal and electrical stimuli were adjusted according to individual pain and detection thresholds. To measure the TGI, participants adjusted the temperature of a further stimulus to the left hand to match perceived temperature of the target right middle finger. **Results**: We found a significant temperature overestimation of the cold stimulus when paired with a warm stimulus, confirming TGI. We found no thermal effects on intracortical inhibition in early sensory SEP components (N20, P27, N33, P45, N80). However, thermal stimulation modulated later cognitive SEP components (P100, N140). Specifically, TGI conditioning increased the N140 amplitude to individual finger stimulation, but not double-digit stimulation. **Conclusions**: Our results suggest TGI conditioning increases the gain of later, "attentional" somatosensory processing, and also increases intracortical inhibition.

Title: Thalamus in chronic low back pain: Insights from vertex-based morphometry and connectivity-based diffusion tensor tractography

Authors: *H. PENG[1], J. G. CRAGGS[2], A. SMITH[2], K. BOLAND[3], D. VILCEANU[4], C. M. CIRSTEA[5]
[1]Psychological Sci., Univ. of Missouri Columbia, Columbia, MO; [2]Physical Therapy, [3]Psychological Sci., [4]Anesthesiol. and Perioperative Med., [5]Physical Med. & Rehabil., Univ. of Missouri, Columbia, MO

Abstract: Background: Chronic low back pain (CLBP) is the leading cause of activity limitation and work absence in the U.S. No therapies are cited in CLBP as having persuasive evidence of improvement free of undesirable side-effects. This is a considerable issue for the

U.S. healthcare system: total cost related to CLBP exceeds $100 billion per year. A better understanding of the neural bases of CLBP is mandatory. Structural brain changes in CLBP are a relatively new concept. Decreased gray matter (GM) volume of certain brain regions, including thalamus -a key brain region in pain matrix- has been reported, yet not present in all studies. Likewise, there is limited evidence of reduced fractional anisotropy (FA) of the thalamic projections, which is generally attributed to altered microstructural architecture. We used vertex-based morphometry and connectivity-based diffusion tensor (DTI) tractography to test the hypothesis that the CLBP is associated with decreased thalamic GM and altered integrity of the thalamic projections to the frontal and parietal lobes. **Methods:** High-resolution T1-weighted MRI and DTI images were obtained in 45 CLBP and 57 age/sex-matched healthy controls. Vertex-based analysis (FIRST, FSL, Oxford, UK) was used to quantify the thalamic surface. PROBTRACKX (5000 samples, 0.2 threshold) was applied to determine the probability of connectivity of each thalamic voxel with the mask of each cerebral lobe (connectivity probability>50%). Thalamic surface and FA values of thalamo-frontal and thalamo-paritetal projections were compared between groups. Pain measures (McGill pain questionnaire) were correlated to DTI measures. **Results:** As predicted, in CLBP compared to controls, the left thalamus exhibited significant regional (anterior superior, posterolateral) changes in shape, suggestive of GM reduction in these thalamic parts. Likewise, the left thalamo-frontal projections showed lower FA (0.34±0.02 in CLBP vs. 0.37±0.02 in controls, $p<0.05$), reflective of reduced axonal density, thickness, or demyelination. Contrary to our prediction, there were no significant changes in the right thalamus shape or bilateral thalamo-parietal projections. No correlations with clinical scores were found. **Discussion:** Individuals with CLBP had distinct abnormalities in thalamic morphometry and thalamo-frontal projections compared with healthy controls. Although the precise mechanisms underlying such changes remain unclear, a reduction of GM volume and an altered white matter integrity may represent a degenerative pain-related process. Additional work is underway to decipher the functional implications of such changes.

Hosp., Gothenburg, Sweden; [3]Neuromuscular and Neurogenetic Disorders of Childhood Section, NINDS, NIH, Bethesda, MD; [4]Div. of Neurol., Children's Natl. Hlth. Syst., Washington, DC; [5]Sensory Cells and Circuits Section, NIH/NCCIH, Bethesda, MD; [6]NCCIH/NIH, Bethesda, MD

Abstract: Objective: A patient with congenital insensitivity to pain presents with no known genetic mutations or gross brain abnormalities. Anecdotal evidence suggests that the patient's autonomic system is reactive to noxious stimuli (increased heart rate, sweating, nausea, skin pallor) despite the absence of reported pain. Therefore, we compared the neural, behavioral, and autonomic correlates of noxious heat stimuli in the patient to healthy controls (HCs).
Methods: The 17-year-old patient and 4 sex- and age-matched healthy controls had 2 sessions of noxious heat stimuli (high=49°C, low=46°C): a behavioral session with heat stimuli (10 trials each) and concurrent autonomic measures (electrocardiogram, skin conductance, respiration) and a functional MRI session with heat stimuli (30 trials each). Pain intensity (0=no sensation; 100=pain threshold; 200=intolerable) and unpleasantness (-100=extremely unpleasant; +100=extremely pleasant) were collected after each trial during the behavioral session. Behavioral and autonomic data were processed and statistically analyzed using, SPSS, AcqKnowledge, and Matlab. Functional MRI data where preprocessed and statistically analyzed using FSL with a cluster correction of $z>2.3$, $p<0.05$, fixed effects.
Results: The patient reported no sensations for all trials in both sessions. The average pain intensity and unpleasantness ratings for HCs were 145.4±10.5 and -43.5±14.6. The patient's pattern of autonomic activity (skin conductance response, heart rate, and heart rate variability) was comparable to that of HCs in response to noxious heat. Healthy controls had significantly greater activations within the insula, anterior cingulate, and primary and secondary somatosensory cortices in response to noxious heat compared to the patient ($z>2.3$, $p<0.05$). No region was significantly more active in the patient than controls. Compared to baseline, the patient had significant activation within the mid-anterior-ventral insula ($z>2.3$, $p<0.05$) in response to noxious heat.
Conclusions: The dearth of activation to noxious heat is consistent with the patient's reported insensitivity to pain. The significant activation within the insula in the patient corresponds to the conserved autonomic responses to noxious input, as this region is a site of visceral afferent input. Furthermore, the insular activation suggests that the central nervous system is reactive to noxious input potentially ruling out a peripheral etiology.

Title: Comparison of surfase-based cortical thickness and voxel-based morphometry in chronic pain patients

Authors: *T. LI, T. KAMMA, S. YANG, T. OTA, J. KURATA
Anesthesiol., Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: [Purpose] Surface-based cortical thickness (CT) and voxel-based morphometry (VBM) are the most commonly investigated in gray matter tissues, which could potentially provide valuable information in the neuroplasticity of pain chronification. However, it remains unclear which of those modalities might be more sensitive in the diagnosis of chronic pain. We compared CT and gray matter volume (GMV) between chronic pain patients (CP) from various etiologies and healthy controls (HC), and sought for brain regions showing anatomical correlation with behavioral characteristics. [Methods] We recruited 62 CP (age, 42.3±13.9 yr; 26 males) and 39 HC (age, 36.4±13.1 yr; 29 males), who underwent high-resolution T1-weighted 3T MRI scans at two hospitals in Japan. Each subject completed short-form McGill Pain Questionnaire (MPQ), painDETECT questionnaire, Beck Depression Inventory (BDI), Brief Scale for Psychiatric Problems in Orthopaedic Patients (BS-POP), and Roland Morris Disability Questionnaire (RDQ). The structural data were processed via CAT12 Toolbox (in SPM) to analyze CT and GMV. Those parameters, at a group level, were compared with two-sample t-test with age and gender as covariates. Behavioral correlations were sought with Pearson Correlation Test. ROC curve analysis was performed to evaluate sensitivity and specificity of each parameter in distinguishing CP from HC. [Results] Compared with HC, CP showed decreased total gray matter volume ($P=0.002$), total intracranial volume ($P=0.014$), and mean cortical thickness ($P=0.007$). After a whole-brain comparison, CP showed decreased GMV in the right superior parietal lobule (SPL) ($P_{FWE}=0.018$), right posterior cingulate cortex (PCC), right lingual gyrus, and left superior frontal gyrus ($P<0.001$). Moreover, CP showed decreased CT in the right precuneus ($P_{FWE}=0.005$), bilateral PCC, and right interior temporal gyrus ($P<0.001$). Furthermore, CT in the right precuneus (AUC=0.717) showed slightly higher sensitivity than GMV in the right SPL (AUC=0.712) in distinguishing CP from HC. Age and pain duration was correlated with GMV, whereas painDETECT, MPQ, BDI, BS-POP, RDQ were correlated with CT in CP patients ($P<0.05$). [Conclusion] CT of the right precuneus showed a high potency in diagnosing chronic pain comparable to that of GMV in the same region. Moreover, CT showed

correlations with more behavioral parameters associated with chronic pain than GMV. CT might be a more suitable alternative to GMV in characterizing specific anatomical changes in pain chronification.

Title: Sex-specific abnormalities in functional connectivity in the descending pain modulation system contribute to chronic pain

Authors: *N. R. OSBORNE, J. C. CHENG, R. L. BOSMA, K. S. HEMINGTON, A. ROGACHOV, J. A. KIM, R. D. INMAN, K. D. DAVIS
Krembil Res. Inst., Toronto, ON, Canada

Abstract: Introduction: Pain is a major public health issue that is difficult to treat when chronic. This is likely due to individual differences which are not addressed by current treatments. Individual variability in pain is thought to involve the brain's descending pain modulation system (DPM). In healthy people, brain activity in a key node of the DPM system, the subgenual anterior cingulate cortex (sgACC), is associated with pain habituation (Bingel et al., 2007). Furthermore, functional connectivity (FC) between the sgACC and the DPM system is stronger in women than in men, while sgACC FC with the salience network (SN) is stronger in men than women (Wang et al., 2014). This sgACC FC may explain why healthy women, but not men, show strong adaption and habituation to sustained, repeated pain stimuli (Hashmi and Davis, 2009). However, sex-specific FC of the sgACC with the DPM and SN in patients with chronic pain is not known. Here, we assessed sgACC FC in patients with a chronic pain condition that is more prevalent in men (ankylosing spondylitis (AS)). The study aims were to determine whether sgACC FC with the DPM and SN in AS 1) is abnormal compared to healthy controls and 2) show the sex-differences we previously identified in healthy individuals.
Methods: Patients with AS and age/sex-matched healthy controls provided informed written consent to the study. All participants underwent a 3T MRI session to acquire resting state fMRI data. FC was determined from the sgACC to nodes of the SN and DPM.
Results: We found that FC between sgACC and a region of the SN (anterior MCC) was greater in women with AS compared to healthy women. However, there were no significant differences

in sgACC FC 1) in men with AS compared to healthy men, and 2) between men and women with AS.
Discussion: Our findings reveal that patients with chronic pain have abnormal functional communication between regions of their DPM and SN, and that these abnormalities are sex specific. The increased connectivity of the sgACC with the SN in women with AS is a pattern more typically seen in healthy men than in healthy women, and thus may reflect increased attention to pain in women with AS. Future studies will explore whether FC of the sgACC with the SN represents a vulnerability or propensity to develop chronic pain in AS. This study also provides a foundation to further examine whether chronic pain treatment outcomes are related to individual differences in DPM or SN dysfunction.

Title: Generalization in placebo analgesia

Authors: *L. KAMPERMANN, C. BUECHEL
Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Placebo analgesia refers to a perceived pain relief due to cognitive modulation induced by expectation and experience. The phenomenon is frequently augmented using a conditioning step adding a positive treatment experience aspect. However, there is only little research on how experiences of pain relief are adaptively transferred to similar but novel situations in the future. The principle of generalization, well-studied in the fear domain, has so far only scarcely been linked to placebo analgesia as one form of appetitive learning. However, it is intuitive to assume generalization in this domain as well: having experienced a substantial pain relief from one treatment in the past, one might expect similar outcomes if the features of a novel treatment resemble the ones experienced before. Using a placebo paradigm including conditioning in healthy humans during functional MRI, we treated heat induced tonic pain on capsaicin pretreated skin. We conditioned participants to expect better treatment from one human (depicted by a face cue; CS+) by pairing it with a stronger temperature decrease, i.e. pain relief, than another human face cue (CS-), which was followed by a more subtle decrease. Following conditioning, participants were tested on a circular continuum of eight face cues ranging from

CS+ to CS-, controlled for their perceived similarity using a simple model of the human visual cortex. In this phase, all faces were paired with the more subtle treatment. Pain relief ratings in the generalization phase showed a significant placebo effect, given by stronger relief ratings for the CS+ vs. CS-, accompanied by decaying (placebo) relief with increasing dissimilarity to the CS+. This gradient in the placebo effect was better explained by a Gaussian fit than a uniform null model ($p < .001$). On the neuronal level, general pain relief was associated with changes of neuronal activity in regions commonly associated with pain and placebo analgesia. Modelling neuronal representations as Gaussian tunings of activity ranging from CS+ to CS- as a Gaussian shaped curve, we identified regions representing generalization at the neuronal level. We conclude that learned analgesic associations are transferred to novel situations to the degree they resemble previous experiences, thus following the principle of generalization. This finding yields important clinical implications, as controlling similarity of treatment features could be used to foster placebo effects wherever beneficial treatment experiences might be transferred to novel situations.

Title: Topological changes in brain connectivity following visceral inflammation

Authors: *L. M. COLON-PEREZ[1], M. FEBO[2], R. M. CAUDLE[3], J. ZUO[4], Q. ZHOU[4]
[1]Dept. of Psychiatry, [2]Psychiatry Dept., Univ. of Florida, Gainesville, FL; [3]Dept Oral Surg, UFCD, Gainesville, FL; [4]Veteran Affairs, Malcom Randall VAMC, Gainesville, FL

Abstract: Recently, the relationship between brain and external immune signaling has elicited interest from researchers. The brain-immune system relationship is complex one with evidence that alterations in one elicits changes in the other and vice versa. In particular, visceral inflammation may provide measurable and significant changes in brain connectivity and organization. To this end Sprague Dawley rats underwent colonic infusion of 20mg trinitrobenzene sulfonic acid and were scanned following visceral inflammation. On the scanning day, rats were induced using 3-4% isoflurane after induction, the anesthesia was lowered to 1.5% isoflurane during scanning. MR images were acquired in a 4.7T/33cm horizontal bore magnet. The MR imaging consisted on resting state scan using a 2-shot spin echo EPI sequence and an anatomical image for image overlay and reference-to-atlas registration. The images were aligned

with a rat brain template, corrected slice timing delays and slight displacements, and time series spikes were removed. Linear and quadratic detrending, spatial blurring, intensity normalization was also performed, and voxelwise temporal band-pass filter (between 0.01 Hz and 0.1 Hz) was applied to the fMRI data. Time series fMRI signals were extracted from each region of interest (ROI) based on the atlas-guided seed location (150 total areas, equally divided in left and right representations of each region) to create symmetrical connectivity graphs. The graphs were thresholded for each subject to create matrices with equal densities (e.g., z values in the top 15% of all possible correlation coefficients). Our results show differences in several brain regions such as: striatum, thalamus, amygdala, hypothalamus and several cortical areas in network features such as node degree, clustering coefficient, and modularity. A t-test of functional connectivity between control and inflamed rats employing the infralimbic cortex displayed positive correlation with 1283 voxels (41.87 mm^3), while 1488 voxels (48.56 mm^3) displayed negative correlation out a total of 68526 voxels (2236.17 mm^3) in the entire brain (correlations $Z > 2.38$, $p < 0.05$). Meanwhile a similar analysis using the thalamus displayed positive correlation with 1804 voxels (58.87 mm^3), while 1269 voxels (41.41 mm^3) displayed negative correlation out a total of 68526 voxels (2236.17 mm^3) in the entire brain (correlations $Z > 2.38$, $p < 0.05$). Our results imply that visceral inflammation elicits several changes in brain connectivity in several autonomic relevant brain regions in turn inducing large scale alterations of topological indices of network connectivity.

Title: The relationship of Sensorimotor Peak Alpha Frequency to regions across the brain is modulated by pain

Authors: *A. FURMAN, S. KRIMMEL, J. ZHANG, M. KEASER, R. GULLAPALLI, D. SEMINOWICZ
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Objective markers of pain sensitivity represent a key tool for identifying individuals who may be at high risk for developing chronic pain. Sensorimotor peak alpha frequency (PAF), the frequency band within the 8-12 Hz alpha range that displays maximal power, may represent one such marker; previous work from our lab has shown that EEG-recorded sensorimotor PAF could predict reported pain intensities to a painful event occurring either 45 minutes or 4 days

later. Understanding how sensorimotor PAF modulates brain activity represents an important avenue for increased understanding of the mechanisms that generate individual differences in pain sensitivity. To address this question we use combined EEG-fMRI (n=10) to probe the relationship between sensorimotor PAF and brain activity during a baseline, eyes-closed resting state scan and a capsaicin heat-pain, eyes-closed resting state scan. Following EEG artifact correction, we extracted PAF from electrodes over sensorimotor cortex and created a PAF timeseries by calculating PAF within 2 second epochs that matched the MRI TR (237 time steps for each scan). We convolved this PAF timeseries with a canonical HRF and treated it as a regressor, predicting each voxel's timeseries. At baseline, PAF positively predicted fMRI in supramarginal gyrus, sensorimotor cortex, cuneus, thalamus, dorsal anterior cingulate cortex (ACC) and negatively in subgenual ACC, precuneus, and lateral prefrontal cortices. These effects tended to be small to moderate. After inducing capsaicin heat-pain, PAF positively predicted a similar set of regions as without capsaicin, but the effects were much larger. After capsaicin, PAF negatively predicted fMRI in rostral ACC, angular gyrus, precuneus, and lateral prefrontal cortex with effect sizes largely equivalent to baseline. In conclusion, we provide analysis from a pilot study relating PAF to spontaneous fMRI signals across the brain and demonstrate the feasibility of this approach. Our results suggest that sensorimotor PAF coupling across the brain is altered by pain, giving a possible mechanism through which PAF affects pain sensitivity.

Title: Abnormal hippocampal and amygdalar volume in children with chronic pain

Authors: *M. MOAYEDI[1], S. LEE[2], L. J. AYOUB[2], J. VINALL[3], C. LEBEL[4], M. NOEL[3]
[1]Fac. of Dent., [2]Univ. of Toronto, Toronto, ON, Canada; [3]Univ. of Calgary, Calgary, AB, Canada; [4]Radiology, Alberta Children's Hosp., Calgary, AB, Canada

Abstract: Pediatric chronic pain affects one in five children. Despite its prevalence, there are few studies investigating brain abnormalities in adolescents with chronic pain. More specifically, there have been many studies investigating brain structure and function in adults with chronic pain. However, these data cannot be extrapolated to pediatric populations. Therefore, there is a need to investigate whether the brain abnormalities present in adults with chronic pain are also present in pediatric pain populations. Recent pain studies in rodents and adult populations have identified that the hippocampus (HC) and amygdala (Amyg) are abnormal in chronic pain, and that abnormalities in these regions predict the transition to chronic pain, and even treatment responsiveness. Specifically, smaller HC/Amyg predict whether an adult with subacute back pain will transition to chronic pain. Here, we explicitly test whether adolescents with chronic pain have smaller HC/Amyg volumes. All procedures have been approved by local ethics committees. Nine adolescents with chronic headache, including migraine (3 girls, 6 boys; 14.77+/- 2.9 (mean+/-SD) years old) and 14 healthy controls (9 girls, 3 boys; 12.80 +/- 2.0 (mean+/-SD) years old). Participants underwent brain scanning at the Alberta Children's Hospital on a General Electric 3 T MR750w system using a 32-channel head coil. A high-resolution 3-dimensional T1-weighted structural MRI scan was acquired for every participant (TR= 8.2 ms, TE= 3.2 ms, 0.8mm isotropic). The structural brain images were analyzed using Freesurfer v6.0. Images underwent standard preprocessing, and bilateral HC and Amyg volumes were extracted. An unpaired two-tailed t-test with Welch's correction for uneven variances was used to determine whether the HC and Amyg volumes were different between healthy adolescents and those with chronic pain. Statistical threshold was set at $p<0.05$. We found that the left Amyg and bilateral HC were significantly smaller in those with chronic pain, compared to healthy adolescents. These data indicate that pediatric chronic pain is associated with abnormal limbic brain regions. Future studies should investigate the functional and behavioural significance of these structural abnormalities.

Title: A pivotal role for the cerebellum in connectomic plasticity of chronic pain patients

Authors: T. KAMMA[1], T. LI[1], T. OTA[1], S. YANG[1], E. SHINTO[1], K. YAMAMOTO[2], *J. KURATA[3]
[1]Anesthesiol., [2]Otolaryngology, Tokyo Med. and Dent. Univ., Tokyo, Japan; [3]Anesthesiol., Tokyo Med. and Dent. Univ. Hosp. of Med., Tokyo, Japan

Abstract: [Introduction] Although some plastic changes in brain network function are involved in chronification of pain, evidence from comprehensive analysis of brain connectomics has been scarce to date. Here we examined functional connectivity across all the brain networks in chronic pain patients to be compared with that in healthy controls, and further sought for its correlations with behavioral parameters. [Methods] We recruited 22 chronic pain patients and 17 healthy volunteers. Each subject underwent several psychophysical tests and multimodal magnetic resonance imaging (MRI) on a 3T scanner, including resting-state functional and 3-dimensional high-resolution MRI. Functional connectivity was comprehensively examined across all the pairs of predefined 116 regions of interest from the Automated Anatomical Labeling atlas and compared between the groups (FDR $p<0.05$) using SPM12 and CONN software. Correlations were sought between functional connectivity and various psychophysical parameters while age and sex were set as covariates (FDR $p<0.05$). [Results] We found six networks with significantly increased and one with decreased functional connectivity, all of which involving part of the cerebellum, in chronic pain patients vs. controls. The cerebellum also showed changes in functional connectivity depending on psychophysical parameters: with the right temporal pole depending on pain intensity ($r=0.703$); right orbitofrontal cortex on pain duration ($r=0.723$); right caudate nucleus on Pain Catastrophizing Scale scores ($r=-0.693$); left amygdala on painDETECT scores ($r=-0.712$); and right parietal lobule on McGill Pain Questionnaire scores ($r=-0.708$). [Discussion] Although roles for the cerebellum in pain processing remain to be determined, many earlier neuroimaging studies have shown cerebellar responses to noxious stimulation. The current study implied that chronification of pain involved specific changes in network plasticity between the cerebellum and emotion- or sensory-related regions in association with various behavioral profiles. The cerebellum might possibly play a pivotal role in the supraspinal mechanisms of pain chronification.

Title: Pain modulation is associated with cingulate morphology in older adults with musculoskeletal pain

Authors: *D. LUSSIER[1,2], M. HORTA[2], E. C. PORGES[3], A. J. WOODS[3], R. COHEN[3], N. C. EBNER[2,3], Y. CRUZ-ALMEIDA[3,5,4]
[2]Psychology, [3]Cognitive Aging & Memory Translational Program, [4]Dept. of Neurosci., [1]Univ. of Florida, Gainesville, FL; [5]Dept. of Aging and Geriatric Res., Inst. on Aging, Gainesville, FL

Abstract: Introduction: Musculoskeletal pain negatively impacts older individuals and is often associated with deficient pain modulation. Multiple brain regions are responsible for pain modulation, but the cingulate cortices (CC) play a significant role with abnormal morphology reported across various pain conditions. While age-related changes in CC structure and function have also been reported, the relationship between CC morphology and pain modulation in older individuals is not currently understood. The present study aims to determine CC volumetric correlates of pain modulation in older adults using self-reported and experimental pain measures. **Methods:** Volunteers (n=40, mean age=71.4 years) within the Neuromodulatory Examination of Pain and Mobility Across the Lifespan (NEPAL) study completed the Graded Chronic Pain Scale (GCPS), a pain modulation procedure (punctate Temporal Summation (TS)), and a structural T1-weighted MRI. We used Freesurfer's *recon-all* to perform whole-brain structural segmentation and obtain volumetric statistics. The residual method was applied to control for intracranial volume with adjusted volumes of interest (VOIs) created for the anterior (A)CC gray matter (GM), mid-ACC GM, mid (M)CC GM, mid-posterior (P)CC GM, PCC GM, caudal ACC WM, rostral ACC WM, and PCC WM. We conducted bivariate and partial correlations of adjusted VOIs with GCPS intensity and disability subscales and TS scores. **Results:** MCC GM volumes were positively correlated with GCPS pain disability ($r = 0.341$, $p = 0.036$), but no correlations were found for any VOI with GCPS pain intensity ($ps > 0.05$). Volumes of mid-PCC GM ($r = -0.38$, $p = 0.018$), mid-ACC GM ($r = -0.390$, $p = 0.021$), left caudal ACC WM ($r = -0.356$, $p = 0.036$), and right rostral ACC WM ($r = -0.355$, $p = 0.036$) were negatively correlated with TS scores. Controlling for sex, age, and education resulted in comparable findings. **Conclusion:** The CC's key role in cognition, affect, and emotion likely accounts for its associations with pain disability, a construct encompassing pain's overall impact on everyday life. The findings that lower GM and WM CC volumes were associated with higher TS scores suggests that brain plasticity may be negatively impacted by pain, above and beyond the impact of aging. In younger samples, pain modulation using TS has been implicated as a key mechanism underlying chronification of pain; and this process may also occur in older individuals. Future research is needed to directly link the role of brain morphology to chronic pain in older adults. Understanding the neurocorrelates of pain in aging has the potential to inform treatment and improve quality of life in later years.

Title: Associations of pain catastrophizing with pain-related brain structure in individuals from different race groups with or at risk for knee osteoarthritis

Authors: *E. L. TERRY[1,2], J. J. TANNER[3], J. S. CARDOSO[2], K. T. SIBILLE[2], S. LAI[4], H. DESHPANDE[5], G. DEUTSCH[5], B. R. GOODIN[6], L. A. BRADLEY[7], C. C. PRICE[3], R. B. FILLINGIM[2]

Psychology, [4]Dept. of Radiation Oncology; CTSI Human Imaging Core, Univ. of Florida, Gainesville, FL; [5]Div. of Mol. Imaging and Therapeutics; Div. of Advanced Med. Imaging Res., [6]Dept. of Psychology, [7]Div. of Clin. Immunol. & Rheumatology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Research provides compelling evidence that non-Hispanic Blacks (NHB) engage in pain catastrophizing (a maladaptive tendency to negatively evaluate one's ability to cope with pain) more often than non-Hispanic Whites (NHW), while NHWs more often use other strategies (e.g., ignoring sensations). These differences may represent an important contributor to poorer pain-related treatment outcomes and greater functional disability in NHBs. Functional neuroimaging studies have revealed that individuals with high levels of trait pain catastrophizing show increased cerebral responses to pain in several pain-related brain regions (e.g., insula, primary somatosensory cortex [S1]), but associations between brain structure and pain catastrophizing remain largely unexplored. Moreover, to date, no neuroimaging studies have investigated the extent to which the influence of pain catastrophizing on pain-related brain regions contribute to ethnic group differences in pain responses. The current project is a sub-study of an ongoing observational cohort investigation conducted by the University of Florida (UF) and the University of Alabama at Birmingham (UAB). Participants were 176 community-dwelling adults between 45 and 85 years old with and without knee pain, including 76 NHB (15

without knee pain) and 100 NHW (33 without knee pain). All participants completed the pain catastrophizing subscale of the Coping Strategies Questionnaire-Revised and Magnetic Resonance Imaging (MRI) data were obtained. High-resolution anatomical MRI (T1-weighted MP-RAGE, 1mm3 resolution) data were acquired at both sites on a 3 Tesla Philips Achieva. Images were processed using FreeSurfer 6.0 (Fischl, 2012). Mean thickness values for each cortical region (i.e., insula, S1; DKT parcellation) were exported to SPSS software, version 24 (IBM, Chicago, IL) for analyses. Partial correlation analyses within race groups were conducted and adjusted for the following covariates: age, education, body mass index, and study site. Results revealed higher pain catastrophizing was associated with thinner left insula ($p < .05$) in NHB participants with or at risk of knee osteoarthritis (OA), while higher pain catastrophizing was associated with thinner S1 bilaterally (ps $< .05$) in NHW participants with or at risk for knee OA. However, there were no significant associations in brain regions (i.e., insula, S1) for either race in the control groups (participants without knee pain) (ps $> .05$). These results suggest that pain catastrophizing might have differing effects on pain-related central pathways and may contribute to ethnic group differences in individuals with or at risk for knee OA.

Title: Specific neural correlates underlie improved clinical outcomes in chronic pain patients following interdisciplinary pain management

Authors: *R. JABAKHANJI[1], C. M. GAGNON[2], P. SCHOLTEN[2], J. W. ATCHISON[2], M. N. BALIKI[2]
[1]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]The Shirley Ryan AbilityLab, Chicago, IL

Abstract: Chronic pain is associated with maladaptive brain functional and anatomical changes. However, brain mechanisms underlying successful pain rehabilitation remain unknown. Here we use anatomical and resting-state functional MRI (rs-fMRI) to examine brain changes associated with improved pain, emotional and ability outcomes in chronic pain patients following a 4 week interdisciplinary pain management program.

25 patients with chronic pain underwent anatomical and rs-fMRI scans at baseline and at the conclusion of the treatment which included pain education, biofeedback, occupational and physical therapy. Behavioral and functional properties were measured using self-reported questionnaires and included pain intensity, central sensitization, pain related anxiety, depression, and disability. We performed a Principle Component Analysis to identify similarities in clinical outcomes. Changes in functional connectivity were assessed using standard graph-theoretical measures. Differences in global and local anatomical properties were computed using standard FSL tools.

Patients showed significant improvement of pain, emotional and functional parameters. PCA identified two factors accounting for 69% of the variance. Factor 1 correlated with pain and emotional improvements including pain intensity, central sensitization, depression, pain related anxiety and catastrophizing. Factor 2 correlated with increased pain coping and daily function. Brain networks of patients exhibited small world properties with high efficiency and clustering not changing following treatment. Their functional connectivity showed increased similarity to healthy subjects following treatment. Factor 1 correlated with decreased Default-Mode Network connectivity with the Saliency Network, Fronto-Parietal network and subcortical regions. No significant connectivity changes were observed for Factor 2.

Patients showed significant increase in Gray Matter Volume following treatment which correlates with Factor 1, but not Factor 2. Factor 1 significantly correlates with increased Grey Matter Density in the right DLPFC, part of FPN, and rostral ACC. Factor 2 was associated with increased GMD in the Thalamus and the Ventral Striatum, centered in the NAC and extending into the Caudate and Putamen.

These results suggest that pain rehabilitation is associated with changes in two behavioral clusters with unique central representations, and provide insight into key neural mechanisms underlying successful pain rehabilitation, which may facilitate the development of behavioral-specific and personalized treatments.

Abstract: Time discounting (TD), a topic of behavioral economics, is a tendency to assign less value to future gains than to present ones. High TD rate is represented in an impulsive personality, which is a risk of substance abuse and addiction. Impulsiveness is also a characteristic aspect of chronic pain (CP) patients. However, little is known about involvement of TD in CP. Furthermore, neuro-mechanism underlying TD is unclear at all. Hereby we investigated the resting-state brain function associated with TD both in CP patients and healthy subjects. Nineteen chronic neck pain patients (pain intensity > 4/10, pain duration > 3 months) and 19 healthy subjects matched for age and gender were recruited. We identified similarity and differences in the brain functional connections underlying TD in healthy and CP with FDR-adjusted p value (< 0.05) and cluster threshold (< 2 links). Finally, we demonstrated mediation analyses to investigate relationship among behavior, brain function, and TD. Behaviorally, TD showed significant correlation with meaningfulness in healthy ($R = 0.41$, $p < 0.01$), but not in CP patients ($R = 0.35$, $p = 0.49$). TD in patients only correlated with pain intensity ($R = 0.56$, $p < 0.01$). Connectivity analysis based on 333 regions of interest (ROIs) in healthy identified 45 links and 51 ROIs significantly relating to TD. When predetermined 13 communities were assigned to each ROIs, the default mode network (DMN) was the community with the most connections (6 links between 8 ROIs) and every links were included in the prefrontal cortex (PFC). The specific network within DMN significantly correlated to TD ($R = 0.89$, $p < 0.01$) and mediated the effect of meaningfulness on TD significantly (indirect effect (IE) = -0.62, 95% confidential interval (CI) = [-1.24, -0.21]). On the other hand, 10 links and 12 ROIs were identified in CP patients as the network significantly related to TD, and they had no overlap with the links in healthy subjects. The right dorsolateral prefrontal cortex (DLPFC) in the cinguro-opacular network was a notable ROI gathering the most connections (7 links) of them. The network of the DLPFC was significantly correlated to TD ($R = 0.83$, $p < 0.01$) and mediated the effect of pain on TD (IE = 0.49, 95% CI = [0.16, 1.12]). CP patients have different behavioral associations and resting-state brain networks underlying TD compared to healthy subjects. While the DMN in PFC is a key network associated with TD in healthy, the DLPFC plays a significant role in TD in CP patients.

Title: Predicting placebo pills response in randomized controlled trials

Authors: E. VACHON-PRESSEAU[1], T. B. ABDULLAH[2], S. E. BERGER[3], L. HUANG, 60611[1], G. A. CECCHI[5], T. J. SCHNITZER, 60611[1], *A. V. APKARIAN[4]

Abstract: Objective
Placebo response is universally observed in randomized controlled trials (RCTs), yet the individual characteristics rendering a chronic pain patient 'placebo responder' remains minimally understood. We used a prospective neuroimaging-based RCT performed in chronic back pain patients to build a model predictive of placebo response. In a second neuroimaging-based RCT, we evaluate the interaction between placebo response and medication treatment in individuals stratified as placebo responders vs non-responders based on our predictive model. Here, we present the model and its accuracy in a second cohorts of patients.
Methods
A first prospective cohort study (N = 63) included a neuroimaging session and a large battery of questionnaires assessing personality traits prior to repeated 2-weeks placebo treatment periods. A predictive model of placebo response was built from a logistic regression weighting the parameters dissociating placebo responders and non-responders prior to treatment. We applied the model in a second cohort study, were chronic back pain patients (N = 90) were stratified into placebo responders and non-responders based on brain scan and questionnaire results at entry. These participants were randomized so that 40% received placebo treatment, 40% active medication (naproxen 500mg bid), and 20% no treatment. The treatment duration of this second study was fixed to 6 weeks.
Results
In a first prospective neuroimaging-based RCT, we identified brain parameters and personality traits that predict the propensity for placebo response. Placebo response depended both on functional coupling of the ventrolateral prefrontal cortex (VLPFC) and the dorsolateral prefrontal cortex (DLPFC) with the periaqueductal grey (PAG) and the precentral gyrus (PreCG); and a set of psychological factors including interoceptive awareness and emotion regulation. We used these parameters to stratified patients from the second prospective neuroimaging-based RCT at

entry. This second study is now closed to enrolment and the model accuracy will be presented at the conference.

Conclusions

We showed that functional connectivity between the VLPFC and DLPFC with the PAG and the PreCG as well as interoceptive awareness and emotion regulation predicted placebo pills response. The generalizability of the model is currently tested in a second group of chronic back pain patients.

Title: Cortical output is driven by transcolumnar pathways in deep layers

Authors: *M. OBERLAENDER[1], R. EGGER[1,2], R. T. NARAYANAN[1], A. BAST[1], D. UDVARY[1], C. P. J. DE KOCK[3]

Abstract: Pyramidal tract neurons (PTs) broadcast the results of cortical processing to a variety of downstream targets throughout the brain. Unraveling mechanisms that drive activity in this major output cell type of the neocortex will thus be essential for understanding how cortical computations orchestrate sensory-guided behaviors. The origin of the PTs' sensory-evoked responses - which are the most broadly-tuned within a cortical column, and which can be as fast as those in the major input layer (L4) of the cortex - remains, however, enigmatic within the present concepts of cortical circuit organization. We find that thalamocortical input drives two orthogonally organized cortical circuits in parallel: the columnar pathway in L4, and a transcolumnar pathway in the deep layers (L5/6). We show that the transcolumnar pathway drives PTs during sensory stimulation, potentially to switch these neurons into an excited state that is required for transforming inputs from recurrent and top-down circuits into behavioral responses.

Title: Towards a microcircuit-based understanding of multiplexed spike codes in the neocortex

Authors: *M. TRAN, L. PRINCE, D. GREY, H. CHASIOTIS, B. RICHARDS
Univ. of Toronto, Toronto, ON, Canada

Abstract: Information about the world is communicated by populations of neurons through their action potentials, or spikes. Deciphering the 'neural code', i.e. the patterns of spikes used to carry information, is a major goal in neuroscience. Currently there exists two hypotheses about how spikes convey information: 1) through the rate of spikes (i.e. a rate code) or, 2) through the precise timing of spikes (i.e. a temporal code). Evidence suggests that neocortical circuits can use both codes, specifically that both the rate and temporal synchrony of spikes are important for information transmission in sensory circuits. An unresolved question is whether there is any microcircuit-based multiplexing, i.e. a separation between the information transmitted by rate and synchrony codes at the microcircuit level. Here, we test the hypothesis that two broad classes of inhibitory interneurons in the neocortex, somatostatin positive (SST+) and parvalbumin positive (PV+) interneurons, are specialized for integrating rate and synchrony codes respectively. To test this, we combined optogenetics with patterned illumination to experimentally control spike rate and synchrony of channelrhodopsin-2 positive (ChR2+) pyramidal neurons in L2/3 of the barrel cortex ex vivo. Cellular responses were then analyzed using machine learning and information theoretic analyses to determine how much information each class of cell carries when receiving information encoded using rate or synchrony codes. We find that there are differences in the amount of information carried by different neuron subtypes, supporting the idea of microcircuit-based multiplexing in the neocortex.

Title: Basal forebrain stimulation modulates vibrotactile responses of rat SI neurons based on cell type, layer, and in a time-dependent manner

Authors: *B. VARDAR, B. GÜÇLÜ
Inst. of Biomed. Engin., Bogazici Univ., Istanbul, Turkey

Abstract: Cholinergic system is thought to increase the effectiveness of sensory inputs in cortex by promoting attention and arousal. Basal forebrain (BF) is the main source of cholinergic projections to the cortex. We electrically stimulated BF of ketamine-anesthetized rats while recording single-unit (n=87) spike activity in the hindpaw representation of SI cortex. The vibrotactile responses were measured with (ON) and without (OFF) BF stimulation (0.5-ms bipolar pulses at 100 Hz; duration: 0.5 s; amplitude: 50 µA). BF stimulation just preceded the vibrotactile stimuli applied on the glabrous skin of the hindpaw (bursts of 5-, 40-, and 250-Hz sinusoidal displacements; duration: 0.5 s; amplitude: 50 µm) in each trial. Each condition was repeated for 10 trials and long-term changes were assessed by performing the entire procedure once again after a 30-minute break. Average firing rates were calculated for different time periods (R_b: background; R_o: during the initial 100-ms of vibrotactile stimulus duration, R_d*: during the last 400-ms of vibrotactile stimulus duration). To quantify entrainment, vector strengths (VS) were calculated for the entire vibrotactile stimulus duration. The short and long-term (after 30 min) effects of BF activation were analyzed for different cells (regular-spiking (RS) and fast-spiking (FS)), vibrotactile frequencies and cortical layers (III, IV, V, VI) by using repeated measures ANOVA. BF activation had both short- and long-term significant effects on entrainment. When first and second runs were compared in terms of VS change in ON vs. OFF, a significant interaction was found between time block, layer and cell type ($p=0.009$). For example, VS of both RS and FS neurons in layer III increased, albeit in different amounts, due to BF stimulation in the second run. However, BF stimulation decreased VS of both neurons in the first run. BF activation did not cause significant main effects (regardless of cell type and layer) on the firing rate measures (including R_b). On the other hand, significant interaction effects between time block (first run ON vs. second run ON), layer and neuron were found on R_d*-R_b and R_o-R_b ($p=0.027$ and $p=0.04$, respectively). These results indicate that BF activation enhances VS in the second run, thus vibrotactile periodicity becomes more prominent. Consistent with previous studies, the effects of BF activation on firing rate developed over time. The main

novelty of current study is that the long-term effects of cholinergic activation are shown to be also dependent on cell type and layer, probably due to the projection pattern from BF.

Title: The cellular composition and connectivity of neocortical layer 1

Authors: *B. SCHUMAN[1], R. MACHOLD[1], Y. HASHIKAWA[1], J. FUZIK[1], G. J. FISHELL[2], B. RUDY[1]

Abstract: Animals must sense and internally represent their surroundings to guide and adjust the behaviors necessary for survival. This process requires the means to interpret sensory information in different internal and environmental contexts. In the mammalian brain, the integration of sensory and contextual signals depends upon computations performed in the neocortex. The outermost neocortical layer (layer 1; L1), contains the distal tuft dendrites of pyramidal cells and receives contextual input from a diversity of regions, including higher-order thalamic nuclei, higher-order cortical areas, neuromodulatory sources, contralateral cortex, and other sensory cortical areas carrying cross-modal input. In addition, L1 contains the dendrites of L2 VIP and chandelier interneurons, and the axons of somatostatin (SST) interneurons in L2-6. Importantly, L1 contains cells that are exclusively inhibitory interneurons and are known to be functionally important for the processing and gating of contextual information. However, the precise role that L1 interneurons play in integrating contextual and sensory information is a mystery because their identities are poorly understood. Starting with utilizing a combination of transgenic mouse lines and genetic tools to investigate the identity of these cells, we found that L1 contains four distinct populations of interneurons, including one - canopy cells - first described here. These interneuron populations can be separated and genetically targeted by their expression of neuropeptide Y (NPY), neuron-derived neurotrophic factor (NDNF), vasoactive intestinal peptide (VIP), and strong expression of the α7 nicotinic receptor (α7). Whole cell recordings in brain slices revealed that each cell population has a distinct intrinsic

electrophysiology, morphology, and connectivity, strongly suggesting that a division of labor exists for L1 interneurons in processing contextual information.

Title: The missing piece of somatosensory evoked potentials (SSEPs): Difference between activation and phase resetting according to a stereo-EEG perspective

Authors: *M. DEL VECCHIO[1], F. CARUANA[2], I. SARTORI[3], V. PELLICCIA[3], G. LO RUSSO[3], G. RIZZOLATTI[2], P. AVANZINI[2]

Abstract: In the present study, we mapped the spatio-temporal dynamics of cortical responses to ipsilateral median nerve stimulation using intracerebral recordings (stereo-EEG) in 38 drug-resistant epileptic patients by examining the increase of power in gamma band. Overall, 50 hemispheres have been explored (28 right, 22 left) including 5872 cortical sites of which 4466 were localized in the grey matter according to the anatomical reconstruction (2783 in the right hemisphere, 1683 in the left hemisphere). The 37 responsive leads were almost exclusively located in the parietal operculum and in particular in its dorso-caudal part corresponding to area OP1. Active leads were found bilaterally in the frontal operculum and in the long gyri of the right insular cortex while only residual activity was found in right inferior parietal cortex (2 leads), left short gyri of insular cortex (2), right premotor dorsal cortex (1) and in primary somatosensory cortex (2). Since previous findings are mostly based on SSEPs recording and identified active clusters in primary somatosensory cortex but inconsistently across subjects and topography, inter-trial coherence (5-145 Hz) was computed for all leads to bridge the gap with existing EEG/MEG literature about somatosensory processing. Results indicated a weak broadband gamma phase-resetting in SI and PMd while opercular and insular regions showed a diffuse response in sub-gamma frequencies. The phase synchronization in gamma band can not be considered as a measure of neuronal recruitment in absence of a significant gamma power increase, thus suggesting that it reflects a transcallosal echo originating from the activation of the contralateral homologue cortical area. This point was hindered so far by methodological constraints. The use of stereo-EEG, instead, allows one to distinguish power increase from phase

synchronization phenomena, offering a valuable insight for interpreting non invasively recorded findings and thus complementing the classical view about the somatosensory system organisation.

Title: The building blocks of first order thalamic nuclei

Authors: *J. YI[1], R. PERIN[1], Y. SHI[2], H. MARKRAM[2]
[1]EPFL, Lausanne, Switzerland; [2]Blue Brain Project, Geneva, Switzerland

Abstract: The lateral geniculate nucleus (LGN) and the ventrobasal (VB) thalamic nuclei in rodents, receiving visual and somatosensory modalities respectively, share similarities in relay morphology and electrical properties. Further comparisons have not been thoroughly investigated. The three distinct morphological types of relay neurons of the LGN are organized within the nucleus based on regional preferences (Krahe et al., 2011). However, the microscopic organization of the VB is currently unknown. In addition, interneurons of the LGN represent 15-20% of the neuronal population (Arcelli et al., 1997). The VB has been reported to contain a local interneuron population percentage ranging from less than 1% (Arcelli et al.,1997) to (3.7%; Cavdar et al., 2014). Given the sparse distribution of interneurons in the VB, their properties and contributions to thalamic functions have been overlooked. However, the morphologies of their LGN counterparts suggest a profound influence on thalamocortical relay excitatory tone throughout the nucleus (Hamos et al., 1985). Thus, a comparison of relay organization and interneuron functionality remains to be completed. Here, we obtained acute slice whole cell recordings and morphologies of VB relay cells and local interneurons of juvenile Wistar han rats and GAD67-eGFP mice. We confirm that relay and interneuron cell types across the LGN and VB are identical. Furthermore, we demonstrate the presence of feedforward inhibition from local interneurons in the VB in response to medial lemniscus electrical stimulation. By isolating excitatory and inhibitory postsynaptic currents, we elucidate two temporal arrangements of feedforward inhibition, paralleling the spatial and temporal arrangements of relay cells and interneurons of the LGN (Blitz and Regehr, 2005). We also investigated the microscopic structure of the VB in juvenile rats using the golgi-cox staining method in serial slices traversing the nucleus and charted the regional preferences of each morphological type. Our results suggests that there is a universality of the building blocks of first order thalamic nuclei, despite

their different densities of cell types. The distinctions between the LGN and VB lie in the proportion of relay cells to interneurons and functional topography. These differences in circuit complexity may be the determinants of how different sensory modalities are perceived. The data gathered from the single cell characteristics and organization of VB cell types are being integrated into an *in silico* model of the somatosensory cortex (Markram et al. 2015) to reconstruct and simulate thalamic nuclei and thalamocortical interactions.

Title: Steady-state responses in the somatosensory system interact with intrinsic oscillatory activity

Authors: *M. J. WÄLTI[1], M. T. BÄCHINGER[2], N. WENDEROTH[3]
[1]Zuerich, Switzerland; [2]ETH Zürich, Neural Control of Movement Lab., Zürich, Switzerland; [3]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland

Abstract: Brain oscillations have been related to many aspects of human behavior. To understand whether there is a causal relationship, it is of great importance to develop methods for modulating ongoing neural activity. It has been shown that external rhythmic stimulation leads to an oscillatory brain response that follows the temporal structure of the presented stimulus and is assumed to reflect the synchronization of ongoing neural oscillations with the stimulation rhythm. This interaction between individual brain activity and the so called steady-state response (SSR) to rhythmic stimulation is the fundamental implication of neural entrainment.Here we investigate whether neural responses to rhythmic vibrotactile stimulation, measured with EEG, are dependent on ongoing individual brain oscillations, and therefore reflect entrained oscillatory activity. We measured aspects of the SSR such as amplitude magnitude and phase synchronization in response to rhythmic stimulation across various frequencies in the alpha (6 Hz - 14 Hz) and beta (16 Hz - 24 Hz) band. To inspect dose-response relationships, three different stimulation intensities were applied for each frequency relative to the individual sensory threshold. Individual alpha and beta frequencies over motor areas were determined for 28 healthy participants before receiving vibrotactile stimulation to the index finger of the dominant hand. We assessed for each participant the EEG electrode over the somatosensory area that would reveal the strongest frequency-dependent response across all stimulation conditions.We found that a higher stimulation intensity, compared to lower intensities, resulted in greater amplitudes of the SSR's, and a more pronounced phase synchronization with the stimulation signal.

Moreover, EEG responses to stimulation frequencies closer to individual peak frequencies within the alpha and beta band showed bigger amplitudes and revealed a higher degree of phase synchronization, compared to stimulation conditions with frequencies that were more distant to intrinsic oscillations. Our findings provide evidence that the efficacy of rhythmic vibrotactile stimulation to evoke a SSR is dependent on ongoing brain oscillations.

Abstract: First-order thalamocortical (TC) pathways provide the main access route for subcortical inputs to the neocortex, while higher-order TC pathways are believed to mainly regulate functional connectivity between cortical areas. These two main types of TC pathways often converge the same cortical columns in complementary laminar patterns. For example, in the vibrissal domain of the rodent primary somatosensory cortex (S1BF), first-order axons from the dorsomedial portion of the ventral posteromedial nucleus (VPMdm) place their synaptic terminals within the barrel domains of layers 4-3, while axons from the higher-order posterior nucleus (Po) target mainly layer 5a and 1. Here, we 3D-reconstructed, measured and compared the main structural parameters of synaptic terminals of axons selectively labeled in S1BF from VPMdm or Po, and their postsynaptic target structures.Virtually all VPMdm and Po synapses are located in boutons. However, VPMdm boutons show significantly different size, mitochondrial content, and number of synaptic vesicles than Po boutons. A much higher percentage of VPMdm axonal boutons are multi-synaptic. The main (80%) postsynaptic target of boutons from both nuclei are dendritic spines of different morphologies, some of which (5-10%) form large dendritic protrusions inserted into the TC bouton. Both populations have postsynaptic densities of similar area. Along with specific receptor distributions, the above structural features may

significantly contribute to differences in efficacy and/or dynamic properties between the VPMdm and Po synapses in S1BF.

(KAUST), Thuwal, Saudi Arabia

Abstract: Neuronal activity in primary sensory areas of the thalamus varies as a function of the brain or behavioral state. However, whether these changes are associated with state-dependent reorganization of spatial activity patterns in thalamic networks is unclear. To address this issue, we performed functional imaging in the ventral posteromedial (VPM) nucleus of awake, head-restrained mice while monitoring whisking, locomotion, and pupil diameter. We expressed the genetically encoded calcium indicator GCaMP6s in transgenic mice expressing the enzyme Cre recombinase in the majority of VPM neurons and we imaged GCaMP6s signals using two-photon microscopy through a GRIN microendoscope. We found that periods with no locomotor activity and no whisker movement (resting periods) were characterized by calcium activities that were sparsely distributed both across neurons and time. In contrast, during periods of locomotion and whisking in air (active periods), which were frequently preceded by the dilation of the eye pupil, we observed an increase in the frequency and amplitude of calcium events across VPM neurons compared to resting periods. During both resting and active periods, neural ensembles displaying significantly correlated activity over hundreds of microns were observed. On average,

each functional ensemble involved a small fraction of the total number of neurons in the field of view. Moreover, for some of the recorded ensembles their appearance correlated with the behavioral state of the animal, i.e specific ensembles were selectively observed during resting periods while other distinct ensembles were selectively engaged during active periods. Altogether, these results show that in primary somatosensory thalamic nuclei the animal's behavioral state is dynamically and specifically encoded in the spatiotemporal structure of spontaneous neural activity patterns.

Title: Intracranial stereo-EEG reveals gamma-band modulation in the human somatosensory cortex during naturalistic gentle touch to the hairy skin

Authors: *E. ERIKSSON HAGBERG[1], D. KRÝSL[2], J. NILSSON[2], K. MALMGREN[3], B. RYDENHAG[3], J. WESSBERG[1]
[1]Inst. of Neurosci. and Physiol., Sahlgrenska Academy, Univ. of Gothenburg, Gothenburg, Sweden; [2]Dept. of Clin. Neurophysiol., Sahlgrenska Univ. Hosp., Gothenburg, Sweden; [3]Inst. of Neurosci. and Physiol., Dept. of Clin. Neurosci., Sahlgrenska Academy, Univ. of Gothenburg, Gothenburg, Sweden

Abstract: The perception of touch to hairy skin is mediated by slow conducting C-tactile (CT) afferents and fast conducting Aβ afferents. Aβ signals are conveyed to primary (S1) and secondary (S2) somatosensory cortices, whereas previous studies using functional magnetic resonance imaging indicate that CT afferents project to the posterior insula but not to S1 or S2. CTs respond strongly to caress-like stimuli, and are believed to play a key role in signaling pleasantness of touch.
This ongoing study, aims to define the changes in brain oscillations following naturalistic gentle touch to the hairy skin in humans. Furthermore we want to investigate if brain responses due to Aβ and CT afference can be distinguished from one another. We hypothesize that oscillatory changes due to Aβ input should occur at a short latency post stimulation onset, whereas any brain responses, e.g., in the posterior insula, following CT activation should have a late onset.

Data was obtained from 5 adult patients (2 female) with focal refractory epilepsy undergoing intracranial stereo-electroencephalography (SEEG) as part of their pre-surgical evaluation. All patients had electrode implantation in the left hemisphere. The number of electrodes and placement was strictly individualized based on the clinical work up of the patients.
SEEG was recorded during soft brush stroking on the forearm. A trained experimenter manually delivered the stimuli with a hand held soft brush. A minimum of 100 repetitions on both contra- and ipsilateral forearm was carried out. The brushing velocity was CT-optimal, i.e. around 3 cm/s. The timing of brush contact with the skin was recorded using a fiber-optic sensor attached to the brush.
The data was analyzed using a bipolar montage between neighboring electrodes. Electrodes showing epileptiform activity was discarded from the analysis. Preliminary results confirmed that gentle touch to the hairy skin induces alfa and beta event-related desynchronization (ERD) and event-related synchronization (ERS) in primary sensorimotor regions (S1 and primary motor cortex), which we have previously seen using magnetoencephalography (MEG). However, SEEG also revealed gamma band ERS in S1 following gentle touch, which we were unable to detect with MEG in a previous study. One patient in the current sample, had an electrode located in the posterior insula, which showed early onset alfa and beta ERD, and gamma ERS to both contra- and ipsilateral stimulation. Thus far, we have failed to identify any brain activity that appears to be exclusively driven by CTs.

Title: Ultrasonic vocalization and c-Fos expression in rats stimulated by 'affective' touch

Authors: *E. TUNCKOL[1,3], R. S. CANBEYLI[2], B. GUCLU[1]
[1]Biomed. Engin., [2]Psychology, Bogazici Univ., Istanbul, Turkey; [3]Psychology, Istanbul Medipol Univ., Istanbul, Turkey

Abstract: The sense of touch consists of two general functional qualities: discriminative and affective, delivered by myelinated fast-conducting Aβ fibers, and unmyelinated slow-conducting C- tactile afferents, respectively. Gentle stimulation of C- tactile afferents is shown to induce a pleasant feeling and activates emotion-related brain regions such as the insular cortex. In the present study, tactile stimulation was delivered manually with an artist’s brush to the right dorsal trunk of male Wistar rats in slow, moderate, and fast speed (3, 9, and 18 cm/s, respectively).

Each rat received stimulation with the three speeds in different experimental sessions separated by one week with the order of the speeds counterbalanced. Ultrasonic vocalizations emitted throughout the experimental sessions, consisting of 10 minutes of habituation, 5 minutes of stimulation and 5 minutes of post-stimulation periods, were recorded as indices of the affective state. Ninety minutes after the last stimulation, rats were anesthetized and perfused for c-Fos staining. The number of c-Fos expressing cells in rostral periaqueductal gray (PAG), trunk region of primary somatosensory cortex (S1) and posterior insular cortices (PIC) of both hemispheres were counted. The number and duration of ultrasonic vocalizations were analyzed with repeated measures ANOVA to test whether different stimulation speeds altered the affective state of the rats. Rats did not emit calls with positive affect (50 kHz) during the experimental sessions. Results showed that fast stimulation of hairy skin increased the number of negative (22 kHz) vocalizations compared to moderate and slow speeds ($p= 0.011$ and $p= 0.001$, respectively). Similarly, rats produced longer 22-kHz calls when exposed to fast stroking than slow stroking ($p= 0.004$). The unilateral tactile stimulation was found to elevate c-Fos expression in contralateral S1 significantly ($p= 0.002$), and in contralateral PIC marginally ($p=0.051$). Finally, rats receiving stimulation with different speed in their last experimental session, did not significantly differ in terms of c-Fos expression in PAG, S1 and PIC of both hemispheres. These results suggest that the stimulation of hairy skin with gentle strokes at different speeds alters the emotional state of rats as vocalization behavior, albeit in a negative affective manner. On the other hand, static marker of neural activity tested here seems to be not much sensitive to such changes. Since affective touch is mostly relevant during social interaction with the conspecifics, information encoded by C-tactile afferents was probably processed differently in this study compared to previous work on humans.

Title: Architectonic characteristics of the grizzly bear thalamus and superior colliculus

Authors: *L. A. KRUBITZER[1], M. K. BALDWIN[2], A. C. HALLEY[3], N. MARINELLI[4], H. T. JANSEN[5]
[1]UC Davis, Davis, CA; [2]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [3]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [5]IPN, [4]Washington State Univ., Pullman, WA

Abstract: The current work is part of a broader comparative effort to determine how the thalamus has evolved in different lineages with alterations in brain size, sensory specialization, and behavior. In this study, we analyzed the architectonic characteristics of the grizzly bear (*Ursus arctos*) thalamus and superior colliculus using various histological stains. The thalamus was cut coronally at a thickness of 60 microns and saved in series, which were processed for cytochrome oxidase (CO), acetylcholinesterase (AChE), vesicular glutamate transporter 2 (VGLUT2), and Nissl substance. The borders of thalamic nuclei were readily visible in Nissl stained sections while subdivisions within nuclei were revealed in tissue sections processed for AChE, CO, and VGLUT2. Despite being much larger than the thalamus of other well studied carnivores such as ferrets and cats, many features of the grizzly bear thalamus were similar to those of other carnivores. These features include a well laminated lateral geniculate nucleus (LGN), architectonically distinct divisions within the lateral posterior/pulvinar complex, and a modular ventral posterior nucleus (VP). However, the modularity of VP was more complex than that observed in other carnivores, and even more complex than in non-human primates and humans. The superior colliculus shares a similar laminar pattern to that observed in most studied mammals. Thus, despite its size, the grizzly bear has retained many features of a general scheme of organization for the carnivore thalamus and superior colliculus, with some specializations of the ventral posterior nucleus.

Title: Cortical fNIRS hemodynamics during saltatory pneumotactile glabrous hand stimulation in neurotypical adults

Authors: *J. GREENWOOD[1,2,3], M. HOZAN[1,2,3], M. K. SULLIVAN[1,3], S. M. BARLOW[1,2,3]
[1]Ctr. for Brain, Biology, and Behavior, [2]Biol. Systems Engin. Dept., [3]Dept. of Special Educ. and Communication Disorders, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: BACKGROUND: The hemodynamic integrity and responsiveness of the human cerebral cortex can be assessed noninvasively using fNIRS to map the dynamic changes in the concentration of HbO and HbR during somatosensory stimulation (Rosner & Barlow, 2016, Somatosensory & Motor Research).

OBJECTIVE: Assess the effects of controlled saltatory pneumotactile velocity arrays applied to the glabrous hand on evoked cerebral hemodynamic signals using fNIRS. Extending previous fMRI BOLD studies (Oh, 2016, PLOSone), hypotheses include: 1)Primary activation of the hand region of S1/S2/M1 of contralateral hemisphere, 2)Reduced and delayed activation of ipsilateral hemisphere, and 3)Significant HRF scaling dependent on saltatory velocity
METHODS: Prospective study involving 20 adults (19-35 yrs), repetitive saltatory stimulation (60 ms pulses, 8-channels TAC-Cell array) presented in randomized blocks (20s ON, 20s OFF; 10 reps/velocity) at 25 and 45 cm/s on the right glabrous hand initiated at P1 of D2-D5 and traversing the palmar surface of the hand to P1 of D1. The fNIRS signals were acquired (NIRx) at 7.8125 Hz using 16 dual-tipped conical LED optodes (760 & 850 nm) and 20 fiber-optic detectors (52 chan pairs) placed bilaterally over sensorimotor cortex. Anatomic MRI (3T; MPRAGE; 0.5x0.5x1.0 mm) was acquired for fNIRS co-registration using a Polhemus head digitizer. Individual/group comparisons processed using NIRS_SPM.
RESULTS: Based on 5 right-handed subjects (2M/3F, mean age=26.8 yrs), a primary evoked HbO/HbR response peak occurs at 13 seconds on the contralateral hand representation in pre-central (M1) and post-central (S1, S2) cortex, with a significantly larger evoked HbO/HbR response during the higher velocity (45 cm/s) saltatory stimulation condition. The ipsilateral hand sensorimotor cortex manifest an attenuated HRF.
CONCLUSIONS: Non-invasive fNIRS methodology reveals cortical somatosensory topography in response to pulsed saltatory pneumotactile dependent on traverse velocities applied to the glabrous hand.

Title: Primary and higher order inputs are differentially integrated by distinct classes of thalamic reticular neurons

Authors: *R. MARTINEZ-GARCIA, B. VOELCKER, S. L. PATRICK, T. STEVENS, B. W. CONNORS, S. J. CRUIKSHANK
Brown Univ., Providence, RI

Abstract: Primary and higher-order thalamic nuclei are dynamically regulated by inhibitory neurons of the thalamic reticular nucleus (TRN). Knowledge of the cellular composition of TRN, as well as the anatomical and functional organization of its afferent inputs, are fundamental to understanding thalamocortical processing. We previously showed that the somatosensory sector of TRN is composed of neurochemically distinct neuron types that are located in topographically separate zones. Most cells along the medial and lateral edges of TRN expressed somatostatin (SOM) whereas cells in the central zone generally expressed calbindin (Calb). We also found that thalamic inputs to TRN segregated topographically in fairly close alignment with the observed neurochemical pattern. The ventral posterior medial nucleus (VPM), a primary somatosensory region, synapsed on cells in the central Calb-rich zone of TRN. In contrast, higher-order posterior medial (POM) axons targeted the SOM-dense medial and lateral edges of TRN.
We have begun to address how these neurochemically and topographically distinct TRN cell types integrate their respective synaptic inputs. Thus we tested the dynamic features of their glutamatergic synaptic currents and the intrinsic membrane properties and firing characteristics that ultimately shape their postsynaptic outputs. We observed that evoked synaptic currents in central TRN cells (triggered by VPM input, above) were strong but had fast decay kinetics, and these currents depressed deeply with repetitive activation. Conversely, synaptic currents in TRN edge cells (originating from POM) were weaker but had slow decay kinetics, and were more stable in magnitude during repetition. Intrinsically, central TRN cells had leaky membrane

conductances, while edge cells were more electrotonically compact. Finally, central cells were highly bursty, whereas edge cells exhibited weak or no bursting.
We are now testing how these zone-specific synaptic and intrinsic properties interact, potentially leading to distinct integrated responses to primary and higher order thalamic input. We predict that Calb-expressing central TRN cells would be ideal for responding phasically to sensory transients. In contrast, SOM-expressing edge cells should be more capable of integrating temporally distributed higher order signals.

Title: L4 SST function during near-threshold sensory detection

Authors: *N. D. JOHNSON[1], K. MANSON[1], I. KRUGLIKOV[1,2], B. RUDY[1]
[1]Neurosci. Insitutute, NYU Langone Med. Ctr., New York, NY; [2]New York Stem Cell Fndn., New York, NY

Abstract: In sensory cortex, the earliest stages of stimulus-evoked activity are shaped by rapid and powerful inhibition by parvalbumin-expressing interneurons (PV INs) situated in layer 4. Thalamocortical feedforward inhibition serves important computational roles (Gabernet et al., 2005; Yu et al., 2016), but this comes at the cost of completely suppressing principal neuron responses to weaker, less coincident stimuli (Ollerenshaw et al., 2014). Somatostatin-expressing interneurons (SST INs) in L4 are known to show a unique axon targeting profile, with restricted arbors that preferentially innervate L4 PV INs rather than spiny stellate cells or excitatory apical dendrites (Xu et al., 2013; Munoz et al., 2016). Despite these connectivity findings, the possible functional role of L4 SST INs in reducing PV-mediated feedforward inhibition during relevant behaviors remains untested. We use Channelrhodopsin-assisted patching (Munoz & Rudy, 2014) to target L4 SST INs in the barrel cortex of awake mice performing a near-threshold detection task, and recorded phasic stimulus-evoked activity. Using viral expression of halorhodopsin in SST INs and targeted light delivery, we photoinhibit L4 SST signals during cue presentation and relate this manipulation to changes in behavioral performance. We test the hypothesis that SST INs in L4 may act to sensitize L4 principal neurons to weak stimuli by suppressing

thalamocortical feedforward inhibition, and that this function distinguishes SST INs in this layer from the apical dendrite-targeting SST INs of other layers.

Title: Distinct firing properties of adult thalamic reticular neurons

Authors: J. O'MALLEY[1], F. SEIBT[2], *M. BEIERLEIN[3]
[1]Neurobio. and Anat., McGovern Med. Sch. at UTHealth, Houston, TX; [2]Neurobio. & Anat., McGovern Med. Sch. At UTHealth, Houston, TX; [3]Neurobiol & Anat., McGovern Med. Sch. At Uthealth, Houston, TX

Abstract: GABAergic neurons of the thalamic reticular nucleus (TRN) form powerful projections to distinct thalamic nuclei, thereby regulating thalamocortical and corticothalamic processing. Rather than forming a uniform structure, TRN neurons are organized into functionally-specific sub-networks. Furthermore, TRN neurons can be classified based on molecular, anatomical, and physiological properties. While previous work has revealed distinct firing patterns in juvenile animals, it remains unclear if these properties are maintained in the adult. Moreover, the involvement of distinct TRN neuronal subtypes in generating rhythmic thalamic activity is not well understood. To address these questions we performed cell-attached and whole-cell recordings from neurons in the TRN and the adjacent ventrobasal nucleus of the thalamus (VB), in slices derived from 3-4 months old mice. Based on their action potential characteristics, TRN neurons could be classified into two main groups. The majority (73 %) of neurons generated T-type channel-dependent bursting and generated multiple bouts of rebound spiking, while the remaining neurons cells lacked bursting and generated only single bouts of rebound spiking with fewer spikes. Interestingly, a sub-group of bursting neurons generated long-lasting plateau potentials (615.5±115.3 ms duration) that mediated persistent action potential activity (99.1±12.7 Hz). In slice preparations that preserved intrathalamic connectivity, bursting cells generating plateau potentials were prominently recruited by thalamoreticular inputs and, in turn, resulted in rhythmic and persistent inhibition in VB, which was highly synchronous for neighboring neurons. Persistent inhibition in VB was fully blocked by AMPAR antagonists but was insensitive to antagonists of group I mGluRs and TRPC4 channels, suggesting plateau potentials in different classes of GABAergic thalamic neurons are mediated by distinct

mechanisms. Together our data identify specific cell classes in the adult TRN and show that bursting cells generating plateau potentials are prominently involved in mediating rhythmic thalamic activity.

Title: A comparison of topography in projections from somatosensory thalamus to cortex

Authors: *H. C. MACOMBER[1], G. M. PIERCE[2,3], R. M. BRUNO[2,3]
[1]Dept. of Biol. Sci., Columbia Univ. in the City of New York, New York, NY; [2]Neurosci., Columbia Univ., New York, NY; [3]Dept. of Neurosci., Mortimer B. Zuckerman Mind Brain Behavior Inst., New York, NY

Abstract: Sensory systems often make use of topography to organize the exterior world into an internal representation. The clear organization of the whisker representation in the primary somatosensory cortex (S1) facilitates investigation of cortical processing. In the mouse whisker-barrel system, touch information passes to S1 through two parallel pathways: one through a primary thalamic nucleus (the ventral posterior medial nucleus, VPM) and another through a secondary thalamic nucleus (the posterior medial nucleus, POm). While VPM clearly encodes whisker information to the cortex in a spatiotemporally precise manner, POm response patterns remain less clear. Furthermore, VPM displays a distinct one-to-one thalamic barreloid to cortical barrel somatotopy in its projections to S1, yet single axon tracing studies have shown that individual POm neurons innervate multiple barrel columns in S1. Because POm projects with less spatial precision than VPM, POm might not be simply relaying touch information, but rather may be involved in more complex information processing. We aimed to quantify the topography in VPM-S1 and POm-S1 projections to better understand how these nuclei might differentially impact S1 processing. We injected two fluorescent tracers into neighboring whisker regions of S1 to retrogradely label both VPM and POm cell bodies. Next, we reconstructed the injection sites and the barrel field in three dimensions to determine injection locations and sizes. In both VPM and POm, the number of cells projecting to each cortical location and the degree to which cell populations overlapped was quantified using confocal and epifluorescence microscopy.

Preliminary results confirm the strict somatotopy of the VPM-S1 projection and suggest that the POm-S1 projection is more widespread. Determining the degree of somatotopy preserved in the thalamocortical projections from VPM and POm to S1 will provide a clearer basis for understanding their functional differences and how these differences can affect cortical processing.

Title: Systemic administration of cocaine, caffeine or their combination alters the pacemaker activity of somatosensory thalamic neurons in mice

Authors: *M. C. RIVERO-ECHETO[1,3], P. P. PERISSINOTTI[2], C. GÓNZALEZ-INCHAUSPE[2], J. L. CADET[4], E. E. GARCIA-RILL[5], V. BISAGNO[6], F. J. URBANO[7]
[1]Neurosci., IFIBYNE, Argentina; [2]Neurosci., IFIBYNE, Buenos Aires, Argentina; [3]ININFA, Buenos Aires, Argentina; [4]Mol. Neuropsychiat Br., NIH, Baltimore, MD; [5]Slot 847, Ctr. for Translational Neurosci, Little Rock, AR; [6]ININFA-CONICET, Buenos Aires, CABA, Argentina; [7]IFIBYNE-CONICET, Buenos Aires, Argentina

Abstract: Caffeine (Caf) is a worldwide consumed stimulant that is widely used in a range of commercially available products. Cocaine (Coc) is an addictive stimulant drug that can cause dependence and several long-term consequences when abused. In South America there is an endemic use of a drug known as “PACO” in which it was found to be chemically composed by a Caf:Coc ratio of 1:4. We tested the hypothesis that Caf:Coc combination alters intrinsic and synaptic properties of thalamocortical neurons. We treated male C57/BL6 mice with binge administrations (3 injections 1 hr apart, i.p.) of Coc (10 mg/kg), Caf (5mg/kg) and their combination (Coc+Caf). Patch-clamp records from ventrobasal (VB) neurons from thalamocortical slices in vitro were obtained 24-hour after either one day (i.e., Acute Binge, AB) or 13-day (i.e., Chronic Binge, CB) binge administrations. An AB of Caf decreased the number

of action potentials (APs) after a post-inhibitory rebound (PIR), whereas a CB of Coc + Caf increased APs frequency compared to other treatments (Ctrl n=6, Caf n=3, Coc n=5, Coc+Caf n=5; ANOVA p<0,05). Since IH (HCN-mediated) and IT (T-type calcium currents) act synergistically to underline VB pacemaker activity, we studied these currents after AB or CB treatments. Coc or Coc+ Caf increased IH current density 24 hour after an AB, but not in a CB treatment. Interestingly, CB Coc+ Caf administration decreased IH current density and shifted steady-state voltage-dependence of HCN channels activation towards hyperpolarizing holding potentials. Coc+ Caf decreased IT current density after an AB treatment (Ctrl n=32, Caff n=10, Coc n=5, Coc+Caff n=7; KW analysis H:13, p<0.001, Dunn´s Post-Hoc test p<0.05), while a CB treatment resulted in greater in IT current density (Control n=21, Caff n=12, Coc n=10, Coc+Caff n=16; KW analysis H:13, p<0.001, Dunn´s Post-Hoc test p<0.05) . We then studied intracellular calcium concentration $[Ca^{2+}]_{int}$ dynamics elicited by a rebound, low threshold spike depolarization using fura-2 ratiometric calcium imaging. Our results showed that $[Ca^{2+}]_{int}$ increased after an AB of Coc+Caf (Ctrl n=6, caff n=6, Coc n=6, Coc+Caf n=6; ANOVA p<0.05). We also found that both Glutamatergic and GABAergic synaptic transmission onto VB neurons was affected by either AB or CB treatments. In conclusion our results showed a greater impact of the Coc+ Caf combination on intrinsic and synaptic properties of thalamocortical neurons, compared to the individual effect of each psychostimulant.

Title: Focused ultrasound neuromodulation: Refining optimal parameters in a swine model

Authors: *W. LEGON[1], T. WANG[1], J. W. L. ELIAS[2]
[1]Neurosurg., [2]Univ. of Virginia, Charlottesville, VA

Abstract: There is a significant interest to use ultrasound for neuromodulation because of its high spatial resolution and transcranial application. Acoustic energy has long been known to influence the activity of electrically-excitable tissues including muscle, peripheral nerves, and the central nervous system. Perhaps the most exciting, unharnessed potential for transcranial ultrasound is for noninvasive neuromodulation and brain mapping. Ultrasound has been used safely and effectively for cortical neuromodulation in mouse, rat, and rabbit and only a few

studies have been performed in large brain animal models including sheep, pig and monkey. There is a need for a consistent, large-brain animal model to comprehensively study and refine low-intensity neuromodulation of the brain. Here, we conduct a systematic analysis of ultrasound parameters to identify the optimal low-intensity sonications that inhibit as well as excite brain function in large brain. In addition, we test the ability of low-intensity focused ultrasound to modulate axonal tracts and test for the safety of these parameters. Preliminary evidence suggests that prolonged duration (> 5 min), low duty cycle (< 20%) ultrasound is effective at suppressing cortical activity whereas short duration (< 2 min) high duty cycle (> 70%) ultrasound is effective for inducing cortical excitation. There is as yet, no definitive data suggesting that low-intensity ultrasound can modulate white matter tracts. Histology demonstrates that these sonication parameters do not result in any damage.

Title: Multimodal validation of a thermal mechanism of transcranial focused ultrasound neuroinhibition

Authors: *B. ELAHIAN[1], D. DARROW[2], P. O'BRIEN[3], T. NETOFF[1], E. EBBINI[3]
[1]Biomed. Engin., [2]Neurosurg., [3]Electrical and Computer Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: INTRODUCTION: Focused ultrasound delivered at low intensities (LIFU) has been reported to evoke responses in the motor, sensory, and visual systems through both inhibition and excitation without inducing histologic changes. The mechanism of activation and reversible lesioning in the central and peripheral nervous system is not well understood. A recent report has shown that ultrasound can induce a startle response that may be a confound in measuring ultrasound effects in the central nervous system. Several mechanisms of ultrasound neuromodulation have been proposed; most generally discount the role of thermal energy. Here we investigate the mechanism and characterize the effects of LIFU neuromodulation of the somatosensory evoked response using a high-precision dual-mode ultrasound mediated through a phased-array that can generate arbitrary waveforms. **METHODS**: Somatosensory-evoked potentials (SSEPs) were elicited in Sprague-Dawley rats by electrical stimulation of the leg. The SSEPs provides a clear neural response and pathway in which to study the effects of LIFU.

Concurrent ultrasound imaging and therapy was applied through a dual-mode 32-channel phased array with a 3.2 MHz carrier frequency. The focused ultrasound was used to targeting the ventral posterolateral nucleus (VPL), through which SSEPs pass on their way from the spinal cord to the cortex. To test the thermal effects on VPL, a 50 mW laser was applied with stereotactic placement of a fiberoptic catheter. **RESULTS**: Ultrasound applied to the VPL contralateral to electrical stimulation reversibly, and with graded amplitude, suppressed the SSEP. Ipsilateral application had no effect. The amplitude of tFUS was found to significantly impact the SSEP amplitude and shape, but LIFU delivered with a constant intensity (spatial-peak temporal average) reproduced a constant effect. Laser-mediated, reversible thermal lesions reproduced suppression of the first two peaks of the SSEP waveform. **CONCLUSION**: Neuroinhibition of a somatosensory circuit by LIFU at the thalamic relay was demonstrated in a fully anesthetized rat with lateral specificity. Spatial specificity indicated that LIFU with a phased array did not act primarily through a startle response. Only suppression of the SSEP was observed, no excitation caused by ultrasound was observed. The creation of a Thermal lesion using light corroborated our hypothesis that thermal effects of ultrasound is the dominant mechanism of LIFU neural suppression.

Abstract: The purpose of this study was to investigate neural activity related to tactile illusions in the human brain, which can help us understand better the neurological mechanisms of tactile sensation. The study employed two well-known tactile illusion conditions (Aristotle and reverse illusions) in which subjects' twisted fingers were lightly touched with different numbers of mechanical stimuli at different locations. In the Aristotle condition, a single stimulus was given to the middle of two twisted fingers (index and middle), possibly leading to the illusory perception of two stimuli. In the reverse condition, two stimuli were synchronously given to the both ends of twisted fingers (index and middle), possibly leading to the illusory perception of a single stimulus. In addition to these conditions of generating a mismatch between the actual and

perceived number of stimuli, the resting state and a control condition (asynchronous stimulations on both fingers) were included in the experiment. Ten subjects participated in the experiment and their fMRI images were obtained using a 3T scanner (3T Magentom Prisma, Siemens, Germany). SPM12 was used to analyze BOLD signal patterns for each condition and to contrast brain responses to each type of stimuli against those in the resting state. This contrast analysis revealed significant neural activations in the bilateral postcentral gyrus (S1) and bilateral inferior parietal lobe ($p<0.001$). Furthermore, a contrast analysis between the Aristotle and asynchronous conditions, with the same number of perceived but different number of physical stimuli, found a significant difference in the activation level of contralateral S1 ($p<0.001$). This may indicate that S1 might not drive tactile illusion alone. Another contrast analysis between the reverse and asynchronous conditions, with the same number of physical but different number of perceived stimuli, found significant differences in bilateral thalamus and contralateral middle frontal gyrus (MFG) as well as contralateral S1 ($p<0.001$). It suggests that tactile illusion may involve interactions among many brain regions along with somatosensory cortical areas. The follow-up studies on functional connectivity between these regions would further verify this conjecture about the neural underpinnings of tactile illusions.

Title: Central sulcus depth profiles of a large human cohort: Incidence of a divided central sulcus and description of the pli de passage fronto-parietal moyen

Authors: *R. SCHWEIZER[1,2], H. GRAETZ[1], J. STROPEL[1], J. FRAHM[1]
[1]Biomedizinische NMR, Goettingen, Germany; [2]Leibniz-ScienceCampus Primate Cognition, Göttingen, Germany

Abstract: Introduction
The structural MRI data of 1200 subjects of the Human Connectome Project Young Adults were utilized to obtain the depth profiles of the central sulcus (CS). These profiles were examined for a comprehensive description of the general location and extent of the pli de passage fronto-parietal moyen (PPfpm), a deep gyrus in the fundus of the central sulcus at the somato-motor hand area. The data additionally allows us to obtain the incidence rate of the rare cases of the PPfpm complete, in which the deep gyrus rises up to the brain surface, thereby forming a

connection between the pre- and postcentral gyrus and causing a divided CS. The only large scale exploration of its incidence rate, performed in by Heschl in 1876/77, included 1087 brains and resulted in 6 cases of a hemisphere with a completely divided CS.

Methods

Unprocessed T1-weighted images were downloaded from the 1200 subject release of the Human Connectome Project. Applying the Morphologist 2015 pipeline within BrainVISA 4.5.0., each hemisphere's central sulcus was detected, manually confirmed and screened for a divided CS as identified by a brain surface pre- to postcentral gyrus connection in the hand knob area and verified on T1-weighted image. The CS depth profile (in mm) for each analyzed hemisphere was automatically determined by the morphologist pipeline (100 values: 0 = medial start, vicinity of the mid-hemispherical cleft, 100 = lateral end, vicinity of the sylvian fissure) and screened with peakdetect.py for the number of local maxima.

Results

Among the 1110 brains (2220 hemispheres) surveyed, 7 hemispheres showed a divided CS with the pli de passage fronto-parietal moyen reaching from the fundus to the brain surface. This observation corresponds to an incidence rate of 0.6 %. The averaged extracted CS depth profile of 1088 hemispheres shows an almost U-like shape with a small incision in the midway position. The average central sulcus depth was 17.11 mm ± 1.05 mm (mean ± SD). The screening for local maxima resulted in 65% of the hemisphere showing one, 8% two and 27% no local maxima.

Conclusion

The incidence rate of 0.6 % corresponds to the rate found by Heschl in 1877, showing a comparable occurrence of the divided CS over the last 140 years and between the different cohorts. This finding suites the hypothesis that this anatomical deviation, having no described clinical or behavioral implications, probably does not underlie a strong evolutionary pressure. The current algorithm detects a local maximum, i.e. a pli de passage fronto-parietal moyen, in approximately two thirds of the CS sulcus depth profiles.

Title: Selective attention enhances cortical processing of binaural gap

Authors: *L. KONG[1], M. WANG[2], Z. XIE[3], L. LU[3], T. QU[4], L. LI[3]
[1]Sch. of Communication, Beijing Language and Culture Univ., Beijing, China; [2]Beijing Key Lab. of Applied Exptl. Psychology, Sch. of Psychology, Beijing Normal Univ., Beijing, China; [3]Sch. of Psychological and Cognitive Sci., [4]Dept. of Machine Intelligence, Peking Univ., Beijing, China

Abstract: Human listeners are extremely sensitive to changes in the similarity of sounds at the two ears (interaural correlation), which is critical to both localizing sound sources and detecting target auditory object against the noisy background. When an interaural time difference (ITD) in milliseconds is introduced, listeners' ability of processing the interaural correlation is associated with spatial unmasking of speech recognition in reverberant environments. Although selective attention is known to be involved in speech recognition under cocktail-party conditions, it is not clear whether the interaural correlation processing can also be modulated by attention. In this study, a binaurally uncorrelated fragment (i.e., binaural gap, interaural correlation = 0) is embedded in the binaurally identical noises and scalp event-related potentials (ERPs) evoked by the binaural gap was recorded when the participants were instructed to detect a binaural silent gap (active listening condition) or count visually presented target letters (passive listening condition). We found that the binaural gap remarkably evoked ERPs even when a 2-ms ITD was introduced. Under either the active or passive listening condition, the ERPs to the binaural gap with a 2-ms ITD were significantly weaker than those with a 0-ms ITD. More importantly, the ERPs to the binaural gap under the active listening condition were significantly larger than those under the passive listening condition. In contrast, the ERPs to the sound onset were not significantly affected by either ITD or attention. Thus, the interaural correlation processing is modulated by selective attention. The paradigm developed by this study is useful for investigating how the primitive auditory memory of fine-structure signals (Li et al., *PLoS ONE*, 8 (4) e63106, 2013) is top-down affected by higher-order processes.

Title: Loss of interaural time difference sensitivity in rabbit inferior colliculus neurons following noise-induced hearing loss

Authors: *H. HARAGOPAL, R. DORKOSKI, G. WHALEY, L. PALMER, M. DAY
Biol. Sci., Ohio Univ., Athens, OH

Abstract: Sensorineural hearing loss (SNHL) is the most common form of permanent hearing loss, usually caused by cumulative overexposure to loud sounds. Individuals with SNHL show impairment in the abilities to both localize sound sources and use spatial cues to aid speech comprehension in noisy environments. However, the effects of SNHL on the circuits underlying sound localization are not known. Humans, and rabbits, localize sound in the horizontal plane (azimuth) via interaural time and level differences (ITDs and ILDs) of the sound waveform. These binaural cues are first encoded in the auditory brainstem, which projects to the inferior colliculus (IC). We measured responses of single-units in the IC of awake rabbits either with or without noise-induced hearing loss in response to auditory stimuli that varied in binaural cues in order to determine the effect of SNHL on sound localization coding. Rabbits were exposed to octave-band noise centered at 750 Hz at 133 dB SPL for 90 min under isoflurane anesthesia. Auditory brainstem response thresholds increased by approximately 30-45 dB between 0.5 and 16 kHz as measured two weeks after exposure, indicating extensive cochlear outer hair cell loss. Neurons from SNHL rabbits had greater sound-level thresholds to pure tones and noise stimuli than those from normal-hearing rabbits, as expected. Azimuth tuning curves were measured in response to noise stimuli with either natural ITD and ILD (ITD+ILD), or with one binaural cue fixed at zero (ITD-only and ILD-only). We quantified neural sensitivity to sound source azimuth (ITD+ILD stimulus) as the mutual information (MI) between firing rate and azimuth. There was a trend towards reduction in median MI for neurons from SNHL rabbits as compared to those from normal-hearing rabbits. We also computed MI between firing rate and ITD for noise stimuli that only varied in ITD (ILD fixed to zero). In this case, median MI was dramatically decreased for neurons from SNHL rabbits, with all MI values near zero, even though stimuli were above sound-level threshold. For neurons from SNHL rabbits, ITD+ILD azimuth tuning curves were very similar to ILD-only tuning curves, indicating neural sensitivity to azimuth was dominated by sensitivity to ILD. Our results suggest that 1) noise overexposure causes a loss of ITD sensitivity in the IC, and 2) any remaining information about sound source azimuth is due to sensitivity to ILD.

Title: EEG activity between right and left handed on a sound localization task: Pilot sex differences study

Authors: *M. CASTRO GONZÁLEZ[1], Y. DEL RÍO-PORTILLA[2]
[2]Neurobio. and Neurosci., [1]Univ. Nacional Autónoma de México, México, Mexico

Abstract: Differences in brain organization and brain processing between right and left handed have been described, nevertheless is continue to be an issue of fact. There is also known that sound processing is different for both hemispheres in relation to sound localization. Sex differences have also be found especially on asymmetry especially on visuospatial attention. The aim of this study was to analyze brain response and behavioral response during task localization task before and after eye movements. We used twenty stimuli (musical note A, 2s each). Stimuli were presented in a classical random block design, for each group (left handed and right handed). After each run, subjects (n=30) respond on a keyboard according to where they heard the stimuli (right or left side) and at the same time to gaze on the direction they heard the stimuli (right or left side). For eye movements recording, we placed electrodes according EOG. Results showed significant differences on brain activity between left and right handed according to sound localization.
According on what we have been studding, on other experiments at the Laboratory, what we expected is an increase on absolute power over widespread brain regions for both hemispheres especially on high frequencies, alpha2, beta1, beta2 and gamma higher for right handed. For behavioral data analysis by comparing PC keyboard answers, we expect right responses for right handed in comparison with left handed, and left answers for left handed in comparison with right handed. Also for EOG analysis.
By the time we might say that brain processing during a sound localization task, is similar for right and left handed according to EEG results in other Laboratory experiments, so we could assume brain widespread response especially in high frequencies. Moreover on behavioral analysis for those studies, it seems that on keyboard answers and eye movements response, there is a difference denoting that for eye movements, laterality plays an important role that might be related to orientation reflex, so eye movement response is faster and spontaneous in relation to keyboard answers where subjects need to be more attend to the task to give an answer.

Title: Decoding trajectories of multiple moving sound sources from EEG in cocktail party environment

Authors: *A. BEDNAR[1], E. C. LALOR[2]
[1]Trinity Col. Dublin, Dublin, Ireland; [2]Neuroscience/ Biomed. Engin., Univ. of Rochester, Rochester, NY

Abstract: We can clearly perceive the location of moving auditory objects in space. However, the cortical representation of auditory space, and auditory motion in particular, is not well characterized. Recently, we showed that in a simple acoustic scene with one sound source, auditory cortex tracks the time-varying location of a continuously moving sound. Specifically, we found that both the delta phase and alpha power of electroencephalographic (EEG) data can predict the azimuth of a moving sound source (Bednar 2017).
However, in natural settings, we are almost always presented with a mixture of multiple competing sounds and so we must focus our attention on the relevant source in order to segregate it from the background noise e.g. the 'cocktail party effect'. While many studies have examined the neural underpinnings of attentional selection in a cocktail party problem - especially in the context of sound envelope tracking by the cortex, it is unclear how we process and utilize spatial information in complex acoustic scenes with multiple sound sources. In this study we aimed to answer two questions: (1) Can we decode time-varying locations of multiple concurrently presented moving sound sources from EEG? (2) How does selective attention influence the sound trajectory tracking in cortex?
Subjects listened to two simultaneously presented noise stimuli having different spectral content over headphones. The stimuli were acoustically modified to be perceived as randomly moving on a semi-circular trajectory in the horizontal plane. Participants were asked to pay attention to one of the two presented stimuli and detect embedded targets. While subjects listened to the stimuli, we recorded their EEG using a 128-channel acquisition system. The data were analyzed by 1) deriving a linear mapping, known as a temporal response function (TRF), between the stimulus and a training set of EEG data, and 2) using the TRF to reconstruct an estimate of the time-varying sound source azimuth from a test set of EEG data.
Preliminary results show that locations of both attended and unattended sound sources are cortically represented and we can decode the trajectories of both sound stimuli from EEG with a

reconstruction accuracy significantly above chance level. We also found that selective attention significantly enhances the cortical representation of the sound trajectory of the attended stimulus. In addition, we found a correlation between our EEG-based trajectory reconstruction accuracy and behavioral performance in the target detection task. We believe this method has the potential to complement established sound envelope tracking-based attentional decoders in cocktail party environments.

Title: Population responses underlying statistical inference in a map of auditory space in the barn owl's midbrain

Authors: *R. FERGER[1], M. V. BECKERT[1], K. SHADRON[1], D. SANCULI[2], W. M. DEBELLO[2], B. J. FISCHER[3], J. L. PENA[1]

Abstract: The barn owl is a nocturnal hunter with outstanding sound localization abilities. It has become a model organism to study neural circuits of extracting binaural cues for sound localization that are relevant for behavior. Neurons in the owl's midbrain are known to respond maximally to acoustic stimuli with a distinct combination of interaural time difference (ITD) and interaural level difference (ILD). Together, these neurons form a neural map of auditory space which supports sound-orienting behavior. However, open questions regarding how the neural population in the map is read out on a trial-by-trial basis remain unanswered. This work reaches beyond responses of single neurons to understand the relationship between the activity pattern across the neural population and behavior.
Recent work has shown that the read out of population activity by a population vector (PV) predicts orienting head saccades, and approximates Bayesian statistical inference by integrating the overrepresentation of frontal directions and the differential shape of spatial tuning curves across the map. We investigated whether the trial-by-trial variability of neural activity matched predictions made under a Bayesian model, which matches a PV to the behavioral output. When a stimulus becomes less reliable, for instance if ITD detection is disrupted by adding independent noise at the two ears, an animal’s performance becomes less accurate. The Bayesian model

predicts that this should manifest in a broadening of the population response in the map. An alternative hypothesis that could explain this behavioral effect is that the reduced reliability induces shifts in the population response, which are indistinguishable from a response to a different ITD, termed differential correlations. Using a microelectrode array to record multiple units across the map, we tested whether the trial-by-trial population activity better matched the Bayesian model or the presence of differential correlations. On single trials the activity matched the pattern of activity predicted by the Bayesian model implemented by a PV. This was consistent across a number of stimulus conditions. Furthermore, the correlation structure of neurons in the map did not support a trial-by-trial shift in the center-of-mass as predicted for differential correlations. This provides additional support for the PV model.

Title: Co-variability across the neural population in the map of auditory space of the barn owl

Authors: *M. V. BECKERT[1], R. FERGER[1], K. SHADRON[1], B. J. FISCHER[2], J. L. PENA[1]
[1]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Seattle Univ., Seattle, WA

Abstract: The midbrain of the barn owl contains a map of auditory space. However, the characterization of the map has been based mainly on single-cell or local multiunit recordings. This approach is blind to co-variabilities in response strength and spike timing that occur on a trial-by-trial bases. However, these correlations have profound effects on information encoded by neural populations, depending on their structure as well as the system they are embedded within. We therefore sought to expand upon previous work by measuring population activity in the map-of-space.
To this end we have developed multi-electrode array recordings, utilizing a microdrive capable of positioning electrodes deep within the brain, allowing access to the midbrain map. Using this approach, data were collected to quantify the similarity of tuning (signal correlation), trial-by-trial co-variability (noise correlation), as well as precision of spike timing (spike-time synchrony).
As anticipated, more distant neurons displayed weaker signal correlations. Additionally, noise

correlations were directly related to the signal correlation between pairs of neurons, similar to observations in the visual system. On the other hand there was no relationship between the level of spike-time synchrony and signal correlation. We assessed the impact of these correlations on information by training a decoder with neural data, which preserved the natural correlations. We compared this to a decoder that removes correlations by shuffling the trials. This work expands upon previous work that investigated the sound localization system of the barn owl using either recordings from single neurons or multiple nearby neurons.

Title: The effect of anticipated cue reliability on behavioral and neural adaptation in barn owls

Authors: *K. SHADRON, M. V. BECKERT, R. FERGER, J. L. PENA
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The brain actively updates the representation of the environment. An open question about this function is whether adaptation is weighted by the predicted statistics of sensory information. Here we asked whether anticipated cue reliability affects the rate of adaptation in the auditory system of the barn owl.
The midbrain of the barn owl contains a map of auditory space, which uses the interaural phase difference to compute sound location in azimuth. Previous work showed that space-specific neurons in this map are tuned to the frequency range that is most reliable for its preferred location. This effect is due to the acoustical properties of the head, causing higher frequencies to convey interaural phase difference more reliably in frontal space and lower frequencies in the periphery. We hypothesized that adaptation to sound location would differ between stimuli expected to be reliable or unreliable. We tested this hypothesis at the behavioral and neural-population levels. We measured the pupillary dilation response, an orienting response that readily adapts upon repetition of a stimulus. Tones were repeatedly presented through earphones to an awake barn owl, either from the front or periphery of the head to measure the habituation rate. To assess the strength of the novelty detection, a deviant in location was then presented to elicit a recovery of the PDR. Trials with higher cue reliability were compared to trials with low reliability to find trends in habituation. To assess this question at the neural-population level, we

conducted recordings of multiple neurons in the space map using a microelectrode array. Adapter and test stimuli were used to assess population and activity and tuning of individual cells before and after adaptation. Frontal and peripheral neurons were compared to test the hypothesis that anticipated reliable and unreliable stimuli lead to different adaptation rates.

Title: Subthreshold oscillations underlie diverse firing phenotypes and impart graded sensitivity to envelopes in neurons of the medial superior olive

Authors: *B. BONDY[1], N. GOLDING[2]
[2]Inst. for Neurosci., [1]Univ. of Texas at Austin, Austin, TX

Abstract: Neurons of the medial superior olive (MSO) compare the arrival time of low frequency sounds to the two ears (interaural time difference, ITD), cues used for sound localization. It has long been assumed that the MSO is composed of identical neurons, regardless of location along the tonotopic axis of the nucleus, but the data testing this assumption is sparse and conflicting. To understand the relationship between physiological properties and tonotopic location, we made >500 whole cell patch clamp recordings from MSO neurons in brainstem slices from Mongolian gerbils (P18-28), subsequently analyzing cell morphology and location within the nucleus. Unexpectedly, we found that MSO neurons could be separated into three groups based on firing pattern: phasic neurons, which fire a single, small-amplitude spike at stimulus onset, oscillators, which fire trains of overshooting spikes in a pause pattern, and tonic neurons, which fire large spikes regularly. All firing types could be found in both high and low frequency regions of the MSO. The membrane properties of MSO cells formed a continuum, with oscillators and tonic neurons exhibiting membrane time constants 3x and 16x those of phasic neurons. All MSO neurons received bilateral excitation and inhibition and sent axons outside the MSO. However, as with their slower membrane properties, oscillator/tonic neurons exhibited poorer temporal resolution in *in vitro* ITD experiments (halfwidths: phasic, 0.51±0.0 ms; oscillator, 0.92±0.2 ms; tonic, 2.1±0.4 ms). The differences in firing patterns were driven in

part by subthreshold oscillations. Large, slow (~25-130 Hz) oscillations in tonic neurons drove low-threshold spiking. Faster, smaller oscillations (~100-425 Hz) promoted spiking in oscillator neurons, while even faster oscillations (~400-750 Hz) were too small to evoke spikes in phasic neurons.To determine how different functional properties of MSO neurons might affect their ability to encoding auditory stimuli with different temporal features, we injected rectified sinusoidal shaped currents into cells over a range of amplitudes and frequencies, to mimic amplitude modulated envelopes. Phasic neurons were unable to respond to frequencies below ~200Hz, whereas most oscillators and all tonic neurons responded robustly across all frequencies. Oscillations in both oscillator and tonic neurons appeared to play a particularly important role in facilitating spiking during low frequency envelopes. In summary, our results show that MSO neurons are far more diverse than previously reported. We postulate that such diversity allows encoding ITDs of both envelopes and fine temporal structure of sounds.

Title: Alterations to the sound localization pathway in fragile X syndrome

Authors: *E. MCCULLAGH, M. M. HUNTSMAN[1], A. KLUG[2]
[1]Dept. of Pharmaceut. Sci., Univ. of Colorado at Denver - Anschutz Med. Campus, Aurora, CO; [2]Physiol. and Biophysics, Univ. of Colorado Denver Dept. of Physiol. and Biophysics, Aurora, CO

Abstract: Hypersensitivity to sound and impaired sound localization are some of the most common sensory symptoms described by people with autism. The sound localization pathway, a neural network within the auditory brainstem, enables us to not only localize the location of a sound source per se, but also to separate between multiple simultaneous auditory streams that enter our ears. Whenever we have a conversation in situations such as a crowded restaurant, a busy public place, or a room where background noises are present, our sound localization circuit helps us to parse this complex situation into multiple narrow spatial channels based on their location. Being unable to localize the source of a sound, and to focus on a conversation when distracting noises are present significantly impairs social interactions in autistic patients. Despite

its importance, our understanding of how the sound localization circuit is impaired in autism is largely unknown. To explore alterations in the sound localization pathway in autism, we can use a mouse model (*Fmr1* KO mice) for the most common genetic form of autism, Fragile X syndrome (FXS). We have shown that there are frequency-specific alterations to the auditory brainstem in FXS mice, we have continued this study by examining alterations to myelin fibers that innervate this area and contribute to the speed of sound processing. We have seen alterations in myelin in the brainstem of FXS consistent with possible alterations to sound localization ability. We have measured myelination using both Transmission Electron Microscopy (TEM) and Coherent Anti-Stokes Raman Scattering (CARS). Using these two techniques we can measure the diameter of myelinated axons as well as the thickness of the myelin in those areas. We have seen changes to the myelination in FXS in the fibers that innervate the medial nucleus of the trapezoid body (MNTB). Determining the cause of sound localization impairments in FXS will help determine future strategies for treatment of these impairments, and perhaps FXS in general.

Title: Investigate what makes it “new” in the old-plus-new strategy of auditory scene analysis in the auditory cortex of marmoset monkeys

Authors: *Y. ZHOU[1], J. BRAASCH[2]
[1]Speech and Hearing Dept., Tempe, AZ; [2]Grad. Program in Architectural Acoustics, Rensselaer Polytechnic Inst., Troy, NY

Abstract: Auditory Scene Analysis (ASA) is an umbrella term that describes the auditory system’s remarkable ability to decompose signal-based acoustic features from a complex sound mixture and regroup them into perceptually relevant auditory objects and streams. A fundamental concept of ASA is the *old-plus-new* strategy, which states that the auditory system correctly interprets the sudden development of new elements in an acoustic mixture as additional, distinct elements added to an existing continuing sound source. Braasch and Hartung (2002) showed that human localization performance of a target sound (200-ms broadband noise) was worsened by a masker sound (different noise waveform) presented simultaneously from a

fixed frontal location. However, the listeners had no difficulties localizing the target if the masker preceded the target by 200 milliseconds. Their model proposed that the correct target localization was possible because listeners could use information from the preceding part of the masker to perceptually separate target and masker using the old-plus-new strategy of ASA. This study investigated the neural mechanisms of perceptual spatial release from masking and the way in which neuronal activities manifest the target spatial information in the presence of a competing masker sound. We used a similar spatial setup to the one used in the human study mentioned above. We collected single-unit activity from the auditory cortex of awake marmoset monkeys. We first measured the rate spatial tuning function of a neuron to a target sound (broadband noise or best-frequency tone) presented alone. We then compared how simultaneous or preceding noise or tonal masker altered the target-alone spatial tuning function. We observed that while the spiking activities of many cortical neurons show hemifield-field spatial tunings (front, back, left and right), the non-responsive regions are actively inhibited, suggesting cortical modulations of auditory spatial selectivity. We found that spatial tuning remains less affected with the preceding than simultaneous maskers, consistent with human studies. However, the extent of spatial release from masking is affected by the onset/sustained patterns of the masker responses and the extent of cortical inhibition/suppression in both target and masker responses. We propose a new model for the old-plus-new strategy in the spatial domain, which integrates two neural processes - adaption and suppression - to reveal the central mechanisms that make the target spatial information become “new” in a multi-source acoustic environment.

Title: Characterization of auditory neurons in the mouse superior colliculus detected using virtual auditory space stimulation

Authors: *S. ITO[1], D. A. FELDHEIM[2], A. M. LITKE[1]
[1]Santa Cruz Inst. for Particle Physics, [2]MCD Biol., Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: We characterized the properties of sound localization of the neurons in the mouse superior colliculus (SC) using large-scale silicon probe recording and virtual auditory space stimulation. We found that the SC contains neurons with responses tuned to localized areas in the virtual auditory space.
The brain computes the sound source location based on auditory signals that arrive at the two ears. The cues for the sound localization are binaural differences of the timing and the intensity, as well as a modulation of frequency spectra. These cues are induced by physical structures of the head and ears that can be modeled by a measured head-related transfer function (HRTF). The computed sound elevation and azimuth are mapped onto the SC. The SC also contains a visual map of space that is aligned with the auditory map. The alignment of the visual and auditory maps has been demonstrated in species such as the cat, the ferret and the barn owl (optic tectum), but in mice the properties of the SC auditory spatial map has not been well established. Characterization of the mouse SC auditory map will open the door for further investigations of the sound localization circuitry using genetic and neural recording tools available for use in mice.
In order to measure the mouse SC auditory map, we developed a system that presents auditory stimulation in a virtual space. First, we measured the HRTFs using a high-frequency speaker located 25 cm from a mouse head with a calibrated microphone coupled with the back of the ear canal. The measured HRTFs are then used to calculate the auditory stimulus with properties consistent with a specific source direction. This stimulus is presented to a mouse via earphones. This system is compatible with large-scale recording methods that require overhead acoustic obstacles and allows automated control of the sound directions in two dimensions.
This virtual auditory stimulation system revealed that there are neurons in the deep SC that are tuned to a specific (virtual) sound source direction. The properties of the auditory receptive fields and the topographic map will be presented. These results demonstrate that the mouse is a model to study mechanisms of auditory circuit formation and function.

Title: Age-related changes in the total number of neurons and the GAD-immunoreactive neurons in human inferior colliculus: Stereological study

Authors: *I. PAL[1], P. KUMAR[1], T. G. JACOB[1], D. BHARDWAJ[2], T. S. ROY[1]

Abstract: The inferior colliculus (IC) in an integration centre in the auditory pathway plays a critical role in the binaural processing of auditory information. Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter (produced by glutamic acid decarboxylase-GAD) in IC that is critically involved in the temporal processing of auditory information. During aging, levels of GABA are known to change in different parts of the brain and some nuclei of the auditory system. In our study, we attempted to estimate the age-related changes in the total number of GAD-immunoreactive neuronal population and have also correlated it to the total number of neurons in the human IC. After obtaining clearance from the Ethics Committee, thirty-one samples were obtained from the mortuary and divided into three age groups- young (10-29 years) middle (30-49 years) and old (50-79 years). The IC was cryoprotected, sectioned transversely at 50 µm thickness and then stained with either Cresyl violet (CV) or for immunohistochemical expression of GAD67 (Abcam ab26116, 1: 1000). The number of CV-stained and GAD67-immunoreactive (GAD67-ir) cells neurons were estimated by Optical Fractionator. The estimated total number of neurons in the IC was 1,269,085 ± 75,682 in young age group, while the number of GAD67-ir neurons was 184107 ± 46,811. A significant decline in the CV-stained and GAD67-ir neurons was observed during aging. The GAD67-ir neurons in the old group were significantly decreased approximately by 32% and 27% when compared to young ($p = 0.0068$) and middle ($p = 0.036$) age groups, while the CV-stained neurons old age decreased by 10% when compared to young age group ($p = 0.02$). Hence, our study provides neuroanatomical proof of the decline in quality of sound processing being affected due to not only a general but significant decline in the total number of neurons in the IC, but also due to a loss of GABAergic neurons, which would affect the inhibitory fields in the IC. Further, it may cause poorer ability to detect gaps in the auditory stimuli, therefore leading to poor speech discrimination.

Title: Effects of deviance direction on frequency and duration mismatch fields: Hemispheric functional difference revealed by monaural presentation

Authors: *T. MATSUBARA[1], T. UEHARA[1], K. OGATA[1], T. MAEKAWA[2], S. TOBIMATSU[1]
[1]Clin. Neurophysiol., Kyushu Univ., Fukuoka, Japan; [2]Neuropsychiatry, Amekudai Hosp., Naha, Japan

Abstract: The mismatch negativity (MMN) and its magnetic counterpart (MMF) reflect the process of change detection in the auditory system. Although behavioral study reported that listeners are more sensitive to increments (Inc) in frequency than they listen to decrements (Dec), little attention has been paid to the deviance direction on MMFs. The present study investigated the effects of deviance direction (increment (Inc) vs, decrement (Dec)) on frequency (Freq) and duration (Dur) MMFs to understand the hemispheric functional difference. Sixteen subjects were tested. Monaural pure tone stimulation was performed. For the Inc condition of Freq-MMF, the standard stimulus was the 500-Hz/100-ms tone while the deviant was the 550-Hz/100-ms tone. In Dur-MMF, the standard was the 50-ms/500-Hz tone whereas the deviant was the 100-ms/500-Hz tone. For the Dec condition, the standards and deviants were reversed in both MMFs. Source localization was performed followed by a non-parametric spatio-temporal clustering method and a two-way ANOVA with main factors of DIRECTON and EAR was carried out. MMFs were defined as a cluster containing the response occurring at around 200 ms in the auditory cortex. Thus, presence of the significant cluster directly implies the different origin of MMFs between the levels by the factor. Clear MMFs were obtained in all conditions in both Freq-MMFs (Fig. 1A) and Dur-MMFs (Fig. 1B). In Freq-MMF, right hemisphere was more activated in the Inc condition than the Dec condition (Fig. 1C). On the contrary, there was no significant effect of DIRECTION in the left hemisphere. In Dur-MMFs, there were also no significant clusters regarding DIRECTION. The current results were in accord with previous studies showing there was a bias to the right hemisphere for frequency activations, whereas duration activations were bilateral or biased to the left hemisphere. Our study also supports the behavioral evidence of better performance for identifying Inc in frequency. Our MMF paradigm focusing on the deviance direction may be useful for investigating the hemispheric functional difference.

Title: Sequence sensitive processing in songbird auditory forebrain

Authors: *M. DONG, D. S. VICARIO
Psychology, Psychology, Rutgers Univ., Piscataway, NJ

Abstract: How stimulus sequence affects neural responses is important for understanding the neural mechanisms of speech processing because speech consists of a rapid sequence of sounds

governed by a set of transition probabilities (e.g. frequently occurring sound sequences may represent words). At the neural level, sequence processing has been widely studied using the "oddball" paradigm, in which one rare deviant sound (oddball) is presented in a series of frequent standard sounds. Neurons in the auditory cortex respond more strongly to the oddball than to the standard (oddball effect). However, these studies have typically used only this simple oddball paradigm and few have investigated neural responses to deviants in more complex sequences (e.g., alternation of two stimuli). Because the oddball effect can also be explained by synaptic habituation or violation of a constant auditory environment, the simple oddball paradigm cannot be used to test whether neural responses are sensitive to the stimulus sequence itself.

Using a more complex paradigm, the current study recorded extracellular neural activity in response to sound sequences, using 16 electrodes in the zebra finch auditory forebrain. Two stimuli were initially presented in either a random or alternating order at 1s intervals. Then a change was introduced: each stimulus was occasionally repeated at random times. When the preceding sequence before repetition was random, the 2nd stimulus in the repetition elicited smaller neural responses (lower single-unit firing rates) than the 1st stimulus, indicating that repetition has a suppressive effect. In contrast, when the preceding sequence was alternating, the suppressive effect was significantly reduced, indicating a neural response to the unexpected repetition. Neural responses were further analyzed at the population level using Linear Discriminant Analysis (LDA). LDA showed that the population responses the 1st and 2nd stimulus in the repeated pair were significantly different, confirming the suppression effect. However, LDA showed that the population responses to 1st and 2nd stimulus in the repeated pair were not distinguishable (reflecting reduced suppression). These results support the hypothesis that neural responses are sequence-sensitive and cannot be simply explained by synaptic habituation or violation of a constant auditory environment. We interpret this as evidence of predictive coding at the neural level that may have implications for the neural mechanisms of sequence sensitivity in speech processing.

Title: Cortical excitatory and inhibitory neurons differentially affect collicular responses to sound

Authors: *J. BLACKWELL, W. RAO, D. RIDOLFI-STARR, M. GEFFEN
Otorhinolaryngology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Within the auditory cortex, excitatory and inhibitory dynamics determine frequency selectivity in excitatory cells (Hamilton et al., 2013, Aizenberg et al., 2015; Seybold et al., 2015; Natan et al., 2015; Phillips et al., 2016). Auditory cortex sends an extensive descending pathway to the inferior colliculus, but how excitatory-inhibitory dynamics in the cortex affect this pathway remains unknown. Previous studies demonstrated that responses of neurons in the inferior colliculus are altered by focal electrical stimulation and pharmacological inactivation of auditory cortex (Jen et al., 1998; Yan et al., 2005; Zhang et al., 2005), but these methods lack the ability to manipulate specific cell-types. In this study, we use optogenetic techniques to modulate activity of excitatory cells, parvalbumin-positive (PV) interneurons, and somatostatin-positive (SOM) interneurons in the auditory cortex to test whether and how this pathway modulates frequency selectivity in the inferior colliculus in both anesthetized and awake mice. As expected from previous studies, activation of cortical excitatory cells increased spontaneous activity and decreased frequency selectivity, while activation of PV interneurons and SOM interneurons decreases spontaneous activity and increased frequency selectivity in putative excitatory cells in the auditory cortex. Furthermore, suppression of PV interneurons had the opposite effects on putative excitatory cell activity. However, whereas activation of excitatory cells decreased frequency selectivity and tone-evoked responses in the inferior colliculus, modulation of PV and SOM interneurons had weak effects on activity in the inferior colliculus. These findings suggest that modulation of frequency selectivity in auditory cortex by inhibitory neurons does not necessarily propagate to the inferior colliculus and that PV and SOM interneurons may differentially affect activity in the inferior colliculus.

Title: Alpha7 nAChR knockout mice exhibit degraded auditory processing

Authors: R. A. FELIX, II[1], D. NOVICIO[1], V. CHAVEZ[1], C. V. PORTFORS[1], *B. J. MORLEY[2]
[1]Human Communication Lab., Washington State Univ., Vancouver, WA; [2]Boys Town Natl. Res. Hosp, Omaha, NE

Abstract: *CHRNA7*, the gene that encodes the alpha 7 subunit in the nicotinic receptor gene family, has been identified as a gene associated with some autism spectrum disorders and other neurodevelopmental conditions characterized, in part, by language impairment. Auditory processing deficits may underlie speech impairment. A reliable indicator of auditory processing disorders is impaired timing of neural activity despite normal ear function, which suggests that problems encoding temporal information arise within the brain. We examined the timing properties of sound-evoked activity following disruption of signaling mediated by the alpha 7 nicotinic acetylcholine receptor (α7 nAChR). Here, we measure auditory event-related potentials of α7 nAChR knockout mice of both sexes and age-matched colony controls. We find a significant timing delay in evoked neural signal that represents midbrain activity in knockouts, despite normal hearing thresholds. To further investigate the delay in midbrain timing, we examine single-neuron spiking activity in the inferior colliculus. We assess the temporal acuity of evoked activity by measuring the precision of first-spike latencies and response durations. In addition, we compare neural correlates of behavioral measures of temporal acuity including gap detection and forward masking in knockout and wild type animals. We find that temporal acuity is impaired in the midbrain of knockouts, whereas other responses properties such as spiking rates are no different than those of wild type controls. We also examine spiking responses of neurons in the superior paraolivary nucleus and the ventral nucleus of the lateral lemniscus, which are brainstem nuclei known to shape spike-timing properties of their synaptic targets in the inferior colliculus. Together, these areas represent a presumptive pathway for encoding timing information needed for identifying natural sounds. These areas also exhibit the highest levels of α7 nAChR expression in the developing auditory system. We find that, like the midbrain, the precision of first-spike latencies, gap detection thresholds, and masking abilities are impaired for brainstem neurons of knockout animals. We conclude that altered temporal processing at the level of the brainstem in α7 nAChR-deficient mice may contribute to degraded spike timing in the midbrain, which likely underlies the observed timing delay in the auditory event-related potentials. Our findings are consistent with a role for the α7 nAChR in auditory processing disorders and identify a neural circuit early in the central auditory pathway that represents a promising target for therapeutic intervention.

Title: Enhanced ability of detecting rat vocalization-in-noise by sound exposure during a critical period

Authors: *N. Y. HOMMA, C. E. SCHREINER
Dept. of Otolaryngology, Univ. of California, San Francisco, San Francisco, CA

Abstract: During critical periods, receptive fields develop to adapt to the sensory environment by forming neural circuits that optimally process relevant stimuli. In humans, this developmental stage is essential for acquiring language and better sound processing. It has been shown that sound exposure during a critical period dynamically altered the receptive field properties in the auditory cortex such as frequency tuning, tuning bandwidth, or temporal resolution (de Villers-Sadani and Merzenich, 2011). However, the relationship between altered neural coding and perceptual abilities is yet largely unknown. In this study, we tested the hypothesis that exposure to moderate levels of structured background noise during the critical period enhances the ability of adult animals to process vocalization-in-noise.
Sprague-Dawley rat pups were raised in moderate noises (~60 dB SPL) of different spectro-temporal statistics during their auditory critical period (P6-45). Once these animals reached adulthood, they were trained to detect vocalizations presented in these noises using a Go/No-go behavioral paradigm and compared to unexposed animals. The sensitivity index (*d'*) was calculated to evaluate the effect of different noise statistics on their ability of detecting vocalizations. Similarly, we investigated primary auditory cortical neuron responses to the same stimulus conditions in normal, exposed and trained animals. Neuronal discriminability was quantified using Euclidian distance-based spike train classifiers.
The noise exposure enhanced, in adult animals, their behavioral performance of detecting rat vocalizations in background noise. Improvement appeared to depend on stimulus statistics used for noise exposure. In addition, cortical signal encoding of vocalizations improved noise-exposed animals accompanied by specific shifts in receptive field properties compared to unexposed animals.
The results support the idea that maturational noise exposure can improve cortical receptive field properties best suited for information extraction in noisy environment thus reducing the impact

of background noise masking and helping the animals to perceptually segregate signals from noise background.

Title: Two-photon imaging reveals “salt and pepper” tonotopy in ferret primary auditory cortex

Authors: *K. WALKER, Q. GAUCHER, M. PANNIELLO, A. IVANOV, J. DAHMEN, A. J. KING
Univ. of Oxford, Oxford, United Kingdom

Abstract: Tonotopic organization has been a widely accepted property of the primary auditory cortex for over 50 years. It has been demonstrated in numerous electrophysiological studies across a wide range of mammals, including rodents, cats, ferrets, and primates. Nonetheless, recent studies in mice have challenged our understanding of tonotopy. Studies using 2-photon calcium imaging (2PI) to examine the activity of auditory cortical cells with unprecedented spatial resolution have shown that although tonotopic organization is visible at a large scale, neighboring neurons can have vastly different frequency preferences (Bandyopadhyay *et al.* 2010; Rothschild *et al.* 2012; Panniello *et al.*, submitted). As 2PI studies of auditory cortex to date have all been carried out in the mouse, it remains unclear whether this “salt and pepper” tonotopy is a general feature of mammalian auditory cortex, or a peculiarity of mice. To address this controversy, we have carried out 2PI in the auditory cortex of a carnivore - *Mustela putorius furo*. Each ferret (n=8) was injected with AAV1 expressing a genetically encoded calcium indicator (GCaMP6m or GCaMP6f) in the primary auditory cortex. After transfection (3-4 weeks), a craniotomy was performed above auditory cortex, and neural responses to sounds were imaged (200 x 200µm imaging fields; 100 - 400µm deep; corresponding to layers II/III) under medetomidine-ketamine anesthesia. Pure tones (1.2 - 41 kHz; 40 - 100 dB SPL) were presented to derive the Frequency Response Area of individual neurons. Our results show that although the classical tonotopic organization is visible across the cortical surface, neurons within an imaging field can widely vary in their frequency preferences. Quantitative analyses confirmed that the local variation in best frequency is similar in mice and ferrets. Therefore, the salt and pepper tonotopy described in the mouse is a common organizational feature of mammalian auditory cortex.

Title: Receptive field characterization using pure tones and broadband stimuli in the mouse primary auditory cortex

Authors: *K. X. KIM, C. A. ATENCIO, C. E. SCHREINER
Dept. of Otolaryngology-Head and Neck Surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: The primary auditory cortex (A1) is a hub that communicates with subcortical and cortical regions. Sound information transferred from the medial geniculate body is further modified via intracortical horizontal pathways in A1. Although detailed anatomical pathway information is needed, functional descriptions of receptive field properties unambiguously illustrate spectral processing. Spectral integration in A1 can be shown via intracellular higher resolution recordings of the subthreshold receptive field. While subthreshold responses with intracellular recordings in A1 have been measured with pure tones, there is little evidence that compares the detailed properties of receptive fields with subthreshold and spiking responses using both pure tone and complex stimuli. We used anesthetized female C57BL/6 mice between 4 and 11 weeks of age and performed in vivo blind patch-clamp recordings in current clamp mode from A1 neurons located at a depth of 300-500 μm by applying pure tone (4-40 kHz, 0-70 dB) and broadband (0.5-40 kHz, 50dB relative to the pure tone threshold) dynamic moving ripple (DMR) stimuli. We constructed the tonal receptive field (TRF) from responses with pure tones and computed the spectrotemporal receptive field (STRF) using the spike-triggered average (STA) analysis for responses with the DMR stimulus. Sharpness of tuning (Q = characteristic frequency / bandwidth) for TRFs and STRFs was measured. TRFs from spiking responses showed narrower tuning than TRFs from subthreshold responses. STRFs in both subthreshold and spiking responses were more sharply tuned than TRFs. We conclude that single neurons in A1 perform spectral integration over a broad range of frequencies. The excitatory/inhibitory weighing for each neuron's spectral integration is modified by dynamic cortical activity resulting from inputs of spectrotemporally complex stimuli.

Abstract: A major challenge in neuroscience is to longitudinally monitor whole brain activity across multiple spatial scales in the same animal. Functional UltraSound (fUS) is an emerging technology that offers images of cerebral blood volume over large brain portions. Here we show for the first time its capability to resolve the functional organization of sensory systems at multiple scales in awake animals, both within small structures by precisely mapping and differentiating sensory responses, and between structures by elucidating the connectivity scheme of top-down projections. We demonstrate that fUS provides stable (over days), yet rapid, highly-resolved 3D tonotopic maps in the auditory pathway of awake ferrets, with unprecedented physiological functional resolution (100µm). This was performed in four different brain regions, namely the auditory cortex, the medial geniculate body, the inferior colliculus, and the lateral lemniscus, this latter being a very small (1-2mm3 size), deeply situated subcortical (8mm deep) and previously undescribed structures in the ferret. Furthermore, we used fUS to map long-distance projections from frontal cortex, a key source of sensory response modulation, to the belt areas of the auditory cortex.

Title: Processing of acoustic signals in the presence of background noise in adult rats exposed to noise as juveniles

Authors: *D. SUTA[1], N. RYBALKO[2], J. POPELAR[2], T.-W. CHIU[3], J. SYKA[2]
[1]Dept. of Cognitive Systems and Neurosciences, CIIRC Czech Tech. Univ., Prague, Czech Republic; [2]Dept. of Auditory Neurosci., Inst. Exp Med. CAS, Prague, Czech Republic; [3]Dept of Biol. Sci. and Technology, NCTU, Hsinchu, Taiwan

Abstract: Noise exposure in rat pups can serve as a model of early deprivation of the sensory input to the central auditory system that allow us to study developmental neuroplasticity of the auditory system. Our previous results demonstrated normal hearing thresholds, but abnormal intensity perception and frequency discrimination in adult rats briefly exposed to noise at the onset of hearing (on the 14th postnatal day, Rybalko et al., Physiol Behav, 2011, Šuta et al., Physiol Behav, 2015). In the present study, we assessed the gap-detection ability, tinnitus- and hyperacusis-like behavior using measurement of the acoustic startle response and its modulation by a gap in background noise or by background noise itself. A significant deficit in the gap detection ability was observed in exposed animals at a moderate level of the background broadband noise (55 dB SPL). An increase of the background noise intensity to 65-75 dB SPL led to strengthening of gap prepulse inhibition in exposed animals, which approached the gap prepulse inhibition values of control animals at those noise intensities. The signs of tinnitus - a deficit in detection of gap in 10 kHz narrow-band background noise but not in noise of other frequency content - were found in 2 of 8 exposed rats. An increased sensitivity to background noise as a typical sign of hyperacousis was manifested in exposed rats by suppression of the acoustic startle response at significantly lower background noise levels than in controls. Our results indicate that acoustic trauma producing only a transient threshold shift during critical developmental period may lead to a permanent impairment in processing of acoustic signals in the presence of background noise, which can be related to a deficit in temporal processing and/or development of tinnitus- and hyperacusis-like behavior.

Title: Preclinical and clinical development of OTO-311, a sustained-exposure formulation of the NMDA receptor antagonist gacyclidine, for the treatment of tinnitus

Authors: *F. PIU, N. TSIVKOVSKAIA, R. FERNANDEZ, X. WANG, J. ANDERSON, K. BISHOP
Otonomy Inc, San Diego, CA

Abstract: Tinnitus, the perception of sounds without a correlated external auditory stimulus, is widely prevalent and often debilitating. Excessive activation of NMDA receptors within the cochlea may be particularly important in altering activity of the auditory nerve and generating tinnitus. OTO-311 is a thermosensitive, sustained-exposure formulation of the potent non-competitive NMDA receptor antagonist gacyclidine. Using a variety of techniques, the profile of gacyclidine/OTO-311 was characterized preclinically. Furthermore, a Phase 1 clinical study, designed to assess the safety and pharmacokinetics of intratympanic administration of OTO-311 was conducted in healthy volunteers. Gacyclidine was found to be a potent and selective NMDA receptor antagonist with low nM affinity, and a relatively rapid on-rate and slow off-rate. In cultured hippocampal or cochlear spiral ganglion neurons, gacyclidine dose-dependently blocked spontaneous activity that was NMDA receptor-dependent. The inner ear pharmacokinetic profile of gacyclidine, administered intratympanically as OTO-311, provided significant and sustained-exposure to the inner ear compartment. The Phase 1 clinical study was a single-center, randomized, placebo- and sham-controlled safety and pharmacokinetic study of OTO-311 administered by intratympanic injection in healthy volunteer subjects. OTO-311 (doses of 0.15, 0.3, and 0.6 mg gacyclidine) was evaluated in 12 healthy subjects per dose cohort (8 OTO-311; 2 placebo; 2 sham-injection). OTO-311 was found to be safe and well-tolerated, with no serious adverse events and no early discontinuations due to adverse events. Peak plasma concentrations of racemic gacyclidine occurred 1-2 hours post-dose and were dose-dependent. Extrapolating from preclinical data, local cochlear exposures were predicted to be in the therapeutic range. Overall, gacyclidine constitutes a potent, selective and attractive NMDA receptor antagonist for the treatment of tinnitus. A Phase 2 clinical study in tinnitus patients with an improved formulation of gacyclidine, OTO-313, is being developed.

Title: Neurons in auditory cortex are sensitive to frequency pattern violation

Authors: *L. GARAMI, C. ANGELONI, K. C. WOOD, M. N. GEFFEN
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The human auditory system efficiently integrates spectral and temporal features of the environment, and auditory objects are often detected through regularities in their acoustical structure. Yet the underlying neural mechanisms remain unknown. Our goal was to identify the neuronal circuitry in auditory cortex (AC) that enables the auditory system to detect regularities in sounds.It has been shown that a network of auditory and frontal brain areas detects regular acoustic patterns. At a gross level, imaging studies showed that the AC and the prefrontal cortical regions exhibit sensitivity to violation of spectro-temporal acoustic regularities. Responses of individual neurons in AC also exhibit sensitivity to temporal regularities in sounds: Individual neurons exhibit stimulus-specific adaptation (SSA), a reduction in their response selective to frequently presented inputs. This adaptation may underlie the population sensitivity to more complex spectro-temporal acoustic regularities. Interneurons, such as Parvalbumin- or Somatostatin-positive neurons, through differential post-synaptic integration, can amplify adaptation to spectro-temporal patterns in excitatory neurons.Here, we adapted an oddball paradigm used for testing prediction errors in humans, to test the hypothesis that neurons in AC detect and encode pitch pattern violations. We used an oddball set up for probing the encoding of pitch structure. Tone pip frequencies of F1-4 were selected at 0.2 octave intervals, narrower than the typical tuning bandwidth of neurons in AC. The 4 different tone pips were arranged in pairs in a way that F1 was either preceded by a tone with an intermediate (standard) or with a large (deviant) difference in pitch. We recorded neuronal activity in AC of head-fixed mice using an

electrode array and compared the strength of responses to the deviant and standard to those in the equal probability condition.In our analysis for F1, we identified a group of neurons across 4 mice that showed stimulus-specific adaptation for this frequency. A subset of these neurons showed a firing rate increase when F1 was preceded by a rare tone (large pitch difference) compared with a standard tone (intermediate difference), suggesting that AC neurons are sensitive to spectro-temporal patterns and that the firing rate is modulated by the violation of the statistical pattern based on the frequency. These results advance our understanding of how an auditory figure would emerge based on adaptation to the spectro-temporal regularities.

Title: Dynamical properties of core vs. matrix thalamocortical networks in the auditory system

Authors: *M. N. O'CONNELL[1], A. BARCZAK[1], T. M. MCGINNIS[2], D. A. ROSS[4], J. SMILEY[3], P. LAKATOS[3]

Abstract: It has been proposed that core regions of thalamic relay nuclei faithfully transfer specific sensory information, while matrix regions are responsible for orchestrating sensory input related modulatory responses (Jones, 1998). In the auditory system the thalamic matrix is dominant in the medial (MGBm) and dorsal (MGBd) subdivisions of the medial geniculate body (MGB), while in the ventral subdivision of the MGB (MGBv) core thalamocortical projections predominate. It has been speculated that inputs originating from the thalamic matrix, or non-specific thalamus (i.e. MGBm and MGBd), are responsible for the mechanism of oscillatory phase reset and entrainment in auditory cortical regions. To investigate this, we recorded neuroelectric activity from primary auditory cortex (A1) and MGB simultaneously using linear array multielectrodes in awake macaque monkeys while auditory (preferred modality) and visual (extramodal) stimulus streams were presented separately. MGB recordings were functionally classified as belonging to either the non-specific, matrix or the specific, core subdivisions of MGB. We found that, as expected, while auditory stimuli activated both core and matrix

subdivisions, the presentation of visual stimuli only resulted in matrix activation. Analyses of single unit responses, as well as functional and effective connectivity within and between MGB and A1, revealed fundamentally distinct cellular-network properties of the core vs. matrix thalamocortical networks, corroborating their proposed distinct functional roles in perceptual processes.

Abstract: A body of research demonstrates convincingly a role for synchronization of auditory cortex to rhythms in environmental sounds such as speech and music. Some studies suggest that a hypothesized oscillator in auditory cortex could underlie important temporal processes such as segmentation and prediction. An important critique of these findings raises the question whether what is measured is in fact an oscillation or is instead a sequence of evoked responses. The two distinct mechanisms could look very similar in the case of rhythmic input, but an oscillator better provides the computational benefits mentioned above. We advance a new approach to adjudicate between the two models: analyzing the phase of synchrony at different stimulation rates. We use two kinds of computational models, evoked and oscillatory, to test this hypothesis. We show that in the evoked case, the phase of synchrony is heavily frequency dependent; the oscillatory model, in contrast, shows a much more consistent phase across frequencies. We compare these results to MEG data of participants listening to the music. The MEG data show a phase consistency that lies in between that of the pure oscillator and pure evoked model. Furthermore, the MEG signal can look more oscillatory (by this metric) depending on certain stimulus

features: the regularity of notes and the dampening of note attacks. The results support an auditory cortical signal that (i) contains components of both bottom-up evoked responses and internal oscillatory synchronization whose strengths are weighted by their appropriateness for particular stimulus types and (ii) cannot be explained by evoked responses alone.

Title: Contributions of distinct types of auditory cortical inhibitory interneurons to spectral surround suppression

Authors: *A. A. LAKUNINA[1], Y. AHMADIAN[2], S. JARAMILLO[1]
[2]Inst. of Neuroscience, Dept. of Biology, Dept. of Mathematics, [1]Univ. of Oregon, Eugene, OR

Abstract: Spectral surround suppression in the auditory cortex is the phenomenon in which a neuron's response decreases when sound power increases in frequencies outside its classical receptive field. This process is potentially useful for filtering out broadband background acoustic noise. The role of different forms of cortical inhibition in generating spectral surround suppression remains unclear. Specifically, it is not known whether different types of inhibitory interneurons play distinct roles in shaping responses to broadband noise in surround suppressed neurons. The two most common inhibitory cell types in the cortex, parvalbumin-expressing (PV) and somatostatin-expressing (SOM) interneurons, differ in their morphology and connectivity, implying a difference in function. To test the hypothesis that PV and SOM cells contribute differently to spectral surround suppression, we used optogenetic tools to tag PV and SOM cells and identify them in awake adult mice during extracellular recordings. We then characterized the responses of PV, SOM, and putative pyramidal neurons to amplitude modulated bandpass filtered noise centered on the cells' preferred frequency. By varying the bandwidth of the stimulus, we determined the effect of adding power to the spectral surround on these cells' responses. We found that both PV and SOM cells exhibit little spectral surround suppression compared to pyramidal neurons. We also found that PV cells tend to respond strongly to the onset of sound stimuli, while their sustained responses to long duration sounds are weak. In contrast, most SOM cells respond over the entire duration of the sound, and have a greater

sustained response as compared to PV cells. These results suggest that SOM cells provide sustained, sound-driven inhibition that mediates spectral surround suppression in the auditory cortex.

Title: Investigation of pitch encoding neurons in the ferret auditory cortex

Authors: *Q. GAUCHER, A. Z. IVANOV, M. PANNIELLO, J. C. DAHMEN, B. WILLMORE, A. J. KING, K. M. M. WALKER

Abstract: Pitch is one of the most salient and behaviourally relevant perceptual features of sound. It is the foundation of musical melody, and it plays a key role in both human and animal communication. Previous research in ferrets has helped to elucidate how the pitch of artificial vocal calls is encoded by auditory cortical neurons. We have shown that ferrets can classify the pitch of sounds as “low” or “high” (Walker *et al.*, 2009), that neurons which are sensitive to pitch cues are distributed widely across the auditory cortex (Bizley *et al.*, 2009, 2010; Walker *et al.*, 2011), and that auditory cortical neurons represent ferrets’ trial-to-trial pitch judgments (Bizley *et al.*, 2013). However, these studies did not examine whether the “pitch-sensitive” neurons neurons were able to maintain their tuning to a preferred fundamental frequency (F0) across a variety of stimuli (“pitch-selective” neurons), like those described in the marmoset pitch area (Bendor & Wang, 2005). In this study, we investigated whether pitch-selective neurons may also exist in non-primate auditory cortex. We recorded the responses of large populations of individual neurons to a variety of sounds that each varied in F0 (17 F0 values; 250 - 4000 Hz). The stimuli included click trains with varied temporal periodicity, pure tones, as well as sounds with filtering and phase manipulations to manipulate resolved harmonic and temporal envelope cues. Data were collected from ketamine and medetomidine anesthetized adult ferrets using high-channel-count multielectrodes (Neuropixels) and by imaging single neuron calcium dynamics with GCaMP6 under a 2-photon microscope. These experiments identified a subset of auditory cortical neurons with pitch selective responses, similar to those previously reported in marmoset (Bendor & Wang, 2005). Ferret pitch-selective neurons usually showed greater

sensitivity to temporal cues than resolved harmonic cues, in keeping with our recent behavioural findings (Walker et al., submitted).

Title: Opposite abnormalities in gap-in-noise sensitivity in the auditory midbrain and thalamus of a mouse model of developmental disorder

Authors: *J. MATTLEY[1], L. ANDERSON[1], J. F. LINDEN[2]
[1]UCL Ear Inst., London, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: The BXSB/MpJ-*Yaa* mouse is a powerful animal model for studying the neural mechanisms of gap-detection deficits. Around 30-50% of BXSB/MpJ-*Yaa* mice have small cortical malformations called ectopias. Previous work has shown that ectopic mice have more difficulty detecting very short gaps in noise than non-ectopic mice (Clark et al. 2000). Furthermore, minimum gap durations required to elicit significant changes in the activity of auditory thalamic neurons are longer in ectopic than non-ectopic mice (Anderson and Linden 2016). Moreover, sound-offset responses --- transient increases in firing at sound termination --- are less common in auditory thalamus of ectopic mice, suggesting the hypothesis that the abnormal thalamic gap-in-noise sensitivity might arise from a deficit in sound-offset responses (Anderson and Linden 2016).
To determine whether neural deficits in gap-in-noise sensitivity and sound-offset responses in the auditory thalamus of ectopic mice are inherited from the midbrain, we made extracellular recordings from the inferior colliculus (IC) in 10 ectopic and 10 non-ectopic BXSB/MpJ-*Yaa* mice. Mice were anaesthetised with urethane (as in the previous thalamic study), and neural responses recorded with 16-channel microelectrode arrays (Neuronexus). In contrast to the previous results from the lemniscal (primary) auditory thalamus, in IC we found that minimum gap durations for evoking responses to gap-in-noise stimuli were *shorter* in ectopic than non-ectopic mice, for neurons with V-shaped tuning curves typical of the lemniscal IC (rank-sum $p<0.001$; ectopic n=133 recordings, non-ectopic n=79). However, in agreement with previous

thalamic results, we found that the proportion of cells with sound-offset responses in IC was significantly reduced in ectopic mice (9% in ectopic, 15% in non-ectopic across all IC recordings; Fisher's exact test p=0.03). These results indicate that the offset-response deficit in auditory thalamus of ectopic BXSB/MpJ-*Yaa* mice may be inherited from the IC. Moreover, the observation that in ectopic mice, minimum gap duration thresholds are abnormally high in auditory thalamic neurons but abnormally low in IC neurons suggests a critical role for midbrain and/or thalamic circuitry in development of gap-detection deficits.

Title: Auditory encoding of temporal and formal regularity in rhesus monkeys

Authors: *M. SCHWARTZE[1], H. MERCHANT[2], S. A. KOTZ[3]
[1]Maastricht Univ., Maastricht, Netherlands; [2]Inst. de Neurobiologia UNAM, Queretaro, Mexico; [3]Dept. of Neuropsychology & Psychopharmacology, UM, Fac. of Psychology and Neurosci., Maastricht, Netherlands

Abstract: Synchronization of motor behavior to events in the environment (entrainment) is readily observable in everyday activities such as sports, dance, or music performance. However, entrainment is also increasingly recognized as a hallmark of non-motor cognitive behavior, including speech processing, most likely serving the predictive allocation of neural and cognitive resources. This requires efficient encoding of recurrent regular stimulus relations as a potentially uniquely human precursor for predictive adaptation to dynamic sensory input. Here we used an experimental design previously tested in humans to assess auditory temporal (rate) and formal (pitch) regularity encoding in two rhesus monkeys (macaca mulatta). The monkeys listened repetitively to sequences of 512 standard (600 Hz) and 128 deviant (660 Hz) equidurational (300 ms, 10 ms rise and fall) sinusoidal tones (standard-to-deviant ratio 4:1). Pseudo-randomization ensured that each sequence started with four standard tones and that no more than two deviants were presented in a row. These sequences were presented with isochronous (900 ms; regular condition) or random (500-1300 ms; irregular condition) stimulus-onset-asynchronies.

Electroencephalographic (EEG) recordings were obtained from five scalp locations (Fz, F3, F4, Cz, Pz according to the 10-20 international system). Analyses focused on amplitude modulations (i.e., relative suppression effects) of the mid-latency P50 and N100 components of the event-related potential (ERP) and on evoked oscillatory responses at stimulation frequency taken as indices for the quality of temporal and formal regularity encoding in predictable and unpredictable contexts. The results confirm a similar pattern of ERP amplitude modulations for formal (amplitude suppression in response to standard relative to deviant tones) and temporal regularity (amplitude suppression for regular relative to irregular stimulus timing) in monkeys as in humans, suggesting that basic principles of regularity encoding also exist in monkeys and are comparable across both species.

Title: Human screams' roughness and pitch synergistically and simultaneously contribute to trigger efficient neural and behavioral responses

Authors: *L. H. ARNAL, P. MÉGEVAND, A.-L. GIRAUD
Neurosci., Univ. of Geneva, Geneva, Switzerland

Abstract: The ability to rapidly communicate danger using vocal signals (screams) is essential to warn conspecifics and promote our survival. Human screams constitute complex signals that exploit a combination of attributes (roughness, pitch) to convey a mixture of ecologically relevant information (about danger and emitter’s sex/age, respectively) to elicit adapted reactions by the receiver.
We previously identified roughness as the key acoustic features to selectively inform conspecifics about danger. Here, we consider another attribute, the pitch, as relevant to the receiver in a dangerous situation. For instance, it might be the case that a child’s high-pitched scream induces a distinct, faster reaction than an adult’s one. Whether these distinct features are concurrently or sequentially encoded in the brain and how they contribute to elicit adaptive behavioral responses is unknown.
Here, we used electroencephalographic (EEG) and intracranial recordings iEEG to investigate the neural encoding of pitch and roughness in the human brain. Sixteen participants (nine women) were required to spatially localize natural and synthetic vocalizations that varied along both pitch and roughness dimensions. We used a general linear model approach to measure the respective influence of these two fundamental features on neural and behavioral responses. We

identified that early neural signals (~P1, 50ms post stimulus onset) simultaneously represent these two features in a concurrent way, revealing a simultaneous encoding strategy. We further quantify the relative effect of these features on localization speed and show that these two features synergistically contribute to trigger rapid reactions to danger. These results show that human screams provide a sophisticated signaling system that rapidly elicits reactions optimally adapted to the ecological relevance of the situation.

Title: Auditory event related activity in children with Tuberous Sclerosis Complex

Authors: *A. M. O'BRIEN[1], L. BAYET[2,4], K. RILEY[3], C. A. NELSON[2,5,7], M. SAHIN[6,3], M. E. MODI[6,3]
[1]Boston Children's Hosp., Waltham, MA; [2]Labs. of Cognitive Neurosci., [3]Dept. of Neurol., Boston Children's Hosp., Boston, MA; [4]Dept. of Pediatrics, [5]Pediatrics and Neurosci., [6]Dept. of Neurol., Harvard Med. Sch., Boston, MA; [7]Educ., Harvard Univ., Boston, MA

Abstract: Tuberous Sclerosis Complex (TSC) is a genetic syndrome caused by a mutation in either the *TSC1* or *TSC2* gene characterized by benign growths throughout the body, including the brain. Within the brain, many individuals present with cortical tubers and alterations in white matter integrity, hypothesized to disrupt neural connectivity. Related to the brain pathology, many individuals with TSC are co-diagnosed with intellectual disabilities and/or an autism spectrum disorder (ASD) including deficits in language acquisition and development. We hypothesize that the deficits in neural connectivity in TSC will be evident through characterization of auditory event related potentials (ERP) in response to both basic auditory stimuli and, notably, in speech associated stimuli. As such, this study used high-density electroencephalography (EEG) to analyze auditory ERP in children with TSC during an auditory gating paradigm and a tone vs. speech mismatch negativity paradigm using both traditional methods of waveform analyses and novel multivariate pattern analyses (MVPA). Nine subjects with a diagnosis of TSC (ages of 4 to 14), and age-matched typically developing (TD) controls participated in the study. Comparison of amplitude and latency of the ERP to white noise stimuli across groups demonstrated children with TSC have significantly increased latency of the early P50 ERP component demonstrating altered basic auditory sensory processing. Deficits were also

seen in the mismatch response to tone stimuli in children with TSC relative to typically developing controls. Additionally, we utilized a novel analysis for EEG-based speech sound processing data, MVPA, to explore the functional specificity of neural processing for speech sounds compared to non-speech stimuli. A linear classifier was trained to decode neural activity between stimulus categories (e.g., standard speech stimuli vs. standard non-speech stimuli) over time by diagnosis. More reliable decoding of speech versus non-speech than of different speech or different non-speech stimuli was found for TD individuals but not for the TSC group in both early and late time windows of response. Using both traditional and novel analytical methods we have identified features of the auditory neural response that differentiate between children with TSC and TD controls. Based on findings in animal models of TSC, we believe the alterations in ERP responses are associated with deficits in axon formation and myelination and thus may be a biomarker of neural connectivity that could be used for both patient stratification and a measure of treatment response in future treatment trials.

Title: Spectral shape based adaptation unravels mechanisms underlying spectral contrast coding in the mouse auditory cortex (ACX)

Authors: *A. MUKHERJEE[1], P. PATEL[2], A. MUKESH[3], M. MEHRA[4], S. BANDYOPADHYAY[5]
[1]Indian Inst. of Technol., Iit Kharagpur, India; [2]Dept. of Biotech., Indian Inst. of Technol., Iit Kharagput, India; [3]Dept. of Biotech., [4]Advanced Technol. and Develop. Ctr., Indian Inst. of Technol., Iit Kharagpur, India; [5]Dept. of Electronics & Electrical Communications Engineerng, Indian Inst. of Technol., Iit Kjaragpur, India

Abstract: Spectral contrast, a feature of auditory stimuli, plays an important role in recognition of sound objects in different situations for example in background noise. Further, spectral contrast plays a role in coding of complex stimuli with wideband characteristics especially in the presence of multiple sound sources and also in binding together auditory streams. Wideband

stimuli with varying spectral contrasts are more naturalistic as opposed to tonal sound stimuli, used generally to study tuning and coding properties of auditory cortical neurons. We study the mechanisms underlying spectral coding by excitatory (EX) and different classes of inhibitory (parvalbumin positive, PV and somatostatin positive, SOM) neurons (EXNs and INNs) in the mouse auditory cortex (ACX; primary ACX, AI and anterior auditory field, AAF) using streams of random spectral shape (RSS) stimuli (R) of varying spectral contrast with embedded deviant RSS stimuli (D; as RRR ⋯ RDRRR), also of different contrasts. Each of such stimulus token comprising the streams used, have a steady spectral shape throughout its duration and each stimulus have random spectral content (frequency resolution $1/8^{th}$ octave) drawn from a Gaussian distribution of different standard deviations, which defines the spectral contrast of the particular stimulus. Responses to RSS stimuli were found to be sparse. Further, using an RSS stimulus of a certain contrast as the repeating standard stimulus (R), neurons adapt based on each neuron's spectral tuning and contrast selectivity and depending on the particular spectral shape used as the deviant (D), each neuron responds weakly or strongly to the deviant. Using 164 such different streams of RSS stimuli with embedded deviants, we present organized estimated underlying synaptic spectral contrast selectivity providing input to supragranular cells in the ACX. Based on a model with synaptic adaptation in conjunction with our data, we conclude the differential roles played by synaptic adaptation and INNs in differential spectral coding by EXNs and PV and SOM neurons.

Title: Validation of advanced cochlear nucleus auditory prosthesis with 3d penetrating microelectrodoe arrays

Authors: *M. HAN[1], D. B. MCCREERY[2]
[1]Biomed. Engin. Dept., Univ. of Connecticut, Storrs, CT; [2]Neural Engin. Program, Huntington Med. Res. Inst., Pasadena, CA

Abstract: For persons with deafness who cannot benefit from cochlear implants, some hearing can be restored by an array of stimulating electrodes implanted on the surface of or in their cochlear nucleus (CN). However, additional research is needed to show that the Auditory Brainstem Implants (ABIs) can restore hearing comparable to that provided by cochlear implants. In particular, the device has to be validated chronically and the encoding scheme has to be revealed. Previously, a clinical trial of a hybrid ABI containing macroelectrodes on the surface of the CN and also penetrating microwire-based microelectrodes showed that the surface electrodes best conveyed the loudness of the electrically-encoded sound but poorly conveyed its pitch, while the penetrating microelectrodes best conveyed the encoded sound's pitch, but with only limited range of loudness. In this study, we have chronically implanted arrays of penetrating silicon-based 3D microelectrode arrays into cats' ventral cochlear nucleus. These are three-dimensional, four-shanked devices that feature five independent electrode sites on each deep-reactive-ion-etched sturdy shank. This allows access to the tonotopic organization of the cochlear nucleus while also minimizing the number of penetrations into the brain (Han, 2012). The cochlear nucleus device also included a macroelectrode that reside on the surface of the nucleus. The neuronal activity induced by modulated electrical stimuli applied though both types of electrodes were recorded by another array of also silicon 3D microelectrode arrays implanted in the central nucleus of the inferior colliculus. Results showed that the temporal modulation of the neuronal activity induced by the modulated stimuli applied in (penetrating) or on (surface) the CN was very similar across a range of modulation frequencies and modulation depths, especially for transient modulation simulating the periodicity of speech. Our findings support the concept of a clinical ABI that employs surface stimulation and intranuclear microstimulation in an integrated manner.

Title: Exploring neural population dynamics in auditory processing from the macaque superior temporal gyrus

Authors: *J. LEE, L. LYNCH, D. M. BRANDMAN, A. NURMIKKO
Brown Univ., Providence, RI

Abstract: The macaque superior temporal gyrus (STG) displays a robust tuning to the low-order auditory features, e.g. frequency, while it also shows a selectivity to high-order features of sound, such as species-specific communication call types and spatial information. Also, compared to the primary auditory cortex (A1), the auditory parabelt on STG is more accessible surgically, which offers an opportunity to explore broad principles of sound perception and possibilities in applying a functional intervention for neural prostheses. Our goal is to characterize neural states of the parabelt by performing intracortical microelectrode array (MEA) recordings in macaques. For study of neural population dynamics, we implanted two Blackrock 100-channel iridium oxide MEAs into the STG of one adult macaque. We also implanted titanium mesh to be ossiointegrated on the surface of the cortical bone to improve the stability of electrode pedestals during the experiment. Using the lateral sulcus and the superior temporal sulcus as a reference, electrode arrays were implanted on caudal parabelt regions above the medial lateral belt and caudal lateral belt. Those two areas are known to has a selectivity for the frequency of sound and the location of the sound source, respectively, and several researchers suggest that that information is also represented on the parabelt. Sinusoidal sound and temporally orthogonal ripple combination (TORC) was used to characterize the spectro-temporal receptive field (STRF) of neurons in STG during passive listening. More complex sound stimuli, such as macaque call and human speech were presented. Data processing including filtering, spike sorting and the cross-correlation with sounds and spikes was done in MATLAB. We report on the population recordings from our experiment and efforts to generate internal models for neurons. Based the model, our goal is to deliver patterned electrical stimuli into STG and assess the effects of the stimuli in the performance of the animal during the behavioral test, such as two-tone discrimination or sound recognition tasks.

Title: Sex differences in frequency tuning in the inner ear of African clawed frogs (Xenopus)

Authors: *A. COBO-CUAN, P. M. NARINS
Univ. of California Los Angeles, Los Angeles, CA

Abstract: Reproductive success in anurans relies on their ability to detect, recognize, and localize sound. African clawed frogs, *Xenopus laevis*, use sex-specific vocalizations that convey sex identity and reproductive state. Recordings of auditory-evoked potentials in this species have demonstrated that auditory sensitivity to species-specific dominant frequencies in the advertisement calls is enhanced in females relative to males. In addition, this frequency sensitivity is affected by endocrine state. However, it is unclear where these sexual differences in spectral sensitivity arise. Here, we examine distortion product otoacoustic emissions (DPOAEs) to determine if the inner ear of this species exhibits a sexually dimorphic frequency tuning. DPOAEs were evaluated in adult individuals of *X. laevis* (5 males, 5 females). The frequency ratio of the species own dyad (1.14) was used as the f2/f1 ratio. A matrix of frequency-level combinations (37 frequencies × 15 levels) was randomly presented with f_2 values from 300 to 4000 Hz (100 Hz steps), and L_2 values from 60 to 90 dB SPL (2 dB steps). Input-output curves of DPOAEs from the two inner ear organs sensitive to airborne sound, the amphibian and basilar papillae, were also measured. Otoacoustic emissions appeared in a frequency range coincident with the spectral sensitivity previously characterized in behavioral and neurophysiological studies. DPOAE responses showed tuning differences between sexes. Males' ears are more sensitive to lower frequencies, while females' ears are tuned to the advertisement call frequencies. Consistent with anatomical adaptations for waterborne hearing, input-output DPOAE functions showed a saturating nonlinearity shifted toward high stimuli levels. We provide evidence that sexually dimorphic tuning in *X. laevis* occurs at the first stage in the auditory pathway. Since DPOAE generation is associated with the nonlinear mechanics in the hair cells, this could be the locus in the auditory periphery where sex differences in hearing emerge. Further studies are needed to determine if hair cells are the target of estrogens enhancing female auditory sensitivity.

Title: Direct cortical localization of the meg auditory temporal response function: A non-convex optimization approach

Authors: *P. DAS[1], C. BRODBECK[2], J. Z. SIMON[1,2,3], B. BABADI[1]
[1]Dept. of Electrical and Computer Engin., [2]Inst. for Systems Res., [3]Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Listening to continuous speech generates an ongoing auditory cortical response. When measured with magnetoencephalography (MEG), the functional relationship between the two can be characterized by the temporal response function (TRF). The TRF quantifies the relation between the acoustic input (speech envelope) and the auditory output (MEG responses) as the kernel of a linear convolution process. By capturing the temporal structure of the stimulus-response relationship, the TRF plays a key role in characterizing auditory information processing. For instance, the prominent negative peak observed in the TRF with a latency of ~100 ms has been shown to be modulated by the attentional state in a competing-speaker environment.

While functional roles of specific components of the TRF captured at the sensor level have been well characterized, the cortical distribution of the TRFs corresponding to underlying neural responses is not well-understood. The existing techniques for analyzing the cortical localization of these TRFs operate in a two-stage fashion: for instance, the raw MEG data are first mapped to the cortical surface using an anatomically constrained distributed source localization technique, followed by estimating TRF for each source location separately. The resulting estimates, therefore, are often highly biased and their quality can be heavily dependent on the correctness of the localization of the raw MEG data.

To address these shortcomings, we provide a unified framework for determining the cortical localization of the TRFs directly from the MEG data, by integrating the TRF and distributed forward source models into one, and casting the estimation task as a Bayesian optimization problem. Though the resulting problem emerges as non-convex, we show that solutions can nevertheless be obtained using an efficient algorithm that leverages recent advances in evidence maximization. We demonstrate the effectiveness of the resulting algorithm in both simulated and experimentally recorded MEG data from humans. Application of our algorithm to MEG responses to continuous speech provides new insight into the functional roles of the auditory and somatomotor cortices in the early and late stages of auditory processing.

Abstract: Auditory cortex is thought to be organized into different cortical fields, each of which encodes multiple acoustic properties. Functional characterization of human cortical fields has largely depended on non-invasive brain imaging techniques such as fMRI. However, because fMRI indirectly measures neural responses via hemodynamic activity, it has limited temporal resolution, making it difficult to study the neural encoding of speech features which vary on the timescale of miliseconds. Thus, here we used direct intracranial recordings from 12 human subjects that were implanted with depth and grid electrodes.We recorded neural data in response to 40 minutes of natural speech and other commonly heard sounds. Using 350 electrodes in primary and secondary auditory cortices, we created seven cortical maps based on tuning for each of seven different acoustic features: frequency, latency, temporal modulation, spectral modulation, phonetic features, speaker features, and speech-specificity. The frequency and latency preferences were calculated from spectro-temporal receptive fields (STRF), estimated from each electrode. The temporal and spectral modulation maps were calculated by filtering the acoustic spectrograms through different cochlear filters and then by selecting the cochlear filters that best represent the temporal modulation preference and spectral modulation preference of the neural data.Consistent with prior fMRI studies, we found that topographic maps of frequency preference, latency, temporal modulation, and spectral modulation were dependent on two axes of medial-lateral and posterior-anterior direction in human auditory cortex. But contrary to prior fMRI studies, we did not find any specialized region for analyzing phonetic features, meaning that all of the four regions of medial Heschl's gyrus (HG), lateral Heschl's gyrus, planum temporale, and superior temporal gyrus (STG) encode the distinctive acoustic features of phonemes, and there was not a significant difference between their preferred phonetic feature. In addition, we found that information about speaker identity was better encoded in early auditory areas such as HG in comparison with secondary areas such as STG. Finally, we found that electrodes in STG selectively responded more to human speech compared to nonspeech sounds, such as animal vocalization, tones and music, confirming prior reports of speech-selectivity based on fMRI.Together, these findings advance our knowledge of the representational and functional organization of human auditory cortex and pave the way toward more complete models of cortical speech processing in the human brain.

Title: A computational model of the underlying mechanisms of temporal coding in auditory cortex

Authors: *J. LEE[1], X. WANG[1], D. A. BENDOR[2]
[1]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD; [2]Univ. Col. London, London, United Kingdom

Abstract: Neurons in the mammalian primary auditory cortex can temporally lock to individual acoustic events up to around 40-50Hz, covering the range of acoustic flutter. While modulation rates within the perceptual range of acoustic flutter are therefore represented temporally, primary auditory cortex neurons can also monotonically increase (Sync+) or decrease (Sync-) their discharge rates over this range of repetition rates that span flutter perception (Bendor and Wang 2007). Although neural mechanisms of stimulus-synchronized and non-synchronized responses have been studied using computational models of single neurons (Bendor 2015, Gao and Wang 2016), the integration of rate coding in stimulus-synchronized responses , to generate Sync+ and Sync- responses, has not yet been directly examined using such computational models. Here we investigated the underlying neural mechanisms responsible for Sync+ and Sync- responses in auditory cortex, and demonstrated that the addition of synaptic depression to a leaky integrate-and-fire excitation-inhibition model can reproduce these two response modes. Specifically, stronger synaptic depression of excitatory inputs relative to inhibitory inputs leads to Sync- responses while weaker synaptic depression of excitatory inputs relative to inhibitory inputs leads to Sync+ responses.

Abstract: Spatial size tuning in the visual cortex has been considered as an important neuronal functional property for sensory perception. However, an analogous mechanism in the auditory system has remained controversial. In the present study, cell-attached recordings in the primary auditory cortex (A1) of awake mice revealed that excitatory neurons can be categorized into three types according to their bandwidth tuning profiles in response to band-passed noise (BPN) stimuli: nonmonotonic, flat and monotonic, with the latter two considered as non-tuned for bandwidth. The prevalence of bandwidth-tuned (i.e. nonmonotonic) neurons increases significantly from layer 4 to layer 2/3. With sequential cell-attached and whole-cell voltage-clamp recordings from the same neurons, we found that the bandwidth preference of excitatory neurons is largely determined by the excitatory synaptic input they receive, and that the bandwidth selectivity is further enhanced by flatly tuned inhibition observed in all cells. The latter can be attributed partially to the flat tuning of parvalbumin (PV) inhibitory neurons. The tuning of auditory cortical neurons for bandwidth of BPN may contribute to the processing of complex sounds.

Title: Attention increases information flow between auditory cortex and subcortex

Authors: *D. PRETE[1], M. BAIN[2], L. J. TRAINOR[2]
[2]Dept. of Psychology, Neurosci. and Behavior, [1]McMaster Univ., Hamilton, ON, Canada

Abstract: Within the auditory neural pathway there are bidirectional projections between the auditory cortex (AC) and subcortical regions, such as the inferior colliculus (IC). Yet, how these

connections influence auditory processing in humans is unclear. To estimate the activity and information flow between the AC and IC we measured EEG while presenting tones to elicit activity from both regions. The tones consisted of a pure tone carrier frequency that was amplitude modulated at 37 Hz. The amplitude modulation was chosen to index AC activity (the classic 40 Hz response), and the carrier to elicited subcortical activity via the frequency following response (FFR). Tones were presented to the right ear in an oddball sequence with a 500 Hz carrier frequency for 80% of trials and a 600 Hz carrier frequency for 20% of trials (these carrier frequencies ensure a subcortical source). Only standard tones are analyzed here. Participants either attended to the sequence by counting the number of deviant tones or passively listened while watching a silent movie. Information flow between the AC and IC was computed using normalized symbolic transfer entropy (NSTE). NSTE measures how much more one signal can predict the future of a second signal, specified by a delay, than past of the second signal. NSTE for each standard tone was calculated using 300 delays from 1 to 299 ms between the tone onset and offset. NSTE was then averaged across trials per participant per delay per direction of information flow and NSTEs at delays of a priori interest (8 ms, the IC to AC delay time; 17ms), as well as the maximum NSTEs across all delays, were extracted. A repeated measures ANOVAs on predictability, attention, direction of information flow and delay (8 and 17 ms) found that, overall, NSTE was greater from IC to AC (bottom up) than vice versa ($p < 0.001$, Cohen's $f = 0.373$), attention increased NSTE overall ($p = 0.005$, Cohen's $f = 0.380$) and the attentional effect was marginally greater from AC to IC (top down) than vice versa ($p < 0.066$, Cohen's $f = 0.115$). Interestingly, the maximum NSTE across all delays was consistently around 230 ms across participants for both directions. A repeated measures ANOVA reveal greater information flow from AC to IC (top down) at this delay in contrast to the shorter delays. A duration around 200ms is interesting as it is around the syllables rate in speech, a time at which sound events are clearly individuated, and features such as pitch and loudness are clearly integrated into auditory objects. We are currently conducting follow up studies to investigate the robustness of this effect.

Title: Cricket song temporal pattern recognition in two populations of ormia ochracea

Authors: *A. T. KIRTLEY[1], N. LEE[1], J. HAO[1], M. C. MASON[2]
[1]St. Olaf, Northfield, MN; [2]Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstract: The parasitoid fly *Ormia ochracea* relies on host crickets for reproduction. Finding host crickets depends on the auditory system to recognize and localize cricket songs. These songs are species-specific and differ primarily in the temporal patterning of sound pulses. *O. ochracea* occur in several geographically distinct regions in the United States and each population targets a different cricket species. In Florida, *Gryllus rubens* is the primary host, which produces a ~50 pulses/sec calling song. In California, the primary host *Gryllus lineaticeps* produce songs at a higher pulse rate. Whether different populations of *O. ochracea* evaluate the same temporal parameter for song recognition is unknown. In this study, we use a high-speed treadmill system to record tethered walking responses to song models that vary in pulse duration and interpulse intervals. We describe song recognition 'maps' for Floridian and Californian *O. ochracea* to test the hypothesis that both populations evaluate pulse periods for recognition and song preferences are based on species-specific pulse periods. These results will guide our investigation of the neural correlates of song recognition in *O. ochracea*.

Title: Composite receptive fields across neuronal populations in songbird auditory cortex

Authors: *N. W. VAHIDI[1], M. THEILK[1], T. GENTNER[2]
[2]Psycholology, [1]UCSD, La Jolla, CA

Abstract: How the brain encodes complex stimuli such as communication signals in a population of neurons and how this encoded information is combined to shape response outputs are important questions in sensory neuroscience. In addition to a diversity of response characteristics across neurons in a population, recent work points to similar response diversity within single neurons. This within-neuron response diversity is observed throughout the secondary auditory cortical regions NCM (caudo-medial nidopallium) and CM (caudal mesopallium) in European starlings, a species of songbird, where increases and decreases in spiking activity of a single neuron are tied to many (typically >10) unique acoustic features. We term these acoustic feature sets the neuron's 'composite receptive field' (CRF). Here we examine auditory CRFs in more detail, asking how these feature sets vary within and between neurons, how they relate to the anatomical positions of neurons along laminar tracts spanning starling auditory cortex, and how natural stimuli drive CRFs in single neurons and populations across

time. Using silicon arrays, we recorded extracellular spiking responses from large neuronal populations comprising single and multi-unit activity in the NCM and CM of lightly anesthetized starlings, while presenting large libraries (> 1 h) of conspecific songs. We then computed the CRF for each unit using the Maximum Noise Entropy model, which allows for identification of relevant receptive field features akin to the spike-triggered covariance but unbiased by the non-Gaussian structure of song. This yielded a pool of acoustic features tied to either significant increases or decreases in spiking activity in each unit. We created a coarse linear map of the population 'spatial tuning' by assigning the CRFs for each unit to the array site with the largest magnitude spike waveform for that unit. We create a 'temporal tuning' map, by aligning the CRFs for each unit to the time varying acoustics of songs using cross correlation. The resulting spatio-temporal organization of CRFs reveals no discernable low-dimensional structure (e.g, frequency range, spectral modulation, etc) within a single unit, or between units across either anatomical space or time. Instead, the CRF feature sets express a rich heterogeneity of spectro-temporal characteristics, that collectively provide a detailed representation of many conspecific songs stable across epochs lasting seconds. Extrapolating from the coverage of the observed spatio-temporal CRF maps, we estimate the approximate number of neurons and CRF features needed to encode an entire conspecific song bout, and the representational capacity of NCM.

Med. at UCLA, Los Angeles, CA; [7]Physiol. & Biophysics, Dalhousie Univ., Halifax, NS, Canada

Abstract: Feedback signaling by horizontal cells regulates the gain of photoreceptor synaptic output and contributes to the center-surround receptive field properties of downstream neurons in the retina. Many studies have shown that horizontal cell membrane potential drives actions leading to the modulation of presynaptic Ca channels in photoreceptors. Emerging evidence suggests that GABA is responsible for this feedback and that it acts not at cones but rather on horizontal cells, the same cells that release it, producing interstitial pH shifts that modulate photoreceptor Ca channels. In support of this hypothesis, the GABA agonist muscimol inhibits cone Ca channels when horizontal cells are depolarized, and blocking GABA receptors produces disinhibition of cone Ca channels. Both of these are pH-dependent actions. That the GABA responsible for this action is released by horizontal cells is shown by using a conditional and cell-type specific knockout of VGAT (Cx57-VGAT) in horizontal cells. VGAT is the transporter that loads GABA into synaptic vesicles and without VGAT, horizontal cells do not release GABA and there is no feedback. Since the reversal potential for current in GABA activated channels, permeable to Cl^- and HCO_3^-, is close to -30 mV, their activation depolarizes the horizontal cell. Depolarization of horizontal cells reduces the driving force on HCO_3^- efflux, allowing normal acidifying influences to dominate cleft pH, and block of NKCCs with bumetanide reduces inhibition of cone Ca channels, similar to the actions of amiloride and cariporide, which block NHEs. Acidification of the synaptic cleft inhibits cone Ca channels, reducing the gain of synaptic signaling to postsynaptic neurons, including bipolar cells. To confirm the site-to-site nature of this pathway, we reproduced the core mechanism that mediates feedback with targeted expression to horizontal cells of an orthogonal chemogenetic anion channel (PSAM-GlyR), an anion permeable GlyR complex. Horizontal cells transduced with AAV-7m8 virus containing a PSAM-GlyR-IRES-GFP construct showed a high degree of expression in horizontal cells and in no other cell types. Activation of PSAM-GlyR with the ligand, $PSEM^{308}$ caused inhibition of cone Ca_v channels, reproducing the site-specific actions of GABA on cone Ca_v channels. $PSEM^{308}$ had no effect in untransduced eyes, indicating that the expression of this engineered GlyR anion pore in horizontal cells is sufficient to reconstitute the Ca channel inhibition in cone photoreceptors produced under normal physiological conditions by autaptic GABA activity in horizontal cells.

Title: Characteristics of ATP-induced extracellular acidification from retinal Müller (glial) cells

Authors: M. GONGWER, 46953[1], B. K. TCHERNOOKOVA[2], L. SHEPHERD[1], H. CARINGAL[1], B. GOEGLEIN[1], T. LEUSCHNER[1], R. P. MALCHOW[2], *M. A. KREITZER[1]

Abstract: Within the retina, acidification of synaptic environments has been shown to significantly attenuate synaptic transmission. This study characterizes a novel non-neuronal pathway in the retina that evokes an extracellular acidification. In this pathway, Müller glia, upon activation by the signaling molecule ATP, acidify the extracellular environment. Measurements of proton fluxes from the apical (photoreceptor) end of isolated salamander Müller cells were performed using H^+ sensitive self-referencing microelectrodes, an effective method for measuring relative ion fluxes from cells (see Kreitzer et al., 2007). Calcium imaging experiments using Oregon Green implicate that ATP binds to a $P2Y_1$ receptor, and in combination with self-referencing experiments point toward the ATP-dependent acidification requiring Ca^{2+} release through an IP_3 pathway. We report here a dependency of the acidification on the presence of extracellular Na^+. Removal of Na^+ was shown to significantly attenuate the ATP-induced extracellular acidification. Attenuation of the acidification by the sodium transport blocker amiloride and the sodium-hydrogen exchanger blocker cariporide were also observed. Surprisingly, the ATP-induced extracellular acidification was sensitive to extracellular K^+. Reintroduction of K^+ from a nominally 0 K^+ solution significantly potentiated the ATP-induced acidification. However, this K^+ sensitivity was dependent upon the presence of Na^+. We hypothesize that Müller glia are potent acidifiers of the extracellular space. This extracellular acidification induced by ATP is mediated by a $P2Y_1$ receptor calcium-dependent pathway and is highly sensitive to the presence of Na^+ and K^+ outside of the cell. Our findings also point to a potential role for Na^+/H^+ exchange in driving this acidification. We hypothesize glial cell based extracellular acidification may be an important regulator of signaling throughout the nervous system.

Abstract: With an increasing number of causative genes identified, the widespread use of gene therapy becomes feasible. For gene therapy, it is desirable to have a delivery method with both high cell type specificity and high efficiency. The need for cell type specificity and high efficiency is particularly important for treating retinal degenerations, which may result from defects in the pigmented epithelium, in rods, or in cones. Viruses are potent gene delivery vehicles for the nervous system, but they suffer from non-specific infection. To address specificity and efficiency in targeting retinal photoreceptors, we have screened various adeno-associated virus (AAV) serotypes for infection patterns in the mouse retina following subretinal injection. We have identified a serotype that specifically and efficiently infects cone photoreceptors. Or study may provide a useful tool for delivering new genetic information to cones for the purpose of restoring genes involving in degenerations.

Title: How feedback at the first visual synapse shapes functional diversity in the retina

Authors: *A. DRINNENBERG[1,2], F. FRANKE[3], R. K. MORIKAWA[1,2], J. JÜTTNER[1,2], A. HIERLEMANN[3], R. A. D. SILVEIRA[4], B. ROSKA[1,2]

Abstract: Horizontal cells reside at a strategic position within the visual system, since they act at the first visual synapse before the signal is split into parallel channels that, ultimately, gives rise to the responses of ~30 types of retinal output neurons. It is known that horizontal cells deliver feedback inhibition to photoreceptors via a sign-inverting synapse. How does horizontal cell feedback shape the dynamics of the retinal output? Are individual retinal output channels differentially affected? Here we specifically and reversibly perturbed the activity of horizontal cells across the entire retina using chemogenetics and combined the perturbation with a system-level and cell-type specific readout of the retinal output. We injected mice expressing Cre recombinase in horizontal cells with adeno-associated virus (AAV) that conditionally express a chemogenetic channel. Intravenous injection of virus coated with the PHP.B capsid led to strong and retina-wide expression of the channel exclusively in horizontal cells. In the same retinas, we targeted the calcium indicator GCaMP6s to cones by injecting AAV that expressed GCaMP6s under a cone-specific promoter. By two-photon calcium imaging of cone photoreceptors in whole-mount retinas, we demonstrate that the perturbation effectively and reversibly blocked the light-modulation of horizontal cell feedback. To monitor the effects in the retinal output, we recorded the light-driven spiking activity in thousands of ganglion cells using high-density microelectrode arrays. We uncovered six effects on the response dynamics and response range of ganglion cells. Unexpectedly, perturbing horizontal cells suppressed or enhanced the responses of ganglion cells of the same polarity at different epochs of the response, even within the same ganglion cell. We then used chemogenetic identification of ganglion cell types on the microelectrode array, functional classification of ganglion cells using naturalistic visual stimuli, and laser-targeted single-cell recordings of genetically identified ganglion cell types to show that the horizontal cell perturbation differentially affects individual ganglion cell types. How can the perturbation of a single interneuron type result in such a variety of effects? We developed a computational model of the retinal circuitry. The model reproduced all observed effects, thus providing insights into how feedback at the first visual synapse can affect the retinal output in

diverse ways. Our combined experimental and theoretical work reveals how a single interneuron type can differentially shape the dynamical properties of distinct output channels of a brain region.

Title: Molecular specification of cells in the primate fovea and peripheral retina

Authors: *Y.-R. PENG[1], K. SHEKHAR[2], W. YAN[1], D. HERRMANN[1], G. S. BRYMAN[3], A. LIU[3], T. VAN ZYL[4], M. T. H. DO[3], A. REGEV[2,5], J. R. SANES[1]

Abstract: The retina, like other parts of the central nervous system, uses complex neuronal networks to perform sophisticated computations. Its genetic accessibility has made the mouse retina a valuable model for analyzing the structure and function of neural circuits. As a model for primate vision, however, it suffers from a severe drawback. High acuity vision in primates is mediated largely by a specialized, central region of the retina called the fovea or macula (with the macula extending into parafoveal and perifoveal zones). Indeed, even though the fovea comprises <1% of the retina, loss of foveal function leads to functional blindness. However, among mammals, only primates have a fovea. Although the same cell classes (horizontal, bipolar, amacrine, and retinal ganglion cells [RGCs], photoreceptors, and Müller glia) are found in fovea and peripheral retina, structural and functional differences abound. For example, cones and rods are the dominant photoreceptors in the fovea and periphery, respectively; and the ratio of photoreceptors to RGCs is many-fold higher in periphery than fovea. Yet, little is known about genes expressed by foveal cell types, and few markers of specific types have been

identified. Here, as a step toward generating a primate retinal cell atlas, we used a high-throughput single-cell RNA sequencing (scRNAseq) platform (10X Genomics) to profile 77,368 foveal and 56,264 peripheral cells from the retina of the macaque monkey, *macaca fascicularis*. Bioinformatic analysis of the data allowed us to identify ~65 foveal and ~80 peripheral subsets of cells. We used *in situ* hybridization and immunohistochemistry to validate selectively expressed genes, and combined molecular with biolistic or viral labeling to characterize morphological features of cell types defined molecularly. We also showed that some of the foveal specializations in macaque are conserved in marmoset and human. Key findings include: (1) molecular difference between foveal and peripheral cones; (2) distinct types of Müller glia in the fovea and periphery; (3) correspondence between 12 bipolar cell types in fovea and periphery but with differences in frequency; (4) 11 types of foveal RGCs with peripheral counterparts, plus 6 types found only in the periphery; (5) markers for the four major RGC types, ON and OFF midgets and parasols; (6) molecular differences between foveal and peripheral RGCs; and (7) selective expression by specific cell types of genes conferring susceptibility to macular degeneration or glaucoma. These results provide a foundation for analyzing gene expression patterns in primate retina that underlie visual function and dysfunction.

Title: An approaching motion selective RGC in the mouse retina

Authors: *F. WANG, Y. ZHANG
Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai City, China

Abstract: Classification and functional study of every type of neurons are the first steps to decipher complex neural circuits such as the retina. There are at least 30 subtypes of retinal ganglion cells (RGCs) in the mouse retina, each of them extracts different features from the visual inputs. Motion is one of the most prominent visual features that the retina extract. RGCs that integrate spatial information nonlinearly are more sensitive to motion within their receptive fields (RFs). And this nonlinear spatial integration is generally thought to reflect how RGCs integrate excitatory inputs from bipolar cells.
We have characterized one type of RGC that integrates spatial information linearly. This RGC does not respond to high spatial frequency stimuli and is insensitive to lateral motion within its

RF, yet it can be strongly activated by approaching motion. Whole cell patch clamp experiments were performed to study how this linear RGC respond to motion in the RF center, and the synaptic mechanisms underlying its selectivity for approaching motion. We found that even though the spiking response of the RGC shows linear spatial integration, its excitatory inputs are non-linear. If we pharmacologically remove the inhibition, the RGC becomes non-linear, and responds to all types of motion without selectivity. This suggests that the non-linear excitation to the RGC is masked by a tonic inhibition, making the RGC insensitive to motion. Further study showed that the approaching motion is the only type of motion that can temporarily disinhibit the RGC under normal stimulus conditions, so the approaching motion selectivity originates from the selectivity of disinhibition. Thus, we present a RGC whose linear spatial integration property depends on the inhibitory inputs from amacrine cells, not on the excitatory inputs from bipolar cells. And this RGC uses a different mechanism to generate motion selectivity than generally observed in the retina.

Title: Heterotypic electrical synapses retrogradely couple melanopsin signaling in retinal ganglion cells to a neuropeptidergic amacrine cell population

Authors: *J. POTTACKAL[1,2], P. RAHMANI[1], J. B. DEMB[1,2,3]
[1]Dept. of Ophthalmology and Visual Sci., [2]Interdepartmental Neurosci. Program, [3]Dept. of Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Intrinsically-photosensitive retinal ganglion cells (ipRGCs) constitute a population of inner retinal photoreceptors, composed of five subtypes (M1–M5) in mice, that express melanopsin and detect irradiance. In addition to signaling anterogradely to several brain targets, ipRGCs also apparently signal retrogradely via heterotypic electrical synapses with amacrine cells, a large class of inner retinal interneurons. Despite recent physiological description of a subset of ipRGC-coupled amacrine cells, both the function of ipRGC-amacrine cell coupling and

the genetic identities of these amacrine cells have yet to be completely elucidated. Here, we report that corticotropin-releasing hormone-expressing (CRH^+) amacrine cells, a neuropeptidergic amacrine cell population, form functional electrical synapses with non-M1 ipRGCs in mice. Current-clamp recordings from CRH^+ amacrine cells during glutamate receptor (GluR) blockade revealed slow depolarizing responses to visual stimulation that persisted for >20 seconds. GluR-independent depolarization was sensitive to the gap junction blocker meclofenamic acid. Additionally, voltage-clamp recordings showed that the amplitude of this response was invariant across holding potentials. We also observed fast inward currents in non-M1 ipRGCs during optogenetic stimulation of CRH^+ amacrine cells. Finally, Neurobiotin injection into non-M1 ipRGCs demonstrated tracer coupling to CRH^+ amacrine cells. Together, these experiments suggest gap junction-mediated electrical synaptic input from non-M1 ipRGCs as the source of GluR-independent visual responses in CRH^+ amacrine cells. During retinal development, ipRGC-CRH^+ amacrine cell coupling is first physiologically detectable at ~P10 (postnatal day 10), achieves maturity shortly after eye opening (P13-P16), and parallels the concurrent elaboration of CRH^+ amacrine cell neurites. These data identify an anatomical circuit linking melanopsin signaling to a neuropeptidergic cell population, suggesting a potentially novel function for retrograde ipRGC signaling in the irradiance-dependent modulation of intraretinal neuropeptide release.

Title: Functional diversity of wide-field amacrine cells with a common molecular marker

Authors: *J. KIM[1], M. INOUE[2], C. RAMAKRISHNAN[2], K. DEISSEROTH[2,3,4], S. A. BACCUS[1]

Abstract: Although the retina is a central place for understanding neural computations, visual processing in the inner retina still remains largely unexplored due to the large diversity of inhibitory amacrine cells. Molecular markers provide a way to study specific types of neurons such as amacrine cells. The specificity of such markers embodies a tradeoff - markers specific

for just a single cell type provide unambiguous access to one type but not others, and those markers present in too diverse a population require extensive further physiological or molecular tests to classify each cell. Here we studied the physiological diversity of amacrine cells that expressed a transcription factor Bhlhb5 (b5), which stains a set of GABAergic inhibitory neurons in the adult mouse with sparsely-branched, long processes. Cells stratify narrowly at different levels of the inner plexiform layer, indicating the potential of a few different cell types labeled by this one marker. Using a b5-cre knockin mouse line (Ross et al, 2010), we expressed a red calcium (Ca) indicator on b5 amacrine cells using AAV in adult retina and performed two-photon imaging under a set of visual stimuli including a uniform field flash, spatiotemporal white noise, and natural movies. Visual stimuli were delivered using a digital light projector with UV (385 nm) and blue (460 nm) LEDs and Ca responses in the ganglion cell layer (GCL) were imaged at a frame rate of 30 Hz using a custom resonant-scanning two-photon microscope. The typical scanning area was a ~300 µm square, allowing up to 80 b5 cells to be imaged within a single field-of-view. In response to a uniform flash stimulus, the molecularly-identified amacrine cells in the GCL showed heterogeneous Ca responses. The time courses of the simultaneously imaged population of cells formed approximately six distinguishable clusters. The spatial distributions of cells within these clusters appeared homogeneous and cells of different clusters were spaced at a distance smaller than those within single clusters. These results indicated that b5 positive cells were comprised of cells with different functional types that were distributed evenly over the retina. We conclude that rather than identifying a single cell type, the Bhlhb5 molecular marker provides a way to study a select population of a few amacrine cell types that can be quickly identified using simple visual stimuli.

Title: Contrast adaptation in the rod bipolar pathway

Authors: *G. E. PERRIN[1], J. B. DEMB[2], J. H. SINGER[3]
[1]Univ. of Maryland, Col. Park, Washington, DC; [2]Ophthalmology & Visual Sci., Yale Univ., New Haven, CT; [3]Biol., Univ. of Maryland, College Park, MD

Abstract: Through a process called contrast adaptation, the retina encodes visual stimuli of wide temporal variability into a relatively narrow range of ganglion cell firing rates. This work examines the circuit level mechanisms (gain controls) behind contrast adaptation in a well-characterized circuit within the inner retina: the rod bipolar pathway. In this pathway, rod bipolar cells (RBs) respond with graded potentials to light stimuli. Depolarization of RBs drives glutamatergic release via ribbon synapses onto AII amacrine cells (AIIs). AIIs then depolarize the terminals of Type-6 cone bipolar cells (T6 CBs) via gap junction coupling. This drives excitatory release from T6 CB ribbon terminals onto ON-α ganglion cells (ON-αs). To determine the circuit loci of gain controls, we pharmacologically ablate photoreceptor responses in the outer retina and use Cre-mediated expression of channelrhodopsin-2 (ChR2) to drive either RBs or T6 CBs directly. Using paired pulse and temporally modulated white noise stimuli, we evoke ChR2-driven responses from either RBs or T6 CBs. Excitatory postsynaptic currents (EPSCs) are recorded from ON-αs, and Linear-Nonlinear (LN) cascade models are generated from the data. These methods allow us to analyze gain changes within the inner retina using naturalistic stimuli, without the limitations of paired patch recordings. Our results show that RB-driven responses exhibit a greater level of synaptic depression as compared to T6 CB-driven responses, and that the majority of contrast adaptation occurs when driving RBs, rather than T6 CBs. In conjunction with previous findings, these results suggest a prominent role for [A] synaptic release from RB terminals, and [B] the activity of AII amacrine cells in contrast adaptation within the rod bipolar pathway.

Title: Info in a bottleneck: The compression of information in neural circuits

Authors: *G. J. GUTIERREZ, F. M. RIEKE, E. T. SHEA-BROWN
Univ. of Washington, Seattle, WA

Abstract: FR and ES-B are joint senior author
Abstract:
Neural circuits can be organized in layers that converge and diverge. In particular, inputs to the retina converge on Retinal Ganglion cells that process information from a subpopulation of bipolar cells. This subunit structure produces an information bottleneck because information is

compressed from tens of bipolar cells that tile the visual field. Additionally, this arrangement enables different ganglion cell types to perform distinct computations using information from the same subset of photoreceptor inputs. ON and OFF ganglion cell types are sensitive to contrast increments and decrements, respectively. However, their response sensitivities are not symmetrical. Likewise, there is an asymmetry in the distribution of contrasts in natural scenes. While the asymmetries in ganglion cell response properties and natural image statistics have been studied, it is not known whether the corresponding asymmetries are optimal for the preservation of visual information.
Using computational models of convergent neural circuits, we simulate datasets of neural responses under different input conditions as well as for different circuit configurations. Our computational circuits have a convergent subunit structure in which input from several subunits is summed by an output ganglion cell. The results are analyzed using information theory methods to determine how much visual information is preserved or lost as it exits the bottleneck of the circuit. We compare results given a generic, symmetric, gaussian distribution of inputs and a natural distribution which is asymmetric. Additionally, different circuit configurations are simulated so that all combinations of linear and nonlinear subunits among the ON and OFF pathways are tested.
Our comparisons indicate that an asymmetric configuration of ON and OFF pathways may preserve more information than the symmetric circuit configuration for natural image distributions, however, this may be dependent on the amount of subunit noise and the placement of the noise in the circuit. In summary, our preliminary results support our hypothesis that the asymmetric configuration of the retina is driven by a general demand of maximizing available stimulus information through a compressive circuit.

Abstract: Blindness affects up to 36M people worldwide and has a major impact on the quality of life. In developing rehabilitation therapies, visual prosthetics are capable of stimulating neurons at different levels of the visual pathway using an array of electrodes. However, only few conductive materials are available for neural interfacing, and their evaluation have shown drawbacks. Material must exhibit not only high electrochemical performance, but also long-term stability and biocompatibility. In addition, complementing with soft material technology is required to achieve an intimate contact with tissue without inducing inflammation. Even with known compatible materials, a difference in mechanical properties can damage neurons at the interface and induce a glial scar. In this study, we propose graphene as suitable electrode material for retinal implants. First, we evaluated bidirectional capabilities of graphene on *ex vivo* pigmented Long-Evans rat retina. Custom microelectrode arrays (MEAs) with graphene electrodes were used to record spontaneous and elicited (via light and electric current) activity of the retina. The results confirmed the functionality of graphene electrodes. Biocompatibility was evaluated with implants having graphene which were placed in the subretinal space of adult P23H rats (retinitis pigmentosa). A follow-up using OCT and fundus of were done to monitor the tissue-implant interface up to 2 months. Afterwards, a biopsy containing the implant was stained for cell nuclei, bipolar cells, microglia, and macroglia. Confocal imaging and image reconstruction reported cell species on the contact area of the implant. Count of microglia and their location in the retinal tissue above the implants suggests a high biocompatibility of the GRM-based implants as compared to the control devices. Additionally, we present preliminary results of implant functionality *in vivo* using blind P23H and pigmented Long-Evans rats under anesthesia. Connected implants were acutely placed in the subretinal space. Stimulation via light or current controlled electrical pulse at the implant were delivered to the eye. Ultrasound recording in the visual cortex measured cerebral blood volume (CBV) in higher visual levels. Results showed an increase in CBV at the superior colliculus and visual cortex correlating to stimulation parameters which indicate implant functionality. The results demonstrate that implants with graphene are compatible and capable of stimulating rat retina. The elicited activity can be correlated to CBV changes found in ultrasound recordings which supports that graphene based implants can be a candidate for visual prosthetics.

Abstract: Neurons in the brain can be subdivided into transcriptomically distinct types, which correspond well to classical distinctions based on morphology, physiology and connectivity. Knowing the full compendium of neuronal types in a given brain region, and having reliable genetic markers for each type will enable neural circuits to be studied at unprecedented molecular resolution in health, development, disease and across different species. We are using large-scale single-cell transcriptomic analysis of the vertebrate retina to address these issues. Building on initial "proof-of-principle" studies (Macosko et al., Cell, 2015 ; Shekhar et al., Cell, 2016), we are completing a comprehensive neuronal atlas of the mouse retina, which will be among the first of its kind for any brain region. We have defined molecular signatures for a total of >120 neuronal types, including 3 photoreceptor, 1 horizontal, 15 bipolar, 45 ganglion, >60 amacrine and ~10 non-neuronal cell types, confirming a large number of them histologically. Using the mouse "retinome" as a foundation, we are pursuing two directions. **First** we are performing large-scale single-cell surveys of two other vertebrate retinas that differ from that of the mouse in key aspects: (a) macaque retina, which contains the fovea, a structure responsible for high acuity vision in primates that is absent in mice, and (b) zebrafish retina, which unlike mice and primates, can regenerate following injury. Using molecular signatures, we have been able to compare the taxonomy of retinal neurons across species, and identify "homologous" neuronal types. In the primate, we have also identified key molecular differences between foveal and peripheral counterparts of each neuronal type, some of which might underlie diseases of the central retina like macular degeneration. **Second**, we are transcriptiomically profiling neuronal and non-neuronal cells of the mouse retina following physical injury to the optic nerve. We showed previously that retinal ganglion cell types differ dramatically in their ability to survive following axonal transection (Duan et al., Neuron, 2015). By comparing changes in gene expression among types following injury, we can identify early transcriptional signatures that correlate with, and may underlie, selective resilience. In addition, we are identifying injury responses of interneurons and non-neuronal cells (glia and immune cells), all of which have been shown to influence survival.

Abstract: Traditional brain atlases in macroscopic resolution (Lein et al., 2007, Amunts et al., 2013, Zingg et al., 2014) typically divide the brain into macroscopic regions so it is not feasible to view individual cells. Other brain atlases such as neuromorpho.org (Ascoli et al., 2007) and wormatlas.org (Hall et al., 2007) provide only the morphology. Here we present a new kind of resource that combines dense maps of both anatomy and physiology at cellular resolution. An online "museum" (http://museum.eyewire.org) provides a 3D interactive view of each cell's anatomy as well as graphs of its anatomical and functional properties (Figure).
3D electron microscopy (EM) after calcium imaging has become established as a powerful approach for obtaining anatomical and physiological information about the same neurons. The resource encompasses exhaustive set of all the ganglion cells, almost 400 cells, that have cell bodies within the 0.3 x 0.35 mm^2 patch of retina. These ganglion cells have been reconstructed from 3D EM by 30,000 members of online community from the crowdsourcing game known as Eyewire. In addition, calcium signal was extracted for individual cells, providing dense sample of physiological data. Previously, dense EM reconstructions in the mouse retina (Helmstaedter et

al., 2013) and larval zebrafish olfactory bulb (Wanner et al., 2016) were only limited to anatomy only. A recent large-scale calcium image study had dense sample of visual responses but included only limited amount of cells' morphology (Baden et al., 2016).
To demonstrate the utility of the resource, we have discovered several organizing principles of the inner plexiform layer (IPL). The resource reveals two aspects of the retina's IPL: an arbor segregation principle governing structure along the light axis, and a density conservation principle governing structure in the tangential plane. Lastly, we relate structure to visual function: ganglion cells with arbors near the layer of ganglion cell somas are more sustained in their visual responses on average.

Title: Study of horizontal cells following light-induced outer retinal cell damage in Sprague-Dawley rats

Authors: *S. GUPTA, T. C. NAG, T. S. ROY
Dept. of Anat., All India Inst. of Med. Sci., New Delhi, India

Abstract: Light-induced damage to the retina resembles retinal degenerative diseases that are observed in humans, particularly age related macular degeneration. It is conceivable that after photoreceptor death, there is a likely secondary degeneration of the neurons of the inner retina, where one of the principal
retinal neurons are horizontal cells (HC). We examined the modifications in the HC after light induced damage to the outer retina. Adult Sprague-Dawley rats (N= 40) of both sexes were kept in an ambient light of 300 lux at normal photoperiod (12 hour light [L] : 12 hour dark [D]) for 7 days and then at 3000 lux
at normal photoperiod and constant light (24 L : 0D) for 2days. After that, rats were brought to normal photoperiod and reared for a period of 15 days. They were sacrificed at different time points to find out how the HC remodeled to the photic insult. Cytoarchitecture of HC was examined by light and transmission
electron microscopy. Localization and expression of GABA were studied by immunohistochemistry and immunoblotting to see the status of HC. We found that light induction caused significant damage to HC, after photoreceptor death, especially in their perikarya, dendritic compartments and axons. There were
swellings in the HC perikarya and alterations in their organelles and cytoskeleton. Immunohistochemically, there was an increased expression of GABA in HC of the retina exposed to continuous light. After reversal to normal photoperiod, there was downregulation of GABA in HC, in the rats reared up to
15 days. The present results show that continuous light induces damage to HC, and remodeling happens with the reversal of the photic insult, implying that HC after light insult can re-establish connectivity with the extant healthy photoreceptors.

Title: Deletion of GD3 synthase modifies retinal structure and impairs visual function in adult mice

Authors: *C. A. SANTANA[1], L. C. T. PINHEIRO[2], A. JORDÃO[2], R. LANI[2], G. NASCIMENTO-DOS-SANTOS[2], J. F. VASQUES[2], R. MENDEZ-OTERO[2], M. F. SANTIAGO[2]

Abstract: Gangliosides are found ubiquitously in several tissues and fluids, being especially abundant in the nervous system. The expression of gangliosides in the brain is highly specific for each region. The ganglioside 9-O-acetyl GD3 is space-temporally correlated with cell migration in the retina, superior colliculus, and to the axonal growth in the optic tract in rodents. However, biological roles of this ganglioside in retinal postnatal development are unclear. Here, we used adult mice lacking GD3 synthase (Siat3a KO), an enzyme that converts GM3 to GD3, which can be further converted to 9-O-acetyl GD3. Using optomotor system we measured visual acuity at spatial frequencies ranging between 0.03 and 0.272 cyc/deg. We observed a significant reduction in adult GD3s -/- mice performance compared to wild-type (WT) mice. Immunohistochemistry analyzes for TUJ1, marker of retinal ganglion cells (RGC), were performed and showed a significant 40% decrease in number of cells in GD3s -/- mice. Also, electrophysiological evaluation of retinal function was performed by two variants of ERG technique. Under particular luminance-stimulus conditions, the Flash-ERG displays components that reflect electrical activity originating from neurons in proximal retina. Responses were averaged per light intensity. For analysis, amplitudes of a-wave were measured in relation to the baseline, whereas the b-wave amplitudes were estimated in relation to a-wave. Oscillatory potentials were sorted by 30-400 Hz bandpass filtering, and the peak-to-peak amplitudes were assessed. We found reduced amplitudes of the a and b-wave in GD3s -/- animals. Pattern Electroretinogram (PERG) analyzes response to contrast reversing gratings or checkerboards, which selectively depends on the presence of functional RGCs, and was also significantly reduced by 75% in GD3s -/- mice, thus

demonstrating significant visual impairment in those animals. Together, these results suggest that GD3 synthase absence alters retinal structure and visual function.

Title: Gap junction circuitry of aii and a8 amacrine cells in the mouse retina

Authors: *S. YADAV, S. TETENBORG, K. DEDEK
Carl Von Ossietzky Univ. Oldenburg, Oldenburg (Oldenburg), Germany

Abstract: AII and A8 cells represent the majority of narrow-field glycinergic amacrine cells in the mammalian retina [1]. Both are bi-stratified and partially share a common stratification profile [4]. Gap junctions of AII amacrine cells are known to undergo remarkable light-dependent and dopamine-modulated plasticity and represent a crucial node in the primary rod pathway [3]. In contrast, the function of A8 cells is poorly understood.
Previous studies indicate that A8 cells form homocellular (A8-A8) and heterocellular (A8-ON cone bipolar cells) gap junctions [2, 3]. Furthermore, A8 cells are likely to receive dopaminergic input [2]. These features make A8 cells very similar to AII amacrine cells. In addition, both cells are likely to receive glutamatergic input from the same bipolar cell they form gap junctions with [3]. However, A8 cells are primarily cone-driven. Therefore, we hypothesized that A8 gap junctions could be dopamine- and/or light-dependent and thus may work in concert with AII cells to amplify/suppress rod signals or facilitate cone signals.
To test this, we injected tracers into whole-mount retinas of wild-type and ier5-EGFP mice and subsequently used a set of somatic and synaptic markers to (1) reveal the type of connexin expressed by A8 cells and their potential gap junction partners; (2) determine whether A8 cells express D1-receptors; and (3) discern the relative location of chemical and electrical synapses on A8 cells. Also, the coupling profile of A8 and AII cells was compared under light-adapted conditions, with and without application of D1-receptor antagonists.
Our data shows that A8 dendrites express less Cx36 puncta than AII dendrites. Interestingly, A8

cells expressed Cx36 on both ON and OFF dendrites, unlike AII cells; however, both amacrine cells couple to secretagogin-positive and -negative ON bipolar cell terminals. Importantly, both AII and A8 cells express D1 receptors; however, A8 cells were coupled to less bipolar cells and did not undergo an increase in coupling with D1 receptor blockade. This points to a different mechanism of gap junction modulation in A8 cells. As the total number of gap junctions on A8 cells is small and the few gap junctions occur close to chemical synapses, we suggest that gap junctions aid A8 cells in facilitating cone bipolar cells signals.

Title: CaBP5 is essential for normal synaptic transmission from rod bipolar cells to AII amacrine cells

Authors: *M. B. KOZHEMYAKIN[1,2], R. HEIDELBERGER[2]
[1]Dept. of Neurobio. and Anat., McGovern Med. Sch. of the Univ. of Texas, Houston, TX; [2]Dept. of Neurobio. and Anat., McGovern Med. Sch. of the Univ. of Texas Hlth. Sci. Ctr. at Houston (UTHealth), Houston, TX

Abstract: CaBP5, a member of the calmodulin (CaM)-like family of Ca^{2+} binding proteins, is required for normal rod-mediated light sensitivity in the mammalian retina. The rod bipolar cell (RBC) expresses CaBP5, however little is known about the role that CaBP5 plays in the regulation of neurotransmitter release from RBC synaptic terminals. To provide this information, we examined miniature-like events (**ml**-EPSCs) and light-evoked synaptic events (**le**-EPSCs) in a neuron postsynaptic to RBCs, the AII amacrine cell (All). Results were compared across retinal slices obtained from $CaBP5^{-/-}$ mice or wild-type (WT) mice. We found that the mean amplitude of **ml**-EPSCs recorded in AIIs in $CaBP5^{-/-}$ slices was significantly larger than that of WT. This was largely accounted for by the emergence of a second peak in the frequency distribution of amplitudes of AIIs in $CaBP5^{-/-}$ retinal slices that was not apparent in WT AIIs. This new peak was of larger amplitude (≈11pA) than the first peak (≈6pA). The frequency of the AII **ml**-EPSCs was also altered in the absence of CaBP5; events had a shorter mean inter-event interval in $CaBP5^{-/-}$ retinal slices than in WT. This was attributed to a significant reduction in events with an inter-event interval greater than ≈75ms that were present in WT AIIs but essentially absent in

AIIs in CaBP5$^{-/-}$ slices. Light-evoked synaptic transmission, generated by a brief light flash, was also significantly altered in retinal slices from CaBP5$^{-/-}$ mice. The mean amplitude of AII **le**-EPSC was decreased by more than 50% in Alls in CaBP5$^{-/-}$ slices, while the **le**-EPSC was longer in duration relative to WT. Together, the results provide a strong indication that CaBP5 regulates RBC exocytosis. Furthermore, the data raise the possibility that CaBP5, via its ability to decrease spontaneous release and augment evoked release amplitude, supports rod-mediated light-responses by improving the signal to noise ratio at the RBC-AII amacrine cell synapse.

Title: Effects of Bmal1 gene deletion in GLAST positive cells on retinal morphology and physiology

Authors: F. BOI[1], S. RICCITELLI[2], D. LONARDONI[1], S. BISTI[1], O. BARCA-MAYO[1], D. DE PIETRI TONELLI[1], S. DI MARCO[2], *L. BERDONDINI[1]
[1]Neurosci. and Brain Technologies, Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [2]Univ. dell'Aquila, L'Aquila, Italy

Abstract: Mammalian physiological functions are modulated with a circadian rhythm both at cellular and tissue level. Light is the main driver of this rhythmicity modulating a wide range of endogenous clock genes that are present in almost all cell populations.
Recent studies by Barca-Mayo et al. have shown that the selective deletion of the clock gene Bmal1 in GLAST positive cells alters locomotor activity and cognition in mice. We wonder whether such a selective deletion in GLAST positive cells of the retina might impinge on retinal function. Interestingly, Storch et al. found that adult mice lacking Bmal1 in all retinal cells modify their retinal information processing.
Here, we studied whether conditional deletion in adult life of the gene Bmal1 in astrocytes and Muller cells interferes with retinal function and morphology. We recorded retinal light responses in Bmal1cKO and control subjects both in vivo (flash-Electroretinogram) and ex-vivo (high-density CMOS multi electrode array). In addition, we collected retinal tissue for morphological and immunohistochemical analyses.
In our experimental condition preliminary results show no major differences between control and Bmal1cKO, suggesting that Bmal1 deletion in GLAST positive cells does not impact on retinal physiology and morphology.

Title: Motion anticipation of inhibitory transmission from amacrine cells

Authors: *D. LEE[1], S. A. BACCUS[2]
[1]Neurosciences Grad. Program, [2]Dept. of Neurobio., Stanford Univ., Stanford, CA

Abstract: Understanding how neurons in a network act together to perform a computation is a central goal of neuroscience, but it is difficult to assess the contribution of individual neurons in the face of diverse dynamic and nonlinear properties and other parallel neural pathways. In the retina, amacrine cells are a diverse population of primarily inhibitory neurons whose dynamic effects on retinal output are poorly understood, especially for ethologically relevant stimuli such as visual motion. Retinal ganglion cell activity anticipates the motion of an object by positioning its activity near the leading edge of a stimulus, but the specific interneurons that contribute to this process are unknown. Here we take an approach to directly measure the contribution of individual amacrine cells to the processing of moving stimuli using simultaneous intracellular recording from a single amacrine cell and multielectrode extracellular recording from a population of ganglion cells in the salamander retina. We manipulated the gain of individual sustained Off-type amacrine cells using simultaneous intracellular and multielectrode recording in the presence of a moving visual stimulus. After recording the response of the amacrine cell to a moving bar, we repeated the presentation of the stimulus while injecting into the amacrine cell timed current calculated to amplify or reduce the response of the amacrine cell to the moving stimulus, while recording ganglion cell responses. We found that although the peak of Off-type ganglion cell responses occurs near the leading edge of the moving bar, amacrine cell responses were more delayed than that of ganglion cells. By changing the gain of the amacrine response, we found unexpectedly that suppression of ganglion cell activity caused by the amacrine response to the moving bar occurs only on the rising phase of amacrine cell depolarization. As a consequence, although the peak of the amacrine cell response lags the moving bar, the peak of inhibitory transmission is shifted toward the leading edge of the bar. These studies show a general approach to directly measure the contribution of an interneuron to a computation, and

that inhibition from sustained Off-type amacrine cells exhibits a computation similar to one seen in the ganglion cell population, motion anticipation that compensates for visual delays.

Title: Connectivity patterns of starburst amacrine cells in the mouse retina

Authors: *S. MU[1], N. L. TURNER[1], W. M. SILVERSMITH[1], J. S. KIM[1], H. SEUNG[2], . EYEWIRERS[3]
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ; [3]Eyewire.org, Princeton, NJ

Abstract: It is well believed that starburst amacrine cells (SACs) contribute significantly to the direction selective (DS) circuits in the mammalian retina. The extent of this contribution, specific mechanisms and effects on innervated neurons, remain unknown. We anatomically reconstructed roughly 400 GCs and 200 SACs from serial electron microscope (EM) images of a $(0.3\ mm)^2$ patch of the inner plexiform layer of the mouse retina. In Bae et al. 2018, we clustered the GCs and identified 47 clusters, 35 out of which were verified to be types. Here, we studied the contacts among the cells by their types, and found intriguing contact preferences among SACs, and between GC and SACs.
It is known that an On-Off direction selective ganglion cell (ooDSGC) prefers to receive synapses from SAC dendrites oriented along its null direction (Briggman et al. 2011), and the same is thought to be true for On DSGCs (Yonehara et al. 2010). We found several other GC types (63, 2aw, 73 in nomenclature of Bae et al. 2018) that receive directionally biased SAC contacts.
We discovered a novel class of contacts between a dendritic termination of one Off SAC and the soma and/or proximal dendrites of another Off SAC. In many cases, the terminating dendrite veers towards the inner nuclear layer (INL), traveling almost parallel to the light axis. This is unexpected because Off SAC dendrites normally stratify at a particular depth in the inner plexiform layer (IPL) and also terminate at that depth. The terminating dendrite often travels in contact with a proximal dendrite, and if it reaches the soma of the other Off SAC, it typically spreads to a lump as it terminates. Most Off SAC cells in our dataset display this type of outbound and/or inbound contacts with one or more other Off SAC cells, with inbound contact patches from up to 4 partner cells observed on any given soma.
We also discovered a novel class of contacts between somas of On SACs. In studying SAC populations, Whitney et al. (2009) reported higher number of “close-neighbor pairs” in the

ganglion cell layer (On SACs) than in the inner nuclear layer (Off SACs). Not only have we found On SACs often pairing up next to each other in the ganglion cell layer, the pairs often form intertwined short twigs in between the two somas. In our specimen, 35 out of the 103 On SACs formed 18 adjoining pairs, with 13 pairs judged to have directly abutting somas, and the rest having dedicated short branch(es) reaching between the two somas from within the ganglion cell layer.

Title: Why threshold modulation leads to sparse responses in the brain

Authors: *W.-M. HSU[1,2], D. B. KASTNER[3], S. A. BACCUS[4], T. O. SHARPEE[1,2]
[1]CNL-T, Salk Inst., La Jolla, CA; [2]Physics, UCSD, La Jolla, CA; [3]EPFL - LCN, Lausanne, Switzerland; [4]Neurobio., Stanford Univ., Stanford, CA

Abstract: Neurons typically have low response rates. Although this limits information transmission, this can reduce metabolic costs that would otherwise rise steeply. Here we report an additional strict limit on the response rate above which information decreases with response rate. This phenomenon occurs in the presence of threshold modulation that happens ubiquitously in the brain. The rate limit also applies to pairs or groups of neurons that jointly encode the same type stimulus feature. This is exemplified by pairs of adapting and sensitizing cells in the retina ganglionic layer. The observed rates for adapting-sensitizing cell pairs are below the predicted rate limit, as are response rates of adapting cells that experience strong threshold modulation. Analysis of data using the two-pathway model that includes threshold modulation identifies amacrine cells as the source for threshold modulation, with minimal input from these cells to sensitizing cells. Overall, these results reveal a novel constraint on neural computation.

Title: Short-term plasticity and upregulation of biopolar-ganglion synapses can resolve the neural states both in the normal and the rd1 retinas

Authors: *K. KITANO[1], K. TANIGUCHI[2]
[1]Ritsumeikan Univ., Kusatsu, Japan; [2]Grad. Sch. of Information Sci. and Engineering, Ritsumeikan Univ., Kusatsu, Japan

Abstract: While the retina of the retinal degeneration rd1 mouse fails to respond to light stimuli due to loss of photoreceptors, the rd1 retina exhibits spontaneous rhythmic activity at a low frequency (<10 Hz) even without light stimuli that is not observed in the normal retina. Experimental results thus far suggest that the spontaneous rhythmic activity could be attributed to the upstream neuronal network including bipolar cells (BCs) and AII amacrine cells (AII-ACs) (Euler and Schubert, 2015). Based on the results, two potential mechanisms have been proposed; one arises from the property of a gap junction network between BCs and AII-ACs and between AII-ACs (Trenholm et al., 2012) whereas the other does from the intrinsic property of AII-ACs (Choi et al., 2014). In either case, the oscillatory activity is enhanced when the AII-ACs are hyperpolarized, suggesting that both AII-ACs and BCs would be more hyperpolarized in the rd1 retina than in the normal retina. Depolarization of presynaptic neuron (BC) would cause activation of the synapse from the BC to the postsynaptic neuron, ganglion cells (GCs), which implies that GC should be more activated in the normal retina than in the rd1 retina. Therefore, it should be solved why the normal retina does not show such an activity as well as how such spontaneous rhythmic activity is generated in the rd1 retina. In the present study, we studied the mechanism for the spontaneous rhythmic activity using a computational model of AII-AC, BC, and GC network. In particular, to solve the paradoxical phenomenon mentioned above, we incorporated a modified short-term plasticity model as the BC-GC synapse (Sagdullaev et al., 2011) because BCs do not generate action potentials. Even at a depolarized state, the synapse model was not activated sufficiently because of short-term depression. If we assume upregulation of the synapses in the inner plexiform layer of the rd1 retina (Dagar et al., 2014), the model could reproduce both the normal and abnormal neural states in the absence of light stimuli: no response in the normal retina and spontaneous rhythmic activity in the abnormal retina.

Title: Retinal light adaptation and dopamine D4 receptor sensitivity is impaired at the ganglion cell level after six weeks of diabetes

Authors: *M. FLOOD[1], E. D. EGGERS[2]
[1]Physiological Sci., [2]Departments of Physiol. and Biomed. Engin., Univ. of Arizona, Tucson, AZ

Abstract: *Purpose:* There is growing evidence to suggest that normal retinal signaling is disrupted early on in diabetes, long before the onset of the vascular pathologies associated with diabetic retinopathy. Previously, we have shown that after six weeks of diabetes in a mouse model, inhibitory inputs to rod bipolar cells are significantly reduced. The purpose of this study was to determine whether these upstream changes have a significant impact at the ganglion cell level, in terms of excitability and adaptation to changing light conditions. *Methods:* Diabetes was induced in C57BL/6J mice at 5 weeks of age by i.p. injections of streptozotocin (STZ, 75 mg/kg) dissolved in citrate buffer. Age-matched controls were given sham injections with citrate buffer alone. Diabetes was confirmed by blood glucose levels > 200 mg/dL. Six weeks post injections, whole-cell voltage clamp recordings of light-evoked (L) and spontaneous (s) excitatory post synaptic currents (EPSCs) were made from ON ganglion cells by holding at -60 mV, the reversal potential for chloride ions. µM). Light responses were elicited at multiple intensities by a 30ms full field LED stimulus (λ = 525 nm). Light adaptation was performed by exposing retinal slices to a 5 minute rod-saturating background. D4 receptors were agonized with the selective agonist PD-168077 maleate (500 nM). Responses were normalized on a cell by cell basis to the maximum response recorded under dark-adapted conditions. All experiments were performed under infrared illumination to preserve retinal sensitivity. The peak and charge transfer (Q) were measured for all evoked responses. All light response data was analyzed by 2- or 3-way repeated measures ANOVA. *Results:* Raw L-EPSC peak amplitudes ($p=0.013$), but not Q ($p=0.631$) were significantly larger for diabetic vs control animals. For the light adapted responses, no significant differences in peak amplitude were found ($p=0.354$), but Q was significantly larger for diabetic animals at 9500, 95000, and 950000 photons/μm^2/s ($p<0.001$ at each intensity). For D4 receptor-activated responses, both Q ($p=0.024$) and peak amplitude ($p<0.001$) were significantly larger in diabetic animals compared to controls, and these differences were most apparent at 95000 and 950000 photons/μm^2/s, cone photoreceptor dominated light intensities. *Conclusions:* After 6 weeks of diabetes, the overall sensitivity of ON ganglion cells is significantly increased, and

their ability to adapt to increased light levels may be compromised. This impairment seems to be due to changes in D4 receptor signaling, suggesting a causative role for dopamine deficiency in diabetic retinopathy.

Title: A much higher density of melanopsin-IR cells in two nocturnal microbat retinas than that in diurnal animals

Authors: M.-J. JEONG[1], E.-B. PARK[1], H.-G. KIM[1], H.-R. SONG[1], *C.-J. JEON[2]
[1]Sch. of Life Sci., BK21 Plus KNU Creative Bioresearch Group, Kyungpoo, Daegu, Korea, Republic of; [2]Kyungpook Nat'l Univ., Daegu, Korea, Republic of

Abstract: Intrinsically photosensitive retinal ganglion cells (ipRGCs) respond to light and play roles in non-image forming vision, such as circadian rhythms, pupil responses, and sleep regulation, or image forming vision, such as processing visual information and directing eye movements in response to visual clues. To investigate the organization of the ipRGCs in the retinas of a nocturnal animal, quantitative analysis of melanopsin-immunoreactive (IR) cells was conducted on the retinas of two microbats, *Rhinolophus ferrumequinum* and *Eptesicus serotinus*. The mean melanopsin-IR cell density was 227.12 ± 11.41 cells/mm^2, and the total number of melanopsin-IR cells was 819.74 ± 52.03. In the *R. ferrumequinum* retina, the total number of the neurons in the ganglion cell layer (GCL) was 12,254.17 ± 660.39 and that of the optic nerve axons was 5,179.04 ± 208.00. Thus, the ipRGCs constituted approximately 15.83% of the total RGC population in microbat *R. ferrumequinum* retina. Another microbat *E. serotinus* retinas also had high melanopsin-IR cell densities: the mean melanopsin-IR cell density was 382.61 ± 13.04 cells/mm^2, and the total number of melanopsin-IR cells was 943.29 ± 42.55. In the *E. serotinus* retina, the total number of neurons in the GCL was 15,672.79 ± 605.02. The proportion of melanopsin-IR cells in microbat *E. serotinus* was estimated to be approximately 10.03% to 15.05%. In addition, the present study identified the types and distribution of melanopsin-IR cells in *R. ferrumequinum* retina. Three types of melanopsin-IR cells were observed in the present study: M1 type in the GCL (M1c; 21.00%) or in the inner nuclear layer (INL, M1d; 5.15%), M2 type (M2; 5.79%), and M3 type in the GCL (M3c; 26.66%) or INL (M3d; 4.69%). Additionally, some M3c cells had curved dendrites leading up towards the OFF sublayer of the

IPL and down to the ON sublayer of the IPL (M3c-crv; 7.67%). Melanopsin-IR cells displayed a medium soma size and medium dendritic field diameters. There were 2-5 primary dendrites and sparsely branched dendrites with varicosities. The present study demonstrates that the nocturnal microbat has a much higher density of melanopsin-IR cells than documented in diurnal animals.

Title: Identification of rod bipolar and dopaminergic cells in the bat retina

Authors: *E.-B. PARK, J.-Y. JEON, E.-S. LEE, C.-J. JEON
Sch. of Life Sci., BK21 Plus KNU Creative Bioresearch Group, Kyungpoo, Daegu, Korea, Republic of

Abstract: A growing number of studies have revealed the functional neuroarchitecture of the microbat retina and suggested that microbats can see using their eyes. To better understand the oranization of the microbat retina, quantitative analysis of protein kinase C alpha (PKCα)- and tyrosine hydroxylase (TH)-immunoreactive (IR) cells was conducted on the greater horseshoe bat (*Rhinolophus ferrumequinum*) retina. As a result, PKCα immunoreactivity was observed in rod bipolar cells, consistent with previous studies on other mammalian retinas. PKCα-IR cell distribution in the inner nuclear layer showed regional differences in density, with the highest density found in the nasal retina. The average density of PKCα-IR cells was 10,487 ± 441 cells/mm^2 (mean ± S.D.; n = 4), with a total of 43,077 ± 1,843 cells/retina. TH-IR cells in the *Rhinolophus ferrumequinum* retina could be classified into four types based on soma location and ramification in the inner plexiform layer: conventional amacrine, displaced amacrine, interplexiform, and intercalated cells. The majority of TH-IR cells were conventional amacrine cells. TH-IR cells were nonrandomly distributed at low density over the retina. The average density was 29.7 ± 3.1 cells/mm^2 (mean ± S.D.; n = 3), with a total of 124.0 ± 11.3 cells/retina. TH-IR processes showed varicosities and formed ring-like structures encircling AII amacrine cells. Our study provides the foundation for understanding the neurochemical architecture of the microbat retina and supports the notion that the eyes do play a role in the visual system of microbats.

Title: Characterization of neuroinflammatory mechanisms associated with diabetic retinopathy using human transcriptomic

Authors: *P. E. FORT[1], Y. SHAN[2], J. E. ROGER[3]
[1]Ophthalmology and Visual Sci., [2]Univ. of Michigan, Ann Arbor, MI; [3]CERTO, Orsay, France

Abstract: Diabetic retinopathy, the major ocular complication associated with diabetes, remains the primary cause of vision loss in the working age population. Using non-targeted transcriptome analysis approaches, several groups have identified specific regulatory pathways affected in diabetic rodents. Use of those animal models has yielded critical discoveries relative to the general changes affecting the retinal transcriptome, but those are limited by the absence of a macula and the limited difference of peripheral versus central retina in rodents. These limitations are critical as diabetic retinopathy is a regional disease that affects the retina heterogeneously, as demonstrated by macular edema, peripheral non-perfusion and regional loss of receptor fields in diabetic patients.Using non-fixed, freshly isolated retinal tissues from human donors, with and without diabetes and with or without retinopathy, we used RNA deep sequencing to assess the transcriptional changes affecting the retina. In this study, we independently analyzed the transcriptome of the macular, perimacular and peripheral regions of the retina (n=6 per tissue and per group) in order to identify the regional impact of diabetes. Results were validated by quantitative pcr analysis using the same samples (n=6) and an independent set of samples (n=12). Pathways identified were then further analyzed using biochemical methods including immunoblot and ELISA. Over 800 genes were statistically significantly affected ($p>0.05$) with region specific patterns as a function of the disease state. Principal component analysis confirmed the clustering of the samples while pathway analysis using the GeneGo/MetaCore integrated software identified specific inflammatory, metabolic and neuroglial regulatory pathway. Using qRT-PCR, consistent significant alterations of the expression of genes associated with inflammation (including the alternative pathway of the complement) and neuroglial regulatory pathways (growth factor signaling) were dissected and demonstrated a regional alteration with a primary diabetes component in the central retina and a primary retinopathy component in the peripheral retina.This study offers the first regional analysis of the pathophysiological mechanisms of diabetic retinopathy with a high potential of identification of

specific therapeutic targets including specific regulators of the inflammatory response and regulation of the neuroglial tissue homeostasis.

Title: The impact of light adaptation and cell type on correlated spiking and retinal population codes

Authors: *K. RUDA[1], J. W. PILLOW[2], G. D. FIELD[1]
[1]Neurobio., Duke Univ., Durham, NC; [2]Psychology, Princeton Neurosci. Inst., Princeton, NJ

Abstract: Retinal ganglion cell (RGC) types encode and transmit distinct visual signals to the brain. RGCs can exhibit precisely correlated spiking with nearby RGCs of the same and different types. The extent to which these signal and noise correlations need to be accounted for to understand retinal coding has been actively debated. At stake are the complexities of both encoding and decoding models that are needed to describe early visual processing. Two key features of retinal function are likely to shape the role of correlations in sensory processing: cell type and adaptation state. Different RGC types exhibit distinct amounts of correlated activity with neighboring cells, and changes in light level alter the strength of correlated activity among RGCs. Thus, we hypothesize that the role of correlated activity in encoding and decoding of visual information depends on cell type and light level. To test this hypothesis, we measured the spiking activity from hundreds of RGCs from rat retina on a large scale multielectrode array. RGCs were functionally classified into >6 distinct cell types according to their response properties to white noise and drifting gratings. We fit recorded responses with a generalized linear model (GLM). This model extends a basic linear-nonlinear-Poisson model by adding a feedback term that depends on spike history and a coupling term that depends on the spiking of other RGCs. This model accurately predicted the spike trains of individual RGCs and pairwise correlations among RGCs. We first tested the significance of correlations for describing RGC activity across light levels and cell types. We compared the encoding performance of the full, coupled GLM to an independent GLM that does not include coupling between cells. At cone light levels, the coupled GLM captures 400% more correlations than the independent model. The

necessity of the coupling term increases at rod light levels, where the coupled GLM captures 500% more of the correlation structure. This result holds for various RGC types. Next, we determined whether correlated activity is necessary for conveying visual information by performing model-based decoding on RGC responses. We found that decoding performance across the independent and coupled GLMs was similarly impacted by light adaptation. These results reveal that accounting for correlations is necessary to fully capture RGC activity and suggest that the role of correlations in retinal processing is altered by light adaptation. Ultimately, this work will constrain how regions downstream of the retina may optimally process RGC output, as well as provide an example of how adaptation can alter the impact of correlations on sensory coding.

Title: Retinoic acid is the trigger for retinal ganglion cells pathophysiological remodeling during retinal degeneration

Authors: *M. TELIAS, Z. HELFT, B. DENLINGER, R. KRAMER
Mol. and Cell Biol., Univ. of California Berkeley, Berkeley, CA

Abstract: Retinitis Pigmentosa (RP) and Age-related Macular Degeneration (AMD) are common forms of blindness, caused by the death of photoreceptor cells (PRs) in the retina. In health, light responses are initiated in rod and cone photoreceptors, processed by interneurons, and synaptically transmitted to retinal ganglion cells (RGCs), which generate action potentials that carry visual information to the brain. In RP and AMD, upon death of PRs, RGCs survive but undergo significant changes in gene expression, morphology and electrophysiological properties, collectively known as ‘RGCs-remodeling’. We have previously shown that two early-on, critical aspects of remodeling involve RGCs becoming hyper-permeable and hyper-excitable, exhibiting a high spontaneous firing rate that obscures responses to dim light from surviving PRs. Therefore, understanding RGCs-remodeling is key for curing blindness, because any form of vision restoration strategy will rely on RGCs response to renewed or super-imposed visual signaling in the degenerated retina. Yet, no study so far has been able to determine the

mechanism responsible for RGCs-remodeling. Here we show that Retinoic Acid (RA), signaling through the retinoic acid receptor (RAR), is the trigger that initiates RGCs-remodeling. Using rodent models for blindness (i.e., rd1 mice, rd10 mice and S334ter rats), we show that loss of PRs leads to an increase in RGCs' RAR-signaling, as measured by a novel genetically encoded double RA-reporter virus. In-vivo and ex-vivo pharmacological and genetic inhibition of RA and RAR-signaling reverses remodeling in rd1 mice, as measured through dye-loading assays and multiple electrode arrays recordings. Conversely, pharmacological and genetic agonism of RA and RAR-signaling in WT mice, induces hyper-permeability and hyper-excitability, mimicking remodeling. Furthermore, in partially blind rd10 mice, we show that inhibition of RAR-signaling dramatically improves RGCs' firing upon residual light-responses of surviving PRs. In this study we identify RA and RAR-signaling as the molecular trigger behind pathophysiological remodeling of RGCs in-vivo. RA and RAR are necessary and sufficient for remodeling to take place, and can be used as drug/gene therapy targets for reversing it. This study presents new therapeutic opportunities for mitigating vision impairment in retinal degenerative disease, as well as for improving signal fidelity in vision restoration techniques.

Title: Retinal stimulation through a DLP based projection system for studying visual cortex responses with voltage sensitive dye imaging

Authors: *A. GROSS, N. IVZAN, N. FARAH, Y. MANDEL
Bar Ilan Univ., Ramat Gan, Israel

Abstract: High-resolution recording of visual cortex in response to patterned stimuli in rodents is an important tool for studying various retinal diseases and vision restoration techniques. Towards this end, we constructed a unique slit-lamp based projection system for localized retinal stimulation based on a DMD projector (912x1140 pixels). The system uses visible light (LED 532nm) and NIR (910nm) sources, for the study of combined visible and prosthetic vision, yielding a retinal image size of 1mm wide and 3mm high. The position of the projected pattern on the desired retinal location is monitored through the slit lamp lens and a camera. The DLP system offers great flexibility and facilitates the generation and projection of visual stimuli at

different intensities, temporal frequencies, pulse durations and light-wavelength. More importantly, the system has the advantage of direct control of retinal stimuli location, with no need to perform back-projection, as is the case in currently available set-ups where a computer monitor is used.
Using this system, we obtained robust VSDI responses (dF/F up to 0.1%) to pulsed retinal stimuli of 3mm in diameter with the response increasing with stimuli irradiance. Moreover, retinotopic mapping of the visual cortex was obtained in response to projection of 8 squares at the size of 0.5mm. The retinotopic map demonstrated an amplification factor of about 30 μm/deg, comparable to previous studies.
This system is a useful tool for studying the cortical response to localized retinal stimulation and may shed light on cortical processes occurring during outer retinal degeneration and on the cortical integration of prosthetic and natural vision in rodents.

Title: A cortical visual area for processing collicular information

Authors: *R. BELTRAMO, M. SCANZIANI
UCSF, San Francisco, CA

Abstract: Two distinct anatomical pathways carry visual signals from the retina to the visual cortex: the “geniculo-striate” and the “collicular” pathways. The geniculo-striate pathway runs through the dorsal lateral geniculate nucleus (dLGN) of the thalamus to the primary visual cortex (V1). From V1, visual information is broadcasted to retinotopically organized higher cortical areas that surround V1 and are targeted by V1 axonal projections. The other route, the collicular pathway, passes through the superior colliculus (SC) and reaches the visual cortex via the pulvinar nucleus of the thalamus (or latero-posterior nucleus, in rodents). While much is known about the role that the geniculo-striate pathway plays in the cortical response to visual stimuli, the role of the collicular pathway is not well understood. In fact, lesions of the SC have either no impact or only a relatively minor role on visual responses in the cortex of primates, carnivores and rodents. Here, we discover that visual responses in the mouse postrhinal cortex (POR), a higher visual area located in the caudo-lateral portion of the visual cortex, are abolished upon silencing the SC. By contrast, despite the axonal projections that V1 send to POR, silencing V1

has only a minor impact on visual responses in POR. Furthermore, we show that the SC connects to POR through a disynaptic input via a region of the latero-posterior nucleus of the thalamus that doesn't rely on V1 activity. Finally, we show that POR neurons greatly outperform V1 neurons at discriminating small objects moving along a linear trajectory. The ability of POR to extract stimulus features poorly discriminated by V1 indicates that the two visual pathways to the cortex capture different aspects of the visual world. These results demonstrate that in at least one visual cortical area, namely POR, the main visual drive is relayed from the periphery through the SC and not via V1. Because of its reliance on the ascending visual input through the collicular pathway, POR could be considered a cortical visual area specialized in the processing of collicular information.

Title: Functional segregation of eye-specific visual pathways in higher visual cortex

Authors: *K. J. SALINAS, J. H. ZEITOUN, H. KIM, S. P. GANDHI
Neurobio. and Behavior, UC Irvine, Irvine, CA

Abstract: The mammalian visual system processes visual information via multiple parallel streams. In primates, the dorsal and ventral streams are central to spatial navigation and object recognition. Evidence suggests that stream segregation is also present in the mouse visual system. In the classical hierarchical model, there are distinct circuits within primary visual cortex (V1) that serve the dorsal and ventral stream. We have recently discovered eye-specific functional specificity of binocular, low spatial frequency and monocular, high spatial frequency cardinal information processing in V1, suggesting that the mouse visual system has an eye-specific organization to its dorsal and ventral streams (Salinas et al., 2017). We asked whether this functional eye specificity is preserved outside of V1, into higher visual areas, and if these differences relate to stream segregation. Widefield retinotopic mapping of CaMK2a-tTa-tetO-GCaMP6s mice (P70-P200, both sexes) were used to delineate visual areas. Awake mice were shown drifting sinusoidal gratings of various spatial frequencies, ranging from 0.03 c/d to 0.96

c/d at 1-2 Hz through the contralateral eye and ipsilateral eye. Recordings were positioned in binocular V1 within layer 2/3 as well as in two higher visual areas, lateromedial (LM) and posteromedial (PM), which have been grouped into ventral and dorsal streams. Here we report eye-specific functional segregation at multiple levels of the hierarchy. Interestingly, we find that areas LM and PM contain similar proportions of binocular cells as compared to V1 (V1: 31%, LM: 34%, PM: 36%). However, ipsilaterally dominated monocular neurons represent a smaller proportion in PM compared to V1 (V1: 28%, LM: 23%, PM: 12%). We find that contralateral-eye dominated monocular neurons formed the majority in all three areas. Contralateral-eye dominated neurons in PM and V1 preferred higher spatial frequencies than those in LM (median preferred spatial frequency in V1: 0.14 c/d, LM: 0.11 c/d, PM: 0.17 c/d). Similar to a previous study, PM neurons were found to be cardinally biased. Our data further revealed that PM neurons preferred cardinal directions regardless of contralateral- vs. ipsilateral-eye dominance. These results demonstrate functional segregation of eye-specific responses in higher visual cortex. The organization of mouse visual cortex into distinct streams may be mediated by eye-specific developmental mechanisms.

Title: Layer-specific cortico-cortical loops in mouse visual cortex

Authors: H. YOUNG, B. BELBUT, *L. T. PETREANU
Champalimaud Res., Champalimaud Fndn., Lisbon, Portugal

Abstract: The mammalian neocortex consists of multiple functionally specialized areas, with each area composed of different layers and different cell types within those layers. These areas are hierarchically organized such that all inter-areal cortical connections may be divided into two types: feedforward (FF) connections propagating information from lower to higher areas, and feedback (FB) connections carrying information in the opposite direction. Finding fundamental rules of connectivity for FF and FB cortico-cortical projections is necessary to constrain and inspire theories of hierarchical cortical computation. Here we use subcellular channelrhodopsin-2(ChR2)-assisted circuit mapping (sCRACM) in combination with retrograde tracers to dissect

the connectional specificity of FF and FB projections for different projection neuron populations in mouse visual cortex. We recorded from pairs of neighboring neurons in the same cortical layer (L) in primary visual cortex (V1) or the higher order lateromedial (LM) visual area in acute brain slices containing FB (LM-->V1) or FF (V1-->LM) ChR2-expressing axons, respectively. For each pair, one cell projected to the source of the ChR2-expressing FF or FB inputs, and one cell projected to a different cortical or subcortical area. For each cell, we measured both the strength and dendritic location of FF or FB monosynaptic inputs.FF and FB innervated projection neurons in L2/3, L5 and L6. Inputs from both FF and FB projections to L5 cortico-cortical projection neurons were, on average, twice as strong as those to neighboring neurons projecting to the superior colliculus. However, the total input strength of FF and FB axons was similar in different populations of L5 or L2/3 cortico-cortical projection neurons, regardless of whether they projected to the source of FF or FB inputs or to other visual areas. By contrast, in L6, the total connectional strength of FF and FB projections was twice as strong in cortico-cortical neurons projecting back to the source of the FF or FB inputs when compared to those projecting to other visual areas. Our results show that, in specific layers but not all, cortico-cortical connections preferentially target specific projection neurons. This specificity results in reciprocal cortico-cortical loops in deep cortical layers, consistent with several theories of hierarchical processing.

Title: Visual scene segmentation in the mouse

Authors: *F. LUONGO[1], L. LIU[2], D. Y. TSAO[2,3]
[1]Caltech, Los Angeles, CA; [2]Caltech, Pasadena, CA; [3]Howard Hughes Med. Inst., Pasadena, CA

Abstract: Mechanistic studies of the rodent visual system have exploded in the past few years owing to the wealth of molecular, genetic, and chemical tools available for neural circuit perturbations. Although mice have lower spatial acuity than primates, responses of neurons in mouse visual cortex show a marked resemblance in their tuning to elementary image features (e.g. spatiotemporal frequency, direction and orientation) when differences in acuity are taken into account. An outstanding question in the field concerns how these elementary visual feature

representations are further transformed by the rodent visual system. For example, does the mouse visual system explicitly extract object boundaries from visual scenes to facilitate object and scene perception? In an attempt to answer this question, we trained mice on a figure-ground segmentation task where figures were defined by either iso oriented gratings in the foreground/background, cross oriented gratings, or naturalistic textures, moving in counterphase to the background. Mice were readily able to report the side of the stimulus containing a texture-defined figure, doing so most readily and with highest accuracy for figures defined by cross oriented gratings. These animals, were able to generalize reports of a visual figure when presented with novel orientations, suggesting that they were able to learn abstract rules about the visual stimulus. Similar, albeit reduced performance could be measured using iso oriented gratings and performance was further reduced for naturalistic textures. We also recorded visual responses when presenting the same iso/cross oriented gratings and naturalistic textures in V1 and extrastriate visual areas RL and LM using both 2-photon calcium imaging and electrophysiology revealing, diverse contextual surround effects. Coherent spatial preference across all texture conditions presented, indicative of a texture-invariant figure response, was never observed. Taken together, these findings serve to inform the limits of the rodent as a model system in the study of scene segmentation.

Title: Distinct roles of cortical interneuron subtypes in contrast-dependent surround suppression

Authors: *D. P. MOSSING[1], J. VEIT[3], H. ADESNIK[2]
[1]Grad. Program in Biophysics, [2]Univ. of California, Berkeley, Berkeley, CA; [3]UC Berkeley, Berkeley, CA

Abstract: Spatial context powerfully influences how sensory cortical neurons encode external input, pooling congruent evidence when signals are weak and reducing redundancy when signals are strong. In primary visual cortex, this manifests as "surround suppression," in which stimuli beyond the classical receptive field can weaken visual responses to stimuli within it. The magnitude of suppression is feature dependent, increasing with higher contrast and more uniform textures; yet the neural circuit basis of this feature dependence is poorly understood. We use a combination of cell-type specific calcium imaging, optogenetics and whole cell recording in V1

of awake, locomoting mice to determine the inhibitory circuit basis for this fundamental neural computation. Our data demonstrate differential roles for somatostatin (SST) and two functional subclasses of vasoactive intestinal peptide (VIP) interneurons in mediating the feature dependence of surround suppression in layer 2/3. The competitive inhibitory dynamics between cortical SST and VIP neurons may represent a conserved neural circuit to mediate flexible modulation of neural coding depending on context.

Title: Neuronal population responses in the human ventral temporal and lateral parietal cortex during arithmetic processing with digits and number words

Authors: *S. BAEK[1], A. L. DAITCH[2], P. PINHEIRO-CHAGAS[2], S. SAHA[2], J. PARVIZI[2]
[1]Princeton Univ., Princeton, NJ; [2]Stanford Univ., Stanford, CA

Abstract: Past research has identified anatomically specific sites within the posterior inferior temporal gyrus (PITG) in the ventral temporal cortex (VTC) and the intraparietal sulcus (IPS) in the lateral parietal cortex (LPC) that are engaged during arithmetic processing. While a small region of the PITG known as the number form area (NFA) is selectively engaged in the processing of numerals, its surrounding area is activated during both digit and number word processing. We compared the timing and selectivity of electrophysiological responses during arithmetic processing with digits and number words in the brain regions surrounding the PITG and IPS. We obtained intracranial recording from 38 electrodes near the PITG and 33 electrodes near the IPS implanted across 8 (6 males; 2 females) subjects during two math tasks. In the first task, subjects performed arithmetic trials in the form of calculations presented in digit numbers and control trials in the form of autobiographical memory questions. This task revealed 9 selective electrodes in the PITG and 11 in the IPS that were considered for further analyses. In the second task, subjects answered true-or-false math questions that were presented in the form of digits (e.g. “2+2=4”) or number words (e.g. “two plus two equals four”). Our recordings revealed early (200 to 400ms after stimulus onset) activations in the PITG, during which stronger high frequency broadband (HFB) responses were observed in response to digits than to number words ($p = 0.015$, $n = 9$, permutations test), and weaker but still significant responses to number

words ($p < 0.001$, $n = 9$, permutations test). Conversely, much slower responses were observed in the IPS region. Specifically, stronger responses to digits than to number words were found late at 500 to 700ms after stimulus onset ($p < 0.001$, $n = 11$, permutations test) in this region. The heterogeneity in the selectivity and temporal signature of the neuronal responses to the two visual formats in the anatomically specific mathematical processing regions in the human brain illustrate the specificity of the brain functions during mathematical cognition.

Abstract: The primate visual cortex comprises a multitude of areas which emerge and mature at different stages of development. It has previously been demonstrated that the primary visual cortex (V1) and the middle temporal area (MT) mature at the same time, leading to the hypothesis that area MT is a “primary-like” area. Apart from its involvement in the perception of motion, MT is a constituent area of the dorsal stream; a network proposed to be involved in the guidance of actions and recognising where objects are in space.
Considering the central position of MT in the dorsal stream and its direct connectivity with component areas, we hypothesise that MT is critical to the establishment of the dorsal stream network and that perturbation in early life results in anatomical, connectional and behavioural changes associated with the stream. To address this, marmoset monkeys (*Callithrix jacchus*) received a unilateral mechanical ablation of left hemisphere area MT at postnatal day 14 (n=3). Animals were allowed to recover from the ablative surgery for 12 months, until adult. During this period, animals underwent longitudinal diffusion tensor imaging (6 and 18 weeks post-lesion) to examine structural changes in the ventral and dorsal streams.

Following 12 months of recovery, animals underwent training to perform visually-guided behavioural tasks, whereby the animal had to reach and grasp static and moving objects. Our results show that the animals showed no perturbation in proficiency in reaching and grasping static objects when compared to non-lesioned controls (n=2). However, when performing a moving task, lesioned animals exhibited abnormal reach-to-grasp behaviour. Lesioned animals showed larger maximum grip aperture when grasping, suggesting a deficit in prehension. When attempting to reach and grasp moving objects, lesioned animals showed reduced performance compared to controls. Specifically, lesioned animals required more attempts in a trial compared to controls, suggesting a perturbation in motion-related reach and grasp behaviour. Diffusion MRI/ tracer studies revealed changes to dorsal stream anatomy and connectivity.
These results suggest that the absence of MT early in life affects numerous dorsal stream areas and additionally leads to perturbations in visually-guided motor behaviours.

Title: V1/V4 intercortical correlations evolve alongside binocular disparity selectivity at different time scales

Authors: *J. E. SMITH[1], A. J. PARKER[2]
[1]Dept. of Phys., Anat. & Gen., Oxford, United Kingdom; [2]Dept. of Phys., Anat. & Gen., Univ. of Oxford, Oxford, United Kingdom

Abstract: Many visual cortical areas respond to binocular disparity, and successive stages of processing are thought to be required. In particular, the transformation from V1 to V4 may help to solve the correspondence problem. To gain insight on this process, we investigated the timescales of correlation between V1 and V4 while both areas responded to stereo images. We recorded from two alert, behaving *Macaca mulatta* that performed an odd-one-out task in which four random-dot stereograms (RDS) were presented. The animals fixated while all RDS were presented with a baseline disparity for 1 or 2 seconds. A step change in the target's disparity would then occur, which the animal had to locate with a saccade. Both animals' reaction times and accuracies improved with increasing step size. Each animal was implanted with two Utah

arrays, one in V1, another in V4. One of the four RDS was positioned to stimulate both V1 and V4 receptive fields (RF) simultaneously, although the RFs did not overlap (V1 RF distance < 1° of fixation, V4 RFs > 3°). V4 responses to the baseline disparity suggested three epochs: an initial peak response, a middle response of decreasing activity, and a late response of increasing activity. By comparison, the ability of units to distinguish different disparities decreased from an initial peak in V1 (mean disparity discrimination index ; initial = 0.288 ; middle = 0.276 ; late = 0.272 ; init vs mid paired Wilcoxon signed rank p = 2.163e-04) and V4 (init = 0.251 ; mid = 0.232 ; late = 0.238 ; p = 0.008). Noise correlations between and within cortical areas were quantified at different timescales using r_{CCG}. All types of correlation rapidly increased within tens of milliseconds and then rose more slowly, similar to earlier studies in V1, V4, and V5. The V1/V4 correlations were also dynamic. The initial responses had stronger correlations at short lags (up to 32 ms) compared with later in the trial (mean r_{CCG}[10ms] ; init = 0.016 ; mid = 0.013 ; late = 0.014 ; one-way ANOVA p = 0.043 ; init vs late paired signed rank p = 2.058e-22), while late correlations were stronger than middle responses for lags up to 190ms (mean r_{CCG}[80ms] ; mid = 0.017 ; late = 0.019 ; signed rank p = 1.580e-14). There was a weak tendency for the initial V1/V4 correlations at short lags to decrease as the similarity in disparity tuning curves increased (r_{CCG}[10ms] vs r_signal Spearman rho = -0.049, p = 9.928e-04), which may serve to reduce redundancy in neural coding. The low latency and dynamic changes of V1/V4 correlations thus may reflect the ongoing process between those areas of detecting and encoding disparity.

Title: A novel pressure regulating brain imaging implant for ultra-large field-of view mesoscopic imaging in nhps

Authors: *O. CABALLERO[1], M. LEDO[2], S. KOLLA[3], S. MARTINEZ-CONDE[2], S. TANG[4], A. NANDY[5], A. YAZDAN-SHAHMORAD[6], E. CALLAWAY[7], J. REYNOLDS[7], M. AVERY[7], P. LI[7], E. SEIDEMANN[8], Y. Y. CHEN[8], S. MACKNIK[2]
[2]Ophthalmology, [3]Radiology, [1]SUNY Downstate Med. Ctr., Brooklyn, NY; [4]Peking Univ., Beijing, China; [5]Yale Sch. of Med., New Haven, CT; [6]Univ. of Washington-Seattle, Seattle, WA; [7]The Salk Inst., La Jolla, CA; [8]Univ. of Texas at Austin, Austin, TX

Abstract: Several problems challenge mesoscopic imaging in the brain: 1) Difficulty with positioning high-NA objectives near the brain; 2) Creating a flat imaging window against the surface of the brain; 3) Adjusting the imaging window to changes in swelling and pressure in the brain, such as those that may occur due to hydration changes and other physiological factors; 4) Preventing growth of dura and biofilms that cloud the imaging window; 5) Follow-on MRI imaging of the animal post-implantation. We propose here a large-windowed radiolucent implant to address these issues. Our approach provides a 3cm diameter window for non-human primates that regulates pressure and employs a stable, strong, and thin design—that is mechanically modeled and stress-tested—to achieve access to the brain by large objectives, with design features that allow for manual repositioning of the imaging lens. To optimize the distance between the objective and the brain, we prioritize a thin implant design. A strong radiolucent implant is created using PEEK plastic, a radiolucent, strong, thermoresistant biostable material. We heighten strength of the chamber's attachment to the skull by positioning screws normal to the surface of the bone, to optimize the bond. The implant design has several parts and contemplates two different potential methods to maintain pressure on the brain. The first method uses springs to maintain even pressure of the imaging window on the brain's surface, irrespective of brain motion relative to the skull. The second method uses a hydrogel plastic cushion to achieve the same goal. Either method allows for the manual repositioning of the cover slip to create a flat imaging window, which can be moved to target electrode penetration slots in the glass, if needed. Lastly, our approach is designed to prevent dural growth by blocking the migration of migratory biofilm-forming cells; we hypothesize that use of dynamic pressure maintenance on the brain is key to the long-term patency of recordings implants that have been reported previously though occasionally. We have also implemented these design elements human prosthetics.

Abstract: Comparative diffusion MRI (dMRI) approach for cerebral white matter can shed light on the complex organization of the human brain and the evolution of major fiber tracts. A recent study demonstrated that there are commonalities between human and macaque vertical occipital fasciculus (VOF), which is an important white matter tract to understand communication between dorsal and ventral visual cortex (Takemura et al., 2017). Here we aim to expand this knowledge by performing dMRI on the common marmoset (Callithrix jacchus), a New World monkey that diverged from humans and macaques approximately 35 million years ago. We collected high-resolution dMRI datasets from two post-mortem marmoset brains using a 7T Bruker MRI scanner (0.15 mm isotropic; 126 directions; b= 4800 s/mm^2). First, we found that a tract seemingly homologous to VOF is clearly visible in marmoset as a principal diffusion signal toward superior-inferior axis. This putative marmoset VOF was located laterally adjacent to optic radiation, similar to humans and macaques. Second, we evaluated the microstructural properties of this tract by collecting Magnetization Transfer Ratio (MTR) map which can approximate myelin volume in white matter. We found that the putative VOF in the marmoset has significantly lower MTR than the optic radiations, suggesting that the degree of myelination of these tracts differs in a consistent manner from classical histological study in human (Vogt, 1904). Third, in order to estimate cortical endpoint of putative marmoset VOF, we performed tractography and estimated which cortical maps are near putative VOF endpoint using histology-based marmoset brain atlas (Hashikawa et al., 2015). We found that the dorsal endpoints of the putative VOF were near cortical areas DM (V6), DA (V3A) and PPm (V6A), and ventral endpoints were near VLA (V4) and ITc (TEO), broadly consistent with findings in the human and macaque. These observations support the idea that the vertical occipital fasciculus serves to transmit visual information across relatively early stages of the dorsal and ventral visual streams. However, one notable difference is that the putative marmoset VOF is a continuous structure spanning a large area of parietal and temporal cortex, whereas human tracts are manifest as multiple bundles (VOF, posterior arcuate, middle longitudinal fasciculus). In sum, this study

demonstrates the key organization principle of VOF may be present at common anthropoid primate ancestor. However, the vertically oriented tracts in marmoset brain have more spatial contiguity and less branching than in humans, differences that stem from the much smaller brain and relative absence of cortical folding.

Title: Spiking noise in visual area V2 of infant monkeys shortly after experiencing monocular defocus

Authors: *Y. WANG[1], B. ZHANG[2], X. TAO[3], E. L. SMITH, 3rd[1], Y. M. CHINO[1]
[1]Col. of Optometry, Univ. of Houston, Houston, TX; [2]Col. of Optometry, Nova Southeastern Univ. Col. of Optometry, Davie, FL; [3]Baylor college of Med., Houston, TX

Abstract: Visual information is encoded and processed by a network of cortical neurons that depends on precisely timed spiking. We previously found that experiencing chronic monocular defocus during early infancy leads to abnormal dynamics of spike counts and the noisy and variable firing of V2 neurons in macaque monkeys that are tightly correlated with their perceptual loss (Wang et al, 2017). To understand how abnormal spiking noise (increased spiking irregularity and higher trial-to-trial fluctuation) and dynamics of spike counts developmentally emerge in V2 of amblyopic monkeys, it is necessary to know how noisy the spiking of V2 neurons is in normal infant monkeys around the time when the monocular defocus was introduced in the above mentioned study (3-4 weeks of age). We previously reported that both the magnitude of spiking irregularity and the trial-to-trial fluctuation in V2 neurons of infant monkeys of comparable ages were much lower than spiking noise in normal adult monkeys (Neurosci abstr. 2017). To gain insights into the neural mechanisms underlying the remarkable 'transformation' from very low spiking noise without experiencing defocus (*normal infants*) to abnormally high noise after experiencing monocular defocus during the critical period (*amblyopic adults*), here we analyzed the spiking noise of V2 neurons *immediately* after rearing infants with a defocus lens (*defocus infants*). Macaque monkeys were reared with a light-weight

helmet containing a defocus lens (-10 diopter) for one eye and a plano lens for the fellow eye between 4 and 8-10 weeks of age. At the end of rearing (without recovery), we recorded from individual V2 neurons under anesthesia. We quantified the spiking noise of V2 neurons in response to brief (640 ms) sine wave gratings that were optimized for orientation and spatial frequency for each neuron and repeated for 25 times. We calculated the square of the coefficient of variation in inter-spike intervals (CV^2) and mean-matched fano factor (m-FF) for stimulus contrast of 0%, 1%, 2.5%, 5%, 10%, 25%, 50% and 80%. Compared to the age-matched normal monkey, we found that: 1) the maintained (spontaneous) firing was much higher, 2) the mean firing rate was also elevated, 3) the onset latency was shorter, and 4) the spiking noise (mean CV^2 and m-FF) was significantly elevated, including the noise during spontaneous firing. However, the overall contrast sensitivity (C_{50}) was unchanged. The results suggest that the developmental alterations of V2 circuitry responsible for the increased spiking noise in adult amblyopic monkeys emerge rapidly after experiencing monocular defocus.

Title: Focal reversible inactivation of macaque inferior temporal (IT) cortex reveals a topographically selective causal role in primate core object recognition behavior

Authors: *R. RAJALINGHAM[1,2], J. J. DICARLO[1,2,3]
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]McGovern Inst. for Brain Res., Cambridge, MA; [3]Ctr. for Brains, Minds, and Machines, Cambridge, MA

Abstract: Primate core visual object recognition --- the ability to rapidly discriminate among objects near the center of gaze in spite of naturally occurring identity-preserving image variability --- is thought to rely on the ventral visual stream, a hierarchy of cortical areas

culminating in inferior temporal (IT) cortex. Previous work has shown that a particular read-out of particular IT population response patterns (a.k.a. neural codes) accurately predicts primate core object recognition behavior for each and every tested core object recognition task.. While this strongly suggests that these IT population codes underlie these behaviors, direct causal evidence for that hypothesis has been equivocal at best, especially beyond the specific case of "face-selective" sub-regions of IT supporting invariant face detection and discrimination behaviors. Here, we aimed to test the general causal role of IT in core object recognition by reversibly inactivating individual, millimeter-scale regions of IT via injection of muscimol while monkeys performed several binary object discrimination tasks, interleaved trial-by-trial. Our results show that inactivation of even single, millimeter-scale subregions of IT resulted in reliable contralateral-biased behavioral deficits and, importantly, that these deficits were highly selective over tasks. Inactivating different millimeter-scale subregions of primate IT resulted in different patterns of task deficits, each significantly predicted by that subregion's neuronal selectivity. Moreover, the effect of inactivation was topographically organized in that the pattern of behavioral deficit was most similar at anatomically neighboring subregions. Taken together, these results provide direct causal evidence that the proposed IT population codes (above) do indeed underlie primate core object recognition behavior, and that those codes are topographically organized.

Title: Stripe-like organization of secondary visual cortex in tree shrew

Authors: *K.-S. LEE, M. SEDIGH-SARVESTANI, N. C. SHULTZ, R. SATTERFIELD, J. W. SCHUMACHER, D. FITZPATRICK
Max Planck Florida Inst., Jupiter, FL

Abstract: The tree shrew has long been recognized as a model for studying functional architecture of primary visual cortex (V1) due to its columnar-organized representation of multiple visual properties and close evolutionary relationship to primates. However, the functional organization of the secondary visual cortex (V2) remains unexplored. Whether V2 of the tree shrew exhibits an interleaved mapping organization like that found in primate V2 (functional stripes) or a single visuotopic organization like that found in the mouse homologue of

area V2 (lateral medial area) is unknown. In this study, we used both anatomical tracing and physiological mapping methods to examine this issue. To characterize V1-V2 projections, tree shrews (Tupaia belangeri, n=25) were injected with adeno-associated viral vectors (AAVs expressing Ruby2sm-Flag, GFPsm-myc, or tdTomato) in V1, followed by a postsurgical survival period of 2-3 weeks. *Post hoc* immunohistochemistry was performed on the flattened brain sections to enhance fluorescence. Consistent with previous results from the Kaas lab (Lyon et al., 1998), we found three distinct areas that receive direct V1 inputs: secondary visual cortex (V2), temporal dorsal area (TD), and temporal posterior area (TP). Unexpectedly, single large injections in V1 (~ 2 mm) produced a stripe-like organization in V2, with multiple bands separated by unlabeled regions, which are spaced periodically and consistently. The intensity profile of fluorescence parallel to the V1-V2 border displays cycles of densely labeled stripes (medium 0.91 mm) interrupted by weakly labeled stripes (thick 1.15 mm, thin 0.34 mm), while fluorescence intensity is relatively uniform along the orthogonal axis. The periodicity and relative bandwidth of this organization are reminiscent of V2 stripes labeled by cytochrome oxidase staining in the primate. To probe the functional properties of neurons in V2 compartments, V2 neurons were labeled with GCaMP6s calcium indicator through AAV injection, and *in vivo* two-photon calcium imaging was applied to measure the tuning properties, such as spatial frequency and color. We found that neurons located in the thin stripes prefer low spatial frequency and are responsive to isoluminant chromatic drifting gratings. In conclusion, both anatomical and physiological results suggest that there is a stripe-like functional specialization in tree shrew V2, which could serve as a model to test the evolutionary significance of the functional stripes and their transformation in higher-level visual processing.

Title: Effective connectivity reveals an interconnected inferotemporal network for three-dimensional structure processing

Authors: *E. PREMEREUR, P. JANSSEN
KU Leuven, Leuven, Belgium

Abstract: Previous single-cell and monkey fMRI studies have shown that disparity-defined three-dimensional shape is processed in both the ventral (inferior temporal cortex, ITC) and the dorsal visual stream. The network of cortical areas that is activated more by curved surfaces than by flat surfaces at different disparities includes, besides parietal areas CIP, PIP, AIP and premotor area F5a, three clearly distinct regions in the ventral stream: area TEO in the Superior Temporal Sulcus (STS); a region in posterior TE on the convexity (pTE); and a region in anterior TE in the STS (TEs). To fully understand an area's role in behavior we have to investigate not only its neuronal properties but also the connectivity of the area under study. The latter can be achieved by combining fMRI with electrical microstimulation. We previously showed that microstimulation of anterior AIP activates a somatomotor network comprising PFG, SII, MIP and ventral premotor cortex (F5), whereas microstimulation of posterior AIP activates areas involved in object processing, including CIP, TEO and TE (Premereur et al, 2015). Here, we investigated the effective connectivity of the inferotemporal 3D-structure nodes. Three macaque monkeys were scanned at a 3T magnet (Siemens Prisma; voxel size: 1.2 mm3 isotropic) during sedation. 40-secs blocks of electrical stimulation were interleaved with 40 secs blocks of no stimulation, for a total of 480 secs. During stimulation blocks, 250 ms trains of stimulation (pulse width: 0.48 ms, freq: 200 Hz, amplitude: 1 mA) were delivered on average every 2.5 secs. We found that electrical stimulation of each of the 3D-structure nodes in ITC elicited increased fMRI activation in the other 3D-structure nodes in the ITC. Importantly, no increased activation was found in parietal areas, nor in prefrontal cortex. Our results indicate that 3D-structure nodes in ITC form a strongly interconnected network, receiving input from parietal areas in the dorsal stream implicated in 3D-structure-processing. The output of this ventral stream 3D-structure network remains elusive.

Title: Asymmetries in the intrinsic 3D connectivity within dorsal and ventral parts of area LIP of macaque

Authors: *B. AHMED, M. RUESSELER, J. SMITH, A. J. PARKER, K. KRUG
Univ. of Oxford, Oxford, United Kingdom

Abstract: Lateral intraparietal (LIP) plays a central role in visuo-motor information processing, saccade planning and decision-making, but its intracortical wiring is not well understood. We examined the 3D pattern of LIP's intrinsic connectivity in 5 Rhesus Macaques (macaca mulatta) after focally injecting either the retrograde tracer Chloro-Toxin beta (CTb, ~80 nL) or Fluorogold (FG, ~160 nL). Injections were placed with a posterior approach. In parasagittal sections (1:5 series, 50 µm), we marked cell bodies under Neurolucida (Microbrightfield) and quantified the pattern of labelled cells. For different layers in each section, we reconstructed the density of labelled cells along the dorso-ventral axis of LIP. Consecutive parasagittal sections were aligned based on nearest neighbour density distributions to yield 2D spatial maps of connectivity patterns in LIP, separately for layers 1, 2-4, 5 and 6.
Anatomically, LIP can be divided into dorsal (LIPd) and ventral (LIPv) regions based on myelination density. In 3 macaques, tracer was injected into LIPd, layers 3 to 5, back-labelling cells across LIPd. The highest density of labelled cells was near the injection site forming a longitudinal run along the dorso-ventral extent of LIPd, with the densest areas on sections just medial to the injection site. In 2 animals, a single, well defined cluster of labelled cells in LIPv was also aligned in the dorso-ventral axis; in the third, a cluster was nearby but slightly offset medially. This pattern was aligned across superficial and deep layers. Also, in LIPd, there were a number of dense patches of labelled cells medio-laterally further away from the injection site, but again aligned across layers. In one macaque, tracer was injected at the border of LIPd/LIPv in Layers 1 to 3a and in another in layers 5 and 6 of LIPv. In these animals, there was a more widespread pattern of label in LIPv, but highest density label was also predominantly running in the dorso-ventral axis.
Apart from distinct point-to-point input from LIPv to LIPd, we show that there is an asymmetry in connections within LIP: a high density of inputs to LIP cells emanate from cells aligned along the dorso-ventral axis across all layers and weighted towards inputs from close-by medial LIP sites.

Title: Macaque MT neurons show a different specialization for horizontal disparity than V1 neurons

Authors: I. KANG, *B. G. CUMMING
Natl. Eye Inst., Natl. Eye Institute, NIH, Bethesda, MD

Abstract: A systematic mapping of disparity tuning along both horizontal and vertical axis has shown that macaque V1 neurons are specialized for horizontal disparity (Cumming, 2002): the response surface of a neuron on the 2-dimensional disparity space is elongated along the horizontal disparity axis, covering a wider range of horizontal disparity than vertical, regardless of preferred orientation. In area MT, odd-symmetric tuning curves (with distinct peaks and troughs) are more common than in V1. Depending on how these are constructed (starting from V1), it is possible that the orientation of the peak-trough axis may behave quite differently than the elongations seen in V1. We recorded responses of 112 MT neurons in one monkey to random dot stereogram (RDS) with combinations of horizontal and vertical disparity. Preferred motion directions were estimated from the response to an RDS or random line stimulus moving coherently in one direction. We fit the 2-dimensional disparity response with a mixture of 2 or 3 Gaussian functions to identify the peak and trough of the response surface. The orientations of the peak-trough axis were non-uniformly distributed ($p < 10^{-25}$, Rayleigh test), centering around 0 deg (mean = 0.4 deg, 95% CI = -4.5 ~ 5.4 deg), despite that the preferred directions were distributed uniformly ($p = 0.65$, Rayleigh test). This indicates that responses are typically an odd-symmetric function of horizontal disparity, regardless of preferred direction. Odd-symmetric functions of vertical disparity were seen much less frequently. MT disparity signals seem therefore to be organized in a way that produces more rapid changes in firing in response to horizontal than to vertical disparity - the opposite of the pattern seen in V1. One simple explanation for this pattern is to suggest that MT combines inputs from two (or more) V1 neurons that systematically differ in their preferred horizontal disparity, while having similar preferred vertical disparities, regardless of preferred direction within the subunits.

Title: Spatial generalization of repetition suppression in macaque inferotemporal cortex

Authors: *N. P. WILLIAMS, C. R. OLSON
Ctr. for the Neural Basis of Cognition, Biol. Sci. Dept., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neurons in macaque inferotemporal cortex (ITC) exhibit repetition suppression. When an image is presented twice at the same location, first as prime and then as probe, the neuronal response to the probe is reduced relative to the response to the prime. This effect is identity-specific as indicated by the fact that suppression is greatest when the probe is identical to the prime (McMahon and Olson, 2009; Sawamura and Vogels, 2013). It is also location-specific as indicated by the fact that suppression is greatest when the probe is at the same location as the prime (De Baene and Vogels, 2010). The aim of the present experiment was to determine how identity-specific and location-specific effects combine to determine neuronal response strength in ITC. We recorded neuronal responses to displays consisting of a prime, a delay and a probe, each 300 ms in duration. The stimuli were 5° images of background-free objects presented in either the upper or lower contralateral visual field at horizontal and vertical eccentricity of 6°. We varied independently across trials the relation of the probe to the prime with respect to identity (same or different) and with respect to location (same or different). Upon analyzing data from 108 neurons (57 in monkey S and 51 in monkey O), we found that the probe response was reduced relative to the prime response under all conditions including the condition in which the probe differed from the prime in both identity and location. However the degree of suppression varied across conditions. To analyze the pattern of variation, we carried out an ANOVA with identity (same or different) and location (same or different) as factors and with firing rate, mean normalized across the four conditions, as the dependent variable. This analysis revealed a significant main effect of identity (greater suppression when identity was the same, $p < 0.0001$, effect size = 7.0 Hz), a significant main effect of location (greater suppression when location was the same, $p = 0.0045$, effect size = 1.5 Hz) and a significant interaction effect (greater identity-based suppression when location was the same, $p = 0.0001$, effect size = 2.4 Hz). The fact that suppression generalized across visual field quadrants suggests that it arises in part at the level of ITC because ITC is the first ventral stream processing stage at which the receptive fields of individual neurons typically span both visual field quadrants. The absence of complete spatial generalization suggests a role for low-level visual areas upstream from ITC. Repetition suppression is likely the culmination at the level of ITC of adaptive processes occurring at multiple stages of the visual processing hierarchy.

Title: Developmental changes in parvalbumin expression in ferret primary and higher visual cortex

Authors: A. KAVUTURU[1], A. A. LEMPEL[2], *K. J. NIELSEN[2]
[1]Krieger Sch. of Arts and Sci., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Changes in inhibitory circuits are considered a critical factor in the development of the visual system. However, while the timeline of inhibitory neuron development has been well investigated in primary visual cortex (V1), data for higher visual areas are lacking. Here, we make use of the ferret's early birth to provide a first systematic comparison of inhibitory neuron development in V1 and higher visual cortex. Our experiments focus on parvalbumin (PV) expressing inhibitory neurons in V1 and PSS, a recently identified higher order motion area in the ferret. More precisely, we investigate developmental changes in the laminar distribution of PV expression in V1 and PSS around eye opening, which marks the onset of direction selectivity development in both areas. PV neurons were identified in brain slices from young animals (age postnatal day (P) 28 - P47) and adults using DAB-peroxidase immunohistochemistry. A Nissl stain was used to identify cortical layers. We then determined the density of PV neurons for each layer in both V1 and PSS. Our data show significant changes in the laminar distribution of PV expression following eye opening (P30 - P32) in both areas. Before visual experience, layers 5 and 6 contain the largest density of PV neurons in V1 and PSS. After eye opening, this laminar profile shifts to the homogenous laminar distribution observed in adults. Intriguingly, our data suggest that the adult profile is reached sooner in PSS than V1, contrary to what would be expected from a strictly hierarchical development. Additionally, we also analyzed tissue from animals before natural eye opening that had been exposed to drifting gratings for 8h. Our results suggest that this premature visual stimulation was sufficient to accelerate development of PV expression in both areas.

Title: A V1-recipient cortical area in the tree shrew contains direction selective neurons

Authors: *M. SEDIGH-SARVESTANI, J. SCHUMACHER, K. MAXIMOV, R. SATTERFIELD, N. SHULTZ, D. FITZPATRICK

Abstract: Comparing cortical circuits across species reveals similarities and differences in their functional architecture. We studied the sensitivity to motion direction in the tree shrew, a small diurnal animal with relatively high visual acuity and columnar cortical architecture. The phylogenetic classification of tree shrews is a subject of debate, but some evidence suggests a close evolutionary relationship to primates. Although the tree shrew has long served as a model system for studies of the striate cortex (V1), little is known about the function of its extrastriate regions.

Area TD is one of three V1-recipient extrastriate regions rostral to V2 in the tree shrew. Based on its anatomical connectivity patterns, TD has been hypothesized to be the homologue of MT in the macaque (Lyon and Kaas, 1998). To determine whether TD contains direction selective neurons, a hallmark of MT, we combined anatomical tracing with functional imaging of single-cells in the awake head-fixed animal.

We found that as predicted, TD contains cells highly tuned for the direction of motion. Nearby cells shared a preferred direction, giving rise to a columnar map of direction in TD. Nearby cells also shared a preferred point in the visual field, giving rise to a retinotopic map in TD. This suggests that tree shrews and macaques share a common extrastriate architecture dedicated to motion direction. To determine whether area TD in the tree shrew is a true functional homologue of area MT in the macaque, we also characterized single-cell tuning for the disparity in depth cues as well as sensitivity to component and pattern motion.

In the macaque, inputs to MT are already direction selective. To determine whether inputs to TD are also direction selective, we have begun to characterize the functional properties of V1, and V2, which provide dense projections to TD. We found that cells in the superficial layers (L2/3) of V1 are not sensitive to the direction of motion, consistent with previous electrophysiology-based findings (Van Hooser et al., 2013). We are in the process of identifying the functional properties of TD projection neurons across various layers of V1 and V2 so that we can understand how direction selectivity arises in TD. This work will clarify the functional similarities in the tree shrew and macaque visual system and will contribute to our understanding of how various diverged cortical circuits can provide solutions to the same computational problem.

Title: Clustering of 3D and 2D shape information in area V4

Authors: *R. SRINATH[1], K. J. NIELSEN[2], C. E. CONNOR[3]
[1]Zanvyl Krieger Mind/Brain Inst., Baltimore, MD; [2]Neurosci., [3]Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Coding transformations in ventral visual cortex convert image information into object and scene understanding. Area V4, an intermediate ventral pathway stage, is known to represent 2D contour shape. Our recent results show that a substantial fraction of V4 neurons are more responsive to 3D volumetric shape (shape-in-depth) than to 2D shape in the image plane. Here, using 2-photon functional microscopy, we observed that 2D and 3D shape tuning cluster separately in area V4.
We used realistic shading cues to render simple volumetric shapes (Cs and Vs with cylindrical cross-sections and smoothly curved joints and endcaps). These shapes were presented at a wide range of 3D orientations so that their constituent fragments spanned the space of surface orientations and curvatures. We contrasted responses to these 3D stimuli with responses to 2D silhouette stimuli with the same outline in the image plane, filled with a single color lighter or darker than the background. Each 3D/2D pair of stimuli shared the same 2D contours, but in the 3D case these appeared as self-occlusion boundaries of volumetric objects, while in the 2D case they appeared as sharp edge boundaries of planar shapes. The 2D boundaries spanned the space of contour orientations and curvatures.
We imaged in anesthetized macaque monkeys using Oregon Green BAPTA-1AM (OGB) to measure neuronal responses. A substantial fraction of neurons (on the order of half) responded more strongly to 3D volumetric shapes compared to congruent 2D shapes. There was strong local clustering of 3D- and 2D-responsive neurons in separate patches on the order of several hundred microns. In addition, however, neighboring 3D and 2D patches were most responsive to congruent 3D and 2D shapes. These results suggest that derivation of 3D volumetric shape from 2D image information is a major constraint on microorganization in area V4.

Title: Monotonic responses to numerosity and second-order contrast in early visual cortex

Authors: *J. M. PAUL, T. C. TEN CATE, B. M. HARVEY
Utrecht Univ., Utrecht, Netherlands

Abstract: Introduction: Humans and many animals have neurons tuned to specific numerosities, the number of visual items in a set. Numerosity tuned neurons respond selectively, decreasing their response amplitude with distance from their preferred numerosity. However, it remains unclear how such tuned responses are derived from visual images. Computational models suggest an initial monotonic stage where response amplitude increases with numerosity. Recent evidence suggests this monotonic stage may occur in early visual cortex. Here, we extend this finding, utilizing the superior spatial resolution of fMRI and pRF visual field mapping to characterize the location and nature of these responses. Method: We acquired ultra-high-field (7T) fMRI data while presenting visual stimuli whose numerosity changed gradually between 1 and 7, with 20 as a baseline. We used various stimulus configurations with different relationships between numerosity and (other) low-level visual features such as luminance, edge length and item size. We quantified the recorded responses using a response model that increases response amplitude proportionally to log(numerosity). Results: In all stimulus configurations, this monotonic response model closely matched responses in early visual areas (V1, V2, V3). The model's explanatory power was highest in V1 and progressively decreased up the visual hierarchy to LO1. Monotonic response model fit depended critically on the visual field position of the voxel's pRF, with goodness of fit decreasing when pRFs fell outside the area where the numerosity pattern was displayed. Responses were affected by stimulus configuration; stimulus configurations featuring very different dot sizes or a smaller, more densely filled pattern area were less well described by a monotonic response. However, numerosity explains responses better than low-level stimulus features which sometimes co-vary with numerosity and have been suggested to underlie numerosity discrimination abilities. To account for visual field stimulation caused variations in contrast energy across the visual field, we modeled second-order contrast from the visual images we presented. Conclusion: Our findings indicate monotonic responses to second-order contrast in our stimuli as a simple, biologically plausible mechanism linking established low-level response properties of early visual cortex with higher-level numerosity-tuned responses and perception.

Title: Theta rhythmic neuronal activation in primate areas V1, V4 and TE and negative BOLD responses in the presence of multiple nearby visual stimuli

Authors: *B. AGAYBY[1], M. AINSWORTH[2], R. KIENITZ[1,3,4], J. T. SCHMIEDT[4], M. ORTIZ-RIOS[1], A. BELL[2,5], M. C. SCHMID[1]

Abstract: Growing evidence indicates that reaction times and behavioral performance can become rhythmically modulated at 3-6 Hz (theta) when attention is distributed in the presence of multiple objects [1–3]. The underlying brain mechanisms for this rhythmic behavioral fluctuation remain little understood. Evidence for theta-rhythmic spiking at the neuronal level has been reported under different task conditions in area V4 of the extrastriate visual cortex and in area TE of macaques [4,5]. It is thought that this neural rhythm might arise from a balance between excitatory and inhibitory processes [6] that could be brought about by receptive field interactions [7] that can also be observed on a larger scale in fMRI [8].
Here we report on experiments in which we recorded multi-unit activity (MUA) using multi-electrode arrays implanted into V1 (monkey K), V4 and TE (monkey V), and in which we measured during separate runs (monkey D) the BOLD activity in visual cortex using fMRI at 4.7T. In all experiments, monkeys maintained passive fixation while either a single visual stimulus alone or together with a second stimulus was presented in the periphery. The stimuli were black disks, rings or rectangles in electrophysiology and rotating checkerboard ring patterns in fMRI. For V1 recordings, stimulus sizes were adjusted to the RF while a larger size was used for V4 and TE recordings. At the neural level, responses to a single stimulus inside the RF tended to be not rhythmic. When, however, a second stimulus was added near the RF, responses became rhythmic at 3-6 Hz in all three sampled cortical areas. fMRI analysis confirmed the emergence, most pronounced in V1, of a negative (compared to baseline) BOLD region between the two stimulus representations associated with a positive BOLD signal nearby.
Taken together, interactions between the excitatory RF center and its inhibitory surround account for the emergence of theta rhythmic activation in electrophysiology and appear to relate to a positive/negative BOLD activation pattern in fMRI across the visual cortical hierarchy. It seems that visual cortex might use this balance of patterned excitation- inhibition during situations that require flexible spatial filtering, such as during distributed attention in the presence of multiple objects.

Title: Saccade-related activity in V4 varies with behavioral outcome in a change-detection task

Authors: *K. ACAR[1,4], M. A. SMITH[2,4,3]
[1]Ctr. for Neurosci., [2]Dept. of Ophthalmology, [3]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [4]Ctr. for Neural Basis of Cognition, Pittsburgh, PA

Abstract: Primates explore the visual world by making a series of rapid, serial eye movements called saccades. When a behaviorally relevant object appears, it is thought that a decision to saccade arises through an interaction between visual cortical neurons representing the stimulus and neurons in oculomotor areas that encode saccade plans. Previous studies have observed an influence of saccade preparation signals on visual information processing in visual cortical neurons, and psychophysical work has shown an improvement in visual perception at the intended target of saccades. Furthermore, neurophysiological studies demonstrate a pre-saccadic enhancement of stimulus-evoked responses in visual area V4 neurons with receptive fields at the saccade target. However, our understanding of the contribution of the saccade-related V4 activity to saccade generation remains incomplete. V4 is an intermediate visual area in the ventral stream that is reciprocally connected with oculomotor control areas such as the lateral intraparietal area (LIP) and frontal eye fields (FEF). Therefore, the pre-saccadic enhancement in V4 activity could have a non-causal role in saccade decisions, simply reflecting a motor signal about an impending saccade. Alternatively, saccade-related V4 activity could be a source of sensory evidence that influences the decision to generate a saccade.
To understand the significance of the saccade-related modulation of V4 activity, we recorded simultaneously from many V4 neurons while rhesus macaques performed an orientation change-

detection task. Importantly, our task introduced a degree of uncertainty as to where and when the change would occur trial to trial, with two potential target locations placed in the same hemifield as the V4 neuronal receptive fields. For analysis, we divided trials by saccade direction and behavioral outcome. We found that saccade-aligned population activity in V4 predicts the direction of saccades in both false alarm and correct trials. Interestingly, the magnitude of the pre-saccadic modulation was greater before “correct” saccades than “false alarm” saccades. We also found that we could predict the direction of the eventual saccade from V4 activity earlier in the trials. A naïve Bayes classifier trained on V4 population activity during the penultimate stimulus flashes (stimuli preceding the eye movement behavior) was able to decode the eventual saccade direction with ~70% accuracy on correct trials and ~60% accuracy on false alarms (cross-validated, 50% chance). Together, these results highlight the confluence of sensory and saccade-related signals present in visual cortex during saccade decision making.

Title: Object representations in rodent visual cortex

Authors: *J. Y. RHEE, C. E. ECHAVARRIA, D. D. COX
Harvard Univ., Cambridge, MA

Abstract: The brain's visual system translates ambiguous patterns of light falling on the retina into a coherent representation of the external world that can be used to guide behavior. The hierarchical organization of sensory cortex is thought to play a key role in this process. However, the nature of transformations that occur from one level of the hierarchy to the next remains poorly understood. An increasing amount of evidence shows that rats have the capacity for sophisticated visual behaviors. Moreover, both anatomical and functional studies have revealed signatures of a hierarchically organized rodent visual cortex. Building on these findings, we have undertaken a systematic investigation of visually-evoked responses in rat extrastriate cortex. Specifically, we test whether neuronal responses across distinct visual areas differ in their selectivity for object stimuli and tolerance to identity-preserving object transformations. We

conduct widefield imaging to characterize the retinotopic organization of rat visual cortex and identify distinct visual areas thought to be involved in object recognition behavior in rodents (V1, LM, LI, and LL). Using acute electrophysiological recordings, we find that selectivity and tolerance both increase from early visual cortex (i.e. V1) to higher-level, extrastriate areas, such as areas LL and LI. To better understand how these visual areas represent information at the population level, we use two-photon imaging to simultaneously record from large populations of neurons. These methods allow us to ask previously intractable questions about the transformation of visual information across cortical populations. We find that there are systematic differences in the representation of visual stimuli across areas of the rat visual cortex.

Title: The functional organization of area MT neurons revealed by 2-photon microscopy in awake marmosets

Authors: *J. PATTADKAL, B. V. ZEMELMAN, N. PRIEBE
Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Area MT contains neurons that are exquisitely sensitive to visual motion and, based on extracellular recordings, is functionally organized for direction. Neurons within a cortical direction column share direction preferences, and preferences smoothly shift across cortex, much like the functional architecture for orientation selectivity in primary visual cortex of primates. The large-scale organization of area MT has not been accessible to optical imaging and electrode arrays, since in the macaque it is located near the bottom of the superior temporal sulcus. To examine the functional architecture of area MT and assay the selectivity of inhibitory neurons, we used the marmoset (*Callithrix jacchus*). These primates have lissencephalic brains in which we have access to activity of large neuronal populations. We used 2-photon microscopy to record from several hundred neurons at single-cell resolution over a 1 mm^2 region of area MT in awake marmosets. GCaMP expression was induced by injecting AAV constructs with promoters that provided specific expression in interneurons within area MT. The motion selectivity of the interneurons was assessed using a full-field patch of random dots moving in different directions. GCaMP signals from inhibitory neurons revealed similar degrees of motion selectivity as that

found from excitatory neurons (median DSI = 0.38, n = 301 cells). Nearby neurons tend to share direction preference, forming a map of direction preference with a period of approximately 300 microns. Finally, we found that the degree of orientation selectivity in MT neurons is weaker (median OSI=0.13) than direction selectivity. In sum, we have revealed the fine functional organization of area MT using 2-photon microscopy in awake marmosets and have demonstrated that MT inhibitory neurons are as direction selective as their excitatory neuron counterparts.

Title: Intrinsic physiology and synaptic integration in genetically targeted thick-tufted layer 5 pyramidal neurons in mouse secondary visual cortex

Authors: *A. R. GALLONI, E. A. RANCZ
The Francis Crick Inst., London, United Kingdom

Abstract: Thick-tufted layer 5 (ttL5) pyramidal neurons have broad dendritic arborizations that span all layers of the neocortex and receive disparate local and long-range inputs from both sensory and internal model-related brain regions. They output to many subcortical targets including the thalamus and brainstem, making them the principal output pathway for locally computed neocortical information, and therefore a good model system to study cortical computations. Here we describe the intrinsic and synaptic properties of a Cre-driver transgenic mouse line (Colgalt2), which selectively labels a sparse population of ttL5 neurons in medial secondary visual cortex (V2m).
We used whole-cell patch-clamp recordings in adult mouse brain slices to obtain a broad electrophysiological characterisation of intrinsic properties, including passive membrane properties, spike and firing properties as well as resonance frequency (4.9 ± 1.1 Hz, SD, n = 31). We find that Colgalt2-Cre neurons constitute a homogeneous population with intrinsic properties and morphology broadly consistent with previous descriptions of ttL5 neurons, with the exception that these neurons do not exhibit strong bursting responses associated with calcium electrogenesis in the apical dendrites, previously shown in ttL5 neurons in primary sensory cortical areas.

We next focused on the properties of two main input pathways, from primary visual cortex (V1) and retrosplenial cortex (RSC), by electrically evoking synaptic potentials. Paired-pulse ratios at 40Hz were similar (V1: 1.5 ± 0.54 SD, n = 14; RSC: 1.48 ± 0.32 SD, n = 14; p = 0.92). When stimulated together, V1 and RSC inputs were found to sum linearly (evoked sum 2.11 ± 0.70 mV, SD; arithmetic sum: 2.39 ± 0.61 mV, SD; n = 9, p = 0.38) and proved to be independent even at varying time-intervals of 5–75 ms. We are currently using spatially structured optogenetic stimulation to map these two different inputs onto the dendritic tree in order to establish the basis of their independence.
In conclusion, we present a genetically defined population of thick-tufted layer 5 pyramidal neurons showing linear summation of synaptic inputs and lacking some of the dendritic supralinearities generally associated with ttL5 neurons.

Title: Whole brain input and output connectivity of layer 5 neuron subtypes in secondary visual cortex of the mouse

Authors: *Z. YE, E. A. RANCZ
The Francis Crick Inst., London, United Kingdom

Abstract: The secondary visual cortex (V2) of mouse consists of multiple retinotopically organized areas and receives direct input from primary visual cortex (V1). Distinct areas of V2 receive differently tuned input from V1 and show preference for different visual features. Layer 5 neurons, with their dendritic arbour spanning most layers, are well placed to integrate disparate long-range and local cortical input streams. At the same time, they provide the majority of cortical output, broadcasting the end result of cortical computation. However, the input and output maps of V2 layer 5 neurons have not been systematically studied. By taking advantage of three layer 5 neuron specific transgenic mouse lines (Colgalt2-Cre, Tlx-Cre and Rbp4-Cre), we have mapped the inputs and outputs of different V2 layer 5 cell types.
We first identified the postero-medial area of V2 (PM) *in vivo* using intrinsic signal imaging to allow for functional targeting of subsequent viral injections. For output connectivity maps, we injected cre-dependent, GFP-encoding adeno-associated virus (AAV) in PM, which enabled us

to identify axonal projection targets. For input connectivity maps, we first injected 2 AAVs coding for the TVA receptor and rabies G protein in a Cre-dependent manner, followed by TVA-pseudotyped N2c rabies virus injection to label first order presynaptic partners. Brains were imaged on a block-face scanning 2-photon microscope, data were registered to the Allen Mouse Common Coordinate Framework and analysed using an automated pipeline.
The main projection targets of Colgalt2 neurons were in the midbrain (superior colliculus), thalamus (lateral posterior nucleus (LP), zona incerta), striatum and the pons. Tlx axons on the other hand remained mostly in cortex, with strong projections to lateral V2, retrosplenial cortex, striatum as well as contralateral medial V2. Rbp4 axons covered all areas typical for Colgalt2 and Tlx axons. Presynaptic input maps for all 3 cell types were qualitatively similar, with input from cortex (lateral V2, V1, retrosplenial cortex) and thalamus (dorso-lateral geniculate nucleus, LP, anteromedial nucleus of thalamus). We are currently focusing on detailed quantitative analysis of presynaptic input maps.

Title: Vestibular and optokinetic eye movement reflexes are both altered in nob mice

Authors: *B. H. WINKELMAN[1,2], M. KAMERMANS[1,4], C. I. DE ZEEUW[1,3]
[1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands; [2]Ophthalmology, [3]Neurosci., Erasmus MC Univ., Rotterdam, Netherlands; [4]Neurogenetics, Academic Med. Ctr., Amsterdam, Netherlands

Abstract: In nob mice, a mutation in the X-chromosomal gene that encodes nyctalopin causes malfunction of the photoreceptor-to-bipolar cell synapse in the retina. This defect leads to congenital stationary night blindness (CSNB) and infantile nystagmus. Here we show that eye stabilization reflexes are severely affected in nob mice. The optokinetic reflex (OKR) responds only transiently to the on- and offset of horizontally moving sine-wave gratings (0.025-0.4 cycles/deg), and a clear gaze-holding defect is observed during presentation of stationary gratings. Remarkably, the vestibulo-ocular reflex (VOR), tested using vertical-axis sinusoidal oscillation (0.0625-4 Hz), deviates from the wildtype VOR in a velocity and frequency dependent manner. While the VOR is relatively normal at high peak velocities (up to 100 deg/s), the eye movement response at low peak velocities (down to 6.25 deg/s) shows a large shift in

phase angle that increases in lag with stimulus frequency and completely inverts the VOR at 0.5 Hz. This VOR behavior in nob mice can be modeled as a control system with two signal pathways: one linear and one nonlinear. The nonlinear pathway is of opposite sign as the linear component, saturates at about 10 deg/s and contains a band-pass filter (~0.6 Hz center frequency, ~2 Hz bandwith). Whereas the VOR is generally regarded to operate as a close-to-linear system, we show that marginal deviations from linearity observed in the wildtype VOR also conform to this model, albeit with a smaller gain of the nonlinear pathway (<0.4) compared to nob mice (>0.9). We hypothesize that the retinal motion detection defect in nob mice causes anomalous cerebellum-dependent VOR adaptation, resulting in an inverted VOR at low velocities.

Title: Genetics reveal the modular organization of movement vectors in the mouse superior colliculus

Authors: *L. MASULLO, L. MARIOTTI, N. ALEXANDRE, M. TRIPODI
Neurobio., MRC Lab. of Mol. Biol., Cambridge, United Kingdom

Abstract: We are surrounded by objects we are able to grasp and manipulate; in order to successfully interact with the environment, animals need to produce accurate movements towards specific positions in space. A crucial region of the brain that guides similar goal-oriented movements is the superior colliculus (SC), a multi-layered midbrain structure formed by a sensory and a motor domain. While several lines of research in different model organisms have confirmed that the SC contributes to the initiation of orienting movements, how functionally distinct neuronal groups within the SC are organized to support the production of such motor outputs is poorly understood.
One of the reasons why the intrinsic circuit organization of the SC remains elusive is the lack of genetic characterization of the neuronal populations of its motor domain. Here, we performed RNA sequencing to screen for genetic markers for neuronal subpopulations in the motor SC. We identified a genetically defined subpopulation of projecting glutamatergic neurons in the motor domain of the SC. Strikingly, this population of neurons displays a modular distribution within this domain, being organised in clusters along the mediolateral and anteroposterior axis.

We then asked whether these modules may act as functional units, each encoding a specific feature of head movement, the main ethologically relevant orienting behaviour in rodents. Optogenetic activation of this modular population in freely moving animals produced a stereotyped, robust head motion characterised by a pronounced quantal nature; furthermore, the amplitude of the elicited head movement varied based on the modular unit activated. Our results suggest that distinct clusters of genetically defined neurons produce head displacement along a characteristic vector.
In conclusion, we found that a population of premotor neurons in the SC is organised in a modular conformation and we suggest that such modularity may represent a physical implementation of a discontinuous motor map for orienting movements encoded in the mouse SC. Our study complements previous observations of periodicity in SC circuitry, as well as its afferent and efferent systems. Exploiting the genetic toolkit available in the mouse, our work begins to address the functional relevance of this modularity and paves the way for future experiments to investigate principles of sensorimotor integration in SC circuits.

Title: Properties of the signals that drive directional learning in smooth pursuit eye movements

Authors: *D. J. HERZFELD[1], M. TRINGIDES[2], D. SUBRAMANIAN[3], S. G. LISBERGER[1]
[1]Dept. of Neurobio., [3]Neurobio., [2]Duke Univ., Durham, NC

Abstract: To shed light on the neural signals that control directional learning in smooth pursuit eye movements, we conducted behavioral experiments that varied the instructive signals for learning and determined how learning generalizes to different contexts. Two monkeys tracked a smoothly moving target. During learning blocks of 100 trials, the target moved in an initial "pursuit" direction for 250ms and then added a component of motion in the orthogonal "learning" direction. We assayed learning in the final 25 trials of each block by measuring eye velocity in the learning direction just before the instructive change in target direction.
We varied the duration of target motion in the learning direction from 50 to 400ms, and found that learning scaled with duration when the target was continuously visible. If, however, the target was extinguished after the selected duration of the instructive stimulus and reappeared

later at the position it would have attained if it had continued to move for a full 400ms, then the magnitude of learning was considerably larger for each instruction duration and quickly saturated for durations longer than 100ms. We conclude that longer duration instructions cause image motion that engages competing learning mechanisms in the opposite direction, and that 100ms of motion is sufficient to instruct maximal learning.
We also varied the speed of target motion in the pursuit direction. Testing the expression of learning with multiple pursuit direction target speeds revealed that learning generalized linearly to speeds slower than the trained speed, but saturated for pursuit speeds faster than the trained speed. Given that learning must operate on signals that are related to initial pursuit, this pattern of generalization suggests that more inputs are recruited as pursuit target speed increases. We tested this hypothesis by running learning trials with a fast target speed, and then washing out the learning using a slower target speed. After learning had been extinguished, we switched to the fast target speed used during learning, revealing re-expression of the previously learned memory. We take this as evidence for inputs to the site of learning that respond during the fast target speed, but not the slow target speed.
Our findings on the effects of instruction duration are compatible with the proposed primacy of climbing fiber inputs in driving pursuit learning. We suggest that learning is a process based on multiple sites and/or mechanisms that, under some circumstances, compete. Our findings on generalization to target speed suggest that parallel fibers encoding target (or eye) speed are recruited in larger numbers as eye speed increases.

Title: Sensorimotor gain control as a mechanism of movement prevention during modulation of preparatory activity

Authors: *T. DARLINGTON, S. G. LISBERGER
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: In cells with firing seemingly tied to movement, an important question is how preparatory activity can evolve without actually producing movement. The smooth eye

movement region of the frontal eye fields (FEF_{SEM}) is a critical node in the neural circuit controlling smooth pursuit eye movement. Preparatory activity evolves in FEF_{SEM} during fixation. Under conditions where the animal can anticipate the ultimate target motion, FEFSEM preparatory activity signals expectation about the impending visual motion and eye movement. We recorded 164 single units in the FEF_{SEM} of two awake behaving rhesus monkeys while they smoothly tracked moving targets during two different blocks of trials: (1) a random 8-direction block to fit a linear model between the population response of our FEF_{SEM} cells during pursuit and eye velocity and (2) a repeated-direction block to provide predictable target motion and study preparatory activity. Recent work in the arm movement system suggests that population activity in M1 and PMd during movement preparation combines linearly in a way that cancels out, or remains confined to an "output-null" space. In contrast, we find that population activity in FEF_{SEM} evolves during fixation in a way that should cause movement. Using linear discriminant analysis, we also find that preparatory and pursuit-related activity progress along similar, "output-potent" dimensions. We understand the progression of preparatory activity along output-potent dimensions in terms of the previous finding that the output of FEF_{SEM} controls the strength, or "gain", of visual motion access to the oculomotor machinery. To test this, we presented brief 50 ms pulses of visual motion at random times during fixation. We find that eye speed responses are larger when the pulses are delivered later during fixation, at times when FEF_{SEM} preparatory activity has progressed further along output-potent dimensions. We conclude that the output from FEF_{SEM} operates downstream to enhance visual-motor gain in anticipation of behaviorally-relevant visual motion. These findings propose a novel mechanism by which preparatory activity in sensorimotor cortex can evolve without producing inappropriate movements: preparatory signals may act as a gain controller in anticipation of imminent command for movement.

Title: The relative contributions of area MT and the frontal eye fields to the latency of smooth pursuit

Authors: *J. MAYO, S. G. LISBERGER
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Correlated features of neuronal activity constrain how the brain uses sensory information to guide behavior. While the majority of research on correlations so far has focused on the size of neuronal responses in terms of firing rate (e.g., spike count correlations), here we focus on correlations between the latency of responses between cortical neurons and their relation to the initiation of smooth pursuit eye movements. Previous work demonstrated that as much as 30-40 percent of the trial-by-trial variation in the timing of pursuit initiation could be accounted for by correlated variation in the timing of neuronal responses in each of (1) extrastriate visual area MT and (2) the smooth pursuit eye movement region of the frontal eye fields (FEFsem). Our goal here was to determine whether these cortical areas contribute independently or synergistically to pursuit latency. We recorded simultaneously in areas MT and FEFsem in rhesus monkeys using 24-channel Plexon V-probes. Monkeys were trained to fixate in the center of a video display and then pursue a patch of dots at various speeds and directions. Trials with saccades during stimulus motion onset or pursuit initiation were excluded, and we collected approximately 100 trials per stimulus condition. We used a quantitative procedure that effectively shifted and scaled each trial's eye speed trace and neuronal response to obtain precise latency and amplitude estimates (Lee et al., Neuron, 2016). Validating previous independent work in our laboratory, we found that trial-by-trial changes in the response latencies of MT and FEFsem neurons were positively correlated with the latency of pursuit initiation. Using simultaneously recorded MT-FEFsem neuron pairs, we assessed whether fluctuations in response latencies across trials covaried between areas. The response latencies of pairs of MT-FEFsem neurons were not correlated, despite the fact that (1) latencies were correlated for pairs of neurons within each area and (2) each area's latencies were significantly correlated with the latency of behavior. These results suggest that MT and FEFsem contribute independently to the timing of pursuit initiation.

Title: Characteristics of saccades to moving targets

Authors: *K. J. MOHSENIAN[1,2], N. J. GANDHI[1,2]
[1]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for Neural Basis of Cognition, Pittsburgh, PA

Abstract: The world is a dynamic environment filled with non-stationary sensory information that can be crucial to survival. Animals extract relevant information from their surroundings by aligning their gaze on both stationary and moving objects. Saccades, rapid eye movements, have been used to study sensory, motor, and cognitive processes in primates. The metrics and kinematics of saccades to stationary targets have been well characterized through countless studies. However, there have been relatively few in-depth studies that describe the kinematics of saccades to moving targets, called interceptive saccades, across a broad range of target speeds and directions. The goal of this study is to provide an understanding for how kinematics of saccades to stationary and moving targets vary as a function of target speed and trajectory. We recorded saccade kinematics from four rhesus monkeys who performed a delayed saccade task in which the delay duration, starting target location, moving target direction (inward and outward), and target speed (range: 15 to 45 deg/s) were varied randomly to elicit saccades with a broad spectrum of amplitudes and directions. Trials using stationary targets placed along the moving target paths were randomly interleaved with trials using moving targets. Eye position was recorded using magnetic search coils or an eye-tracker system. Preliminary analysis suggests that main sequence properties for monkeys may be more idiosyncratic than previously observed. Of the four subjects, two showed no difference in their main sequence properties between saccades to stationary and moving targets, as the peak velocity and duration of amplitude-matched saccades were similar. This effect was maintained across different moving target parameters (speed and direction). The other two subjects showed distinct differences: peak velocity was attenuated, and duration was longer for amplitude-matched saccades to moving targets. For all subjects, saccade latency for interceptive saccades was similar to saccades to stationary targets. Saccadic error, the error of the animal's gaze relative to the target location at saccade end, increased as a function of saccade eccentricity and target speed, and in general, was greater for trials with a moving target. Since all four subjects performed the same task, the range in kinematics for interceptive saccades most likely reflects subject-to-subject variability. These results therefore reveal a potential diversity in strategy used by different subjects to process a moving stimulus and direct the line of sight toward it.

Title: A new tectal premotor input for the control of lens accommodation

Authors: *P. J. MAY[1], S. WARREN[1], I. BILLIG[2], J. J. QUINET[3], P. D. R. GAMLIN[3]
[1]Neurobio. and Anatom. Sci., Univ. Mississippi Med. Ctr., Jackson, MS; [2]Systems Neurosci. Inst., Universsity of Pittsburgh Med. Ctr., Pittsburgh, PA; [3]Dept. of Ophthalmology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: In order for the visual system to compensate for target distance and maintain stereopsis, three different motor actions are employed in the "near response": the activities of the medial and lateral recti muscles are modulated to produce vergence movements and so direct the eyes at the target, contraction of the ciliary muscle produces lens accommodation to focus the image on the retina, and sphincter pupillae muscle tone is increased to decrease pupil size and increase depth of field. We recently identified two populations of premotor neurons that control lens accommodation: one in the supraoculomotor area (SOA) and the other in the central mesencephalic reticular formation (cMRF). These were labeled using the retrograde trans-synaptic transport of the N2c strain of rabies virus from injections into the ciliary muscle of macaque monkeys. Here we describe a third population of midbrain neurons located in the midbrain tectum of the same animals. These neurons were labeled at survival times that allowed the virus to cross two synapses, the same time course as the SOA and cMRF groups, indicating that they are also premotor neurons supplying the preganglionic motoneurons in the Edinger-Westphal nucleus (EWpg). The labeled neurons were arranged bilaterally, in a rostrocaudally oriented column within the midbrain tectum. The rostralmost cells were located in the medial pretectal nucleus, while cells at more caudal levels were found just off the midline, medial to the intermediate gray layer (SGI) of the superior colliculus. This caudal region has been previously designated the tectal longitudinal column (TLC). The labeled neurons were relatively small, with a modest number of poorly branched dendrites. Labeled neurons were not found in the superior colliculus at these time points. Since this premotor population is a novel one, we also examined this projection with conventional tracers. Injections of wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) into the SOA, which included EWpg, retrogradely labeled neurons in the same region, as well as within the SGI of the superior colliculus. Injection of BDA into the midline tectum, produced anterogradely labeled terminals that lay over EWpg motoneurons on both sides. The function of this tectal premotor population is unknown, but its presence may help explain changes in lens accommodation that have been reported in cats following electrical stimulation of the superior colliculus and pretectum.

Title: Projection of the superior colliculus to the supraoculomotor area in macaque monkeys

Authors: *S. WARREN[1], P. MAY[1], A. K. HORN-BOCHTLER[2], S. UPADHYAYA[3], V. E. DAS[3]
[1]Neurobio. & Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [2]Inst. of Anat. and Cell Biol. I, LMU, Muenchen, Germany; [3]Col. of Optometry, Univ. of Houston, Houston, TX

Abstract: In 1978, Edwards and Henkel reported that the rostral superior colliculus of the cat projects to the supraoculomotor area (SOA). They hypothesized that during saccades, this projection might allow the superior colliculus to directly control the activity of vertical gaze motoneurons that extend dendrites from the oculomotor nucleus (III) into the overlying SOA. However, the SOA contains a number of other cell populations that might be targeted, including: preganglionic motoneurons of the Edinger-Westphal nucleus (EWpg), peptidergic, centrally projecting Edinger-Westphal neurons (EWcp), motoneurons of the C- and S-groups that supply multiply innervated fibers (MIFs) within the extraocular muscles, and midbrain near response neurons that control vergence. We have investigated the projections of the superior colliculus onto the SOA in macaque monkeys in order to provide greater insight into the possible targets of this pathway. Anterograde tracers injected into the superior colliculus label terminals within SOA, whether they are placed in the rostral or caudal superior colliculus. The terminal field extends bilaterally within SOA, with an ipsilateral predominance, and includes EWpg and the region between the two sides of III, where S-group motoneurons are found. Retrograde tracer injections that included SOA produced labeled neurons in the intermediate gray layer (SGI) of the superior colliculus. When superior colliculus injections are combined with injections of the ipsilateral medial rectus and superior rectus muscles, no evidence of anterogradely labeled terminals contacting retrogradely labeled motoneurons within III was observed. Furthermore, only a few close associations were observed with retrogradely labeled medial and superior rectus MIF motoneurons found in the C- and S-groups, respectively. This suggests motoneurons are not a primary target of the SOA projection. In addition, data from trans-synaptic transport of the N2c strain of the rabies virus injected into the ciliary muscle suggests that the SC does not project directly to EWpg motoneurons. These negative findings suggest that the most likely target for this tectal projection may be the midbrain near response neurons. Indeed, the terminal field in the SOA is denser, caudally, where this premotor population is more numerous. Since these SOA cells do not modify their activity during conjugate saccades, the presence of such a projection would suggest that the superior colliculus may enhance the activity of near response neurons during disjunctive saccades or that the input is supplied by rostral superior colliculus neurons that encode near response signals, not saccades.

Title: Saccadic directional precision across the horizontal and vertical meridians

Authors: *T. MALEVICH[1,2], Z. M. HAFED[1,2]
[1]Werner Reichardt Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Hertie Inst. for Clin. Brain Res., Tuebingen, Germany

Abstract: Saccades rapidly re-align gaze with objects of interest. Even though saccades are spatially precise, they do exhibit significant trial-to-trial variability in eye movement trajectories and landing positions. This may suggest that the oculomotor system is simply "sloppy", contradicting the idea that saccades precisely re-align gaze. Here we hypothesized that saccadic variability is related to variability in starting eye position due to fixational eye movements. Using scleral search coils, we measured eye movements precisely in 3 rhesus macaques performing horizontal or vertical 5 or 10 deg visually guided saccades. We observed significant saccadic curvature in all conditions even though the targets were placed along cardinal directions. We then binned saccades of a given size (e.g. 10 deg rightward saccades) according to initial fixational eye position at saccade onset. We found that saccade direction/curvature precisely corrected for deviations in fixational eye position that were present at the time of triggering the saccade. For example, rightward saccades with fixational vertical eye position at saccade onset in the lowest quartile of eye positions curved upwards, whereas rightward saccades with fixational vertical eye position in the highest quartile curved downwards. This suggests high precision of individual saccades, which we further demonstrated by presenting targets in the cardinal directions but having +/- 1.7, 3.5, or 5.3 min arc deviations in the orthogonal direction (e.g. a target at 10 deg rightward and 1.7 min arc upward from the fixation position). This resulted in "true" saccade directional deviations from the cardinal axes of only +/- 0.3, 0.7, and 1 deg for 5-deg saccades and +/- 0.15, 0.3, and 0.5 deg for 10-deg saccades. Saccade curvature in all cases was adjusted accordingly such that the angular deviations of the target were corrected for by saccade end. We then ran 5 human subjects on a similar task but asked them to report whether the target (disappearing at saccade onset) deviated upward (for horizontal saccades) or rightward (for vertical saccades) from the imagined meridian axis locations. Perceptional precision of the small angular deviations in target vector was significantly worse than for saccades, and it also exhibited strong biases; perceptual estimates were particularly poor for downward locations. Our results indicate that saccades are much more precise than assumed, and that fixational eye

movements render “purely” vertical and horizontal saccades rare events. This alleviates challenges of programming such “pure” saccades from neural tissue in which the visual fields are anatomically or functionally dissociated.

Title: Testing egocentric vs allocentric models in the frontal eye field (FEF) during a cue-conflict task in head-unrestrained monkeys

Authors: *V. BHARMAURIA[1], A. SAJAD[2], X. YAN[1], H. WANG[1], J. D. CRAWFORD[1]
[1]York Univ., North York, ON, Canada; [2]Vanderbilt Univ., Nashville, TN

Abstract: The brain could encode information about an external object in an egocentric or an allocentric fashion. By employing a classical memory-guided saccade task in head-unrestrained monkeys, we have already tested different egocentric models and have shown that the visual burst of the FEF neurons encodes for the target relative to eye (Te) and the motor burst best describes the gaze relative to eye (Ge) (Sajad et al. 2015; Sajad et al. 2016). Here, by using a cue-conflict paradigm (wherein the monkeys were trained to saccade toward a remembered target in relation to a shifting allocentric cue in different directions), we have recently examined the relative contributions of egocentric vs allocentric cues on goal-directed behavior in the saccadic system (Li et al. 2017) and found out that there was a 25% displacement of the gaze end-points toward the virtually displaced target, suggesting that gaze representation is weighted between the egocentric and allocentric cues. Here, we sought to examine the neural underpinnings of this weighing between the egocentric and allocentric frames in a cue-conflict task in head-unrestrained monkeys. Using single neuron electrophysiology in the FEF while the monkeys performed the cue-conflict task, we tested the best fitting of the visual and motor responses in different egocentric and allocentric reference frames, such as Te’ (virtually shifted target in eye-coordinates). It was revealed that the visual neurons (n=12) still encode Te and motor neurons (n=17) best encode the Ge, that is, so far the data are fitting and describing the canonical egocentric models better than the allocentric models. This suggests that the allocentric influence is processed at a different stage in the visual system. However, further analysis needs

to be performed with intermediate codes, especially the continuum between the Te and Te', and to see if it shifts partially like behavior.

Title: Microsaccades in blindsight monkeys

Authors: *M. YOSHIDA[1,2], Z. M. HAFED[3]
[1]Dept Syst. Neurosci, Natl. Inst. Physiol Sci., Okazaki, Japan; [2]Sch. of Life Sci., The Grad. Univ. for Advanced Studies, Hayama, Japan; [3]Werner Reichardt Ctr. For Integrative Neurosci., Tuebingen, Germany

Abstract: Patients with damage to primary visual cortex (V1) demonstrate residual performance on laboratory visual tasks despite denial of conscious seeing (blindsight). Macaque monkeys with a unilateral V1 lesion have been used as an animal model for blindsight. Previously, we have demonstrated that blindsight monkeys retain some cognitive and attentional capacities including visual spatial memory (Takaura et al 2011) and endogenous attention (Yoshida et. al. 2017). Here we examined whether a unilateral V1 lesion affects microsaccades, which are small, unconscious, fixational eye movements. Our first question was whether microsaccades during fixation are affected. After a surgical lesion in the left side of V1 in two monkeys, the number and/or amplitude of leftward microsaccades (towards the normal visual field) were larger than those of rightward microsaccades (towards the affected visual field). Analysis of horizontal eye positions at the onset of microsaccades (Tian et. al. 2018) revealed that the average horizontal eye position of blindsight monkeys was shifted towards the affected (right) visual field, suggesting that the increased number and/or amplitude of leftward microsaccades compensated for a lesion-induced rightward eye-position shift. We then asked whether microsaccades during peripheral and central cueing were affected. Before the V1 lesion, in a memory-guided saccade task (Takaura et al 2011), peripheral cue onsets transiently decreased the number of microsaccades. A rebound in frequency followed, and most rebound movements were directed away from the cues, consistent with our previous finding in monkeys and humans (Tian et. al.

2016). After the V1 lesion, the overall patterns of inhibition and rebound were not affected. However, the number of cue-directed microsaccades occurring <120 ms after cue onset ("express microsaccades", Tian et. al. 2018) increased for leftward microsaccades and was almost completely abolished for rightward microsaccades. In a Posner task with informative central cues (Yoshida et. al. 2016), the number of express microsaccades was also affected in a similar manner to the peripheral cues. These results suggest that: 1) V1 lesions affect the balance of leftward and rightward microsaccades, which is consistent with the push-pull equilibrium model of microsaccade dynamics (Hafed 2011); and 2) V1 is not necessary for transient inhibition of microsaccades after peripheral cues. These results help constrain models of microsaccade dynamics after peripheral and central cueing, and they highlight how V1 can contribute to such dynamics, in addition to visual-oculomotor areas such as FEF and the superior colliculus.

Title: Saccade target selection in superior collicular neurons during a categorical search task with naturalistic images

Authors: *B. M. COOPER[1], R. M. MCPEEK[2]
[1]Biol. Sci., State Univ. of New York Col. of Optometry, New York, NY; [2]Biol. Sci., SUNY Col. of Optometry, New York, NY

Abstract: The target of visual search is not always defined with exacting specificity. Rather, orienting behaviors often direct attention using more broad constraints. Categorical search tasks, for example, have demonstrated search guidance via multiple features common to the target category (categorical target templates; Yang & Zelinsky 2002). Here we present the physiological responses from visual, visuo-movement, & movement (V, VM & M respectively) superior collicular (SC) neurons of non-human primates (NHPs) as they perform a visual categorical search task that utilizes images of naturalistic objects from various object categories. After an initial fixation period, NHPs were allowed to free-view an image array of 'real-world' objects (animals, kitchen utensils, cars, etc.). On target present (TP) trials, reward was contingent on fixating an image from one of two categorical image families (Teddy Bears or Butterflies) while target absence (TA) was indicated by fixating a specified location in the far periphery. We examined the visual response to stimulus onset as well as the first search saccade of each trial.

For the majority of cells sampled, when saccades were made into the response field (RF), responses were larger (for both targets and distractors) than when saccades were made elsewhere. This was pronounced in M as well as VM neurons with a negative visuo-movement (predominantly motor) index. It was observed that a number of V & VM neurons had a biphasic peak in visual activity. The first burst rarely displayed a significant difference in activity for saccades made to targets in the RF compared to distractors in the RF. However, often the differences in the second peak of activity carried significance. This is in keeping with results for search tasks using relatively simpler single feature search (Keller & McPeek 2002). Overall, a majority of cells had a stronger response for in RF saccades made to a target compared to that of in RF distractors. Furthermore, a subset of these target discriminating cells had significantly higher responses for saccades made to distractors in the response field on TP trials verses TA trials. We interpret this as reflecting a perceived categorical target template probability. This is supported by the finding that first saccade distractor fixations for TP trials had a higher likelihood of sharing feature similarity with the target category than the distractors fixated for TA trials. Taken together, these findings support a role for the SC in serving as a final gateway of a categorical target template selection process.

Title: Engaging spatial visual working memory expands superior colliculus neurons' response fields

Authors: *K. F. WILLEKE[1,2], A. BUONOCORE[1,2], X. TIAN[1,2], Z. M. HAFED[1,2]

Abstract: Superior colliculus (SC) neurons are known to produce movement-related bursts before, during, and after the execution of high-speed, or saccadic, eye movements. Because these neurons show selectivity for saccade direction and amplitude, they are often described in terms of their response field (RF) location and size. However, saccade-related SC RF's have been typically mapped using visually-guided saccades. Here we show that the shape and size of SC RF's can be significantly altered by the demands that spatial visual working memory imposes on the oculomotor system. We trained two macaque monkeys to perform a memory-guided saccade

task. In this task, an eccentric flash was presented briefly (~50 ms). The monkeys maintained flash location in spatial visual working memory for ~300-1100 ms, after which the fixation spot disappeared, providing a "go" command to generate a saccade to the remembered target location. We then collected data from trials of random target eccentricities (0.1-16 deg) and directions (0-360 deg). The monkeys also performed a delayed-saccade task, in which the target flash was replaced with persistent stimulus presentation until trial end. This allowed for a direct comparison between saccades being triggered towards a memory-location versus saccades that were visually-guided. We recorded from 252 SC neurons that showed significant saccade-related activity in both tasks, and we characterized the size and location of their RF's. We found that SC RF's significantly expanded in size for memory-guided saccades when compared to visually-guided movements, such that saccades with identical amplitudes were associated with significant saccade-related discharge for memory-guided movements but not for visually-guided ones. Crucially, the RF expansion was not spatially uniform, but it exhibited a larger shift towards more central eccentricities. Thus, there was an "inward" RF expansion towards the fovea during memory-guided saccades. Despite this expansion, RF hotspot locations were not systematically altered. We conclude that SC RF's are highly malleable by task demands. These results offer a possible mechanism by which spatial visual working memory acts on the saccadic system, and thus could provide insights both into the nature of spatial visual working memory and also the SC's role in it. Our results also suggest that foveal magnification in SC topography might mediate inward RF expansions during working memory engagement, and therefore also mediate potential systematic errors that would be present for memory-guided saccades when compared to visually-guided ones.

Title: Immunohistochemistry is required to visualize virally-mediated fluorescent protein transgene expression in the neuronal visuomotor circuitry of non-human primates

Authors: *M. O. BOHLEN[1], H. G. EL-NAHAL[2], M. A. SOMMER[2]

Abstract: Optogenetics has been transformative for neural circuit analysis in rodents. To use optogenetics, primate researchers must resort to viral delivery of genes encoding opsin proteins that usually include a fluorophore conjugate. In ongoing work, we are characterizing a range of viral vectors to identify promising candidates for efficient transduction and patterns of intracellular labeling of targeted neuronal populations. This work will lead to new insights into the anatomical connectivity and physiology of the visuo-motor systems of macaque monkeys. To this end, we have targeted several gaze-related areas including the frontal eye field, V1, mediodorsal thalamus, superior colliculus, and brainstem motor nuclei. We have identified several AAV vectors which exhibit strong labeling of neurons either locally, anterogradely or retrogradely. Concurrently, we have tested the capacity for vectors to retrogradely label motoneurons following intramuscular injections in craniofacial musculature. To characterize a vector, we routinely use fluorescent microscopy and immunohistochemistry (IHC) to assess the efficacy of candidate viruses at delivering fluorescent protein genes. Different vectors contained different fluorescent proteins including GFP, eGFP, mCitrine, YFP, eYFP, RFP, tdTomato, and mCherry. In each monkey, adjacent sections were compared for the presence of fluorophores using (1) fluorescent microscopy and (2) immunohistochemical reaction using a primary antibody to the fluorophore and bright-field microscopy. To our surprise, there were dramatic differences in the degree of neuronal labeling observed using fluorescence compared to IHC visualization using bright-field microscopy across all monkeys. In some instances, fluorescent microscopy revealed no discernable labeling while IHC revealed dense neuronal labeling. In other instances, labeling could be seen under the fluorescent scope, but more neuronal details could be visualized and labeled neuronal structures could be observed using IHC. Our results suggest caution in assessing virally-mediated transduction solely using fluorescence microscopy, as this metric may substantially underestimate the true degree of neuronal labeling. Our results also suggest that IHC processing is necessary for detailed visualization of neuronal labeling in virally mediated experimental work, particularly anatomical and physiological optogenetic experiments.

Title: Muscarinic blockade modulates oscillatory activity in primate prefrontal cortex during rule-guided behaviour

Authors: *A. J. MAJOR, S. VIJAYRAGHAVAN, L. MA, S. EVERLING
Western Univ., London, ON, Canada

Abstract: Acetylcholine is heavily involved in executive processes such as attention and working memory and is important for optimal cognitive behaviour in primate prefrontal cortex (PFC; Croxson et al., *Nat Neurosci*, 2011). The disrupted cholinergic system of individuals with schizophrenia and Alzheimer's disease is thought to contribute to cognitive deficits such as impaired working memory. Although the effects of local cholinergic receptor modulation on neuronal discharge rate and tasked-related activity have been explored in nonhuman primate PFC (Major et al., *J Neurosci*, 2018), the effects of cholinergic compounds on oscillatory activity have been less thoroughly examined (Thiele et al., *Soc Neurosci Abstract #389.01*, 2016). Here, we have iontophoretically applied muscarinic receptor antagonist scopolamine to rhesus dorsolateral PFC during performance of pro- and antisaccades. In many recordings, we observed increased oscillatory power in the theta and alpha frequency bands. This was interesting considering scopolamine application unequivocally resulted in decreased neuronal discharge rate in PFC neurons (Major et al., *J Neurosci*, 2015). Others have reported cholinergic stimulation can enhance oscillatory power (Pafundo et al., *J Physiol*, 2013). These preliminary results suggest prefrontal muscarinic receptors are contributors to oscillatory activity during cognitive behaviour, and may contribute to the altered prefrontal oscillatory responses in conditions with altered muscarinic receptor expression, such as in Alzheimer's disease and schizophrenia (Kurimoto et al., *Neuroimage*, 2012; Senkowski and Gallinat, *Biol Psychiatry*, 2015).

Title: Central and peripheral correlates of eye movement planning

Authors: S. RUNGTA[1], *A. N. MURTHY[2]

Abstract: Accumulator models in which a signal rises to a fixed threshold have been used successfully to understand initiation of saccadic eye movements. In this study we examined

whether certain aspects of a central plan could be assessed by looking at the recruitment pattern of motor units from peripheral neck muscles using the accumulator framework. Towards this purpose, we recorded from frontal eye fields (FEF) and neck muscles in macaque monkeys while they were involved in a memory guided saccade task. We observed modulations in the neck muscles that paralleled the activity in FEF during the visual, delay and movement epochs. Not surprisingly, there were very few motor units which showed stimulus evoked response. Interestingly, the activity during the delay period in periphery could not be used to infer the direction of an upcoming movement. However, it was weakly correlated with the time it took to initiate saccades. For few sessions, we observed that the units that showed modulation during the delay period had smaller amplitude and higher spontaneous activity compared to the units which showed modulation only during the movement epoch. Similar accumulator models could explain the changes seen in FEF and neck muscles during planning. Our results suggest that the spatial information about the upcoming saccade gets gated out but temporal information leaks through possibly via smaller motor units into the periphery during planning. Also, accumulator models could be used to assess motor plans from periphery in more than one way.
